The role of domestic animals in bridging the gap between sylvatic plague and human infection has been studied extensively.[41,47,51] Cats and dogs are susceptible to natural and experimental plague. Epizootics in cats have been observed in conjunction with plague epidemics in humans.[47] Experimentally infected cats develop severe systemic illness, with bacteremia and abscess formation at the site of the inoculum. Between 1977 and 1998, 23 cases of feline-associated human plague infection were reported.[22] Five of these cases were fatal; two of the patients presented with primary pneumonic plague, and one presented with septicemic plague. Many of these cases were misdiagnosed at presentation, leading to delays in treatment and, in some cases, fatalities. This diagnosis should be considered especially in the western states of Arizona, California, Colorado, and New Mexico. No seasonal variation in the occurrence of cat-associated illness was noted.[22]

Ten other cases reported in the literature of feline transmission of plague to humans involved four veterinarians.[18] Dogs also are susceptible, but the disease is milder.[51] Swine are resistant to plague, the only evidence of subclinical infection being the presence of antibodies to the fraction 1 antigen of *Y. pestis*. Domestic animals, by virtue of their intimate contact with wildlife and humans, may be responsible for some cases of human plague. This danger is accentuated by a dearth of symptoms in some animals.[41]

VECTOR

Plague is transmitted to humans by the bite of an infected flea, the skinning and evisceration of infected animals,[32] or the inhalation of infected droplets from a case of pneumonic plague.[35] Infrequent portals of entry include the conjunctiva[41] and the pharynx.[40,49]

The efficiency of the flea as a vector for human disease depends on the likelihood that the infected flea will feed on a person and that the flea will regurgitate the bacillus into the victim's bloodstream in the process of feeding.[31] Flea species vary in both of these attributes. Wild rodent fleas are reluctant to feed on humans and do it only under duress (e.g., when the natural host dies). Fleas of domestic animals are more likely to bite humans. The Oriental rat flea, *Xenopsylla cheopis*, is the most efficient transmitter of plague because of its willingness to bite people and its propensity for regurgitating large numbers of bacilli in the process.[31] When the Oriental rat flea ingests infected blood, the actions of a coagulase produced by *Y. pestis* and a trypsin-like enzyme present in the flea's stomach result in the formation of an infected clot that blocks the flea's proventriculus. In obstructing the flea's intestinal tract, the clot allows further replication of bacteria. When the flea tries to feed again, it regurgitates large numbers of plague bacilli. The formation and dissolution of the fibrin clot are temperature-dependent. At temperatures greater than 27° C (>80.6° F), a fibrinolytic enzyme is activated that dissolves the clot and allows the flea to dispose of the bacillus. One postulation is that this temperature-dependent phenomenon is responsible for the observed cyclic nature of urban plague epidemics, which tend to subside with the advent of hot weather.[7]

In contrast, fleas in which the intestinal tracts do not become blocked contribute to the endemicity of plague by harboring the organism and transmitting it in sublethal doses.[9] Sylvatic plague depends on the rodent flea as the vector. This flea, although not as efficient as the rat flea in transmitting the bacillus, may itself become a reservoir of *Y. pestis* by surviving for 12 to 15 months after the original host dies. In the new season, it reintroduces the plague bacillus into the new rodent population.[47] The observation that *Y. pestis* can survive in the soil during interepizootics suggests another possible mechanism of transmission of plague.[25]

EPIDEMIOLOGY

More recent studies have suggested that plague is an ancient disease of mammals; the plague bacterium emerged 1500 to 20,000 years ago as a clone that evolved from *Yersinia pseudotuberculosis* that first caused outbreaks in Africa.[1] The plague bacillus exists in enzootic cycles involving wild animals or domestic rats. In urban plague, the course of events usually is initiated by the introduction of the plague bacillus from an enzootic focus into a susceptible rat population. With humans and rats living in proximity, an epizootic in rats may be followed by an epidemic in humans.[47] The epidemic may subside with the advent of hot, humid weather[7] or the obliteration of the rat population.[47] Such epidemics rarely occur today but have been described in the former South Vietnam[4,33] and more recently in India.[13] Between 1985 and 1999, 23 countries reported a total of 29,020 cases of plague to the World Health Organization, with an average mortality rate of 11 percent; major epidemics and outbreaks occurred in Tanzania (1991), Zaire (1992, 1993), Peru (1993, 1994), India (1994), and Madagascar (1995), with fatality rates ranging from 4.6 to 22.3 percent.[55]

In the United States today, humans become infected most frequently by direct contact with a sylvatic reservoir of infection. Sporadic human cases usually result from working or hunting in a plague-infested area[31] and increasingly from living near foci of infection as suburban spread encroaches on the natural habitats of rodents.[14] In recent years, domestic animals, especially cats, have been responsible for a significant proportion of human cases. During 1990 to 2005, 107 cases of plague were reported in the United States, a median of 7 cases a year. By September 2006, 13 plague cases, with 2 deaths (case-fatality 15%), had been reported from four states (New Mexico, Colorado, California, and Texas). Such resurgences often occur after ecologic changes resulting in population increases in ground rodents such as prairie dogs, ground squirrels, mice, and rats in the American Southwest.[15]

Sylvatic plague epizootics occur in the summer. Most cases of rural plague occur between April and September. The rare occurrence of human plague in the winter usually is associated with hunting and direct exposure to infected tissues.[12,32]

The continental United States has a large enzootic focus that includes 130 counties in 15 western states. Surveillance for plague in rodents during the 1990s has identified infected animals farther east than ever before reported. The plague bacillus now has been isolated in wild rodents in eastern Montana, western Nebraska, western North Dakota, and eastern Texas.[14] Between 1925 and 1965, the number of reported cases in the United States averaged between two and three per year.[8,10] During the 1970s, 105 cases were reported.[32] The number of cases reported in 1980 through 1982 showed a similar increasing trend.[10] Between 1970 and 1979, 53 percent of cases were in females, in contrast to the period 1926 to 1969, when only 27 percent were in females. Approximately 60 percent of cases occur in individuals younger than 20 years.[32] Of 10 confirmed cases reported in the United States in 1993, however, the age distribution was 22 to 96 years. Five of the patients were older than 65 years.[14] Native Americans

living on reservations in Arizona, New Mexico, and Utah are at increased risk. In the period 1970 to 1979, 35 percent of cases in these three states occurred in Native Americans.[10,32] Many of the patients were infected within 1 mile of their residence and almost all within their state of residence.[27] Seven of the 10 patients described in 1993 were exposed in their home sites, and one, a veterinarian, was exposed at work.[14]

Occasionally, plague has been acquired by a traveler in an endemic area who then traveled during the incubation period to a plague-free region of the country. This set of circumstances shows why all physicians need to be aware of the presenting symptoms and signs of plague and to obtain an accurate travel history.[34]

PATHOGENESIS AND PATHOLOGY

The portal of entry of the plague bacillus determines, to some extent, the form of disease. The most common portal of entry is the skin when it is bitten by an infected flea. Broken skin may provide access for direct inoculation while infected animals are being handled. After overcoming the skin barrier, the organisms move through the lymphatics to the regional lymph nodes, where they elicit an inflammatory response. The infection may be localized at this site, with subsequent formation of antibody and recovery. This clinical form is known as *pestis minor*. The bacillus commonly is disseminated through the bloodstream. Distant organ involvement may include the liver, spleen, kidneys, lungs, and meninges. Disseminated intravascular coagulation is common in fatal cases. Coagulation defects, including thrombocytopenia and elevated fibrin split products[4] and fibrin deposits in the glomeruli,[21,47] may be present. Bacteremia is not synonymous with severe disease and occurs commonly in mild cases.[47]

The major determinant of severity seems to be the presence of high levels of endotoxin. The toxin of *Y. pestis* has the biologic properties of typical endotoxin. When injected into experimental animals, it can cause the clinical symptoms and signs and pathologic changes characteristic of endotoxic shock and death. The quantity of endotoxin necessary to kill is estimated to be comparable to that present in a lethal dose of live bacteria.[2,54] The murine toxin of *Y. pestis* has a direct inhibitory effect in vitro on the respiration of heart mitochondria of rats and mice, whereas it has little or no effect on the mitochondria of rabbits, chimpanzees, dogs, and monkeys. The differing sensitivities in vitro correlate with the susceptibilities in vivo of these species to *Y. pestis* infection.[50]

Achieving high levels of toxin depends on the ability of the bacillus to replicate in the infected host. Resistance to phagocytosis had been assumed to be related to virulence. More recent experimental evidence has shown that virulent *Y. pestis* organisms are phagocytosed, but, in contrast to avirulent ones, are not killed. They continue to replicate freely in macrophages, allowing the accumulation of endotoxin.[30,50]

When the lung is the portal of entry, the disease usually is more fulminant. After being inhaled, bacilli replicate freely in the alveolar spaces. Severe pneumonia, endotoxemia, and septicemia ensue and, if untreated, cause death. In fatal cases, the thoracic lymph nodes show infarction, necrosis, and liquefaction, with pus formation. Edema and inflammation of the surrounding tissue are common.[47] The mucosa of trachea and bronchi is covered by bloody, frothy exudate. Submucosal hemorrhages and areas of necrosis may surround the trachea. The pleural surfaces contain hemorrhagic lesions and fibrinous adhesions. The lung parenchyma may be consolidated or show signs of acute edema.[47] The predominant histologic feature is an alveolar exudate consisting of histiocytes and polymorphonuclear leukocytes.[21]

Other organs also are involved. The kidneys may appear grossly hemorrhagic and contain areas of necrosis. Microscopic examination reveals leukocytic infiltrates of congested veins and capillaries. Glomeruli with fibrin thrombi frequently are found in patients with disseminated intravascular coagulation.[21] Biopsy of purpuric skin lesions reveals subepithelial hemorrhages and fibrin deposit in the capillaries. These changes are indistinguishable from the changes seen in a generalized Shwartzman reaction.[4]

CLINICAL MANIFESTATIONS

The incubation period of *Y. pestis* generally is 3 to 4 days, but ranges from a few hours to 10 days. The onset of illness usually is abrupt, beginning with fever, malaise, weakness, and headache.[47,48] Fever is high, frequently accompanied by shaking chills.[41] The appearance of a visible and palpable bubo may be preceded by pain and tenderness at that site.[48]

On physical examination, the patient is "toxic," apprehensive, and tachycardic. The inoculation site in the skin may not be evident, or it may be marked by a carbuncle. In bubonic plague, typical large, fixed, edematous, and exquisitely tender nodes are present at one anatomic site.[33] In decreasing order of frequency, the areas of nodal involvement are the groin (including femoral and inguinal nodes), axilla, and neck.[47] Any lymph node may suppurate, sometimes presenting an atypical picture (e.g., if intra-abdominal nodes are involved, an acute abdominal emergency may be suspected).[48] Septicemia as an initial presentation of *Y. pestis* infection is common.[27] Twenty-five percent of the patients presented without adenopathy in the 71 confirmed cases of plague in New Mexico from 1980 to 1984. All patients with septicemic presentation had fever and chills, and most had tachycardia, tachypnea, and relative hypotension. Seventy-two percent had gastrointestinal symptoms. Plague pneumonia was twice as likely to occur among septicemic as among patients with bubonic plague. Septicemic patients were significantly older and more likely to die than were patients with a bubonic presentation. Although septicemic plague occurred more often in older patients, patients younger than 30 years with septicemic presentation were more likely to die.[27]

As a result of its nonspecific presentation, septicemic plague is difficult to diagnose early. Of 27 patients with plague admitted to Indian Medical Center in Gallup, New Mexico, between 1965 and 1989, 5 presented with a nonspecific febrile syndrome with upper respiratory symptoms. They were prescribed penicillin. Three of the five patients died. Another five patients presented with a nonspecific febrile syndrome associated with chills, myalgias, and anorexia. These patients were not treated initially with antibiotics, and three of the five died.[18] The index of suspicion must be high because early diagnosis is imperative for avoiding a high risk of mortality. Individuals presenting with what seems to be community-acquired, gram-negative sepsis and who reside in or have a history of recent travel to endemic areas of plague must be evaluated for and treated with antibiotics effective against *Y. pestis*.[39]

Gastrointestinal symptoms occur in patients with plague, especially patients with septicemic plague.[26] Between 1980 and 1984, more than half of the 71 patients with plague in New Mexico presented with gastrointestinal symptoms that sometimes preceded the appearance of the buboes in the bubonic cases. Common symptoms are abdominal pain, nausea, vomiting, and diarrhea. These symptoms are thought to be a general response of the body to gram-negative septicemia. Occasionally, hepatosplenomegaly and mesenteric or retroperitoneal lymphadenopathy have masqueraded as an acute abdomen.[28,34]

Neurologic manifestations caused by the effects of toxin on the brain are common. A patient with plague may have insomnia, delirium, stupor, weakness, staggering gait, vertigo, disorders of speech, and loss of memory.[38] *Y. pestis* meningitis is a rare occur-

rence, but it does occur. Children younger than 15 years old seem to be more susceptible, and septicemic patients are four times more likely to develop meningitis than are patients with bubonic plague. It often manifests while the patient is well into a course of antibiotic therapy for bubonic or septicemic plague.[3] When intravascular coagulation supervenes, renal involvement may be manifested by acute cortical or tubular necrosis. Hepatic involvement may be evidenced by mildly elevated liver enzymes.[47] Hantavirus pulmonary syndrome may mimic septicemic or pneumonic plague; they share similar geographic distribution, and patients for whom this diagnosis is contemplated should be treated with antibiotics to cover the possibility of plague.[45]

Primary pneumonic plague has identical constitutional symptoms but follows a fulminant course with a more pronounced pulmonary component. Within 20 to 24 hours after the onset of the illness, tachypnea, dyspnea, and cough productive of bloody mucopurulent sputum supervene. If early and effective treatment is not instituted, the patient usually dies.[47]

DIFFERENTIAL DIAGNOSIS

Because of the rare incidence of plague today, the diagnosis often is delayed or missed. Bubonic plague may be confused with other diseases affecting the skin and lymph nodes. The diagnosis of staphylococcal or streptococcal adenitis can be established easily by culture. Lymphogranuloma venereum is more indolent, has milder systemic symptoms, and is associated with anogenital ulcer. Syphilitic adenitis usually is nontender. With cat-scratch disease and *Pasteurella multocida* infections, the constitutional symptoms are few, and the patient typically has a history of animal exposure. Tularemia has a more gradual onset.[47] In their later stages, the ulcerated skin lesions of plague may resemble anthrax.[33]

DIAGNOSIS

The most important factor in promptly establishing the diagnosis of plague is having a high index of suspicion. Suspicion should trigger immediate notification to the local or state health department. The state reference laboratory can arrange for rapid diagnostic tests.

Bacterial staining of lymph node material by Giemsa, Wayson, or Wright stain often shows the typical bipolar plague organisms. In the septicemic form of the disease, similar bacterial staining of venous blood frequently permits visualization of the plague bacillus.[36] Fluorescent antibody staining of direct smears and tissues may provide a rapid, presumptive diagnosis of plague.[29] More recent rapid tests, such as enzyme-linked immunosorbent assay for F1 antigen and polymerase chain reaction, have shown promise in the laboratory or in outbreaks, but they are not widely available,[12] (*pla* and *caf1* genes).

TREATMENT

Therapeutic decisions cannot await culture results. All patients suspected to have plague should receive prompt antimicrobial therapy after appropriate blood and tissue have been obtained for cultures, fluorescent antibody staining, and serologic testing.

The sulfonamides and streptomycin proved effective when they were introduced first in the 1940s. Resistant strains to one or the other of these antibiotics soon appeared.[6,49] Despite the paucity of published trials in humans on antibiotic effectiveness, other than streptomycin and tetracycline, the Working Group on Civilian Biodefense Consensus Statement[29] recommends gentamicin as an effective alternative to streptomycin for patients needing parenteral antibiotics. Gentamicin has been used frequently in recent years and has shown comparable outcomes to streptomycin in one case series.[3] In vitro and in vivo studies in mice corroborate its effectiveness against *Y. pestis* infections.[53]

For acutely ill patients thought to have plague infection, streptomycin and gentamicin are the drugs of choice. If available, streptomycin is given intramuscularly, 20 to 30 mg/kg/day in two divided doses.[38] Gentamicin is administered intravenously or intramuscularly, 7.5 mg/kg/day to children and 3 to 5 mg/kg/day to adults in three divided doses. Antibiotic susceptibility testing should be done because *Y. pestis* plasmid-mediated, multiple-antibiotic resistance has been described.[23]

When plague meningitis develops, chloramphenicol, 50 to 100 mg/kg/day (after administration of an initial dose of 25 mg/kg) intravenously in four divided doses, is the treatment of choice. Duration of therapy is determined by the length and severity of the illness. Treatment is continued for at least 7 days in patients with uncomplicated disease.[13]

Patients older than 8 years who do not require hospitalization receive tetracycline at a dose of 25 to 50 mg/kg/day every 4 to 6 hours up to a total daily dose of 1 g in children and 2 g in adults. When outpatient treatment is given, the patient should be observed closely for the first 3 days to ensure resolution of the disease.[13] Sulfonamides may be used for prophylaxis in pediatric patients as an alternative to the tetracycline class of antibiotics.[29] Doxycycline at a dose of 4 mg/kg/day (up to a maximum of 200 mg) divided into two doses may be substituted for tetracycline).

PROGNOSIS

In outbreaks of untreated plague, the mortality rate has ranged from 40 to 70 percent. Pneumonic plague almost invariably is fatal without treatment. With prompt specific antimicrobial therapy, the overall mortality rate for plague has decreased to 5 percent.[35] Complications during convalescence include polyarthritis, small lung abscesses, delayed suppuration of buboes,[33] and meningitis. *Staphylococcus aureus* and *Pseudomonas* spp. may superinfect involved lymph nodes.[48] Immunity usually ensues after clinical or asymptomatic infection occurs, but natural re-infection rarely has been observed.[48]

PREVENTION AND CONTROL

Institution of hygienic measures and eradication of rats from areas of human habitations have all but eliminated epidemics of urban plague. When epizootics occur in wild rodents, control measures must be directed against rodents and fleas. Vector control can be achieved by the use of insecticides in fields and housing areas. In plague-endemic areas, the public must be instructed to avoid burrows, not to handle sick or dead rodents, to deflea household pets, and to eliminate trash near living areas.[10] The immune status of domestic animals can be used as a surveillance tool to ascertain the presence of *Y. pestis* in the community. Dogs, cats, and swine develop antibodies to the fraction 1 antigen of *Y. pestis*.[41,51]

Patients with plague should be isolated with respiratory precautions until they are bacteriologically sterile. Contacts of patients with pneumonic plague should receive chemoprophylaxis with tetracycline at 25 to 50 mg/kg/day up to 2 g in adults and up to 1 g in children 8 years and older. Younger children receive trimethoprim-sulfamethoxazole at 40 mg/kg/day (sulfamethoxazole) in two equal doses orally.[29] The 6-day quarantine period for international travel for contacts of patients with plague does not guarantee the clearance of the bacillus from asymptomatic pharyngeal carriers.[6] Public and professional education in endemic zones is paramount for ensuring prompt reporting of human and animal cases.

Plague vaccines had been used since the late 19th century for individuals at high risk for occupational exposure. They are no longer being manufactured in the United States. Research in this area is continuing.[29]

CHAPTER 123

OTHER *YERSINIA* SPECIES

Charles R. Woods, Jr.

Yersinia spp. are gram-negative, coccobacillary organisms that are primarily zoonotic. The genus is a member of the family Enterobacteriaceae and consists of 11 species, 3 of which clearly are human pathogens:[69] *Yersinia pestis*, *Yersinia pseudotuberculosis* (both formerly included in the genus *Pasteurella*), and *Yersinia enterocolitica*. *Y. pestis*, the causative agent of plague, is found in rodents and insect vectors and is discussed in Chapter 122.

Y. enterocolitica and *Y. pseudotuberculosis* are responsible for a variety of syndromes, some of which originally were called *pseudotuberculosis*. Infections caused by these enteropathogenic *Yer-*

sinia spp. now are collectively called *yersiniosis*, which is the focus of this chapter. Molecular phylogenetic analysis suggests that *Y. pestis* evolved from *Y. pseudotuberculosis* 1500 to 20,000 years ago.[4] The genomes of representative strains of the three pathogenic *Yersinia* spp. have been sequenced.[194]

During the past 3 decades, *Y. enterocolitica* has been recognized as an important human pathogen worldwide and is a common cause of gastroenteritis in some pediatric populations of the industrialized world.[1,47,56,118] *Y. enterocolitica* also has drawn attention because of its immunologic or postinfectious manifestations, which include reactive arthritis and erythema nodosum.[47] *Y. pseudotuberculosis*, although widespread in nature, is a much less common cause of human disease.[69] In Japan, it has been associated with clinical illness that sometimes has resembled Kawasaki disease.

HISTORICAL ASPECTS

In 1883, Malassez and Vignal[130] described a bacterium that produced a disease they named *pseudotuberculosis*. When injected into guinea pigs, the organism produced tuberculosis-like lesions. It grew at 4° C and multiplied better at 22° C than at 37° C. This observation was confirmed in 1910 by Albrecht,[11] who labeled the disease *enteritis follicularis suppurativa*. The first case of mesenteric adenitis, the most common syndrome produced by *Y. pseudotuberculosis*, was reported in 1913 by Saisawa.[173] A second instance of disease that indicated its capacity to produce death (bacteremia and multiple hepatic abscesses) was recorded in 1949 by Hassig and colleagues.[79] Masshoff[132] was the first to recover the organism from a culture of mesenteric lymph nodes of a patient with the clinical picture of acute appendicitis. Masshoff and Dolle[133] subsequently described the histologic picture produced by *Y. pseudotuberculosis*. In 1954, Knapp and Masshoff[106] first reported the clinical features of infection produced by this organism. Only 14 cases of this infection had been described up to that time.[55]

The existence of a species of *Yersinia* other than that causing pseudotuberculosis was suggested in 1933 by Gilbert,[62] who reported an unusual infection in animals. Schleifstein and Coleman[174,175] examined numerous organisms that were isolated between 1933 and 1957 from stool cultures of human cases of diarrhea from which *Salmonella* and *Shigella* organisms could not be recovered and that resembled the infections in animals reported by Gilbert. These investigators identified an organism that had not been described previously and named it *Bacterium enterocoliticum*. In 1964, it was named *Y. enterocolitica* by Frederiksen.[59]

The genus is named for A. J. Yersin, the French bacteriologist who first isolated the plague bacillus.[186] During the past 40 years, an extensive literature detailing the microbiology, pathology, epidemiology, molecular pathogenesis, and clinical features of disease caused by *Y. pseudotuberculosis* and *Y. enterocolitica* has accumulated.*

MICROBIOLOGY

Yersinia organisms are large (0.5 to 1 μm × 1 to 2 μm or larger), gram-negative, and ovoid or rod-shaped. *Y. enterocolitica* and *Y. pseudotuberculosis* are motile at 22° C to 25° C but not at 37° C. Similar to other members of Enterobacteriaceae, *Yersinia* organisms are facultative anaerobes and grow well on ordinary media. On Gram staining, *Y. pseudotuberculosis* appears as a large coccobacillus. Staining with methylene blue and carbol fuchsin discloses a bipolar (safety pin) morphology of most, but not all, strains. *Y. enterocolitica* is smaller and shows little, if any, bipolarity.[183,186]

Yersinia organisms may be confused with coliforms, such as *Escherichia coli*, *Morganella*, *Proteus*, *Shigella*, *Salmonella*, and *Providencia*, or with *Y. pestis*, *Brucella*, and *Achromobacter*, unless careful biochemical and physiologic studies are conducted. *Yersinia* organisms reduce nitrates and are oxidase-negative, catalase-positive, urease-positive, and citrate-negative. They ferment glucose, maltose, mannitol, glycerol, xylose, and fructose, producing acid but no gas with each sugar. *Yersinia* organisms usually do not ferment lactose but produce α-galactosidase. They do not ferment dulcitol, inositol, raffinose, or rhamnose. On lysine-iron agar slants, *Yersinia* organisms produce an alkaline slant with an acid butt. They do not produce hydrogen sulfide. The Voges-Proskauer reaction is negative at 37° C but may be positive at 25° C for some strains of *Y. enterocolitica*. All strains of *Y. pseudotuberculosis* and most strains of *Y. enterocolitica* isolated in Europe are indole-negative. Most strains of *Y. enterocolitica* found in the United States have been indole-positive.[50,66,88,146,151,183,186]

Although these two species of *Yersinia* share many properties, they are distinguishable on the basis of several biochemical activities, antigenic structure, and sensitivity to various *Yersinia* phages.[171] *Y. enterocolitica* produces an acid slant and acid butt on triple sugar iron agar caused by fermentation of sucrose, whereas *Y. pseudotuberculosis* produces an alkaline slant and an acid butt. *Y. enterocolitica* elaborates ornithine decarboxylase and ferments sucrose and amygdalin. *Y. pseudotuberculosis* does none of these, but it ferments adonitol, which *Y. enterocolitica* does not.[88,186]

Commercially available tests used to identify Enterobacteriaceae in clinical laboratories may not contain the biochemical reactions needed to identify specific *Yersinia* spp. Traditional macroscale biochemical testing may be required to distinguish *Y. enterocolitica* and *Y. pseudotuberculosis* from nonpathogenic *Yersinia* spp.[73,122] On solid culture media, colonies of the pathogenic species typically are small, smooth, opaque colonies. The colonies of nonpathogenic species are larger and more translucent.[100]

TYPING OF *YERSINIA* STRAINS

Biotyping and serotyping have been the predominant methods used to characterize strains of *Y. enterocolitica*. At least 54 to 60 serotypes of *Y. enterocolitica* exist on the basis of variability of somatic O antigens, but only 11 typically are associated with human disease.[21,23,56,69,197] Six biotypes of *Y. enterocolitica*, designated 1A, 1B, and 2 to 5, have been defined on the basis of differences in the following: lipase activity; salicin acid production; esculin hydrolysis; indole production; ornithine decarboxylase; Voges-Proskauer test; pyrazinamide activity; nitrate reduction; and fermentations of xylose, trehalose, sorbose, and inositol.[23,33,196]

Only a few serotype : biotype combinations are regarded as human pathogens: O:8, O:4, O:13a,13b, O:18, O:20, and O:21 (biotype 1B); O:9 and O:5,27 (biotype 2); O:1,2,3 and O:5,27 (biotype 3); O:3 (biotype 4); and O:2,3 (biotype 5).[202] These pathogenic strains, which carry *Yersinia* virulence plasmids (pYV), generally have negative test results for pyrazinamidase activity, esculin hydrolysis, and salicin fermentation. Nonpathogenic strains, generally of biotype 1A, have positive test results for each of them.[41,54,98] Data suggest that some biotype 1A strains that lack pYV and other *Yersinia* virulence factors also may cause gastroenteritis.[68,179]

Strains of *Y. enterocolitica* can be typed genetically by repetitive element-based (inter-repeat) polymerase chain reaction (PCR), arbitrarily primed PCR,[148] pulsed-field gel electrophoresis,[141] and

*See references 14, 21, 23, 24, 45, 47, 53, 55, 81, 82, 87, 92, 104-107, 118, 125, 137, 169, 183, 185, 186, 189, 200, 212.

ribotyping.[123] These methods allow distinction among strains within biotypes and serotypes and may be useful for outbreak and other epidemiologic investigations.

At least 11 antigenic groups of *Y. pseudotuberculosis* exist on the basis of variation of somatic O antigens. They have been labeled 1a, 1b, 2a, 2b, 2c, 3, 4a, 4b, 5a, 5b, and 6.[84,91,129] Type 2 is related antigenically to *Salmonella* group B, and type 4 is related to *Salmonella* groups D and H.[66] *Y. pseudotuberculosis* strains also can be typed by arbitrarily primed PCR.[129]

EPIDEMIOLOGY

Although most of the early reports of yersiniosis caused by *Y. pseudotuberculosis* and *Y. enterocolitica* came from northern Europe, these microbes have been identified with increasing frequency in all parts of the world,[13] with the possible exception of South America. During 1996 to 1998, the rate of foodborne disease caused by yersiniosis microbes in five areas of the United States was 1 per 100,000 population.[35]

YERSINIA ENTEROCOLITICA

Y. enterocolitica is distributed worldwide but is isolated most frequently in cooler climates.[138] Whether such geographic differences reflect differences in reservoirs or culinary practices that may enhance the risk of acquisition of this organism, or rather represent differences in surveillance for the disease and use of more sensitive culturing techniques in these areas, is unclear.[47] Increased frequency of infections during fall and winter has been reported from Europe[192] and the United States,[1] but no seasonality is evident among outbreaks of disease where more than three cases of *Y. enterocolitica* disease have been identified.[47]

Geographic differences in serotype distribution and frequency also exist. Sporadic infections caused by serotypes O:3 and O:9 are common in Europe,[9,85] but outbreaks rarely have occurred.[47] In North America, multiple serotypes have been responsible for sporadic disease,[18,22,33,65,177,181] but more recently serotype O:3 has become predominant.[33,51,118] Five outbreaks in the United States have been caused by serotype O:8, and two outbreaks in Canada have been caused by serotypes O:5 and O:5,27.[47] Disease caused by serotype O:8 has been reported in Europe.[85]

The true incidence and prevalence of *Y. enterocolitica* infection are unknown.[47] The reported proportional frequency of isolation of *Y. enterocolitica* from stool cultures from patients with diarrhea has ranged from 0 to 3.2 percent in series from Europe, the United States, and New Zealand (Table 123–1).[49,56,85,118,131,136,177] Symptomatic infection occurs more commonly in children. Most series show a slight male predominance of approximately 1.3 : 1.[51,56,131,196] Surveillance at five FoodNet sites in the United States during 1996 to 1999 found that African-American infants had far higher rates than white infants, with a peak occurrence from November to February (Fig. 123–1).[162]

Animals and water sources are the primary environmental reservoirs for *Y. enterocolitica*, but the biotypes and serotypes of the strains found in them usually differ from those causing human disease.[33,47,177] Blood transfusions also may be a source of *Y. enterocolitica* infection.[34]

Animal Reservoirs

Y. enterocolitica strains have been isolated from a wide variety of mammals (dogs, pigs, sheep, rabbits, guinea pigs, cows, horses, chinchillas, monkeys), frogs, fish, flies, fleas, snails, crabs, and oysters. Birds do not seem to be a major reservoir for *Y. enterocolitica*, although avian isolates have been reported.[47,88,125]

Pigs seem to be an important reservoir for the human pathogenic serotypes O:3 and O:9 in Europe and Japan and serotype O:3 in North America and South Africa.[47,118,158] The biochemical and phage typing profiles of isolates from pigs are similar to those of strains commonly responsible for human infections.[200] *Y. enterocolitica* has been isolated from the tongue, tonsils, and cecal contents of swine and from pork, ham, and butcher shop cutting boards.[47,66] Pig farmers in Finland were 3 times and 2.4 times as likely to have seropositivity to serotypes O:3 and O:9 than were berry farmers.[176]

Wild rodents captured in areas of Japan where human infections caused by *Y. enterocolitica* serotype O:8 had occurred were shown to harbor isolates of the same serotype.[43] Two distinct serotype O:8 strains, defined by restriction enzyme analysis of the virulence plasmids, were isolated from humans and rodents. This finding suggests that rodents are a potential source of sporadic human infection in Japan.

Apparent transmission to humans from dogs and cats also has been reported. A fecal-oral or oral-oral route has been postulated but not confirmed. Little evidence supports airborne or insect vector–borne transmission.[47]

Foods and Water

In countries with high numbers of cases of yersiniosis, ingestion of raw pork has been common. Infection with serotypes O:3 and O:9 was highly associated with ingestion of raw pork during the 2 weeks preceding the illness in a case-control study.[192] In Belgium, laboratory surveillance that began in 1967 showed yearly increases in cases through 1986. After a media campaign was launched to dissuade people from eating raw or undercooked

TABLE 123–1 Percentage of Stool Cultures Yielding *Yersinia enterocolitica*

Country	Years	Population	Total Cultures	Percentage *Y. enterocolitica*
Canada[131]	1977-1978	Symptomatic children	6364	2.8
The Netherlands[85]	1982-1984	Enteritis patients <40 years old	827	2.9
Italy[136]	1981-1985	Children with diarrhea	2500	1.4*
New Zealand[56]	1988-1993	Patients with gastroenteritis	231,128	0.6
U.S. (Detroit, MI)[49]	May-November 1977	Children with diarrhea	1262	0

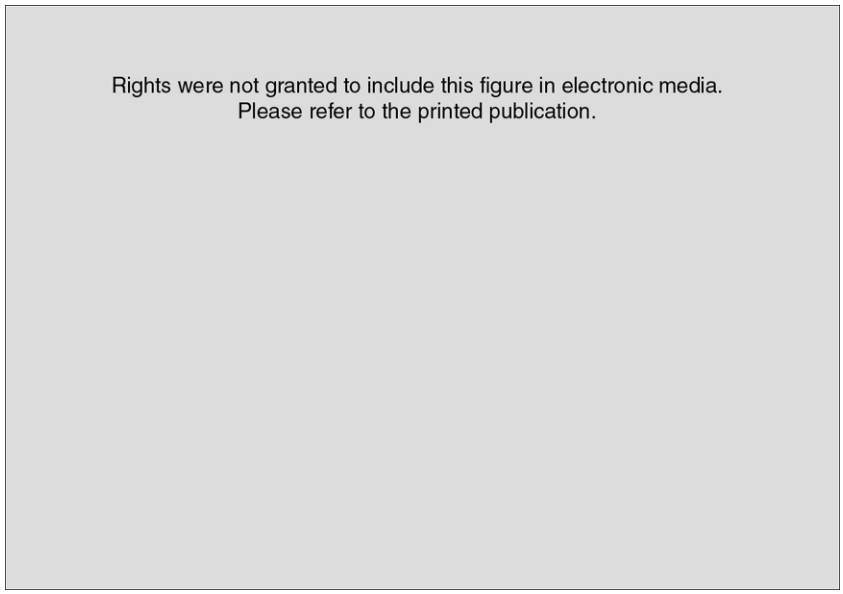

Figure 123–1 Adjusted incidence of *Yersinia enterocolitica* (YE) infection, by race and age. Average incidences are given over the 4-year surveillance period (1996 to 1999) by age group and adjusted race/ethnicity. *(From Ray, S. M., Ahuja, S. D., Blake, P. A., et al.: Population-based surveillance for* Yersinia enterocolitica *infections in FoodNet sites, 1996-1999: Higher risk for disease in infants and minority populations. Clin. Infect. Dis.* 38:*S181-S189, 2004.)*

pork or pork products and to educate consumers regarding good hygiene practices during food preparation, the number of isolations of *Y. enterocolitica* decreased from a high of 1469 in 1986 to 707 in 1996.[202] Changes in techniques for slaughtering also may have contributed to this decline. Preparation of chitterlings in the household was a risk factor for *Y. enterocolitica* infection among children in Michigan[1] and Illinois.[36]

Ingestion of water contaminated with serotype O:8 has led to sporadic cases and outbreaks.[47] Bean sprouts that had been immersed in contaminated water were the source of an outbreak in Pennsylvania in 1982. Ingestion of tofu (bean curd) packed in untreated spring water that subsequently was found to be contaminated with *Y. enterocolitica* caused 44 cases of symptomatic infection in Washington state in 1981 and 1982.[191] Serotypes commonly found in water samples rarely are isolated from humans with symptomatic disease, however.[33]

Contaminated milk has been implicated as the source of several large outbreaks of *Y. enterocolitica* infection.[19,47,197] Whipped cream and ice cream may harbor the organism. Contamination of milk products after pasteurization has been documented. *Y. enterocolitica* has been found in raw milk samples from cows and goats. Samples of beef, lamb, poultry, oysters, and a variety of vegetables also have been found to be contaminated with *Y. enterocolitica*.[30,47,66]

Serotypes O:3, O:4,33, O:5,27, O:7,8, O:8, O:10, O:13, and O:16 cause most human disease in North America but rarely are isolated in surveillance of water or food samples. Serotype O:8 strains have been cultured from cattle, milk, and water samples[146]; serotype O:4,33 strains have been isolated from pigs and cattle; and serotype O:4,32 strains have been found in cheese, ham, sausage, raw beef, and one pancake specimen.[33,177,197]

Incubation, Carriage, and Transmission in Humans

The incubation period of *Y. enterocolitica* enterocolitis ranges from 1 to 14 days, with a median of approximately 4 days.[33,47,118] The minimal infective dose of *Y. enterocolitica* is unknown. Ingestion of 3.5×10^9 organisms by a volunteer resulted in diarrhea in less than 1 day, but such large inocula are unlikely to be encountered clinically. The duration of excretion of the organism after development of infection in children ranges from 14 to 97 days (mean 42 days).[131] The impact, if any, of antibiotic treatment on the duration of carriage is unknown.

Transmission to household members occurs uncommonly, even among young children, who are at higher risk for development of symptomatic disease.[19,131,191] Six percent of household contacts developed disease in one outbreak,[191] but several large outbreaks with no secondary household cases have been reported.[47]

Yersinia enterocolitica and Blood Transfusion–Related Sepsis

Sporadic cases of *Y. enterocolitica* sepsis related to contamination of transfusions of red blood cells have been recognized since 1987 and have occurred in the United States, Europe, and Australia.[34] *Y. enterocolitica* is the most common cause of transfusion-related sepsis.[97] Among 20 cases from the United States, chills occurred in 16, fever occurred in 14, hypotension occurred in 13, and disseminated intravascular coagulation occurred in 7.[42] Death attributable to *Y. enterocolitica* infection occurred in 12, half of which occurred within 25 hours of receipt of the contaminated transfusion. Among the 20 donors, 13 had had gastrointestinal symptoms within the month before receiving a blood donation, and 16 had titers equal to or greater than 1:128 (considered positive).

In many cases of transfusion-related sepsis, the contaminated red blood cell units had been stored for 25 days or more.[80] After experimental inoculation of small numbers of *Y. enterocolitica* into packed cells kept at 4° C, the organisms continue to replicate, reaching concentrations of 100 colony-forming units (CFU)/mL in 7 days and 10^6 CFU/mL in 21 days. High levels of endotoxin can result from such replication and have been documented in samples from red blood cell units that led to transfusion-related sepsis.[42]

Human Outbreaks

Outbreaks of *Y. enterocolitica* disease have involved communities, families (with interfamily spread), hospitals, and schools. The sources of the organism have been various foods and animals, especially dogs. A review of these outbreaks suggests that infection may occur more commonly than has been recognized. Yersiniosis also resembles disease caused by *Salmonella* and *Shigella* organisms in many respects, including the environmental sources

of the organisms, the clinical syndromes, and the occurrence of asymptomatic infection.

OUTBREAKS IN SCHOOLS AND COMMUNITIES

A community outbreak caused by a serotype O:8 strain occurred in New York state in 1976.[19] At least 222 children and employees had a yersiniosis-like illness during a 10-week period. Illness was associated with drinking chocolate milk that was contaminated after pasteurization during hand mixing with chocolate syrup. Transmission of infection from ill children to household contacts was not observed. School-related outbreaks also have occurred in Japan.[15,215]

In the summer of 1982, an estimated several thousand individuals in several southern states who consumed milk from a single dairy developed yersiniosis. A total of 172 culture-positive infections were confirmed, many as a result of hospitalization for illness. Seventeen patients underwent appendectomy; 24 others had extraintestinal spread of infection. The strain involved was designated serotype O:13a,13b.[197] An outbreak associated with consumption of pasteurized milk in Vermont and New Hampshire in 1995 probably resulted from contamination after pasteurization with a serotype O:8 strain, possibly from rinsing bottles with untreated well water.[5]

During November to December 2002, nine infants in the Chicago area developed gastroenteritis caused by *Y. enterocolitica*. Eight were African-American and were exposed to caretakers who had prepared chitterlings for holiday meals. All recovered, although six were hospitalized for a median of 5 days.[36]

FAMILY EPIDEMICS

In North Carolina, 21 individuals from four families were involved in an outbreak of yersiniosis that had an unusually high attack rate.[70] Of the 21 affected individuals, 18 were children aged 3 to 13 years; 16 of the 21 had diarrhea and fever, and 5 were asymptomatic. *Y. enterocolitica* was recovered from the spleen of the youngest child at autopsy. The diagnosis was established serologically in the others. A dog that had given birth to puppies that had died of a diarrheal illness a week before the families became ill seemed to be the source of the infection.

NOSOCOMIAL OUTBREAKS

A young child who was hospitalized in Finland with acute gastroenteritis was the source case of infection in a housekeeping worker and four nurses who cared for her.[195] The infecting strain was serotype O:9. Another hospital outbreak involved nine patients in Canada.[161] It was caused by a serotype O:5 strain. Person-to-person contact was considered the likely mode of transmission.

Prevention of Disease

During outbreaks, efforts should be made to identify environmental sources and vehicles of transmission.[47] A single environmental source can harbor multiple serotypes of *Y. enterocolitica*, such that resulting outbreaks may be polyclonal in nature.[191] Enteric precautions should be used for hospitalized patients with diarrhea caused by *Y. enterocolitica* (as with other causes of gastroenteritis).[47] At the population level, decreased consumption of raw or undercooked pork products potentially can reduce the incidence of infection.[192,202]

YERSINIA PSEUDOTUBERCULOSIS

Y. pseudotuberculosis may infect individuals of all ages, but at least 75 percent of patients with clinically apparent disease are children younger than 15 years old.[91,171] Infection in young infants has been reported.[91,208] Of 130 cases diagnosed in Great Britain from 1959 to 1970, boys were involved three times more frequently than girls.[125] Infections occur more commonly during the cold months of the year.[91,171] The seasonal winter peak of human infection produced by *Y. pseudotuberculosis* is similar to that seen in wild and domesticated animals.[104,105,171]

The attack rates for children living in rural and urban areas seem to be the same. *Y. pseudotuberculosis* occasionally has been recovered from healthy individuals. Exposure to the organism seems to be uncommon; antibody to *Y. pseudotuberculosis* was detected in only 1 of 2000 sera from individuals with no history of yersiniosis.[59,171]

Y. pseudotuberculosis is distributed worldwide in a large variety of animals and birds, but infection seldom occurs.[63] Guinea pigs, rodents, and rabbits are infected most often[125] and may experience a plaguelike illness.[63,88] Lesions in guinea pigs may be confused easily with lesions caused by *Y. pestis*. Rats and other rodents also may have plaguelike disease caused by *Y. pseudotuberculosis*. The microbe can be cultured from tongue, tonsils, intestines, and large organs of infected animals.[145]

Infection has been reported in various domestic animals (cattle, sheep, goats, cats, dogs, hamsters), commercially raised fur bearers (chinchillas, mink, coypu), and other wild or captive animals (rabbits, raccoons, foxes, deer, beavers, monkeys, puma, kangaroos). *Y. pseudotuberculosis* has been found in more than 50 species of birds,[75,99,125] and epizootics have occurred among turkeys, ducks, pigeons, and doves and in aviaries of canaries and finches. Strains obtained from animals and birds in the United States are predominantly of serotypes 1a, 1b, and 3.[125,171]

The incubation period for human disease ranges from 41 hours to 20 days.[91] In a food-associated outbreak in Finland, the median incubation period was 8 days (Fig. 123–2).[94] The organism can survive in fresh tap water for 46 days at room temperature and for 8 months at 4° C. It can survive at 4° C in meat for 145 days and in milk and bread for 2 to 3 weeks.[125]

A family outbreak of mesenteric adenitis caused by *Y. pseudotuberculosis* that involved four siblings aged 7 to 14 years has been reported.[160] A pet dog was shown to have increasing antibody titers at the time the children were ill.

Periodic outbreaks have been reported in Japan, northern Europe, and areas of the former Soviet Union. Sandwiches prepared by a single bakery were the primary risk factor for 67 cases that occurred in a 3-week period in Japan.[91] Drinking unchlorinated well water or mountain stream water has been the source of other outbreaks. Children were much more likely to have clinical disease than adults. More recent outbreaks in Finland have been associated with contaminated lettuce and grated carrots.[94]

PATHOLOGY

The diseases produced by *Y. enterocolitica* and *Y. pseudotuberculosis* are similar and share the histopathologic theme of involvement of the lymphoid tissues of the intestinal mucosa and mesentery.

YERSINIA ENTEROCOLITICA

Y. enterocolitica infection predominantly affects the gastrointestinal tract. The most severe clinical symptoms correlate with an acute terminal ileitis. The mucosal surface of the ileum and other involved sites may be inflamed diffusely. Ulcerations may occur throughout the gastrointestinal tract and may be small and superficial or extend to the muscularis propria. Mucosal and submucosal hyperplasia of Peyer patches occurs with scattered microabscess formation.

Figure 123–2 Distribution of incubation periods for *Yersinia pseudotuberculosis* infection to onset of gastrointestinal (GI) symptoms and erythema nodosum after point source exposure to contaminated carrots. Of 72 case patients with a known date of onset, 51 had GI symptoms and 38 had erythema nodosum only; 28 had GI symptoms and erythema nodosum and appear twice in the graph. *(From Jalava, K., Hakkinen, M., Valkonen, M., et al.: An outbreak of gastrointestinal illness and erythema nodosum from grated carrots contaminated with Yersinia pseudotuberculosis. J. Infect. Dis.* 194*:1209-1216, 2006.)*

Ulcers occur primarily over the sites of lymphoid tissue within the mucosa, which accounts for their more longitudinal appearance in the small intestine and an oval or punctate appearance in the stomach and colon. Ulcerations are characterized by necrosis of the epithelial layer. In the colon, the necrosis also may extend through the superficial third of the crypts. Large colonic ulcerations covered by pseudomembranes or mucoid debris are seen occasionally. Ulcerations may progress to perforation, with subsequent development of peritonitis or gastrointestinal hemorrhage in severe cases.[27,64,200,201]

The inflammatory response in the mucosa consists mainly of neutrophils and mononuclear cells. Lymphocytes and plasma cells also may be seen. Giant cells are not seen, although a granulomatous appearance can be imparted by the presence of plump epithelioid histiocytes. Numerous colonies of gram-negative bacteria often can be seen beneath the mucosal ulcerations and within the microabscesses that occur in the lymphoid tissues.[64,200,201]

The appendix usually appears normal on gross inspection, but small focal ulcerations frequently are present.[7] Large areas of necrosis are found occasionally, and acute, suppurative appendicitis has been reported.[27,96,131] Periappendicular inflammation may result from a true appendicitis or an adjacent terminal ileitis.[200]

Mesenteric adenitis, the hallmark of infection caused by *Y. pseudotuberculosis*, also is a common feature of enterocolitis caused by *Y. enterocolitica*. The lymph nodes usually show numerous large pyroninophilic cells and mitotic figures in the cortical area and marginal sinuses. Small collections of leukocytes in the germinal centers are seen in some cases and suggest formation of microabscesses. In severe cases, extensive areas of necrosis circumscribed by a neutrophilic infiltrate may be seen. The sinusoids can become filled with neutrophils and mononuclear cells. The germinal centers often appear reactive.

The histopathologic appearance of the mesenteric adenitis of infection caused by *Y. enterocolitica* can resemble the adenitides caused by cat-scratch disease (*Bartonella henselae*), toxoplasmosis, infectious mononucleosis, and *Y. pseudotuberculosis*.[7,200,211] The necrotizing epithelioid granulomata that may be present in mesenteric adenitis caused by *Y. pseudotuberculosis* have not been described in infection caused by *Y. enterocolitica*. A more recent study of six cases suggests that biotype 1B strains may be more likely to cause suppurative inflammation, whereas biotype 2 through 5 strains may be more likely to cause granulomatous infection.[115]

YERSINIA PSEUDOTUBERCULOSIS

Numerous reports* collectively have described the pathology of infection caused by *Y. pseudotuberculosis*. Grossly enlarged, soft, and inflamed mesenteric lymph nodes are the predominant finding on laparotomy. They frequently are located at the ileocecal angle. Punctate hemorrhages and small, yellow microabscesses may be present on the surfaces of the nodes at the height of infection. The appendix usually appears normal, but the terminal ileum and cecum occasionally appear inflamed. A necrotic purulent mass sometimes is seen in the mesentery.

Histopathologic findings in the mesenteric lymph nodes include enlarged follicles and small abscesses; hyperplasia of reticulum cells; necrosis of the nodes with infiltrates of neutrophilic leukocytes and plasma cells; and, in some instances, punctate hemorrhages. Scattered clusters of neutrophils may be seen within the sinusoids and germinal centers without formation of abscess or necrosis. Atypical mononuclear cells, some of which may be mitotic, may be present in the sinusoids. When necrosis is absent, large numbers of eosinophilic leukocytes occasionally are seen surrounding reticulogranulocytic infiltrates in the nodes. Giant cells can occur and may cause the histologic picture to be confused with that of tuberculosis.

The mesenteric adenitis produced by *Y. pseudotuberculosis* seems to progress through histopathologic stages akin to those of other pyogenic infections that can lead to formation of abscesses.[50,71] Reticulogranulocytic infiltration is followed by formation of an abscess, with subsequent organization and clearing of the abscess. The inflammatory process of *Y. pseudotuberculosis* seems to remain confined to the lymph nodes without rupture through the nodal capsule.

Focal mucosal ulcerations may be seen in the ileum and are more likely to be found at the site of Peyer patches. Aggregates of neutrophilic leukocytes similar to those in mesenteric nodes may be seen in germinal centers within mucosal lymphoid tissue. Fibrinoid material may be a prominent feature at these sites. Small areas of necrosis surrounded by reticulum cells and leukocytes also may be present in the submucosal follicles.[57,105,107,207] Ulcerated lymphoid follicles in the intestinal wall are connected to the regional lymph nodes by a lymphangitis. This anatomic situation is analogous to the primary complex of tuberculosis.

Despite a clinical picture of acute appendicitis as the presenting feature of infection by *Y. pseudotuberculosis*, the appendix typically is grossly and microscopically normal. Inflammatory changes, when present, usually are in the form of a periappendicitis. Phlegmonous appendicitis can result from infection caused by *Y. pseudotuberculosis*, but is rare.[50,84]

PATHOGENESIS

The pathogenesis of infection by the two enteropathogenic *Yersinia* spp. has been studied extensively. After ingestion and successful transit to the small intestine have occurred, these *Yersinia* spp. are able to penetrate into the lamina propria primarily by passing through the cytoplasm of M cells that reside on the mucosal surface of Peyer patches. The bacteria are internalized in membrane-bound vacuoles in which they survive, but do not replicate. After reaching the lamina propria, the microbes multiply as extracellular microcolonies in lymph follicles and Peyer patches, where they may reach densities of 10^9 CFU/g of tissue.[52]

Neutrophils and macrophages infiltrate these sites in response to the infection, ultimately creating microabscesses, but *Y. enterocolitica* is able to resist phagocytosis and intracellular killing by neutrophils and macrophages. *Yersinia* spp. also inhibit production of tumor necrosis factor-α and interferon-γ and induce apoptosis in host macrophages. The microbes disseminate to the mesenteric lymph nodes, apparently through lymphatic vessels. Infection usually is contained at this point, although abscesses often develop within the nodes. Systemic spread occurs occasionally, more commonly with infection by serotype O:8 strains.

Control of infection caused by *Y. enterocolitica* is the result of T-cell responses that lead to restriction of bacterial growth in infected organs through stimulation of production of *Yersinia*-specific antibody by B cells and cytokine-mediated activation of macrophages. These responses ultimately overcome the antiphagocyte strategies of *Yersinia*. Production of tumor necrosis factor-α and interferon-γ seems to be an essential part of the host response to *Yersinia* infections. *Yersinia* microbes generally do not survive within granulocytes after they have been successfully phagocytosed.[43,45,46,149]

Only a few of the many serotypes of *Yersinia* spp. are capable of infecting humans. Numerous virulence factors have been identified among these "pathogenic" strains (Table 123–2). Most of them are encoded on the *Yersinia* virulence plasmid pYV. At least eight chromosomal loci that encode novel *Yersinia* virulence factors have been found by tagged mutagenesis studies.[67] Much of this knowledge has been gained through mouse and rabbit models of human infection and observations of interactions of *Yersinia* organisms with in vitro cell culture models.[26,43,83,127,156]

The distinctions in pathogenesis between the two enteropathogenic *Yersinia* spp. and *Y. pestis* seem to be caused partly by the presence in *Y. pestis* of (1) two additional plasmids that encode a plasmin activator and a mouse exotoxin and (2) a hemin storage locus on its chromosome. These additional factors may enable *Y. pestis* to survive in and transmit between fleas and rodents. Such transmission does not occur with the enteropathogenic *Yersinia* spp.[167]

BACTERIAL DETERMINANTS OF MUCOSAL INVASION

Two outer-membrane proteins encoded by chromosomal genes permit entry into various mammalian cell types in vitro and are likely to be responsible for the ability of *Yersinia* to invade into and through the intestinal mucosal epithelium. They have been named *invasin* and the *attachment invasin locus protein* (Ail). All isolates of *Y. enterocolitica* that are virulent in humans contain DNA sequences that encode for invasin and Ail. Nonpathogenic strains do not contain the genetic code for Ail but most contain invasin genes that cannot be expressed because of chromosomal rearrangements. These proteins apparently are unique to the genus *Yersinia*.[92,135,153]

Invasin attaches to receptors in the β_1 integrin family and induces an actin-mediated endocytosis of the microbe. It binds to β_1-chain integrin receptors with approximately 100-fold higher affinity than do natural ligands, such as fibronectin. Such high-affinity binding triggers endocytosis-like internalization that involves clathrin.[46] Invasin is expressed maximally at ambient temperatures when the organism is in stationary phase. *Y. enterocolitica* microbes living in the environment probably exist in a stationary phase–like state and may be primed maximally for invasion of the host after ingestion. Invasin expression also can remain elevated at 37° C when the pH is 5.5, and such conditions are encountered during passage through the intestinal tract. Ail is expressed maximally at 37° C, functions as an adhesin and an invasion factor, and plays a role in the resistance of *Y. enterocolitica* to the bactericidal activity of human serum.[92,93,153]

High levels of β_1-chain integrin receptors are found on the luminal surface of M cells, which are antigen-sampling epithelial cells found in highest numbers overlying Peyer patches in the intestinal tract.[76] Flagellum-dependent motility seems

*See references 50, 55, 57, 87, 105, 126, 132, 133, 137, 160, 207.

TABLE 123–2 Known and Putative *Yersinia* Virulence Factors*

Stage of Pathogenesis	Determinant	Genomic Origin†	Function	Conditions of Expression
Gastric transit	Urease	Chromosome	Aids survival of gastric acidity	
Mucosal invasion	Invasin (inv)	Chromosome	Attachment, invasion via β_1 integrins; broad host/cell range	28° C
	Attachment invasion locus (AiL)	Chromosome	Attachment, lesser invasion factor; more host-specific than invasin; serum resistance	37° C
	Yersinia adhesin A (YadA)	Plasmid	Attachment, invasion; reduces opsonization by C3b by binding complement factor H; ? role in resistance to antibacterial polypeptides (e.g., bactericidal permeability-increasing protein)	37° C and *any* calcium concentration
Disruption of phagocyte function	Effector proteins (act on host cells)	Plasmid	Tyrosine phosphorylase that prevents phagocytosis by macrophages by preventing assembly of focal adhesion structures of phagocytes	37° C and low calcium concentration
	YopH[d]		Phagocytosis resistance via induction of host cell actin filament rearrangements	
	YopE		Cysteine protease that inhibits mitogen-activated protein kinase and nuclear factor κB signaling via interruption of post-translational covalent additions of ubiquitin-like molecules to these enzymes. This prevents production of cytokines (tumor necrosis factor-α), inhibits the host immune response, and triggers apoptosis of macrophages. Inhibits kinase phosphorylation via an acetyltransferase function	
	YopJ/P		Serine kinase, causes rounding up of cells, specific target unknown	
	YpkA/YopO		Disruption of actin filaments	
	YopT		Role unclear. Inhibits thrombin-induced platelet activation in vitro but is delivered intracellularly during infection. Leads to depletion of natural killer cells and alters expression of interleukin-15 and interleukin-15 receptors	
	YopM			
	Host cell membrane attachment, pore insertion proteins	Plasmid	Pore formation in host cell membrane to allow translocation of effector proteins into the host cell. ? Suppression of interleukin-8 secretion by epithelial cells	37° C and low calcium concentration
	YopB and YopD		Controls translocation via modulating the size of the putative YopB, YopD pore in the host cell membrane	
	YopQ (YopK)		Involved in control of translocation, perhaps stabilizing contact between the bacterium and host cell membranes	
	YopN		Assists extrusion of Yops B and D to the host cell membrane. Homologue of the *Y. pestis* V antigen. Antibodies against V antigen seem to be protective at the serotype level	
	LcrV[e]			
	Yop secretion apparatus (Ysc) (28 proteins in total)	Plasmid	Form a complex that spans the inner bacterial membrane (? gated pore/channel)	37° C and low calcium concentration
	YscD, YscR, YscU, and LcrD/YscV		Forms a pore in the outer bacterial membrane that may connect with the inner membrane pore	
	YscC secretin		ATPase that energizes Yop transfer across the membranes	
	YscN		Negative *yop* gene regulators that, when secreted, decrease in concentration in the bacterium, allowing *yop* expression	
	LcrQ (in *Y. pseudotuberculosis*), YscM1 and YscM2 (in *Y. enterocolitica*)			
	Cytosolic chaperones (Syc) (6 proteins in total)	Plasmid	Secretion/translocation pilots or antidegradation roles for effector proteins	37° C and low calcium concentration
Colonization of Peyer patches and lymph nodes	*Yersinia* phospholipase A	Plasmid	? Serum resistance, ? inhibition of phagocytosis	37° C and low calcium concentration
Iron metabolism	Yersiniabactin	Chromosome (high pathogenicity island)	Siderophore	37° C, iron starvation

TABLE 123–2 Known and Putative Yersinia Virulence Factors*—cont'd

Stage of Pathogenesis	Determinant	Genomic Origin†	Function	Conditions of Expression
Diarrhea	*Yersinia* heat-stable enterotoxin (Yst)	Chromosome	Fluid secretion in intestine. Precise role in pathogenesis of disease in humans is unclear, but found in clinical isolates from children with diarrhea	28° C (in vitro)
? Systemic invasion	O antigen	Chromosome	Component of lipopolysaccharide. ? Complement/serum resistance	

**The pathogenesis/virulence roles of several gene products encoded on the Yersinia virulence plasmid pVY have yet to be determined, and additional functions may be identified for other gene products. Additional chromosomally encoded virulence factors are suspected, with investigations ongoing.*
†Plasmid refers to the Yersinia virulence plasmid pYV.
Lcr, low calcium response; Yop, Yersinia outer membrane protein (although not all such designated proteins reside in the outer membrane).
Data from references 23, 44, 45, 67, 83, 102, 111, 119, 140, 149, 167, 179, 180, 214.

to be required for invasin-mediated invasion of cells by *Y. enterocolitica*.[213]

YERSINIA ADHESIN A

Yersinia adhesin A (YadA) is a multifunctional virulence factor of *Y. enterocolitica*. YadA is approximately 50 kd and probably forms tetrameric fibrillae on the microbial surface. Its gene resides on the pYV plasmid and is transcribed at 37° C independently of the calcium concentration. YadA binds to extracellular matrix proteins, such as collagen, and mediates adhesion to cells. It may play a role in translocation of Yop effector proteins into eukaryotic phagocytic cells. YadA also inhibits the terminal complement attack complex, reduces opsonization by C3b through binding of complement factor H, and contributes to the ability of *Y. enterocolitica* to resist killing by antimicrobial polypeptides of human granulocytes. YadA knockout mutants are far less virulent in mice than is the parent wild-type strain.[45,82,205]

VIRULENCE PLASMID AND TYPE III SECRETION SYSTEM

Pathogenic strains of *Y. enterocolitica* harbor a plasmid that consists of approximately 70 kb (denoted pYV) and encodes the low calcium response system of *Yersinia* spp., which involves a complex response to environmental conditions of 37° C and calcium concentrations of less than 2.5 mM, both of which describe the intracellular compartment of mammalian cells.[45,180] Plasmid-encoded factors are required for survival and extracellular multiplication after reaching Peyer patches. Plasmid-cured derivatives are ingested rapidly and killed by neutrophils in Peyer patches, whereas wild-type strains are able to proliferate and spread through the lamina propria to adjacent villi. Plasmid-encoded factors are not required for *Y. enterocolitica* to penetrate the intestinal mucosa.[82]

In DNA cross-hybridization studies, the pYVs of *Y. enterocolitica* serogroups O:9, O:3, and O:5 show 90 percent nucleotide identity with one another, 75 percent identity with the pYV of serogroup O:8, and 55 percent identity with the pYV of *Y. pestis* and *Y. pseudotuberculosis*. Despite the nucleotide divergence among the pYVs of the three *Yersinia* spp., the overall structures and most of the genes are highly similar among them. The *Yersinia* low calcium response plasmids are nonconjugative.[45,180]

The *Y. enterocolitica* pYV contains approximately 70 genes, of which approximately 53 have protein products with known or putative functions (many of these are listed among the virulence factors in Table 123–2). pYV encodes *Yersinia* adhesin A and a system of six effector proteins that are delivered into host cells (primarily phagocytic granulocytes) through a complex mechanism of regulatory proteins, secretion chaperones, and proteins that act as secretion channels or pores in the bacterial and host cell membranes. This system, called a type III secretion system, denotes secretion of the bacterial proteins only in response to contact with a mammalian cell. The effector proteins and several others involving pore formation are designated Yops (*Yersinia* outer-membrane proteins), although we now know that most of them do not reside in the outer membrane. Similar type III secretion systems are found in *Salmonella* and *Shigella* spp.[45,180]

The secretion system is composed partially of syringe-like organelles—called *Ysc injectisomes*—that develop when *Yersinia* organisms are incubated at mammalian body temperatures. These injectisomes are protein pumps that span the peptidoglycan layer and the two bacterial cell membranes, topped by a needle-like structure protruding outside the bacterium. Twenty-seven proteins are involved in the structure; 10 of them are located internally and appear to be similar to the basal body of a flagellum. The structure also includes an ATPase that functions as a proton pump. A homomultimeric ring-shaped structure extends through the outer membrane, with a central pore diameter of about 50 Å.[31]

As the injectisomes assemble, stocks of intracellular Yops are synthesized. Active transcription of Yop genes is limited to bacteria in close contact with eukaryotic cells. The secretion channel of the injectisome remains closed, with negative feedback mechanisms to prevent overproduction of Yops. On close contact with a phagocyte, the injectisome channels open, and secretion of effector Yops into the target cell begins.[31]

After secretion into a phagocytic cell occurs, Yop H, Yop E, Yop T, and YopO/YpkA disrupt its cytoskeletal dynamics, blocking phagocytosis (see Table 123–2). Other Yops inhibit production of tumor necrosis factor-α, interleukin-8, and other inflammatory chemokines and induce apoptosis of macrophages.[31]

SUMMARY OF *YERSINIA* PATHOGENESIS

Pathogenic strains of *Y. enterocolitica* require calcium concentrations equivalent to those of serum and extracellular fluids in humans for growth at body temperature. Plasmid proteins are synthesized maximally, however, at 37° C under conditions of low calcium concentrations, such as those found intracellularly. These regulatory effects of environmental calcium concentrations permit free growth of *Yersinia* organisms during extracellular life and production of factors that inhibit phagocytosis by macrophages and neutrophils when *Yersinia* organisms pass through the intracellular compartment during mucosal invasion or come into contact with these granulocytes.[43,45,82]

A model of how pathogenic *Yersinia* organisms living in cold (≤28° C) environmental reservoirs are able to establish infection in the mammalian host can be described at the molecular level (see Table 123–2). *Yersinia* microbes living in the environment

express invasin, which renders them ready to attach and invade the intestinal mucosal M cells after ingestion. Expression of invasin continues at body temperature during gastric passage to the intestines. Survival of gastric acidity is assisted by a urease-producing system.

During intracellular passage through M cells in the small intestine, pYV genes are likely to be activated (conditions of low calcium, 37° C). YadA can be produced at body temperature and may assist in mucosal invasion. Transcytosis from the intestinal lumen to the lamina propria seems to occur by a clathrin-mediated process that probably is a normal function of the host cell, after internalization is triggered. Ail also is synthesized after ingestion occurs and probably promotes attachment to migrating cells in the lamina propria that may facilitate extracellular spread of the microbes to regional lymph nodes and perhaps the liver and spleen.

To survive this journey, *Yersinia* organisms must evade phagocytosis by macrophages and neutrophils. YadA can inhibit complement opsonization, reducing the likelihood that phagocytosis will occur. When contact between the microbe and a host granulocyte occurs, the previously activated type III secretion system (described earlier) encoded by the pYV plasmid comes into play. A contiguous pore is inserted into the granulocyte cell membrane (involving Yops B, D, Q, and N and LcrV). Effector proteins (Yops E, H, J/P, O/A, M, and T) then are translocated into the granulocyte cytoplasm, disrupting its abilities to ingest the bacterium and produce cytokines and triggering apoptotic cell death (see Table 123–2). Although this system of virulence factors is robust enough to facilitate short-lived infection that often causes mild to moderate clinical symptoms, the microbes that do not succumb to the innate immune response ultimately are contained and then eliminated by the adaptive host response.

IRON METABOLISM AND VIRULENCE

Iron is an essential growth factor for most bacteria, many of which release siderophores (high-affinity chelators) that bind ferric iron and then are taken up again through receptors by the microbe. *Y. enterocolitica* serotype O:8 and other biotype 1B strains synthesize a chromosomally encoded siderophore, designated *yersiniabactin*, which sits on the outer membrane of the bacterium. The presence of this siderophore decreases the concentration of environmental iron required for optimal growth and probably accounts for the increased virulence observed for serotype O:8 strains.[47,82] The gene encoding yersiniabactin and the genes required for its biosynthesis, transport, and regulation compose the core of what is termed a *high-pathogenicity island* because of the high lethality for mice that its presence confers.[159]

Serotypes O:8, O:4, O:13, O:18, O:20, and O:21 (all biotype 1B and historically considered "American" strains) are highly lethal to mice after intraperitoneal injection and are able to evoke a keratoconjunctivitis after inoculation into the conjunctival sac of guinea pigs (the positive Sereny test result). Oral infection in mice predominantly produces the features of mesenteric adenitis and systemic infection, rather than simple gastroenteritis, which is characteristic of human infection by American strains. The "European" serotypes, O:3, O:9, and O:5,27, yield a negative Sereny test result and cause mild diarrhea but not death in mice. The European serotypes of *Y. enterocolitica* do not produce yersiniabactin, but are able to use siderophores synthesized by other organisms.[43,82,135]

Deferoxamine, a *Streptomyces*-derived siderophore used clinically to treat iron overload states, can be used by *Y. enterocolitica* strains as a source of iron. The increased availability of ferric iron that exists in iron overload states, such as hemochromatosis and diseases such as thalassemia, that require frequent red blood cell transfusions also facilitates survival and growth of *Y. enterocolitica*. Iron overloading and deferoxamine are independent risk factors for development of systemic disease after intestinal infection with *Y. enterocolitica*.[47]

ENTEROTOXIN PRODUCTION

All enteropathogenic strains of *Y. enterocolitica* produce a heat-stable enterotoxin that closely resembles the heat-stable toxin of *E. coli*. Both enterotoxins induce increases in levels of cyclic guanosine monophosphate levels in intestinal epithelial cells. The *Y. enterocolitica* enterotoxin is not plasmid-encoded, and its presence does not correlate with the expression of other virulence phenotypes.[63] Because the enterotoxin is not produced in vitro at temperatures exceeding 30° C, production in the gastrointestinal tract and a causative role in diarrhea were thought to be unlikely.[47] Observations in the young rabbit oral infection model have shown, however, that enterotoxin-negative mutants did not induce diarrhea, and that the wild-type strain did. Clinical biotype 1A isolates from children with diarrhea in India produce *Y. enterocolitica* stable toxin-b. These findings suggest that *Yersinia* enterotoxins may play a role in causing the diarrhea frequently associated with *Y. enterocolitica* infection in children.[82,152,179]

GASTRIC ACIDITY AS A PROTECTIVE HOST FACTOR

Although *Y. enterocolitica* is able to grow under conditions at pH 5.0 to 9.0, optimal growth occurs at pH 7.0 to 8.0. Gastric acidity may play a protective role against some *Yersinia* inocula, although pathogenic *Yersinia* organisms produce a urease enzyme that facilitates survival. Therapeutic agents or clinical conditions that result in reduced gastric acidity may predispose patients to development of infection. *Y. enterocolitica* bacteremia has been reported after gastrectomy.[47,111]

CLINICAL MANIFESTATIONS

Clinical disease caused by *Y. enterocolitica* occurs far more frequently than that caused by *Y. pseudotuberculosis*.[56,120,121] Historically, diarrheal illness has been considered the hallmark of *Y. enterocolitica* and the pseudoappendicular syndrome of mesenteric adenitis indicative of *Y. pseudotuberculosis*. Each species can cause enterocolitis and mesenteric adenitis, however. Various other clinical infections and postinfection syndromes also are caused by these microbes. In a series of patients presenting with acute abdominal pain suggestive of appendicitis, the incidence of serologic evidence of *Yersinia* infection has ranged from 7 to 31 percent.[16]

YERSINIA ENTEROCOLITICA

The clinical features of the disease caused by *Y. enterocolitica*, primarily an acute enteritis, have been described by many investigators.* The clinical manifestations depend partly on the age and physiologic condition of the host.[47,131,160] Enterocolitis is the most common presentation and occurs most often in young children. The pseudoappendicular syndrome, which results primarily from mesenteric adenitis and mimics acute appendicitis, occurs more commonly in older children and young adults.[19,47,86,96,147,166]

NS, not specified.

Asymptomatic infection can occur, but the relative frequency compared with symptomatic disease is unknown. The predominant clinical features of *Y. enterocolitica* infection in children are summarized in Table 123–3.

Enterocolitis

Y. enterocolitica enterocolitis is characterized by diarrhea and abdominal pain. The diarrhea usually persists for 7 to 14 days.[118,131,200] A range of 1 to 46 days of diarrhea has been reported.[109] Ten percent of cases may persist for 30 days or more,[131] and chronic diarrhea persisting for several months has been described.[51]

During the first week of symptoms, patients commonly have 3 to 10 stools per day, with a gradual decrease in frequency thereafter. Stools typically are greenish, exhibit variable consistency (usually watery or mucoid), and are not remarkably malodorous. Gross blood is noted in approximately 25 to 50 percent of patients. Vomiting occurs in 40 percent of cases. Nausea is a common symptom. The abdominal pain can be colicky, diffuse, or localized to the right lower quadrant or epigastrium. Fever occurs commonly and usually is low-grade, but may exceed 40° C; it usually resolves within 1 week.[1,128]

Most cases are self-limited, but some children require hospitalization. Among 60 children hospitalized in Michigan between 1990 and 1997, the mean number of hospital days required was 4 (range 1 to 17 days).[1]

Fecal leukocytes are present commonly but not universally. The peripheral white blood cell count may range from 5600/mm^3 to more than 30,000/mm^3. Most counts are greater than 15,000/mm^3. Band forms often exceed 15 percent of the total. Infants frequently exhibit an immature-to-total neutrophil ratio greater than 0.5.[1,118,128] An absolute monocytosis may be seen in two thirds of patients.[113] Culture-negative cerebrospinal fluid pleocytosis can occur.[1]

Radiologic examination by upper gastrointestinal barium studies in 24 adult patients with severe diarrhea caused by *Y. enterocolitica* showed abnormalities of the terminal ileum in 21 cases.[201] Diffuse thickening of the mucosal folds was seen in 16 cases, and nodular filling defects were seen in 11. The radiographic appearance suggested the presence of one or more ulcerations of the terminal ileum in 11 patients. Dilation of the terminal ileum was noted in 12 patients, and extrinsic compression, presumably from enlarged lymph nodes, was present in 4. In some instances, the findings suggested the terminal ileitis of Crohn disease. Follow-up studies performed 2 months after acute illness showed decreased but persistent thickening of mucosal folds in eight patients. Barium enema studies were done in 15 patients and showed no striking abnormalities other than mucosal ulcerations, which were seen best on air-contrast studies.[200]

Figure 123–3 Mesenteric lymphadenopathy (*solid arrow*) and thickened bowel wall (*open arrow*) seen on computed tomography scan of a toddler with a 1-week history of severe abdominal pain, fever, vomiting, and nonbloody diarrhea. Stool culture on cefsulodin-irgasan-novobiocin agar yielded growth of *Yersinia enterocolitica*, serotype O:8. *(From Tuohy, A. M., O'Gorman, M., Byington, C., et al.: Yersinia enterocolitis mimicking Crohn's disease in a toddler. Pediatrics 104[issue 3]: e36, 1999.)*

Mesenteric lymphadenopathy can be seen on computed tomography scans (Fig. 123–3).[199] Among 13 adults who had colonoscopy or sigmoidoscopy for severe diarrhea caused by *Y. enterocolitica*, abnormalities were seen in 8; the mucosa appeared diffusely swollen, erythematous, and friable in 6 individuals, and 2 had only small, 1- to 2-mm aphthoid ulcerations. Serial procedures showed macroscopic and microscopic healing of ulcers within 4 to 5 weeks.[201] Aphthoid ulcerations may be seen throughout the colon (Fig. 123–4).[199]

Pseudoappendicitis-Mesenteric Adenitis

The syndrome of pseudoappendicitis, characterized in most cases by a normal appendix and an intense suppurative mesenteric adenitis, has attracted considerable attention since it was reported first in 1953.[132,133] The first recognized cases were caused by *Y.*

Figure 123–4 Multiple mucosal aphthoid ulcerations, 2 to 3 mm in size, as seen during colonoscopy in the child described in Figure 123–3. *(From Tuohy, A. M., O'Gorman, M., Byington, C., et al.:* Yersinia *enterocolitis mimicking Crohn's disease in a toddler. Pediatrics* 104*[issue 3]: e36, 1999.)*

pseudotuberculosis, but most cases reported in recent years have been caused by *Y. enterocolitica*.[28,95,117]

Fever, abdominal pain, right lower quadrant tenderness, and leukocytosis are the primary features of *Y. enterocolitica*–induced pseudoappendicular syndrome.[47,96] Some patients also have features of enterocolitis (nausea, vomiting, and diarrhea). The clinical presentation often is highly suggestive of acute appendicitis, such that laparotomy is required. Among a series of 581 patients in Scandinavia who underwent laparotomy for suspected appendicitis, 3.8 percent of cultures of stool or operative specimens yielded *Y. enterocolitica*.[147] Another 284 patients with similar symptoms were observed, and 5.6 percent of stool cultures from these cases yielded *Y. enterocolitica*. In a similar Scandinavian series of 205 patients who underwent appendectomy, 22 subsequently were diagnosed by serology as having *Y. enterocolitica* infection.[96] The findings on laparotomy usually are mesenteric lymphadenitis, terminal ileitis, and a normal or slightly inflamed appendix.[19,47,96,147]

A study of 40 cases of granulomatous appendicitis found evidence suggesting infection caused by *Y. enterocolitica* in 4 specimens, *Y. pseudotuberculosis* in 4 specimens, and both in 2 specimens by PCR analysis.[116] Two patients in the series subsequently were diagnosed as having Crohn disease, but causation cannot be inferred.

Asymptomatic Infection

In an unknown number of cases, infection by *Y. enterocolitica* is entirely asymptomatic. In a study of the distribution of antibodies to *Y. enterocolitica* in sera collected for various purposes in Ontario, Canada, from 4209 individuals who had no evidence of infection by this organism, specific antibody was present in 199 (serotype O:3 in 158 and serotype O:9 in 41).[196]

Other Presentations of Acute Infection

Bacteremia can occur[32,39,47,139] and may result in spread of infection to virtually any body site. Such events occur uncommonly and are seen more often in adults than in children. In children, bacteremia occurs more commonly in infants than in older children.[1] The risk for development of bacteremia during gastroenteritis in infants younger than 3 months may be 30 percent.[142] Bacteremias may be transient and asymptomatic or lead to septic shock and death. Septic cases tend to occur among patients with underlying illnesses and are associated with mortality rates of 34 to 50 percent.[47]

Y. enterocolitica may cause focal infections in many extraintestinal sites, even in the absence of detectable bacteremia. Pharyngitis has been reported and occurs primarily in adults. Cervical adenopathy may be associated with *Y. enterocolitica* pharyngitis, and gastrointestinal symptoms may be absent.[47] One adult with pharyngitis died of associated septic shock.[168] Conjunctivitis and panophthalmitis caused by *Y. enterocolitica* have been described. Parinaud oculoglandular syndrome,[40] inguinal adenopathy,[208] and suppurative lymphadenitis[198] have been reported.

Cellulitis, soft tissue abscesses, and wound infections also have been reported. Cellulitis may have associated vesiculobullous lesions. An erysipelas-like rash, maculopapular rash, and urticaria also have been described in association with infection caused by *Y. enterocolitica*.[17,28,47,72,177,191,209]

Pancreatitis, cholecystitis, diverticulitis, and intestinal perforation have been described.[120,157] Peritonitis also can occur but is extremely rare,[163] especially considering the frequency of mesenteric adenitis. Pneumatosis intestinalis has been reported in an infant.[1] Pneumonia, pleural empyema, lung abscess, hepatic and splenic abscesses, urinary tract infection, and renal abscess also have been reported.[47] Glomerulonephritis that usually is transient has been reported.[48,60] Cases of meningitis, osteomyelitis, septic arthritis, pyomyositis (including psoas muscle abscess), endocarditis, mycotic aneurysm, and intravenous catheter–related infection caused by *Y. enterocolitica* have been described.[12,29,47,83,184,186] Thrombocytopenia[65] and hemolytic anemia[108] have occurred in association with infection caused by *Y. enterocolitica*.

Underlying Conditions That Predispose to Bacteremia

Y. enterocolitica bacteremias that occur in patients beyond early infancy most often occur in patients with chronic illnesses or iron overload states. Thalassemias are such conditions that occur most commonly in children.[38,58,101] Among 144 Italian children with thalassemia who were receiving deferoxamine therapy and frequent blood transfusions, 14 developed infection caused by *Y. enterocolitica* during a 12-month period.[38] Septicemia occurred in 5 of the 14 and was preceded by enterocolitis or mesenteric adenitis in each case. All 14 recovered after receiving 2 weeks of therapy with intravenous trimethoprim-sulfamethoxazole. A similar proportion of children with thalassemias observed in two centers in Canada between 1979 and 1994 also developed invasive disease caused by *Y. enterocolitica*.[6] Bacteremia can be associated temporally with blood transfusions in such patients, suggesting that transfusions may be the source of infection or predispose to development of infection in some cases.[120]

Hemochromatosis, cirrhosis, and other liver diseases may facilitate development of *Y. enterocolitica* bacteremia, also on the basis of excess availability of serum iron. Deferoxamine therapy itself is a risk factor for development of sepsis caused by *Y. enterocolitica* because of the ability of the microbe to extract iron from this compound. Immunosuppressive therapies, diabetes mellitus, and malnutrition also may predispose to development of *Y. enterocolitica* bacteremia.[47]

Postinfectious Syndromes

A reactive arthritis may occur 1 to 14 (usually 4 to 10) days after the cessation of acute illness.* Most such events occur in adults,

*See references 7, 8, 10, 13, 83, 86, 166, 193, 201, 210.

with a slight female predominance, but 8 of 74 cases in one series from Sweden were in children aged 11 to 20 years old (5 boys, 3 girls).[210] In a series from the Netherlands, 10 percent of children with yersiniosis, most of whom were aged 7 years old or older, developed arthritis.[86] The knees, ankles, and wrists are affected most commonly, and in approximately 50 percent of cases, only one or two joints are involved. Hands, fingers, toes, shoulders, hips, and elbows also may be involved. Pain usually is severe, and the arthritis is additive and usually not migratory. The inflammatory process is self-limited and may persist for 2 months or longer in two thirds of cases, with one third persisting for 4 months or longer.

The erythrocyte sedimentation rate exceeds 60 mm/hr in approximately 50 percent of cases. Joint effusions usually are inflammatory, but cell counts and differentials vary and occasionally mimic septic arthritis. Immune complexes have been found in joint fluid. Nonsteroidal anti-inflammatory drugs and corticosteroids, intra-articular and systemically administered, have been used for symptomatic relief for this process.[165]

Erythema nodosum also occurs as a postinfectious manifestation, more often in adults than in children. It can occur alone or in association with arthritis.[86] Tendinitis, myositis, myocarditis, urethritis, uveitis, and conjunctivitis also can occur in association with arthritis. Many but not all patients who develop these postinfectious reactions are HLA-B27 positive.[1] Some patients manifest full Reiter syndrome.[86,109,170,182] Acute glomerulonephritis has been linked to infection with serotype O:3 strains in one series of adults.[60]

Yersinia antigens, but not intact bacteria, have been found in synovial tissue obtained several weeks to months after onset of reactive arthritis. *Y. enterocolitica* is able to survive within in vitro cultures of human synovial cells for 6 weeks, with resultant deposition of residual antigen aggregates within the cells.[90] Synovial fluid–derived T cells from patients with *Y. enterocolitica*–induced reactive arthritis have been shown to respond to several *Y. enterocolitica* antigens: heat shock protein 60, urease beta subunit, ribosomal L2 protein, and a region of the plasmid-encoded tyrosine phosphatase YopH that is highly homologous to the catalytic domain of eukaryotic protein tyrosine phosphatases.[114,134,155]

Epitopes on *Yersinia*-produced proteins likely trigger cross-reactive immunologic recognition of host proteins that leads to chronic inflammation in susceptible individuals.[95] High levels of antibodies that react with 60 kd recombinant *Yersinia* heat shock protein have been found in HLA-B27–positive individuals with acute anterior uveitis or pars planitis.[31]

Antibodies against *Y. enterocolitica* have been detected in patients with disorders of the thyroid, including Graves disease, thyroid adenoma, and Hashimoto thyroiditis.[178] A Danish twin study found no increased risk of thyroid antibodies after *Y. enterocolitica* infection, however.[77] These observations may reflect autoantibodies that cross-react with *Yersinia* epitopes, rather than a causal link between yersiniosis and thyroid disease.[47,164]

Brachial plexus neuropathy and transverse myelitis, each occurring after the resolution of gastrointestinal symptoms caused by *Y. enterocolitica*, have been described in one patient.[187] Various chronic ailments have been described among a group of 160 Scandinavian patients observed for 4 to 14 years after having acute yersiniosis.[172] Ailments included persistent joint complaints, ankylosing spondylitis (in HLA-B27–positive patients), iridocyclitis, chronic hepatitis, chronic abdominal pain, rheumatoid arthritis, chronic nephritis, thyroid disease, and neurologic ailments. Observed deaths among these patients exceeded the expected number. These findings require confirmation before causal links can be considered.

YERSINIA PSEUDOTUBERCULOSIS

The pseudoappendicular syndrome that results from mesenteric adenitis is the primary disease produced by *Y. pseudotuberculosis*.* The chief complaint is abdominal pain, either diffuse or localized to the right lower quadrant. Fever (38° C to 40° C) almost always is present. Tenderness over the McBurney point usually is present. All of these symptoms are highly suggestive of acute appendicitis. Diarrhea may occur but often is absent. Mild leukocytosis occurs, but white blood cell counts usually are less than 20,000/mm^3. The clinical course almost always is benign, with recovery usually beginning approximately the fifth day of illness. On laparotomy, the appendix is normal in most cases but occasionally appears inflamed or suppurative. The mesenteric lymph nodes are enlarged and may appear necrotic.

Efforts have been made to distinguish the pseudoappendicular syndrome caused by *Y. pseudotuberculosis* from that caused by *Y. enterocolitica*.[24,66] *Y. pseudotuberculosis* adenitis is less likely to have associated enterocolitis and may have a shorter febrile course, but no clear distinction can be made on clinical grounds alone.

A fulminant typhoidal or septicemic form of infection caused by *Y. pseudotuberculosis* can occur but seems to affect primarily older adults with debilitating conditions, such as diabetes or liver disease. This syndrome often is fatal.[105,171] Isolated cervical adenitis, liver abscess, and terminal ileitis have been described.[79,207] Subacute and recurrent disease can occur.[126]

Erythema nodosum[171] and nonsuppurative arthritis[37] also have been reported in association with infection caused by *Y. pseudotuberculosis*. In an outbreak related to eating contaminated grated carrots in Finland in 2003, erythema nodosum was seen in numerous patients with gastrointestinal illness.[94] Median time from exposure to development of gastrointestinal symptoms was 8 days. Median time from exposure to development of erythema nodosum was 19 days (see Fig. 123–2). One patient developed reactive arthritis in a similar time frame.

Yersinia pseudotuberculosis and Kawasaki Disease–like Illness

In Korea and Japan, *Y. pseudotuberculosis* strains have been responsible for a clinical syndrome that can mimic Kawasaki disease.[37] This manifestation of disease occurs primarily in outbreaks and has been described as scarlet fever–like.[150] A transient (2 to 3 days) erythematous maculopapular rash, strawberry tongue, conjunctivitis, and desquamation can occur, generally in association with gastrointestinal symptoms and fever. Erythema nodosum, lymphadenopathy, uveitis, and coronary aneurysms have occurred in some of these cases, as has acute interstitial nephritis, which can lead to transient renal failure.[3,112,150] Among a series of 33 patients (median age, 5 years) with such presentations, 20 had elevated antibody titers against *Y. pseudotuberculosis*–derived mitogen, which can function as a superantigen.[3] As in Kawasaki disease, Vβ3 T lymphocytes were increased in many of these patients compared with healthy control subjects.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of *Yersinia* enterocolitis includes viral and other bacterial causes of acute gastroenteritis. When the symptoms of mesenteric adenitis are predominant and severe, appendicitis and other causes of an acute abdomen must be considered. The acute terminal ileitis caused by *Yersinia* infections

*See references 20, 50, 55, 57, 66, 84, 89, 104, 105, 126, 150, 169, 171, 203, 207.

also can be similar to the gastrointestinal manifestations of Crohn disease, ulcerative colitis, cat-scratch disease, anisakiasis, amebiasis, actinomycosis, typhoid fever, and lymphoma.[64,86,150,200,207] Cases of infection caused by *Y. enterocolitica* with concomitant recovery of *Salmonella*, *Campylobacter*, and rotavirus antigen in stool specimens have been observed.[1]

DIAGNOSIS

The most effective approach to the diagnosis of yersiniosis is isolation of the organism from the stool of patients with enteritis caused by *Y. enterocolitica* or from the infected mesenteric lymph nodes of patients infected by *Y. pseudotuberculosis*. *Y. enterocolitica* occasionally can be recovered from involved mesenteric lymph nodes or the distal ileum.[47] Cultures of feces from individuals with acute suppurative mesenteric adenitis usually fail to grow either organism.

Isolating *Yersinia* organisms from extraintestinal specimens such as lymph nodes and blood is not difficult because they grow on ordinary media (e.g., blood agar) and on several selective and differential media employed for enteric bacteria. Isolating from fecal specimens is more difficult, however, because *Yersinia* multiply more slowly than other enteric bacteria at 37° C and have no characteristic colony morphology. Selective media have been developed, but many clinical laboratories culture stool specimens for *Yersinia* spp. only on request because of the costs of these media and the relatively low frequency of occurrences of these pathogens in the community.

Yersinia organisms grow well on MacConkey agar but are much smaller than are other enteric bacteria after standard incubation at 37° C. Cefsulodin-irgasan-novobiocin agar plates have been designed specifically for the isolation of *Yersinia* spp. from stool specimens. After being incubated for 48 hours, *Yersinia* colonies appear dark pink with translucent borders and occasionally are surrounded by a zone of precipitated bile. Cefsulodin-irgasan-novobiocin agar inhibits the growth of most other bacteria except for *Citrobacter* spp. (positive citrate reactions of which allow their distinction). If a dedicated medium for *Yersinia* isolation is not used, MacConkey agar can be examined after 24 hours at 35° C to 37° C for small colorless colonies that become much larger after an additional 24 hours of incubation at room temperature. Most *Y. enterocolitica* strains are lactose-negative.[69] *Yersinia* spp. can be differentiated readily from *Salmonella* spp. because the latter are motile at 37° C, urease-negative, citrate-positive, and lysine-positive. Most *Salmonella* strains also produce gas during fermentation and produce hydrogen sulfide. *Shigella* are urease-negative and lack motility at room temperature.[186]

Yersinia spp. grow faster at 37° C than at room temperature. Growth occurs readily at 22° C to 28° C, however, and these lower temperatures are recommended for primary isolation.[69] Because of the ability of *Yersinia* spp. to grow at even colder temperatures, specimens can be inoculated into phosphate-buffered saline, refrigerated at 4° C to 6° C, and subcultured periodically (up to 4 weeks) if the routine plates that were inoculated with the specimen remain negative. Such "cold enrichment" greatly enhances the isolation rate of *Yersinia* spp. and may be the most reliable method for isolating these organisms from fecal specimens. Many of the *Yersinia* isolates recovered by cold enrichment, however, represent either *Y. enterocolitica* serotypes, which usually are not associated with human disease, or other *Yersinia* spp., which have roles that remain unclear.

Pathologic or virulent *Yersinia* strains can be distinguished in most instances from nonpathogenic strains by three biochemical tests that are associated with absence of the virulence plasmid. The virulent strains lack pyrazinamidase activity, do not ferment salicin, and do not hydrolyze esculin. On Congo red–magnesium oxalate agar during incubation at 36° C, fresh pathologic isolates (but not those that have been subcultured serially) grow as small red colonies, showing the virulence plasmid-determined properties of Congo red dye uptake and calcium-dependent growth.[54]

SEROLOGY

Serology can be performed with microtiter techniques and is most reliable for serotypes O:3 and O:9 of *Y. enterocolitica*. Antibody to the infecting serotype usually is absent at the onset of disease. Peak titers usually are reached 3 to 4 weeks after onset of clinical illness and decrease during the next 3 to 5 months. Low postconvalescent titers may persist for months. Microhemagglutination, complement fixation, and enzyme immunoassays are available in a few commercial laboratories.[25,69,200]

Agglutinin titers of 1:128 or higher for *Y. enterocolitica* in previously normal healthy individuals suggest infection. Titers of 1:200 or greater were present within 3 weeks of onset of illness in 62 of 65 Canadian children who had infection with serotype O:3. Fourfold increases in titer rarely were seen. Negative or minimal titers (≤1:32) do not rule out yersiniosis in infants or immunosuppressed patients. Serologic responses occur more commonly and are of higher titer among patients with extraintestinal systemic infection. Prozone reactions may occur at dilutions of 1:32 or lower. Marked cross-agglutination occurs between *Y. enterocolitica* serotype O:9 and *Brucella abortus*, *Morganella morganii*, and *Salmonella*.[25,131] Antibodies to *Y. pseudotuberculosis* often are detectable at the onset of clinical signs of infection and may be highest during the acute phase of illness.[84]

MOLECULAR TECHNIQUES

PCR assays have been developed for *Y. enterocolitica* and *Y. pseudotuberculosis* with use of primers that allow assessment of 16S rRNA sequences and of specific plasmid-encoded and chromosome-encoded genes.[37,116,143,144,204,206] PCR techniques have been used to identify *Yersinia* organisms in blood, tissue, stool, water, and food samples.[78,115]

TREATMENT

Most patients with yersiniosis do not require treatment because the disease usually is self-limited. Seriously ill patients generally have responded to treatment with chloramphenicol, gentamicin, or tetracyclines, but clinical success has not been uniform. Of these agents, tetracyclines have been the traditional agent of choice.[66,200] *Y. enterocolitica* isolates resistant to the tetracyclines have been reported in recent years, however. Two percent of a sample of *Y. enterocolitica* isolates from Canada in 1992 were resistant to tetracycline,[154] and 10 percent of a sample of *Y. enterocolitica* isolates from the Netherlands from 1982 to 1991 were resistant to doxycycline.[188]

More than 99 percent of 1060 isolates of *Y. enterocolitica* collected in Canada in the years 1972 to 1976, 1980, 1985, and 1990 were susceptible in vitro to piperacillin, cefotaxime, aztreonam, gentamicin, tobramycin, amikacin, trimethoprim-sulfamethoxazole, chloramphenicol, and ciprofloxacin. No evidence of decreasing susceptibility to any of these agents was found across the periods that were sampled. These results were mirrored by a study of 335 isolates obtained in the Netherlands from 1982 to 1991. All of these isolates were susceptible to ceftazidime, cefepime, imipenem, trimethoprim-sulfamethoxazole, ciprofloxacin, and ofloxacin. Aminoglycosides were effective against more than 99 percent, chloramphenicol was effective against 94 percent,

and cefuroxime was effective against 90 percent. Seven multidrug-resistant isolates were present among the isolates from Canada, but none was found among the isolates from the Netherlands.[154,188]

Most *Y. enterocolitica* isolates, regardless of serotype, are resistant to ampicillin, ticarcillin, and first-generation cephalosporins. Most of them also are resistant to amoxicillin–clavulanic acid. Azithromycin was active in vitro against 50 percent of the 335 isolates in the Netherlands, but almost all isolates were resistant to erythromycin and clarithromycin.[154,188]

The decreasing effectiveness of tetracyclines in vitro raises the question of whether these agents should be the first choice for treatment of infection caused by *Y. enterocolitica*. A retrospective review of 43 cases (with patient ages ranging from 3 to 89 years) treated for *Y. enterocolitica* septicemia in France between 1985 and 1991 showed that third-generation cephalosporins were effective in 85 percent of cases in which they were used, although aminoglycosides or fluoroquinolones usually were administered concurrently.[61] Fluoroquinolones alone or in combination with other agents cured all 15 patients. Seven children with bacteremia and diarrhea in Michigan responded well to cefotaxime.[1]

In a double-blind, placebo-controlled trial of trimethoprim-sulfamethoxazole for treatment of children with gastroenteritis caused by *Y. enterocolitica*, the clinical course of illness was not shortened.[151] The children had been ill for a mean of 12 days before treatment was begun, however.

Systemic infections, extraintestinal focal infections, and enterocolitis in compromised hosts should be treated with antibiotics.[47] The in vitro susceptibilities and limited clinical data suggest that children with such infections should be treated with a third-generation cephalosporin, an aminoglycoside, or both. Trimethoprim-sulfamethoxazole also may be used.[38,86] Fluoroquinolones also probably would be effective. Cefotaxime and ceftriaxone were effective in treating bacteremia in a series of 12 children.[2]

Even fewer clinical and in vitro susceptibility data are available for *Y. pseudotuberculosis*. These infections probably can be managed identically to *Y. enterocolitica* infections. All isolates of *Y. enterocolitica* and *Y. pseudotuberculosis* should be examined for susceptibility to a variety of antibacterial drugs.

OTHER *YERSINIA* SPECIES

Eight other "non-*pestis*" *Yersinia* spp. (*Yersinia frederiksenii*, *Yersinia intermedia*, *Yersinia kristensenii*, *Yersinia aldovae*, *Yersinia bercovieri*, *Yersinia mollaretii*, *Yersinia rohdei*, and *Yersinia ruckeri*) occasionally have been isolated from clinical specimens, but their roles as human pathogens remain unclear.[69,177,189] Each except *Y. aldovae* has been isolated from humans worldwide, including individuals with gastrointestinal disorders.[189] These microbes also can be found in fresh-water sources, sewage, dogs, pigs, cattle, wild mammals, birds, reptiles, fish, and some foods, especially milk and meat products.

These organisms are similar biochemically to one another and have been termed atypical *Y. enterocolitica*.[47] None contains the *Yersinia* virulence plasmid pYV.[135] Some contain other large plasmids distinct from pYV, carriage of which may be associated with the ability to cause diarrhea in humans.[152,189] A heat-stable enterotoxin has been found in isolates of *Y. bercovieri*.[190] These *Yersinia* spp. can grow at 4° C and on cefsulodin-irgasan-novobiocin agar and can multiply in refrigerated foods.

These species occasionally may cause diarrhea and other gastrointestinal symptoms, especially in immunocompromised hosts or individuals with gastric acid suppression.[124] Use of cold enrichment techniques may enhance recovery of these organisms. Their isolation from clinical specimens neither should be disregarded nor should be deemed causative of clinical disease without careful epidemiologic considerations.[69] *Y. bercovieri*, *Y. mollaretii*, and *Y. rohdei* can be misidentified as *Y. enterocolitica* by commercial identification systems used in many clinical laboratories. Differences in colony morphology, pyrazinamide reactions (negative for *Y. enterocolitica*), and other biochemical tests can be used to distinguish them from *Y. enterocolitica*.[73,100]

CHAPTER 124

Miscellaneous Enterobacteria

Randall G. Fisher

This chapter focuses on three less commonly isolated organisms of the family Enterobacteriaceae: *Edwardsiella tarda*, *Hafnia alvei*, and *Pantoea agglomerans*. Each of these organisms, although uncommon, can cause significant disease in certain clinical circumstances.[51]

EDWARDSIELLA TARDA

BACTERIOLOGY

E. tarda is a non–lactose-fermenting, gram-negative bacillus that is indole-positive and produces hydrogen sulfide. It ferments only glucose and maltose. The species name *tarda* reflects its biochemical inactivity. It usually is lysine-positive and ornithine decarboxylase–positive.[21] The organism resembles *Salmonella* biochemically and clinically.[33] *Salmonella* usually ferments mannitol, sorbitol, and rhamnose, however. The innate resistance of *Edwardsiella* to colistin also distinguishes it from *Salmonella*.[54] *E. tarda* grows well on usual differential media in the laboratory and produces smooth, glistening, semitranslucent colonies.

EPIDEMIOLOGY

E. tarda is an organism associated with fresh-water and marine life and has been isolated from turtles, fish, pelicans, alligators, seals, and toads.[33] It also is found in snakes and lizards. Case reports of human disease have implicated ornamental fish,[76] pet turtles,[55] snakes,[64] and catfish,[6,13,29] and injuries in fresh and brackish water.[70]

Patients with chronic liver disease, chronic ethanol abuse, steroid therapy, and hemoglobinopathy particularly are prone to developing infection with *E. tarda*.[33] Any condition associated with iron overload also is a potential risk factor. Serious infection with *E. tarda* in otherwise well individuals also can occur.[70]

Infection with *E. tarda* is global but occurs more commonly in tropical and subtropical climates, particularly Southeast Asia, Africa, and Latin America.[34] The elderly and the very young seem to be at increased risk for developing severe illness.[9] Asymptomatic carrier states have been documented well,[60] but no true epidemic has been reported, and person-to-person transmission has not been established directly.[19]

PATHOPHYSIOLOGY

Invasiveness of the organism in HeLa and HEp-2 cells,[61] siderophore production, the elaboration of a cell-associated hemolysin,[30] and resistance to complement-mediated lysis may contribute to virulence, although no clear associations have been made.[37] Hemolytic activity requires the presence of two genes, *ethA* and *ethB*. The *ethA* gene codes for the hemolysin, whereas the *ethB* gene codes for an activation/secretion protein, which is necessary for activation of the hemolysin. Transcription of the *ethB* gene is regulated by iron, which may explain the association between iron overload states and severe *E. tarda* infection.[30] Hemolysin activity seems to be necessary for cell entry and cytotoxicity.[73]

CLINICAL MANIFESTATIONS

Infections with *E. tarda* can be divided broadly into two types: intestinal and extraintestinal. Approximately 80 percent of infections are intestinal.[70] Gastrointestinal infection usually causes self-limited enteritis, with intermittent watery diarrhea and low-grade fever.[39] Nausea and vomiting usually are not seen. Occasionally, enterocolitis or a dysentery-like illness is noted.[47] Because most laboratories do not culture stool specimens specifically for *Edwardsiella*, most cases are unrecognized.

Wound infection is the most common extraintestinal infection. Most of the wounds are caused by fish fins or snakes; wounds sustained in automobile accidents also have been implicated.[33] Cellulitis or abscesses may be produced. Coinfection with other organisms, particularly *Aeromonas hydrophila*, is common.[29,70] One case of necrotizing fasciitis and myonecrosis in an immunocompetent man has been reported. Cultures obtained at surgical débridement yielded a pure growth of *E. tarda*.[70]

Septicemia with *E. tarda* is a rare but serious infection that carries a mortality rate of approximately 45 percent. Most patients with septicemia have underlying conditions, such as liver disease, iron overload, and immunosuppression. Septicemia occasionally follows a mild diarrheal illness.[13] Infants without other risk factors have been reported.[78] Septicemia manifests with high fever, shock, and, often, disseminated intravascular coagulation. Meningitis also has been reported.[59,68] Death sometimes occurs despite administration of appropriate antimicrobial therapy.

Other syndromes associated with *E. tarda* infection include an enteric fever–like illness,[13] multiple or solitary liver abscesses,[45,86] osteomyelitis,[64] septic arthritis,[6] cellulitis,[24] myonecrosis,[70] necrotizing fasciitis,[50] endocarditis,[56] uterine pyomyoma,[84] tubo-ovarian abscess,[62] and peritonitis.[13] A case of puerperal intrauterine infection in a woman without obvious risk factors has been reported; her infant was not affected.[52] Patients with sickle-cell disorders may be predisposed to bony infection with *E. tarda*, as they are with *Salmonella*.[68,83] Reported cases all are in patients with sickle-cell hemoglobinopathy, rather than homozygous sickle-cell disease.

DIAGNOSIS AND TREATMENT

Diagnosis rests on identification of *E. tarda* in culture. The major pitfall is mistaking it for *Salmonella*.

E. tarda is sensitive in vitro to most antibiotics used routinely in the treatment of gram-negative infections, including β-lactams, cephalosporins, aminoglycosides, and fluoroquinolones.[12] It also is sensitive to chloramphenicol, trimethoprim-sulfamethoxazole, and tetracycline.[72] Resistance to polymyxin B, colistin, and, occasionally, penicillin has been shown.[12,13] The organism almost universally elaborates a β-lactamase, but no resistance to β-lactams other than penicillin[12] and oxacillin[72] has been reported.

Gastrointestinal disease usually does not require treatment. Severe disease, such as septicemia or meningitis, probably should be treated with the combination of a β-lactam and an aminoglycoside,[33] even though synergy has not been shown.

HAFNIA ALVEI

BACTERIOLOGY

H. alvei is a facultatively anaerobic, gram-negative bacillus, formerly referred to as *Enterobacter hafnia*.[69] This indole-negative, catalase-positive, and oxidase-negative organism is positive for lysine and ornithine decarboxylases. It is motile at lower temperatures, but may be immotile at temperatures of 35° C and greater. *H. alvei* ferments mannitol, maltose, and sucrose. It grows well on blood or MacConkey agar as a nonlactose fermenter, producing gray-white, slightly elevated, glistening colonies.[20]

EPIDEMIOLOGY

H. alvei has been found in soil, dairy products, sewage, and the feces of humans and animals. Some question exists as to whether it is part of the endogenous microflora of the gut[65] or whether an asymptomatic "carrier" state exists. One study from Japan cultured *H. alvei* from 13 percent of healthy subjects[49]; other epidemiologic surveys have shown the incidence to be less than 2 percent.[66] Long regarded as a nonpathogen, *H. alvei* now has been associated clearly with enteritis and rarely has been isolated in pure culture from other sites, including blood, cerebrospinal fluid, peritoneal fluid, and urine. Infection seems to be opportunistic.

PATHOPHYSIOLOGY

The pathophysiology of *H. alvei* has been investigated most thoroughly with regard to its production of gastrointestinal symptoms,[2] although whether *H. alvei* is actually a diarrheagenic pathogen remains controversial. Albert and associates[3] showed that although *H. alvei* elaborated neither enterotoxins nor a Shiga-like toxin and was not invasive in HeLa cell assays or by Sereny test, it did produce diarrhea in experimental animals whether given parenterally or by mouth. Sections of intestines from infected animals showed lesions indistinguishable from those caused by enteropathogenic *Escherichia coli*. "Diarrheagenic strains" of *H. alvei* also were thought to differ from other strains in that they possessed the *eaeA* gene.[32] Janda and colleagues[36] first presented data suggesting that diarrheagenic *H. alvei* isolates were actually either unusual biotypes of *E. coli* or a new species in the genus *Escherichia*. Subsequently, the same group showed that organisms originally called *H. alvei* reported to produce attaching-effacing lesions and to possess the *eaeA* gene are actually a novel species, *Escherichia albertii*.[31] Information about the pathophysiology of extraintestinal infection is sparse.[35]

CLINICAL MANIFESTATIONS

Cases of diarrhea caused by *H. alvei* (possibly *E. albertii*) have been reported primarily in children.[2,3] Most patients with gastroenteritis secondary to *H. alvei/E. albertii* report 6 to 12 episodes of watery diarrhea per day, low-grade or no fever, and nausea with or without vomiting. Mucus sometimes is found in stools, but blood is not.[65,82] In most patients, symptoms last for a few days, but in some patients, symptoms persist for more than a week.[65] One patient with a reactive arthritis from *H. alvei/E. albertii* enteritis has been reported.[57] A unique case has been reported of an 11-year-old girl who had a 3-day history of red lesions on the forehead, neck, and trunk associated with abdominal pain, emesis, and decreased urinary output, with one bloody diarrheal stool the day before admission, who then developed hemolytic-uremic syndrome. Stool cultures repeatedly were negative for *E. coli* O157:H7, but positive for a toxigenic strain of *H. alvei* from two consecutive cultures.[15]

Traditionally, extraintestinal *H. alvei* infections were thought to occur mostly in hospitalized patients and to be hospital-acquired. In one large series, the organism was isolated from 80 samples collected from 61 patients; 57 (93%) patients had underlying illnesses, most commonly malignancies.[28] Nearly half of isolates were from the respiratory tract. Other sites included blood, skin, wounds, urine, and intra-abdominal abscesses. In 60 (75%) samples, other organisms were cultured concomitantly. In a more recent, larger study from Canada, two thirds of 138 isolates were of community onset, 112 (81%) were from the urinary tract, and 94 (68%) were from monomicrobial infections.[40] Older age and female gender were risk factors for development of infection.

One 20-day-old premature infant with necrotizing enterocolitis grew *H. alvei* from blood and stool.[25] Yeager and associates[85] reported four cases of pneumatosis intestinalis in patients after they had undergone bone marrow transplantation, and one of the four grew *H. alvei* in pure culture from blood. An 8-year-old boy with acquired immunodeficiency syndrome (AIDS) developed recurrent episodes of *H. alvei* bacteremia.[14] Both episodes were associated with fever and diarrhea; the second episode also was associated with pneumonia and pleural effusion, the cause of which is unclear. A well-documented case of pneumonia in a 54-year-old woman with AIDS has been reported in which the pleural fluid grew a pure culture of *H. alvei*.[22]

Wound abscess caused by *H. alvei* has been reported.[1] A 2-year-old liver transplant recipient developed hepatic abscess and bacteremia with *H. alvei* and *Enterococcus faecalis*.[7] One case of meningitis in a 1-year-old infant without known predisposing risk factors has been reported.[53] A case of a woman with rheumatoid arthritis who contracted endophthalmitis with *H. alvei* in mixed culture has been described; the woman used snake powder as a food seasoning.[11] Two case reports are described in the older literature of persistent bacteremia with this organism, alone and in mixed cultures. One of these patients was a previously well 13-year-old girl.[27]

DIAGNOSIS AND TREATMENT

Diagnosis is established by isolation of the organism from stools or from normally sterile body fluids. Gunthard and Pennekamp[28] reported the susceptibility results of 80 *H. alvei* isolates recovered from 61 patients over a 2.5-year period. All isolates tested were susceptible to ciprofloxacin. Isolates also were generally susceptible to tobramycin (99%), imipenem (99%), piperacillin (92%), trimethoprim-sulfamethoxazole (90%), ceftriaxone (88%), and ceftazidime (88%). Nearly all isolates were resistant to ampicillin and to amoxicillin-clavulanate.

H. alvei is constitutively cephalothin-resistant.[82] One report describes an inducible β-lactamase that rendered the isolate ceftazidime-resistant.[74] In one study, the antimicrobial susceptibility of *H. alvei* was compared with that of *E. albertii*, the organism with which *H. alvei* is confused most frequently. *E. albertii* isolates were naturally susceptible to all β-lactams except for penicillin and oxacillin; they also were susceptible to azithromycin. In contrast, *H. alvei* strains were naturally resistant to tetracycline, amoxicillin, amoxicillin-clavulanate, ampicillin-sulbactam, azithromycin, and the narrow-spectrum cephalosporins.[72]

Treatment probably is unnecessary for most cases of gastroenteritis. Treatment for invasive infection should be based on susceptibility testing. Empiric therapy with a third-generation cephalosporin and an aminoglycoside is reasonable pending susceptibility results.

PANTOEA AGGLOMERANS

First identified as a plant pathogen and named after Erwin Smith in 1917, the genus *Erwinia* has an extended domain as an infectious microbe, including production of disease in humans.[10,63,71] A member of this group of organisms, *Pantoea agglomerans* (*Enterobacter agglomerans*, *Erwinia herbicola*) has been established as a cause of conjunctivitis,[10] central nervous system infections,[10,69] urinary tract infections,[62,68] pneumonia,[4] and nosocomial infections secondary to contaminated intravenous fluids.[24,38]

BACTERIOLOGY

Species definition within *Erwinia* has been controversial and confusing. It has been suggested to rename the anaerogenic clinically relevant *Erwinia* of the *herbicola-lathryi* group *E. agglomerans* or *P. agglomerans*.[21,33,71] In clinical microbiology, both of the latter terms tend to be used interchangeably. This species consists of facultatively anaerobic, fermentative, hydrogen sulfide–negative, gram-negative rods; they do not possess oxidase, phenylalanine deaminase, proteinase, or arginine dehydrolase.[21] None decarboxylates ornithine.[33] They are motile, have peritrichous flagella, and produce a yellow pigment. Strains grow well at 37° C (98.6° F) on standard agar. When colonies are viewed microscopically after growth for 18 to 20 hours, characteristic biconvex spindle-shaped bodies and bacterial aggregates often can be seen.[10,69] Almost all strains isolated from clinical specimens and grown on agar slants show characteristic elongated, spheroidal aggregates,[69] called *symplasmata* by Cruickshank,[16] who first described them.

EPIDEMIOLOGY

Microorganisms of the genus *Erwinia* long have been recognized as phytopathogens producing dry necrosis, wilts, and soft rots in plants, and more recently they have been associated with disease in trout and leafhoppers.[63,71] *P. agglomerans* (*E. herbicola*) first was isolated in humans from stool specimens of patients with typhoid fever in the 1920s and given the name *Bacterium typhi flavum* because of the organism's alleged capacity to be transformed into *Salmonella typhi* in subculture. Identification of saprophytic human strains followed, and the biochemical and cultural identity of *B. typhi flavum* with the *E. herbicola-lathryi* group finally was established.[21]

The first reports of *P. agglomerans* as a human pathogen appeared in the 1960s. Subsequently, a nationwide outbreak of infection caused by this organism was traced to contaminated liners from caps of parenteral solution bottles.[43,44] The importance of this organism as a nosocomial cause of bacteremia is emphasized by the 17 percent mortality rate in patients receiving an infusion with the contaminated intravenous fluid.[43] A trend was noted for an increased mortality rate in infected individuals younger than 20 years old. In neonatal intensive care units, the situation seems to be even more dire; in one study, the mortality rate for infants with blood cultures positive for *P. agglomerans* was 88 percent (seven of eight).[77] Lipid-based medications support rapid bacterial growth at room temperature and, in the absence of strict aseptic handling have been implicated in more recent nosocomial *P. agglomerans* bloodstream infections.[8] *Pantoea* outbreaks also have been traced to contaminated blood products; prolonged storage of packed red blood cells at 4° C provides conditions that allow these organisms to grow and subsequently produce high concentrations of endotoxin.[5] Cotton used to filter heroin has been implicated as a source of infection ("cotton fever") in intravenous drug users.[23]

Outbreaks in pediatric hospitals caused by contaminated intravenous solutions also have been described.[48] At least one retrospective review of *Erwinia* organisms isolated from clinical specimens suggested a predisposition to infection in the pediatric age group[10]; however, other studies have noted no preference based on season, sex, age, or residence in hospitals.[71] A large pseudo-outbreak traced to contamination of cotton pledgets also has been reported.[38]

PATHOPHYSIOLOGY

The true incidence of clinical infection caused by *P. agglomerans* is difficult to ascertain because of the common association of this microbe with other organisms when obtained from clinical specimens. Nonetheless, the accumulation of case reports in which this organism is isolated in pure culture from infected material leaves little doubt that *P. agglomerans* can be a human pathogen, apart from its role as a nosocomial contaminant. This organism has little inherent invasiveness. Evidence for animal pathogenicity of *Erwinia* strains isolated from plants and humans is limited; 10^{13} washed organisms injected intraperitoneally into mice or guinea pigs do not cause symptoms, whereas inoculation of 10^{27} organisms leads to death within 36 hours.[16]

Most strains seem to act as saprophytes in humans,[79] but the organism has been isolated from purulent wounds of the extremities acquired through lacerations or thorn pricks, which suggests agricultural injury as a possible mode of infection.[79] Thorn injuries also have led to septic arthritis and osteomyelitis.[17] A delay of 4 to 6 weeks often occurs between the injury and the bone or joint infection. Most serious infections have occurred in individuals with a breach of host defenses (e.g., immunocompromised individuals or patients who received contaminated intravenous fluid).

CLINICAL MANIFESTATIONS

P. agglomerans bacteremia often is associated with fever, shaking chills, and systemic toxicity characteristic of gram-negative sepsis. These symptoms frequently have been misinterpreted, however, in hospitalized patients who unknowingly were administered contaminated intravenous fluids.[44] Premature neonates with sepsis owing to *P. agglomerans* tend to have a rapidly progressive sepsis with prominent pulmonary involvement, including hemorrhage and acute respiratory distress syndrome. In the largest pediatric series reported to date, 21 of 53 (about 40%) *P. agglomerans* isolates from normally sterile sites were grown from central venous lines; of these, two thirds were polymicrobial.[17]

Eye and skin infections caused by *P. agglomerans* are particularly prominent. Bottone and Schneierson[10] included six cases of conjunctivitis, five of which occurred in infants, from whom this organism was isolated. Only two of the isolates were in pure culture, however, and a description of the clinical course of these children was not included in the report. *Erwinia* endophthalmitis has been associated with foreign body penetration of the eye in a 14-year-old boy.[58]

Skin infection in association with a casted fracture has been described in an elderly patient,[79] and wound infections from which this organism was isolated have been described subsequently, most often in association with agricultural injury.[79] Four isolates were obtained in mixed cultures from skin lesions of children younger than 5 years old, but their possible role in those infections was not confirmed.[10] In a recent series, 14 cases of abscesses required drainage; all 14 were polymicrobial.[17] *P. agglomerans* was the only organism isolated from six consecutive blood

cultures in a 9-year-old boy with osteomyelitis.[46] A 13-year-old boy developed septic arthritis caused by *P. agglomerans* 1 month after sustaining a plant thorn injury to his knee.[18] A case of *P. agglomerans* spondylodiskitis has been reported.[63] In many cases of *P. agglomerans* osteomyelitis or septic arthritis, the patient is afebrile and blood cultures are negative. In addition, measures of inflammation and joint fluid findings may be largely unremarkable.[17] A high index of suspicion of *P. agglomerans* must be maintained when bone or joint infection follows plant thorn injury.

Primary lung disease caused by these bacteria is a rare occurrence; it has been reported in an adult with chronic bronchitis.[4] This organism is a very rare cause of meningitis. A contaminated incubator has been implicated in two cases of neonatal central nervous system infection,[75] and a cisternal tap revealed the presence of *P. agglomerans* in an unrelated newborn case whose clinical course was not described.[10] A 57-year-old man with tetralogy of Fallot and cyanosis had a brain abscess in which *P. agglomerans* organisms grew in pure culture.[80] Presenting manifestations included headaches, seizures, and left-sided weakness, which occurred over a 2-week period before admission. The patient recovered after undergoing drainage of the abscess and gentamicin therapy. One case of peritonitis in a patient on continuous ambulatory peritoneal dialysis has been reported; it was thought to be secondary to a rose thorn injury.[41]

DIAGNOSIS

Difficulty in identifying this organism is common; in March 1972, as part of a quality control program, *P. agglomerans* was sent as an unknown organism to 250 U.S. hospitals and was identified incorrectly 45 percent of the time.[44] Even when fully identified in isolates from human sources, *P. agglomerans* often is considered a contaminant or saprophyte. The organisms have been identified mistakenly as *Citrobacter*, *Escherichia coli*, *Flavobacterium*, and *Klebsiella*. In addition to routine microbiologic studies, identification of yellow-pigmented colonies and observation of the characteristic spindle-shaped bodies and symplasmata can aid in this differentiation. Symplasmata (elongated, spheroid aggregates) are seen best in the condensation water of slant cultures.[79] Spindle-shaped bodies termed *Wetzsteinformen* by German authors are observed best on standard agar with a low-power microscope lens.[71]

TREATMENT

Most localized infections respond to treatment that includes an aminoglycoside. The presence of persistent localized infection with this organism should prompt a search for an organic foreign body, given the organism's tendency to live as a saprophyte or as a pathogen in vegetable material. In addition to appropriate antimicrobial therapy, treatment of bacteremia should include removal of any potentially contaminated intravenous access. The physician should be alert to the possibility of a common source of infection in nosocomial outbreaks.[44] In view of the rarity of bacteremia caused by *P. agglomerans*, single sporadic cases should be investigated, and clusters of two or more cases should lead to immediate inquiry into possible sources of contamination. Formal surveillance programs have been the key to early recognition and abortion of epidemics.[44]

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 125

AEROMONAS

Ralph D. Feigin ✪ Roger K. Nicome

Aeromonas spp. were recognized for their role in disease first by Sanarelli in 1891. His findings associated aeromonads with bacteremic "red leg" disease in frogs.[131] Studies by Hill and associates in 1954 further linked the first human disease, acute fulminating metastatic myositis, with *Aeromonas* infection.[23] Generally, *Aeromonas* spp. have been considered opportunistic pathogens for humans; however, these organisms have been identified with increasing frequency as primary pathogens in normal individuals and in compromised hosts.

Aeromonas bacteria are ubiquitous. They are found as normal flora in nonfecal sewage and are isolated from tap water, canals, streams, and rivers. They also have been isolated from clinical and food samples. Aeromonads are pathogens for cold-blooded animals (fish, amphibians, and reptiles).

EPIDEMIOLOGY

Ewing and associates[46] and other investigators have isolated *Aeromonas* from tap water and from the water or sediments of rivers, especially during periods when the water temperature was relatively warm.[75,97,139] Hazen and colleagues[61] recovered *Aeromonas hydrophila* from 135 of 147 natural water sources in 30 states of the United States and reported that its density was higher in flowing (lotic) than in calm (lentic) water systems and lower in fresh-water than in saline systems; however, *Aeromonas* could not be recovered from waters in which the saline content approached that of sea water or from extremely polluted waters. Leclerc and Buttiaux[83] found *Aeromonas* in 30 percent of more than 9000 samples of drinking water in France. *Aeromonas* also have been recovered from hospital water supplies.[97,113,114] More recently, Pin and colleagues[116] isolated these organisms from clinical and food samples, including poultry, shellfish, pork, and beef, where they thrived even at low temperatures.

Aeromonas organisms survive readily on surfaces such as bench tops and moistened paper towels. Slotnick[144] recovered *Aeromonas* organisms from a moistened paper towel that had been allowed to dry 24 hours after the application of the organisms. When the towel was placed in a humidified closed environment, the period was extended to 2 weeks.

A. hydrophila may be found in the mouths of fish, alligators, turtles, tadpoles, and frogs.[65] It also has been found in the feces of guinea pigs and laboratory mice.[40] Ticks are another source of *Aeromonas*. Unusual sources of *Aeromonas* infection include contamination of home or hospital hemodialysis equipment,[71,121] tsunami-associated wound contamination,[64] and contamination of blood or blood products.[118,122] San Joaquin and colleagues[133] noted that *Aeromonas* organisms also have been found in ornamental aquaria belonging to patients with *Aeromonas*-associated gastroenteritis; however, they found that isolates from the aquaria differed in susceptibility testing from the gastrointestinal isolates, so the aquaria probably were not the sources of infection.

Aeromonas also have been isolated from a large proportion of ready-to-eat salads.[93] Of *Aeromonas* salad isolates, 35 percent were *A. hydrophila* or *Aeromonas sobria*. All isolates tested in this study had at least one marker of enteropathogenicity, including hemolysin and cytotoxin production. Nonetheless, few if any, cases of diarrhea have been associated with ingestion of these salads in immunocompetent hosts.

In 1988, California made infection by *Aeromonas* a reportable condition, permitting the first population-based study of the epidemiology of infection caused by this organism. The overall incidence rate for *Aeromonas* isolation was 10.6 cases per 1 million population. The gastrointestinal tract was the most common site of infection (81% of cases), followed by wounds (9%). Five (2%) of 219 patients with *Aeromonas* infection died; all had serious underlying medical conditions.[78] *A. hydrophila* has been placed on the U.S. Environmental Protection Agency Contaminant Candidate List of emerging pathogens in drinking water because it has the potential to grow in water distribution systems and to be resistant to chlorination.[14]

ETIOLOGIC AGENT

Aeromonas organisms are motile, asporogenic, gram-negative rods that contain a single polar flagellum. The organisms are oxidase-positive and catalase-positive and produce acid or gas during carbohydrate fermentation. They can grow at temperatures between 0° C and 41° C. Growth may occur within a pH range of 5.5 to 9. Lipase, gelatinase, DNase, and other exoenzymes are formed by these organisms.[45,138,156]

Aeromonads grow well on blood agar; most strains produce a large zone of beta-hemolysis on this medium, although nonhemolytic strains exist. *Aeromonas* colonies on blood agar have a ground-glass appearance and a fruity odor.[158] Aeromonads also grow on MacConkey, eosin-methylene blue, *Salmonella-Shigella*, and triple sugar iron media.

The sensitivity and specificity of various media for detection of *Aeromonas* spp. in fecal specimens have been evaluated.[103,126,155] Isolation is achieved readily on any of the following: prilxylose-ampicillin agar, xylose-sodium, deoxycholate citrate agar, alkaline peptonic water, inositol–brilliant green bile salts agar, trypticase soy broth with ampicillin, and dextrin-fuchsin-sulfite agar.[155] The colonies appear almost colorless on these media, with the exception of growth on dextrin-fuchsin-sulfite agar, on which they appear dark red.

Mishva and associates[99] evaluated five selective agars. Of these, sheep blood agar with 30 mg of ampicillin/L (ASBA 30) permitted the greatest number of *Aeromonas* colonies to grow, while also inhibiting the competing fecal flora. They recommend that ASBA 30 be used with DNase–toluidine blue agar (DNTA) to detect the ampicillin-susceptible strains and the nonhemolytic strains. The combination of ASBA 30-DNTA allowed 98 percent of all isolates to be detected.

Strains of motile *Aeromonas* isolates can be identified to species level by use of the following tests: production of nitrate reductase; fermentation of D-glucose and trehalose; failure to use mucate; and the inability to produce acid from D-arabitol, dulcitol, erythritol, and xylose.[1] Detection of *Aeromonas* organisms by use of strain-specific fluorescent antibody has been described.[155] The technique is not satisfactory; only a small percentage of isolates react with prepared antisera, which suggests the presence of numerous serogroups. The use of a monoclonal antibody against *A. hydrophila* has been shown to overcome this problem, however.[38] This monoclonal antibody could prove beneficial in the future as a screening tool. Additionally, the study of selected housekeeping genes has been helpful in establishing phylogenetic relationships among members of the aeromonads.[147]

Aeromonas previously was considered a member of the Vibrionaceae family, which included the genera of *Vibrio* and *Plesiomonas*.[119] Molecular genetic techniques have identified that these three genera are not related evolutionarily, however, and aeromonads represent a family of their own.[34] *Aeromonas* have long been viewed as belonging to one of two major groups on the basis of their ability to grow at different temperatures. Mesophiles were strains that grew at 35° C to 37° C, and psychrophilic strains were more prevalent at lower temperatures (22° C to 28° C). These two groups could be distinguished not only by optimal growth conditions but also by elaboration of pigmentation on tyrosine agar and production of indole. The mesophilic strains are motile, and the psychrophilic strains are nonmotile.

Fourteen *Aeromonas* spp. have been recognized, and this number is expected to increase as new strains are isolated and identified.[1] Although the number of strains of psychrophilic *Aeromonas* spp. has remained stable, the number of various strains of mesophilic species isolated has increased. Several classification schemes within the genus are in use. The strains are classified based on biochemical assays or the use of genotyping techniques such as DNA-DNA hybridization and restriction fragment length polymorphism of the 16S rRNA, or both. Genetic techniques have been used to differentiate the genus into genomospecies or hybridization groups (HG), allowing more precise identification.[15]

Abbott and associates[1] classified *Aeromonas* based on the results of the Møeller decarboxylase and dihydrolase reactions. They also were able to place the strains they studied into complexes based on certain biochemical reactions. The *Aeromonas* strains that produced elastase, pectinase, and stapholysin were grouped into the *A. hydrophila* complex (*A. hydrophila*, *Aeromonas bestiarum*, *Aeromonas salmonicida*). Similarly, the *Aeromonas carviae* complex includes *A. caviae*, *Aeromonas media*, and *Aeromonas eucrenophil*, and the *Aeromonas sobria* complex comprises *Aeromonas veronii* HG8, *Aeromonas jandaei*, *Aeromonas schubertii*, and *Aeromonas trota*.

In addition, other species, including *Aeromonas media* (similar to *A. salmonicida*),[5] *A. veronii*,[63] *A. schubertii*,[22,62] *A. jandaei*,[20] *A. trota*,[21] *Aeromonas allosaccharophila*,[91] *Aeromonas encheleia*,[44] *A. bestiarum*,[6] *Aeromonas popoffii*,[68] and *A. eucrenophila*,[138] have been described. A new species, *Aeromonas culicicola*, was isolated more recently.[115] Other isolates include *Aeromonas enteropelogenes* and *Aeromonas ichthiosmia*, which seem to be similar to previously identified species.[33] Of the species isolated currently, *A. hydrophila*, *A. caviae*, and *A. veronii* have been associated most often with human infections.[69]

Aeromonas is confused most frequently with Enterobacteriaceae. The oxidase test always should be performed to aid in differentiation; *Aeromonas* organisms generally are oxidase-positive, whereas Enterobacteriaceae organisms are oxidase-negative. McGrath and associates[95] described oxidase-variable strains of *A. hydrophila*. These strains are oxidase-positive when grown on nonselective media but oxidase-negative when grown on differential or gram-negative media. Organic acid end-products of lactose fermentation can inhibit the oxidase reaction. Paik[110] also has shown that a platinum wire loop should be used for oxidase testing; use of an iron-containing loop can cause false-positive oxidase results.

Aeromonas is susceptible to ceftriaxone (8 μg/mL), chloramphenicol (2 to 4 μg/mL), gentamicin (0.5 to 2 μg/mL), streptomycin (16 μg/mL), and trimethoprim-sulfamethoxazole (<0.5/9.5 μg/mL).[46,47,108,109,123,155] Reinhardt and George[124] determined that the most active on a weight basis were ciprofloxacin, enoxacin, and norfloxacin; nalidixic acid and trimethoprim-sulfamethoxazole also possessed good activity. Neither sulfamethoxazole nor trimethoprim alone was active. In addition, they did not note appreciable differences in susceptibility among species or in susceptibility between fecal versus nonenteric isolates. In contrast, Motyl and colleagues[102] noted higher levels of resistance to various antibiotics among *A. hydrophila* strains compared with *A. sobria* or *A. caviae*, as judged by minimal inhibitory concentration. Susceptibility to cephalothin may serve as a useful criterion in the identification of *A. sobria*.[102,133]

Aeromonas organisms consistently are resistant to penicillin, ampicillin, carbenicillin, cephalothin, erythromycin, clindamycin, and vancomycin. Sawai and associates[137] showed that resistance to β-lactam antibiotics is caused by the production of a species-specific, chromosome-mediated β-lactamase. It is not R plasmid–mediated. In 1980, McNicol and coworkers[96] reported the recovery of *Aeromonas* isolates from the Chesapeake Bay that were resistant to tetracycline and polymyxin B. They also noted that 57 percent of isolates from Bangladesh had a multiple streptomycin-chloramphenicol-tetracycline resistance phenotype that correlated with the presence of a larger plasmid.

PATHOGENESIS

In addition to its pili, *A. hydrophila* produces numerous virulence factors, including extracellular toxins and enzymes that are involved in the pathogenesis of *A. hydrophila* infection. Some of the toxins elaborated by *A. hydrophila* include hemolysins, aerolysin, and enterotoxins.

Alpha-hemolysin is released from cells during a stationary growth phase. Alpha-hemolysin has a molecular weight of 50,000[87,88] to 65,000[88] and is stable at room temperature between pH 3.5 and 9.5. It is heat-labile. Alpha-hemolysin is cytotoxic to HeLa cells and human embryonic lung fibroblasts.[154] When injected into rabbit skin, it causes dermonecrosis. Intraperitoneal injection of alpha-hemolysin is lethal for rabbits and mice.

Beta-hemolysin has a molecular weight of 49,000 to 53,000 and is released near the end of the logarithmic phase of growth of the *Aeromonas* organism. It is heat-labile and resists destruction by trypsin and pronase.[88] It causes dermonecrosis of rabbit skin and is lethal for rabbits, rats, and mice. It is cytotoxic to HeLa cells and to human diploid lung fibroblasts.[152] It also has been shown to induce impairment in the intestinal epithelial barrier and to stimulate active chloride secretion in human colon cell monolayers, contributing to enteritis.[43]

Alpha-hemolysin and beta-hemolysin may be significant virulence factors. Most clinical isolates are beta-hemolytic, and hemolysis is a common feature of infection caused by *Aeromonas* spp. Alpha-hemolysin and beta-hemolysin in high concentrations produce hemorrhagic enteritis in a rabbit ileal loop; however, neither alpha-hemolysin nor beta-hemolysin is clearly established as a virulence factor in diarrheal disease.[89] Antibodies to either hemolysin neutralize both toxins.

Aerolysin is a pore-forming toxin that shares some homology with beta-hemolysin.[43] After inserting into its target cells, it disrupts ion gradients and membrane potentials, leading to cell lysis.[82] Caco-2 cells derived from human intestine have been shown to be very sensitive to the effects of aerolysin.[2]

In 1975, Sanyal and associates[135] showed that the enterotoxins from *A. hydrophila* were enterotoxigenic. Subsequently, enterotoxigenic *A. hydrophila* has been isolated from humans,[19,55-58,75,157] water sources, fish, and pigs.[16,108] Sha and colleagues[140] have characterized three enterotoxins from *A. hydrophila*. The cytotoxic enterotoxin has hemolytic, cytotoxic, and enterotoxic activities and has a molecular weight of 52,000. It is a pore-forming toxin that has been shown to cause fluid secretion and tissue damage in mouse ileal loops.[82] The other two are cytotonic enterotoxins. One has a molecular weight of 44,000 and is heat-labile. The second has a predicted molecular weight of 71,000 and is heat-stable. These cytotonic enterotoxins cause elevation of cyclic adenosine monophosphate and prostaglandin levels in Chinese hamster ovary cells and fluid secretion in rabbit ileal loops.[140] All three enterotoxins have been implicated in *A. hydrophila*–induced gastroenteritis. *Aeromonas* spp. also produce proteinase A and B, endopeptidase, staphylolytic enzyme, fibrinolysin, and leukocidin.[87] The precise relationship of these toxins and enzymes to the pathogenesis of human infection is unclear.

Strains of *Aeromonas* produce proteases, DNase, lecithinase, and elastase.[3] These extracellular enzymes may have pathologic significance. *Aeromonas* strains that possess hemolytic and cytotoxic capabilities and that are characterized as HG1/BD-2 type strains have been related strongly to patients with diarrheal disease.[81]

Antihemolysin and agglutinating and precipitating antibodies to *A. hydrophila* have been detected in patients with systemic *Aeromonas* infections but not in patients with superficial infections. Increases in the antihemolysin titer to 1:1280 and in the agglutinin titer to 1:640 have been noted.[24]

Burke and colleagues[18] found that many strains associated with diarrhea were able to hemagglutinate cells from human, horse, rat, and guinea pig. Of these strains, 68 percent displayed fucose-resistant hemagglutination. The investigators suggested that these properties may contribute to virulence.

Ketover and associates[76] showed that normal serum promotes phagocytosis and intracellular killing of *Aeromonas* organisms by normal white blood cells. In contrast, sera from two patients with fatal *Aeromonas* infections failed to do so. One patient had an

increase in the serum opsonic antibody titer from less than 1:5 in the acute stage of disease to 1:5120 in the convalescent stage. These studies suggest that a specific opsonizing antibody that is present in normal serum and normal bactericidal activity of neutrophils are required to prevent invasive *A. hydrophila* infections.

The flexible type IV pili of *Aeromonas* are the predominant pili expressed on fecal isolates of diarrhea-associated species of *Aeromonas*. They represent a family of type IV pili that has been designated Bfp (bundle-forming pili). Kirov and associates[79] have presented compelling evidence to support the concept that Bfp are important intestinal colonization factors. More recently, this group also showed that *Aeromonas* flagella are adhesins for human intestinal cells, playing a role in its enteropathogenicity.

Serogroup analysis may be helpful in establishing which *Aeromonas* isolates can cause human disease. Serogroups O:11, O:34, and O:16 predominate as causes of clinical infection.[70]

Clear correlation between known virulence properties and enteropathogenicity in humans is lacking. This lack of a clear correlation has been attributed to the heterogeneity of *Aeromonas* spp., the great variety of *Aeromonas* virulence factors, and the loose association between virulence factors and the phenotype and genotype.[69] Consequently, many researchers have proposed a multifactorial pathogenesis with the involvement of numerous cellular and extracellular virulence factors.[29]

CLINICAL MANIFESTATIONS

Aeromonas spp. have been implicated as a cause of septicemia, gastroenteritis, peritonitis, skin and wound infections, osteomyelitis, septic arthritis, ocular infections, myositis, urinary tract infections, pneumonia, meningitis, and hemolytic-uremic syndrome in children. Most of these infections have been noted in normal and compromised hosts.[13,48,111,112]

Sepsis caused by *Aeromonas* spp. has been reported in children.* Because *Aeromonas* infection is not a reportable disease, the total number of affected children is unknown. Although septicemia caused by *Aeromonas* spp. has occurred in normal children, most children affected have had a disorder known to impair the normal host response to infection or a disorder in which the intact skin as a barrier to infection has been destroyed. *Aeromonas* infection has been noted in children with leukemia (particularly those with neutropenia), aplastic anemia, cirrhosis, hemoglobinopathies, malnutrition, burns, and renal failure.

The clinical manifestations of septicemia are similar to the manifestations noted in other gram-negative enteric bloodstream infections with high fever and shock. During the course of septicemia in some of these patients, ecthyma gangrenosum also has been noted. The reported case-fatality rate of 50 percent despite administration of antibiotic therapy presumably is related to the severity of the underlying disorders and not to an unusual virulence of the organism. The propensity for infection in the compromised host suggests that *Aeromonas* organisms are of low virulence for the human host. Bacteremia with *A. sobria* and *A. punctata* also has been described.[71,122,143]

Meningitis caused by *Aeromonas* spp. also has been reported in children.[49,50,159] In one reported review of 21 years' experience with gram-negative bacillary meningitis, *Aeromonas* spp. accounted for 2 percent of the cases.[154] The course was fulminant, and the patients died despite having received antibiotic therapy. All of these children could be considered immunocompromised as a result of sickle-cell anemia (a 23-month-old child) or age (neonates).

Gastrointestinal infections caused by *Aeromonas* spp. have been reported with greater frequency in pediatric patients. *A. hydrophila*, *A. sobria*, *A. caviae*, and *A. punctata* have been recovered from stool specimens of patients with gastroenteritis.[19,28,51,71,101] In 1961, Martinez-Silva and colleagues[92] described an epidemic of enteritis in a newborn nursery affecting nine infants (eight as newborns and one at 7 days old). *Aeromonas* spp. were found in the stools of six of these infants. One newborn, the only patient with a pure growth of *Aeromonas* in a stool specimen, died. In 1964, Rosner[129] reported severe gastroenteritis in a child with growth of *A. hydrophila* from four stool cultures. In 1991, one study reported 224 cases of *Aeromonas* gastroenteritis in Iowa from January to June.[120] Taneja and associates[150] described an outbreak of diarrhea caused by *Aeromonas* spp. on a hematology-oncology ward in a pediatric hospital during March-April 2001 where 6 of 18 children were infected. *Aeromonas* spp. were found to be the sole enteropathogen in five of the six children. Aeromonads have been detected worldwide as the sole pathogen causing diarrhea in 2 to 20 percent of affected children and in only 0 to 2 percent of children without diarrhea.[29,39,56,151]

In an attempt to assess the role of *Aeromonas* spp. in diarrheal disease, numerous investigators have evaluated the fecal carriage rate of the organism.[60] Freij[50] described a study performed by other investigators who recovered *Aeromonas* from 0 of 300 adults and from 31 of 4426 (0.7%) children younger than 2 years. Pitarangsi and coworkers[117] reported carrier rates of 16 to 27 percent in various districts in Thailand and noted the same frequency of *A. hydrophila* in stools of Thais with and without diarrhea. In contrast, *A. hydrophila* was recovered from the stools of American Peace Corps volunteers more frequently when they had diarrhea than when their stool frequency was normal. Only three *Aeromonas* isolates were reported from 1685 rectal swab cultures obtained from 1217 children hospitalized for gastroenteritis in Manitoba, Canada. Bhat and colleagues[10] recovered *Aeromonas* organisms from 7 of 133 patients with acute diarrhea in a valley in India and found *Aeromonas* and *Plesiomonas shigelloides* in the well water commonly used by these individuals. Soltan Dallal and Moezardalan[148] isolated *Aeromonas* spp. from 14 of 310 Iranian children in a case-control study.

Gracey and associates[57,58] described a prospective study in Australia of 1156 children with diarrhea and an equal number of age-matched and sex-matched control subjects. Enterotoxigenic *Aeromonas* organisms were isolated from 10.2 percent of children with diarrhea compared with 0.6 percent of healthy children. *Aeromonas* was the only potential pathogen recovered in 6.5 percent of children with diarrhea. Cases of *Aeromonas* infection peaked during the summer months. The mean duration of diarrhea was 15.3 days, and 33 percent of the children required hospitalization. These investigators described three clinical syndromes of *Aeromonas* gastroenteritis: (1) watery diarrhea, vomiting, and low-grade fever in 41 percent; (2) diarrhea with blood and mucus in 22 percent; and (3) prolonged diarrhea of more than 2 weeks' duration in 37 percent.

Many investigators[4,27,104,106,132] have attempted to describe gastrointestinal infections caused by *Aeromonas* spp. Gluskin and associates[53] performed a 15-year study of the rate of *Aeromonas* spp. in gastroenteritis in hospitalized children. A total of 146 strains of *Aeromonas* spp. were isolated from 32,810 fecal specimens from 13,820 hospitalized patients. These isolates constituted 4 percent of all pathogenic bacterial strains cultured. Most of the cases of diarrhea (94%) occurred in children younger than 3 years old. The peak incidence occurred in infants aged 2 to 6 months. Bloody diarrhea occurred in 7 percent of children. Several investigators[4,132] have detected a larger number of cases of *Aeromonas*-associated diarrhea in the summer months than in other months, whereas Challapali and colleagues[27] found no seasonal patterns of *Aeromonas* isolation. The greatest number of cases occurred in children younger than 12 months to 3 years of age.

Symptoms included diarrhea, bloody stools, vomiting, abdominal cramps, mild dehydration, and fever. *Aeromonas*-associated

*See references 17, 32, 36, 59, 67, 76, 105, 111, 128, 136, 158-160.

diarrhea resembled other types of bacterial diarrhea, except that fecal leukocytes were absent in children with *Aeromonas*-associated diarrhea; in contrast, fecal leukocytes were found in 60 percent of children with other types of bacterial enteritis.[27] A cholera-like illness caused by enterotoxigenic *A. sobria* has been described.[28] Gastroenteritis caused by *A. sobria* and *A. hydrophila* tended to be acute, whereas diarrhea associated with *A. caviae* frequently was chronic, lasting 4 to 6 weeks in untreated patients.

San Joaquin and Pickett[132] described three patients with *A. caviae* diarrhea who originally presented with failure to thrive presumed to be secondary to formula intolerance. Diarrhea in these patients improved after administration of trimethoprim-sulfamethoxazole. Moyer[104] noted that although *A. caviae* is considered nonpathogenic, five pediatric patients with otitis media who were treated with penicillin or ampicillin subsequently developed diarrhea in which *A. caviae* was the only potential enteric pathogen. The prior therapy with antibiotics to which *Aeromonas* spp. are known to be resistant probably contributed to colonization of the gastrointestinal tract with *A. caviae* and subsequent development of diarrhea. These four patients also were treated successfully with trimethoprim-sulfamethoxazole.

Outbreaks of diarrhea associated with *Aeromonas* in daycare centers have been described.[39] *A. caviae*, *A. hydrophila*, and *A. sobria* were the strains recovered most commonly.

Complications of *Aeromonas* intestinal infection included gram-negative bacteremia, intussusception, internal hernia strangulation, hemolytic-uremic syndrome,[13,125] and failure to thrive. Peritonitis has been reported in a 5-year-old patient with a ruptured appendix.[67] No additional clinical information about this patient was provided.

A. hydrophila has been recovered from the skin or from wound infections of children.* Most of these patients have been normal hosts; three had leukemia. In 40 percent of these cases, *Aeromonas* organisms were not recovered from the lesion in pure culture. The lower extremity was involved in 75 percent of these cases. Exposure to water was noted in 40 percent of these cases; alligator bites, snakebites, stepping on glass, and burns were other presumed predisposing factors. Clinical manifestations included cellulitis, hemorrhagic blebs, and purulent diarrhea with fever and leukocytosis. Secondary bacteremia and osteomyelitis have been reported.[12]

We (R.D.F.) have recovered *Aeromonas* organisms from skin lesions that have been the result of tick bites. In each of these cases, a circumscribed area of purple discoloration has surrounded the bite, and nonpurulent drainage from the center of the lesion yielded the organism. These patients sought medical attention because the local lesion had persisted or had increased in size over the course of 1 to 2 weeks. *A. schubertii* also has been isolated from traumatic wound infections.[22]

Ecthyma gangrenosum caused by *A. hydrophila* has been described in several children with leukemia.[76,105,141] We (R.D.F.) have seen ecthyma gangrenosum in several children with *Aeromonas* septicemia who have had malignant or hepatobiliary disease. Clark and Chenoweth[31] isolated *A. hydrophila* from an 18-month-old boy and a 2-year-old boy, both of whom had liver transplants for biliary atresia and subsequently developed cholangitis. In both instances, these were polymicrobial infections.

Lopez and associates[90] described an 8-year-old child with acute myelogenous leukemia with bacteremia and osteomyelitis; *Aeromonas* organisms grew from a bone aspirate of this patient. Blatz[12] reported finding osteomyelitis and *Aeromonas* bacteremia in a previously healthy 16-year-old patient; a bone aspirate was not attempted. Septic arthritis caused by *A. hydrophila* also has been described in a child with leukemia; the organism was recovered from the second metacarpophalangeal joint at autopsy.[36] Elwitigala and colleagues[42] also recovered *A. hydrophila* in a previously healthy 13-year-old girl who developed severe septic arthritis of the knee after injury sustained in a private fresh-water lake. This infection frequently is rapidly progressive.

Aeromonas has been recovered from the conjunctiva of a previously healthy 7-year-old boy whose eye had been penetrated by a safety pin[145] and from the anterior chamber of an 8-year-old boy who developed endophthalmitis after receiving a corneal laceration from a fishhook.[32] *A. sobria* endophthalmitis has been described in a 14-year-old patient after a penetrating eye injury occurred in which a cormorant pecked the patient's eye.[84]

Although numerous cases of *Aeromonas* urinary tract infections have been reported in adults, only a few cases have been reported in children. McCracken and Barkley[94] reported the recovery of *A. hydrophila* in pure culture from the urine of a 5-month-old boy with diarrhea. Bartolomé and colleagues[9] described a case of urinary tract infection associated with diarrhea in a newborn boy with bilateral ureterohydronephrosis and bladder involvement from posterior urethral valves. Ojeda-Vargas and associates[107] reported the case of an 18-year-old girl with severe pyelonephritis requiring admission to the intensive care unit. *A. hydrophila* and *Pseudomonas* were isolated from her urine cultures.

Myositis caused by *Aeromonas* also has been described in children. A 9-year-old girl and a 16-year-old boy required amputation of their legs as a result of *Aeromonas* myositis.[37,146] Necrosis of muscle was noted in both cases, and gas was seen on the radiographs before amputation in the 9-year-old girl. Fatal myofascial necrosis also has been reported in a patient with a history of aplastic anemia.[54] *A. hydrophila* also has been isolated from abscesses caused by snakebites.[72]

Pneumonia caused by *A. hydrophila* is a rare event in children. Kao and associates[74] reported that there have been a total of seven case reports in the literature so far, and four patients died of fulminant disease. Of the seven patients, four had accompanying medical conditions, including acute leukemia (two patients), cavernous hemangioma with thrombocytopenia (one patient), and nephrotic syndrome (one patient). One patient was the victim of a near-drowning, and two patients were previously healthy.[74,123,142] One of the previously healthy patients was described by Kao and associates[74] in their case report and literature review. The patient was a 5-year-old girl who presented with fulminant sepsis and pneumonia and quickly died. *A. hydrophila* was recovered from her blood, endotracheal aspirate, and postmortem pleural fluid. Neither a bone marrow aspirate nor an immunologic work-up was performed, so whether she had an underlying malignancy or immunodeficiency that might have contributed to her rapid demise is unknown. *A. hydrophila* has been isolated from lung abscess at autopsy of a 16-year-old girl with *A. hydrophila* septicemia and leukemia.[36]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Aeromonas should be considered a possible cause of infection in children with any of the disorders previously noted. It always should be included as a possible cause of gastroenteritis, bacteremia, and skin infection in a compromised host. Generally, *Aeromonas* organisms are recognized only when they grow from body fluids or tissues that normally are sterile. The best methods for isolation of *Aeromonas* organisms have been described (see the section on etiologic agent).

A. hydrophila in food can be detected by an enzyme-linked immunosorbent assay and polymerase chain reaction.[11,98,153] These organisms also have been identified in environmental

*See references 9, 12, 37, 48, 67, 76, 94, 105, 112, 128, 141, 149, 155.

samples by use of 16S rDNA–targeted oligonucleotide primers.[41] Many sophisticated techniques, including rRNA sequencing, DNA-DNA reassociation techniques, and polymerase chain reaction, have been used to continue to identify and differentiate *Aeromonas* spp.[15,35,69,77]

TREATMENT AND PROGNOSIS

Aeromonas infection occurs infrequently; controlled studies to permit recommendation of one antibiotic over all others are unavailable. Penicillin-hydrolyzing β-lactamases have been detected in most strains of *Aeromonas*, rendering those strains resistant to ampicillin.[100] Piperacillin shows variable activity against *Aeromonas* spp., whereas ticarcillin-clavulanate generally is active. In vitro, *Aeromonas* organisms generally are susceptible to chloramphenicol, aminoglycosides, trimethoprim-sulfamethoxazole, aztreonam, quinolones, and the third-generation cephalosporins.[73,80,130]

In our (R.D.F.) experience, chloramphenicol or third-generation cephalosporins have proved efficacious. A drug to which the organism is sensitive should be provided (usually intravenously). The duration of administration depends on the site of infection and the clinical response to therapy. The occurrence of *Aeromonas* infections predominantly in compromised hosts accounts for the high case-fatality rate despite administration of an antibiotic agent to which the organism is susceptible.

CHAPTER 126

PASTEURELLA MULTOCIDA

Barbara W. Stechenberg

In 1878, Kitt first isolated a bacterium of the *Pasteurella* group from wild hogs during an epidemic; 2 years later, Pasteur described the organism that causes fowl cholera. Since that time, the same organism has been implicated in rabbit septicemia, swine plague, hemorrhagic septicemia, and wildseuche (a fatal disease in deer). Hueppe applied the term *hemorrhagic septicemia* to this group of infectious diseases in lower animals because of the characteristic hemorrhagic areas scattered throughout most of the viscera. Original names for the causative organisms included *Pasteurella aviseptica*, *Pasteurella boviseptica*, *Pasteurella suiseptica*,

and *Pasteurella lepiseptica*, but these organisms now are classified under the name *Pasteurella multocida*, a small, nonmotile, gram-negative rod.[38]

Although *P. multocida* primarily is a pathogen in animals, recognition of its potential for infection in humans has been increasing. Brugnatelli reported the first bacteriologically proven case in a human in 1913. Schipper[39] did an extensive review of the literature from 1930 through 1947 and reported only 40 cases of infection with *P. multocida*. Since then, an increasing number of human infections with *P. multocida* have been reported.

ORGANISM

P. multocida generally appears as a short, ovoid, gram-negative rod; however, it also may appear as coccobacilli with convex sides and rounded ends. The length ranges from 0.3 to 1.25 μm, and the diameter ranges from 0.15 to 0.25 μm. *P. multocida* may appear singly or in pairs, chains, or clusters. Healthy organisms stain easily with aniline dyes and are gram-negative. They may show bipolar staining, especially when smears are made directly from animal tissue or fluids. They become increasingly pleomorphic on subculture and may resemble enterics in broth. They do not grow on eosin–methylene blue, MacConkey, deoxycholate, or any other bile-containing agar. They are facultatively anaerobic and nonmotile. They do not require X or V factor for growth, an important differential point in distinguishing them from *Haemophilus influenzae*.

Colonies are nonhemolytic and translucent, usually 1 to 2 mm in diameter, and generally low, convex, and butyrous. Occasionally, they may be larger and mucoid. In a study of 30 strains isolated from humans, Heddleston and Wessman[17] reported that 9 of the cultures produced watery mucoid colonies, 4 produced iridescent colonies, 10 produced blue colonies, and 3 produced a mixture of iridescent and blue colonies. Colonies on blood agar are smaller, opaque, and grayish white. In broth cultures, turbidity, often with a flocculent sediment, is present.

Cultures tend to autoagglutinate in saline and have a peculiar odor described as musty, similar to semen or burning hair. They are catalase-positive, usually oxidase-positive, and indole-positive. They usually ferment galactose, glucose, fructose, mannitol, mannose, and sucrose without production of gas. Some variability occurs in the fermentation of other sugars. They reduce nitrates but have negative urease, methyl red, and Voges-Proskauer reactions. Using fermentation reactions, Oberhofer[31] developed a biotyping system in which correlation of biotype, 61 percent A and B, was found with cat-bite isolates but not with dog-bite isolates.

The pathogenicity of the organism varies; most mucoid and smooth colony-forming strains produce a capsule and usually are highly pathogenic for mice and rabbits. The capsule is antiphagocytic, resisting intracellular killing by neutrophils.

Nielsen and Rosdahl[29] have developed a bacteriophage typing system for typing toxigenic and nontoxigenic strains. DNA hybridization studies have led to a reclassification of the genus *Pasteurella*. *P. multocida* now includes three subspecies—*P. multocida* subsp. *multocida*, *P. multocida* subsp. *septica*, and *P. multocida* subsp. *gallicida*. Of 159 strains recovered from 46 infected humans, 95 were identified as *P. multocida* subsp. *multocida*, and 21 were identified as *P. multocida* subsp. *septica*; the remainder were divided among multiple other species.[16] The use of serology in conjunction with DNA fingerprinting can classify isolates for epidemiologic studies.[51]

Immunity to *P. multocida* can be shown in many animals, and vaccines have been developed with known efficacy, especially in birds and cattle. The precise mechanisms involved in this immunity and, more important, in natural immunity are being elucidated. Antibodies to somatic and capsular antigenic determinants develop within 2 weeks of development of clinical infection, with the capsular antibodies being longer lasting.[5] The precise role of these antibodies in human host defenses is unclear. Woolcock and Collins[52] developed models in pathogen-free mice that may help uncover these mechanisms. The efficacy of heat-killed vaccine has been shown to be considerable when multiple doses are used. With the use of an aerogenic mouse model for the stimulation of respiratory spread, however, the protection is reduced. Local instillation of the vaccine can be used with this model to develop local antibodies, but preliminary results show protection only with modest challenge doses.[3] A footpad inoculation model may help elucidate the mechanisms in local human infections.

TRANSMISSION

The organism is found in the oral flora of many different animals; 67 percent of cats may harbor this organism in their mouths or throats. Smith[40] found that *P. multocida* could be recovered from the tonsils of 54 percent of dogs and from the nose of 10 percent of dogs. Schipper[39] grew *P. multocida* from 14 percent of wild rats trapped in the Baltimore area. Hansmann and Tully[15] showed that *P. multocida* may remain as a commensal for prolonged periods in the mouth of a cat. They described a patient who had been bitten on two occasions 3 years apart by the same healthy pet cat; each time, an abscess caused by *P. multocida* developed. *P. multocida* also has been isolated from lion, tiger, panther, buffalo, mink, and opossum.[4,20]

Although verifying the mode of transmission has been easiest when an infection has been related specifically to a pet or farm animal, many cases of infection caused by *P. multocida* have been documented despite a negative history of such exposure. Respiratory infection with this organism has been described in veterinarians, farmers, milkmen, and individuals employed where animal tissues are processed. Meningitis caused by *P. multocida* has been described in a patient after undergoing brain surgery in which rabbit muscle was used for hemostasis.

The possibility of a reservoir of infection in humans with resultant interhuman transmission rarely has been considered. In a study of veterinary students, Smith[40] described 2 of 71 with positive throat isolations. The organisms were present in one student for a few days and in the other for the full 4 months of the study; both patients were asymptomatic. Several other cases of isolation of the organism from the human respiratory tract, many without associated symptoms or known animal contact, have been made.

In addition, interhuman spread by nasopharyngeal excretions, feces, and urine also may occur because the organism has been recovered from these sites. The female genital tract is another potential source, especially for cases of septicemia and meningitis that occur during pregnancy and in the newborn period.

Investigators of an outbreak in a chronic disease hospital showed that *P. multocida* may be viable on a hand towel for 24 hours. Although the source in this outbreak was not established, this finding may have implications for spread in other situations, particularly for pet owners.[23]

EPIDEMIOLOGY

P. multocida has been isolated from humans in all areas of North America and Europe, with some reports coming from other areas. In the United States, it is not a reportable organism, so incidence

and prevalence data are unavailable. Lee and Buhr[26] have cited a seasonal variation in the number of reported cases related to dog bites, with the highest incidence being in the fall and winter months, possibly related to increased nasal carriage in dogs during that period. Other investigators have found no seasonal differences.[9,21]

No difference in attack rate has been found between the sexes. The attack rate is higher in individuals of both sexes in very young (0-4 years old) and in older (>55 years old) individuals.

PATHOGENESIS AND PATHOLOGY

In animals that are stressed, a benignly parasitic strain may invade the mucous membrane on which it is carried. With highly virulent strains, a picture of hemorrhagic septicemia may develop. It may be characterized by high fever, cardiac weakness, toxemia, and early death. Organisms can be cultured from the blood; autopsy findings may be minimal or include petechial hemorrhages on mucosal and serosal surfaces and in various organs. Less acute forms, such as a pneumonia with serofibrinous exudate in the interlobular septa of the lungs, a hemorrhagic gastroenteritis, and subacute and chronic infections such as otitis in the rabbit, may occur. The mechanisms by which these bacteria invade the mucosa and cause systemic disease continue to unfold. Key virulence factors are the capsule and lipopolysaccharide, with others still being identified.[16]

In humans, three major types of infections occur.[50] In the first and most common type, local infection occurs after a cat bite or scratch, a dog bite, or, rarely, the bite of another animal. Approximately 15 to 20 percent of dog-bite wounds and more than 50 percent of cat-bite wounds become infected. Many cases have been associated with non-bite exposure, such as licking.[11] These cases usually are characterized by a rapidly progressive, acute cellulitis with lymphangitis, local lymphadenitis, or both. Cat-bite wounds may progress to osteomyelitis of the underlying bone. This development is not because of any known predilection of *P. multocida* for the bone but because the sharp fangs of a cat deposit the organism on or under the periosteum.

The second type includes cases of chronic pulmonary infection in which the organism may be the only isolate or one of several organisms. Cases of bronchiectasis and empyema have been reported, usually in patients with underlying pulmonary disease. In a series of 28 cases of bronchiectasis in which the organism was recovered, it usually appeared as a secondary invader. It seems to have low pathogenicity in the respiratory tract until some other infection or physiologic disturbance decreases the natural resistance of the host, which enables active infection, most commonly liver disease such as cirrhosis, to occur.

Pasteurella infection also may be septicemic or occur with meningitis. The pathology and pathogenesis are similar to those of other organisms.

CLINICAL MANIFESTATIONS

In cases of local infection from a scratch or bite, the usual clinical pattern shows swelling, erythema, and tenderness within a few hours of the bite; most symptoms occur within the first 24 hours. A gray serous or sanguinopurulent discharge from the puncture sites may be present. Signs of systemic toxic effects, such as chills and fever, may or may not be present; regional lymphadenopathy often is evident. Less commonly, the infection may be lower grade and smoldering.[35] As noted, osteomyelitis and tenosynovitis most often occur after cat bites because of the sharpness of cats' teeth.

Lee and Buhr[26] found *P. multocida* to be the most common infecting organism in a report of 69 dog bites that had been cultured; 20 of the bites became grossly infected, and *P. multocida* was isolated from 10. Of 30 wounds that were sutured, 14 (47%) were infected with *P. multocida*. Other unusual localized infections include chronic skin ulcers, secondary infection of a gouty joint, and infection of a compound fracture site and an amputation site.[46] Preexisting joint disease seems to be a risk.

Clinical manifestations of patients having respiratory complaints are not unusual. Most of the isolates have been associated with chronic bronchitis, bronchiectasis, chronic sinusitis or otitis media, and pneumonia. Several cases of massive pulmonary abscesses, pleural effusion, and empyema also have been reported. Larsen and Holden[25] described a 14-year-old girl with chronic otitis media for 2 years who developed a *P. multocida* cerebellar abscess. A case of epiglottitis caused by this organism has been reported in an adult.[24] A child developed Ludwig angina after having a non-bite exposure.

In a report of 136 cases of *P. multocida* infection that were not related to animal bites, the most common site of infection after the respiratory tract was the abdomen; the organism was recovered from 10 patients with appendicitis. Eight isolates were from the female reproductive tract, four from the urine, and one from a chronic sacral abscess.[21] Whether these cases are secondary to ingestion of the organism or to hematogenous spread has not been determined. Raffi and colleagues[34] described three children with appendiceal peritonitis associated with *P. multocida*. The organism also has been seen in cases of peritoneal dialysis-associated peritonitis secondary to puncture of dialysis tubing.[27,28]

The disseminated infections are the other major clinical group of *Pasteurella* infections. Isolated bacteremia may be present[33]; however, most of these cases have been meningitis, many of which were mistaken for *Haemophilus influenzae* or *Neisseria meningitidis* infection because of the morphologic similarities among these organisms. In a review of the subject in 1967, Controni and Jones[7] noted 14 confirmed cases of *Pasteurella* meningitis; 11 occurred in adults, and 3 occurred in children. Eight of the 14 patients had a history of accidental or surgical trauma. The mortality rate was 50 percent, but only five patients were treated with antibiotics. Evaluation of the cerebrospinal fluid showed white blood cell counts ranging from 580/mm^3 to 5200/mm^3, all with a predominance of polymorphonuclear leukocytes. More recently, Green and coworkers[14] reviewed 29 cases of *P. multocida* meningitis in adults.

The first reported newborn with *Pasteurella* meningitis died at 88 hours of age.[1] The mother had a fever in the postpartum period, but her pretreatment cultures were lost, so verification of the source was impossible.[7] Since then, a case of *Pasteurella* chorioamnionitis associated with premature delivery and neonatal sepsis and death within 1.5 hours of delivery has been reported.[42] Gingival cultures of a pet cat that had scratched a mother numerous times during pregnancy also yielded *P. multocida*. Subsequently, several young infants with septicemia and meningitis caused by this organism survived without apparent sequelae after treatment with penicillin or ampicillin and gentamicin.[2,10,36,45] Pizey[32] reported another case of neonatal infection in a 3-week-old infant with septic arthritis. *P. multocida* infection may take a rapidly fatal course even in an older infant.[39] Clapp and associates[6] described two infants whose disease was associated with nontraumatic facial licking by pets, an avoidable exposure. In another report, a case of in utero infection at 12 weeks' gestation was described.[48] A newborn with meningitis and cervical spine osteomyelitis with full recovery has been reported.[18]

DIAGNOSIS AND TREATMENT

Although *P. multocida* is one of the more likely pathogens to cause infection of cat or dog bites, its clinical manifestations are not unusual. Diagnosis of *P. multocida* infection can be made definitively only by culture. It may resemble several other organisms morphologically, but identification should not be difficult to make. The fact that it does not require X and V factors for growth should distinguish it from *H. influenzae*. Its production of indole should differentiate it from the *Neisseria* group, and its inability to grow on MacConkey agar or a bile salt medium should distinguish it from *Acinetobacter* spp. and the enteric organisms.

The drug of choice for *P. multocida* infection is penicillin, to which the organism is exquisitely sensitive. This feature may be used as a rapid means of distinguishing it from *H. influenzae* or the enterics. Rare strains producing β-lactamase and resistance to penicillins have been recovered.[37] The organism usually is sensitive to a wide variety of other antibiotics, including ampicillin, other broad-spectrum penicillins (e.g., ticarcillin, piperacillin, mezlocillin), amoxicillin–clavulanic acid,[12] tetracyclines, parenteral cephalosporins (particularly second-generation and third-generation),[30] cefuroxime, cefpodoxime, and chloramphenicol. Semisynthetic penicillins (e.g., nafcillin, dicloxacillin), erythromycin, some orally administered cephalosporins (cephalexin, cefaclor), clindamycin, and aminoglycosides have relatively low activity against *P. multocida*.[8,13,41] Azithromycin seems to have acceptable activity,[6] as does ciprofloxacin.[22] Trimethoprim-sulfamethoxazole may be an alternative, particularly for patients unable to take a β-lactam antibiotic.[38] Surgical drainage or débridement also may be necessary. The duration of treatment depends on the primary disease process. Seven to 10 days generally is adequate for local infections.

PROGNOSIS AND PREVENTION

Proper cleansing and débridement of wounds caused by animal bites or scratches are important in prevention of *P. multocida* infection. Lee and Buhr[26] found that suturing wounds caused by dog bite was associated with a higher incidence of infection. Whether a wound is sutured often depends on the site and the potential cosmetic result. The use of prophylactic antibiotics to prevent infection after animal bites is controversial. Some experts recommend their use if a delay occurs in seeking medical assistance and for cat bites or for patients with immunocompromising conditions.

Limiting contact with wild and domestic animals that may harbor the organism probably is the only definitive way to prevent infection. Teaching proper handling of pets and keeping pets from licking infants and young children, particularly on the face, may help. No vaccine for human use is available.

Prognosis depends on the particular site of infection. With appropriate treatment, resolution usually occurs, but the healing process may be very slow, particularly in local infections with extension to the bone or tendons.[9,47]

CHAPTER 127

Cholera

Matthew B. Laurens ✪ James P. Nataro

Cholera is a toxin-mediated diarrheal illness caused by the gram-negative organism *Vibrio cholerae*. Cholera is invariably a watery diarrhea syndrome that can range from mild and self-limiting to the severe life-threatening manifestation known as *cholera gravis*. Severe cholera can cause rapid intravascular volume depletion, shock, and death. The remarkable efficacy of rehydration therapy in preventing cholera deaths is one of the great triumphs of 20th century medicine.

Cholera may have existed since before the time of Hippocrates, and the infection continues to cause significant morbidity and mortality in areas where sanitation is poor. The infection is particularly prevalent in the Indian subcontinent and in parts of Africa. In 2005, a 30 percent increase in the global incidence of cholera was noted, mostly resulting from outbreaks in West Africa that accounted for 58 percent of all confirmed cases. The case-fatality rate decreased from 2.3 percent in 2004 to 1.7 percent in 2005.[6] This improvement likely is attributable to improved diagnostic tools and treatment, including availability of oral rehydration therapy and access to intravenous fluids for severe cases. On the forefront of prevention are the oral cholera vaccines, which have emerged as useful public health tools to combat the disease, especially in highly vulnerable transient populations.

HISTORY

Cholera has long been indigenous to the Ganges river valley in northern India. Although it exhibits a seasonal regularity, the annual epidemics are inconsistent, at times ravaging the population and at other times tolerable. In the absence of a known vertebrate reservoir or carrier state, the cause of this erratic pattern has remained mysterious until more recently.

With increased European incursion into the Indian subcontinent, the cyclical nature of cholera epidemics took on global proportions, occurring in a series of discrete pandemics through the 19th and 20th centuries. These disastrous events are largely responsible for the evolution of public health as an effective discipline. The first recorded cholera pandemic began in 1817, extending from India to southern Russia. During the second cholera pandemic, beginning in 1826, many jurisdictions were induced to establish local sanitation and health boards, eventually evolving into the first organized public health apparatus. During the London cholera epidemic of 1854, Dr. John Snow first showed the association of the disease with contaminated drinking water derived from the city's infamous Broad Street pump; this episode is widely considered the first scientific public health investigation. In 1866, an epidemic in New York City led to the creation of the first Board of Health in the United States, and cholera became the first reportable disease.

During the fifth pandemic in 1884, the causative bacterium, *V. cholerae*, finally was identified. The seventh pandemic began in Indonesia in the 1960s and marked the introduction of biotype *El Tor* strains. The seventh pandemic was the most widespread on record, involving Asia, Africa, southern Europe, and the Americas.[54] A new cholera serogroup O139 Bengal emerged in India and Bangladesh in the 1990s; it represents the first non-O1 serogroup isolated in association with an epidemic.[54]

MICROBIOLOGY

V. cholerae is a curved gram-negative rod that is classified by biochemical tests and subdivided into serogroups based on the somatic O antigen. It belongs to the family Vibrionaceae, which differs from the related family Enterobacteriaceae in being oxidase-positive and motile with a single flagellum. Vibrios are fermentative and oxidative in metabolism. They have few nutritional requirements and can grow in glucose as the sole source of carbon and energy. Most vibrios are marine organisms, and most grow best in 2 to 3 percent sodium chloride under aerobic conditions. Although neither the typical comma shape of *V. cholerae* nor its motility can be observed on Gram stain, both are apparent in wet mount even on fresh fecal samples, a characteristic that can be useful for rapidly establishing the diagnosis. A presumptive diagnosis of cholera can be made immediately by

adding anti-*Vibrio* antiserum, which results in cessation of motility of only the homologous organism.

Numerous *Vibrio* spp. exist, most of which are nonpathogenic in humans. Within the species *V. cholerae* are more than 200 serogroups according to the antigenic characteristics of the lipopolysaccharide O antigen.[11] To date, only *V. cholerae* organisms carrying the somatic O antigens O1 and O139 are associated with epidemic disease. Some non-O1 *V. cholerae* serogroups are associated with sporadic diarrheal illness, which can be severe and sometimes invasive and inflammatory.

The O1 serogroup is divided further into two biotypes, Classical and El Tor, based on biochemical properties and phage susceptibilities. The Classical biotype traditionally is associated with a more severe disease, but the El Tor biotype may be better adapted to persistence in the environment and cause more persistent epidemics. The expression of genes conferring human virulence seems to be higher in the Classical biotype, whereas in the El Tor biotype, enhanced expression of genes for biofilm formation, chemotaxis, and transport of amino acids, peptides, and iron is higher.[11] Classical and El Tor biotypes are divided into three serotypes (Ogawa, Inaba, and Hikojima) based on their dominant heat-stable lipopolysaccharide somatic antigens. Media used to isolate cholera organisms in stool include thiosulfate citrate bile salts sucrose (TCBS) agar and tellurite taurocholate gelatin agar. The appearance of yellow ("popcorn") colonies on TCBS agar is considered to be highly suggestive of *V. cholerae*. The bacterium is confirmed further by its ability to grow in the presence (or absence) of salt and by serology.

PATHOGENESIS

The pathogenic paradigm of *V. cholerae* comprises colonization of the small bowel mucosa followed by release of one or more enterotoxins, the most potent of which is the oligomeric cholera toxin (CT) itself. The bacteria first must pass through the acidic gastric environment to reach the upper small intestine, and compromised gastric acidity is a classic risk factor for infection.[34] *V. cholerae* attaches to the intestinal mucosa by virtue of proteinaceous hairlike fimbriae, the most important of which apparently is the toxin-coregulated pilus.[54] Colonization is facilitated by chemotaxis and motility of the organism, accelerating its approach to the intestinal mucosa.

The infectious dose varies with gastric pH because the organism does not typically tolerate acidic conditions. When water is the source, 10^3 to 10^6 bacteria are needed to cause disease. Only 10^2 to 10^4 bacteria are required when ingested with food.[16,17]

V. cholerae organisms shed in the stool of an infected individual apparently are more virulent than are strains acquired from an environmental source, and serial passage through multiple patients may augment virulence further, partly accounting for the violent epidemics occurring throughout history.[42] On intestinal passage, genes required for acquiring nutrients and motility are up-regulated, whereas genes required for chemotaxis are down-regulated. This increased virulence is confirmed in an animal model in which *V. cholerae* shed by mice have a 10-fold lower infectious dose than organisms grown in vitro.[42] Reduced chemotaxis prevents dispersion in environmental waters and increases the clumping of the bacteria[14]; the resulting increased concentration of organisms also could contribute to the vigor of cholera outbreaks.

The principal secretogenic factor, the oligomeric protein toxin CT, is composed of five identical binding (B) subunits and one active (A) subunit. Similar in structure and function to the heat-labile toxin produced by enterotoxigenic *Escherichia coli*,[46] CT binds to the GM_1 ganglioside receptor on the surface of intestinal epithelial cells. The A subunit is transported into the cell, where it activates adenylate cyclase. As a result, cyclic adenosine monophosphate is up-regulated, causing an increase in chloride secretion from the intestinal crypt cells and a decrease in sodium chloride absorption by the villous cells. In addition to this mechanism, cholera toxin may have effects on prostaglandins and the enteric nervous system that may contribute to the voluminous diarrhea characteristic of the disease.[34] The loss of electrolytes is followed by water along the osmotic gradient into the intestinal lumen. The dramatic loss of fluid and electrolytes rapidly leads to decreased intravascular volume and the complications of hypovolemic shock and metabolic acidosis. Although CT is responsible for much of the pathogenicity associated with the organism, strains mutated in CT still elicit mild diarrhea.[34]

The genetics of *V. cholerae* provide insight into the organism's pathogenicity and spread. The genome comprises two circular chromosomes, the larger of which contains genes for growth and pathogenicity, whereas the smaller one contains elements of metabolism and regulation. The genes required for virulence can propagate laterally and among different strains. Required for pathogenicity are the CT genetic element and the vibrio pathogenicity island, which encodes the toxin-coregulated pilus. The CT-encoding genetic element can exist as a plasmid or as a prophage integrated into the chromosome. Transfer of genetic material can lead to the emergence of virulence in a previously avirulent organism, or it can lead to the emergence of a new epidemic strain. The O139 Bengal strain derived DNA from a more pathogenic O1 strain, resulting in the emergence of a new pathogen.[54]

EPIDEMIOLOGY

V. cholerae O1 is distinguished by its ability to cause explosive outbreaks and pandemics. Now truly pandemic, *V. cholerae* O1 occurs (although rarely) in the U.S. Gulf Coast region, where it is associated with consumption of shellfish. Cases were described in the wake of the severe hurricanes occurring in 2005.[5]

V. cholerae is isolated commonly from surface water of moderate salinity, where the bacterium associates itself with zooplankton and phytoplankton. Pathogenic *V. cholerae* exist in thick layers (biofilms) of partially dormant cells on plankton, which may be the infectious form first encountered by humans at the start of an epidemic. When human cases begin to occur in a community, direct contamination of food and water may occur, circumventing the need for the aquatic reservoir.[21] Although *V. cholerae* have been isolated from animals, their role in transmission is probably minimal.[56] Person-to-person transmission also seems to be uncommon.[47]

During acute cholera disease, infected individuals excrete 10^7 to 10^8 organisms per 1 g of stool.[38] If the infected individual survives the episode, shedding of organisms may continue for 1 to 2 weeks after recovery in the absence of antibiotic treatment, and in some cases may continue for even longer. Transient asymptomatic carriers often are found in the households of individuals affected with acute illness.[34] Although environmental reservoirs seem to be important in the initiation of epidemics, highly virulent strains seem to be more readily isolated from areas contaminated by human feces.[34] Clinical studies suggest that increased pathogenicity of organisms occurs after passage through the human intestine.[14]

A great deal of attention has been devoted to understanding the epidemiology of cholera during interepidemic periods, and findings suggest a complex interaction between humans and their environment. Seasonal patterns have long been recognized for cholera outbreaks, with a predilection for warmer months. *V. cholerae* can remain dormant in aquatic environments in a nonculturable but viable state.[32,61] When aquatic conditions are

conducive to growth, *V. cholerae* proliferates.[19] Environmental conditions play an important role in the seasonal variations. In a 33-year observational study in Bangladesh, outbreaks were predicted by an increase in temperature and concentrations of cyanobacteria in local waters.[30] More recent climate changes in Bangladesh (El Nino/Southern Oscillation) are associated with 70 percent of the variance in cholera incidence seen during specific time intervals of heightened activity of climate change.[53]

More recent studies suggest that an increase in ocean water temperatures as a result of global warming has had an effect on cholera epidemics.[19,27,51] The ecology of vibrio-infecting phages also may affect the abundance of *V. cholerae* in the environment.[22]

Cholera classically is described as a water-borne illness, but it also can be transmitted via contaminated food. The incubation period depends on the inoculum, with lower inocula corresponding to a longer incubation period and decreased stool volumes.[34] Incubation generally is 1 to 3 days, with a range of several hours to 5 days. Symptoms usually last 2 to 3 days, and patients treated with antibiotics may be infectious for several days. Patients who are untreated remain infectious for 1 to 2 weeks. Although water-borne transmission is typical in developing countries of Asia and Africa, *V. cholerae* that is found in marine environments can be transmitted via undercooked shellfish.[20] Person-to-person transmission is rare, owing to the high infectious dose.

Factors that predispose the human host to cholera include age, immunity, blood type, reduced gastric acid production, and other factors that have not been determined. Age groups commonly affected by cholera typically include young children because susceptibility depends on the level of preexisting immunity. In endemic areas such as Bangladesh, cases of cholera are concentrated in the 2- to 9-year-old age category, followed by women of childbearing age.[34] The increased susceptibility of children is supported further by a more recent prospective study in Kolkata, India, which found that the burden of cholera was greatest in children younger than 2 years old and that cholera cases were more likely to have a household member with diarrhea.[58] Individuals with blood type O also are at increased risk of experiencing severe cholera for reasons not completely understood.[23,57,59] Host factors in addition to reduced gastric acidity also are thought to play a role because volunteers who received the same inoculum had large variations in the amount of stool they produced.[34]

Because of the potential for epidemic disease, cholera outbreaks should be reported to local and national health authorities. In 2004, five laboratory-confirmed cases of cholera were reported to the Centers for Disease Control and Prevention. Four were acquired outside the United States, and one occurred in Hawaii, thought to have been acquired through imported seafood.[33]

CLINICAL MANIFESTATIONS

Most individuals infected with *V. cholerae* have only mild symptoms, indistinguishable from symptoms caused by other enteric infections. Individuals who develop severe disease urgently need fluid resuscitation and replacement of ongoing losses. In areas where cholera is indigenous, the populations have developed a (generally healthy) respect for the potential life-threatening nature of diarrheal illness and seek early medical treatment. Of all causes of infectious diarrhea, stool volumes passed and the rapidity by which dehydration develops are greatest with cholera.[55] In severe disease, stool volume can exceed 250 mL/kg body weight in a 24-hour period.[44,52]

The most distinctive clinical feature of cholera is the painless passage of voluminous, watery stools. Termed "rice water stools" because of the watery, colorless diarrhea dotted with mucus, cholera stools may have a fishy smell or may be nearly odorless. Other common symptoms include abdominal cramping and vomiting. Abdominal cramping is probably due to increased abdominal secretions and resulting small bowel distention. Vomiting commonly occurs a few hours after the onset of diarrhea, but it also occurs later in the course of the illness.[17,28,48]

Complications of cholera relate mostly to the massive loss of intravascular volume and electrolytes. If cholera is not treated promptly, diarrhea and vomiting eventually lead to dehydration, which is most often isotonic. Patients with severe cholera may experience vascular collapse, shock, and death rates of 50 percent,[54] starting within hours after the onset of diarrhea. Related to the massive loss of intravascular volume and hypoperfusion, bicarbonate losses in stool, and hyperphosphatemia, acidosis also may develop.[64,66] Compensatory tachypnea may be observed in patients with acidosis. In addition to bicarbonate losses in stool, potassium also is lost and may not be reflected in serum potassium levels; acidosis induces the shift of intracellular potassium into the intravascular space in exchange for hydrogen ions, resulting in decreased total body potassium and potentially normal serum potassium values. As the acidosis is corrected, serum hypokalemia may result. In cases complicated by severe malnutrition, in which body potassium stores already are depleted, hypokalemia may be quite severe and manifest as paralytic ileus. This hypokalemia rarely is associated with severe cardiac arrhythmias, but it may manifest as changes on electrocardiogram.

After dehydration, hypoglycemia is the second most common cause of death in pediatric patients with cholera.[10] At the International Center for Diarrheal Disease Research, Bangladesh, the mortality rate in pediatric patients with hypoglycemia caused by cholera was reported to be 15 percent compared with 1 percent mortality in patients with normoglycemia.[10] Although the precise mechanism of hypoglycemia is unknown, children who are malnourished and acutely ill have lower glycogen stores and impaired gluconeogenesis. Special attention should be given to monitor patients with concomitant malnutrition and cholera for hypoglycemia.

Severe cholera is diagnosed in individuals who present with clinical signs and symptoms of severe dehydration (loss of ≥15% of total body water, or loss of approximately 10% of body weight). Common signs of severe volume depletion include a combination of decreased skin turgor, depressed anterior fontanelle in infants, lack of tears and sunken eyes, dry mouth, anuria, tachycardia, decreased peripheral perfusion, and hypotension (Fig. 127–1). In

Figure 127–1 An adolescent girl with severe dehydration from cholera. Characteristic features include obtundation, sunken eyes, and "tenting" of the abdominal skin and subcutaneous tissues after firmly pinching the abdomen.

TABLE 127–1 Electrolyte Concentration in Cholera Stool and in Fluids Used for Rehydration and Replacement of Stool Losses

	Electrolyte Concentration (mmol/L)

§As lactate.
WHO, World Health Organization.

some cases, mental status changes may be a sign of volume depletion, but more common are somnolence, restlessness, and lethargy. Table 127–1 summarizes the clinical findings associated with various degrees of clinical dehydration.

LABORATORY FINDINGS AND DIAGNOSIS

Laboratory abnormalities in patients with cholera relate to the massive loss of volume and electrolytes. The hypovolemic state can lead to hemoconcentration, causing increased hematocrit, serum specific gravity, serum protein, serum creatinine, and blood urea nitrogen.[64,66] Because of the loss of sodium that accompanies water loss, serum sodium is either slightly low[52] or normal.[34] As noted earlier, although potassium loss occurs in the stool, serum potassium may be normal, whereas total body potassium may be decreased. Acidosis caused by loss of bicarbonate in stool and lactic acidosis may result in a serum bicarbonate concentration of less than 15 mmol/L.[64,66] Serum creatinine and blood urea nitrogen also are elevated as a result of a decreased glomerular filtration rate. The common abnormalities of sodium, potassium, bicarbonate, and glucose mandate early determination of serum glucose and electrolytes as a guide to therapy.

Although presumptive diagnosis is made on the basis of typical oxidase-positive colonies from stool samples that agglutinate with O1 or O139 antiserum, conventional culture methods remain the gold standard. The characteristically motile organisms can be visualized directly using darkfield microscopy,[9] but few laboratories except those in cholera-endemic regions are experienced with this technique. If cholera is suspected, special culture media, such as TCBS agar, should be used to culture the organism.

In epidemic settings or in areas of intense transmission, a rapid vibrio dipstick test may be used. This is a one-step immunochromatographic test developed by the Institut Pasteur for rapid detection of cholera O1 and O139 from stool samples. The method has been tested in Madagascar, Bangladesh, and Mozambique, where the specificity ranged from 84 to 100 percent and sensitivity ranged from 94 to 100 percent.[49,65] It is especially advantageous because it requires minimal technical skill and can be read in 10 minutes.[49] This test also has been shown to be useful in detecting cholera from rectal swabs.[12,65] Confirmation of *V. cholerae* in stool also can be done through polymerase chain reaction amplification and use of oligoprobes.[31,43,63]

TREATMENT

The cornerstone of cholera management is fluid resuscitation. When fluid resuscitation is initiated, previous losses must be estimated and replaced, and ongoing losses must be quantified and replaced. Replacement fluids in children with cholera should be similar to fluids that are lost, such as Ringer lactate solution (Table 127–1).[4,30] The ideal solution contains amounts of bicarbonate and potassium sufficient to replace what is lost in stool.[8]

At the International Centre for Diarrhoeal Disease Research, Bangladesh, where thousands of cholera patients are treated annually, patients of all ages present with severe dehydration of rapid onset. Many present in hypovolemic shock. The extent of dehydration is determined as shown in Table 127–1. One or two intravenous catheters are inserted, and isotonic resuscitation solution is administered rapidly. The composition of the preferred solution at the Center (Dhaka solution) is listed in Table 127–1. The solution contains Na^+, Cl^-, K^+, and HCO_3^-, but no glucose. The complete estimated deficit is administered over 4 hours, whereupon ongoing losses and maintenance fluids are provided. Serum glucose and electrolytes are determined rapidly, with administration of glucose as needed based on these results.

Because severely dehydrated patients characteristically are anuric, concern may exist over early administration of potassium. The rapid onset of dehydration in cholera patients reduces this risk, however, and acute tubular necrosis rarely is seen.[52,66] A greater concern may be the rapid shift of potassium from the circulation on correction of acidosis. Patients treated in this manner respond dramatically. After the 4-hour resuscitation phase, most patients can begin to accept oral rehydration solution (ORS). Close attention to fluids and electrolytes is required for the duration of the diarrhea.

Although oral and intravenous rehydration methods are acceptable in theory for the management of cholera, the severity of losses renders intravenous rehydration the mainstay for treating cases of severe cholera. Not only do intravenous fluids allow predictable and rapid expansion of intravascular fluid volume to occur, they also ensure timely replacement of ongoing losses that may be difficult because of excessive purging.[50] Mild cases can be managed with ORS (see subsequently).

Because of the massive volumes of fluid that are lost during cholera gravis, the volume deficit frequently is underestimated, and rehydration therapy often is inadequate. Dehydration is not clinically apparent until a child has lost at least 5 percent of his or her body weight and can be diagnosed from the parent's history.

The use of a "cholera cot" is extremely helpful in quantifying ongoing fluid losses and for patient comfort (Fig. 127–2). It is constructed of a simple cot with a hole in the center through which a plastic sheet drains via a funnel into a graduated bucket below. This allows for accurate quantification of ongoing losses and permits the patient to remain horizontal, an important advantage if the patient is initially hypotensive. Attention given to tachycardia and signs of hypoperfusion in prostrate patients is essential.

The World Health Organization–approved oral rehydration salts (see Table 127–1) are recommended for patients with no detectable dehydration or mild dehydration, provided that the patient can drink sufficient quantities to replace the deficit and keep pace with ongoing losses. ORS also can be used for patients with severe dehydration to replace ongoing losses after initial intravenous replacement therapy. For cholera, ORS that is made with rice rather than with glucose, as carbohydrate seems to be more effective because it reduces the purging rate.[45,67] Food should be offered to patients as soon as they are able to eat and should not be restricted.

Effective use of ORS requires extra effort in treating pediatric patients with cholera. Parents need to be instructed to encourage

and supervise ORS intake by the child, including taking small amounts frequently. Parents also need to be reassured that oral rehydration is still effective despite occasional vomiting.

A short course of antibiotics should be given to children with clinically significant cholera. This approach has been shown to shorten the duration of the illness and to decrease the amount of diarrhea.[25,54] Because of high resistance rates in some areas, the organism should be isolated and tested for susceptibility using standard methods for gram-negative enteric bacteria. Patients not treated with antibiotics may continue to shed organisms for 1 to 2 weeks after symptoms have abated.[34]

Treatment options for cholera in pediatric patients are derived from adult studies (Table 127–2). The treatment of choice for *V. cholerae* O1 and O139 is tetracycline for 3 days or a single dose of doxycycline for children older than 8 years.[3] This therapy generally is not recommended for children younger than 8 years old because of the risk of dental staining. This risk is cumulative, however, and the life-threatening nature of cholera may justify this risk. Trimethoprim-sulfamethoxazole is an alternative treatment for children younger than 8 years of age, although resistance may be present among O139 strains.[1] If tetracycline-resistant strains are encountered, other options include ampicillin, trimethoprim-sulfamethoxazole, erythromycin, and single-dose ciprofloxacin.[13,24,35,36] Single-dose azithromycin proved to be as effective as is a 3-day course of erythromycin in children 1 to 15 years old in Bangladesh.[37] Although transmission rates in endemic areas may decrease with prophylactic treatment of household members, this approach may promote resistance.[41] In the United States, where secondary transmission rates are low, prophylactic treatment of contacts is not recommended.

Antibiotic resistance to cholera seems to fluctuate with local usage patterns, showing alternating resistance and sensitivity. Conjugative plasmid–mediated, multiply-resistant *V. cholerae* O1 has been reported from several cholera endemic countries.[54] Appropriate antibiotics, usually prescribed before obtaining sensitivity testing results, should be administered according to local resistance patterns, and should be monitored for increased or decreased sensitivity patterns. *V. cholerae* O139 strains first appeared carrying a novel conjugative, self-transmissible, chromosomally integrating "SXT" element that conferred resistance to sulfamethoxazole, trimethoprim, chloramphenicol, and streptomycin. Multiple mechanisms of drug resistance are reported in *V. cholerae* and include proton-motive, force-dependent efflux and modifying enzymes.[7,26,62]

Figure 127–2 A cholera cot: a simple folding cot covered with plastic that has a hole and bucket for collecting the stool output, as used for the care of cholera patients at the International Centre for Diarrhoeal Disease Research, Bangladesh. The bucket is calibrated, and the volume of stool (and replacement fluids required) can be calculated easily. The plastic sheet is cleaned daily and between patients.

PREVENTION

Because contaminated food and water are the main routes of transmission of pathogenic *V. cholerae*, strategies to improve access to safe water sources and a clean food supply are the best methods of prevention. Proper sanitation methods also play a key role. During outbreaks, measures to increase awareness of cholera transmission and means to decrease spread should be communicated to the public; these measures include proper handwashing (especially after defecating), proper cooking of food, and identifying ill individuals so that they can be treated.

Vaccination is another method of preventing cholera. Parenteral and oral vaccines have been developed. The whole-cell, killed parenteral vaccines stimulate short-term immunity to cholera, but they are not effective in young children. Because of limited efficacy and frequent local adverse reactions, this vaccine no longer is available.[29]

Two oral cholera vaccines, one composed of killed cholera bacteria and the other composed of a living attenuated organism, currently are licensed for use in children at least 2 years old.[29]

TABLE 127–2 Antimicrobial Therapy of Cholera*

Agent	Single Dose	Multiple Dose
Erythromycin	Not evaluated	40 mg/kg/day erythromycin base divided into 3 doses for 3 days; maximal dose 1 g/day
Azithromycin	20 mg/kg	
Furazolidone	7 mg/kg; maximal dose 300 mg†	5 mg/kg/day divided into 4 doses for 3 days; maximal dose 400 mg/day
Ciprofloxacin‡	30 mg/kg; maximal dose 1 g	30 mg/kg/day divided into 2 doses for 3 days; maximal dose 1 g/day
Trimethoprim-sulfamethoxazole	Not evaluated	8 mg trimethoprim/40 mg sulfamethoxazole/kg/day divided into 2 doses for 3 days; maximal doses 320 mg trimethoprim and 1.6 g sulfamethoxazole daily
Ampicillin	Not evaluated	50 mg/kg/day divided into 4 doses for 3 days; maximal dose 2 g/day

**Antimicrobial therapy is an adjunct to fluid therapy for cholera and is not an essential component. It reduces diarrhea volume and duration, however, by approximately 50 percent. The choice of antimicrobial agent is determined by the susceptibility pattern of local strains of Vibrio cholerae O1 or O139. Resistance to all agents except fluoroquinolones, such as ciprofloxacin, has been reported and is common in some areas.*

†Single-dose therapy with these drugs has not been evaluated systematically in children, and recommendations are extrapolated from experience in adults.

‡The fluoroquinolones, such as ciprofloxacin, are not approved for use in children <18 years old in the United States because when given in high doses to juvenile animals, they cause arthropathy. Clinical experience indicates that this risk is very small in children when used for short courses of therapy.

The killed cholera vaccine (rBS-WC; marketed by SBL Vaccines [Sdna, Sweden] under the trade name Dukoral) consists of 1 mg of recombinant cholera toxin B subunit and approximately 1×10^{11} inactivated whole cells of the Classical and El Tor biotypes of *V. cholerae* O1, serotypes Inaba and Ogawa. The vaccine is approved for children older than 24 months of age and generally is well tolerated. The rBS-WC vaccine is supplied as 3-mL single-dose vials, each provided with a sachet of sodium bicarbonate buffer. The buffer solution is prepared by dissolving the sachet in 150 mL of water immediately before consumption. In one study, each dose of vaccine was mixed with 40 mL, 75 mL, or 150 mL of buffer solution for individuals 2 to 4 years, 5 to 11 years, or older than 11 years.[40] The vaccine must be refrigerated during shipping. Two doses administered at least 15 days apart are recommended. In a cohort of children and adults in Beira, Mozambique, studied during a cholera outbreak, receipt of one or more doses of rBS-WC vaccine was associated with 78 percent protection (95% confidence interval 39 to 92%; $P = 0.004$) against culture-confirmed cholera. Most vaccinees had received two doses. All of the cases were caused by infection with *V. cholerae* O1 El Tor Ogawa, and all occurred within 6 months of immunization. The vaccine was equally effective in children younger than 5 years old and older individuals. Protection induced by the killed vaccine persists for at least 3 years in adults, but it declines significantly after 6 months in children 2 to 5 years old.[18] The rBS-WC vaccine also may provide herd immunity in endemic settings.[2]

The live-attenuated cholera vaccine, CVD 103HgR, provided 100 percent protection against the homologous strain in challenge models for at least 6 months.[60] This vaccine also was proven to be effective in an outbreak of naturally occurring cholera in Micronesia[15]; a single dose of CVD 103HgR provided 79 percent protection (95% confidence interval 72.9 to 84.6%) against clinically defined cases of cholera during the 3-month post-vaccination period.

Both vaccines are available for travelers to developing countries with active transmission of cholera. The use of cholera vaccine in addition to initiation of proper sanitation methods should be considered in outbreaks in refugee camps, in relief and disaster workers, and in individuals who are traveling to endemic areas where access to medical care is limited.

Acknowledgments

The authors thank Dr. David Sack, Director of the International Centre for Diarrhoeal Disease Research, Bangladesh, for helpful discussions during the preparation of this chapter.

CHAPTER 128

VIBRIO PARAHAEMOLYTICUS

David Y. Hyun

Vibrio parahaemolyticus is recognized worldwide as a cause of foodborne disease associated with consumption of seafood, in particular crustaceans and mollusks, and occasionally as a cause of wound infections and sepsis in immunocompromised hosts. *V. parahaemolyticus* was isolated first in Japan during a foodborne outbreak in 1951. Almost 10 years after it was first described, the organism was classified correctly in the genus *Vibrio*,[8] and its distribution in coastal waters and estuaries of temperate climates around the world was recognized. The regional differences in the incidence of this disease are related to patterns of consumption of marine products and practices of food preparation. In Japan and Taiwan, where fish and shellfish are a major source of dietary protein and frequently consumed raw, *V. parahaemolyticus* accounts for 10 to 40 percent of foodborne outbreaks.[57,73] In the United States, the first confirmed foodborne outbreak occurred in Maryland in 1971, secondary to consumption of contaminated crabmeat.[17] Since then, sporadic outbreaks have been reported,[5,6,17,18,55] showing the potential risk for development of infectious and toxic syndromes from marine products in the United States.[24]

BACTERIOLOGY

V. parahaemolyticus is a gram-negative, non–spore-forming, curved rod with rounded ends that possess a polar flagellum.[45] On surfaces or in viscous environments, *V. parahaemolyticus* can differentiate into swarmer cells equipped with additional shorter lateral peritrichous flagella.[44] *V. parahaemolyticus* is a facultative anaerobe with respiratory and fermentative metabolisms. Similar to most vibrios, it is an oxidase-positive nonfermenter of lactose.[7] It is arginine dihydrolase–negative and ornithine decarboxylase–positive. The requirement of sodium and enhancement of growth in a specific range of concentration differentiate it from *Vibrio cholerae* and *Vibrio mimicus*. The optimal sodium concentration range is 2 to 4 percent; a concentration greater than 8 percent inhibits its growth.[72]

V. parahaemolyticus produces round, blue-green colonies on the widely used *Vibrio*-selective thiosulfate citrate bile salt sucrose (TCBS) agar. This medium inhibits most fecal flora by the presence of bile salts and a highly alkaline pH. Direct plating on TCBS agar may be used for feces and other clinical specimens,

but food samples that are not heavily contaminated require enrichment either in alkaline peptone water supplemented with 3 percent sodium chloride or in a strongly selective medium, such as glucose salt teepol broth.[72] The optimal pH for growth is in the neutral range, but *V. parahaemolyticus* can survive in alkaline media. Optimal growth temperatures are between 35° C and 39° C.[76] Growth is remarkable in conventional media and foodstuff, with generation times of only 8 minutes[36]; a significant number of organisms can be found after a short period of inappropriate storage. Growth is inhibited at temperatures of 44° C or greater. Degree of inactivation is greater with increased temperatures; a million-fold decline occurs in viable bacteria in shrimp homogenate kept at 100° C for only 1 minute.[70] In laboratory conditions with low temperature and nutrient supply, *V. parahaemolyticus* has been shown to enter a viable but nonculturable state, during which the organism no longer can be cultured on routine growth media, but its viability can be confirmed using direct microscopic assays.[25,74]

The genome of *V. parahaemolyticus* consists of two circular chromosomes. Genes for a type III secretion system (TTSS) were identified in a pathogenicity island on chromosome 2.[42] TTSS, which is considered a central virulence factor in salmonellae and shigellae, possesses needle-like structures, which facilitates direct injections of bacterial proteins into target host cell, and is related strongly to the pathogenicity of inflammatory diarrhea seen with *V. parahaemolyticus* infections. This finding suggests that the presence of TTSS in *V. parahaemolyticus* differentiates its pathogenicity from that of *V. cholerae*, which does not carry the genes.[42]

EPIDEMIOLOGY

In the United States, *V. parahaemolyticus* is found along the East, West, and Gulf coasts.[20,36] Water, sediments, suspended particulates, plankton, fish, and shellfish have been shown to harbor the organism.[4,47] The organisms are present in highest numbers in water at temperatures between 17° C and 35° C and containing 0.5 to 2.5 percent salinity.[34] Marked seasonal and geographic variations occur, with maximal mean concentrations occurring during late summer and spring along the Gulf Coast.[20] The seasonal distribution correlates with outbreaks, predominantly between June and October.[3]

Finfish and all types of shellfish products, including oysters, clams, crabs, and shrimp, may be involved in the transmission of the infection (Table 128–1).[34] The risk of acquiring infection is higher with molluscan shellfish because of their ability to concentrate contaminants and bacteria by filter feeding.[4,25,76] In oysters, the density of *V. parahaemolyticus* may be 100 times greater than in the surrounding water.[20] The levels of contamination of seafood generally are low in freshly collected oysters, with the highest mean density of only 160 bacteria/g found in the United States.[20] In Japan, higher counts (up to 10^3 to 10^4/g) have been reported in market shellfish.[13] The minimum infective dose is thought to be in the range of 10^5 to 10^7 organisms, based on volunteer feeding studies.[23] More recent outbreaks of illness caused by oysters that met bacteriologic safety standards have raised questions about current recommendations, however.[18]

During the period 1973 to 1987, only 23 of 1869 foodborne disease outbreaks with known bacterial etiology reported to the Centers for Disease Control and Prevention were caused by *V. parahaemolyticus*.[5] In 18 of these outbreaks, a shellfish was recognized as the food vehicle. No fatal cases were reported. Contributing factors included inadequate cooking (92%), improper holding temperature (75%), and food acquired from an unsafe source (75%).[5,6] Most of the affected individuals were adults, and no patterns of unusual susceptibility by age group or gender were noted. No evidence of secondary spread was found among family members. Between 1988 and 1997, 345 sporadic cases were reported to the Centers for Disease Control and Prevention. Most infections were related to eating raw oysters. Most of these infections (59%) were gastroenteritis.[19]

Until more recently, *V. parahaemolyticus* infections were casually associated with multiple serotypes and occurred as sporadic cases or localized outbreaks.[49] In 1996, a sudden increase in incidence was seen in India, and 50 to 80 percent of the cases were attributed to a single serotype, O3:K6.[54] Shortly thereafter, O3:K6 strains were isolated from clinical samples from other countries in Asia. In 1998, two outbreaks of gastroenteritis in the

TABLE 128–1 Selected Outbreaks of *Vibrio parahaemolyticus* Infection

Setting	Persons Ill/Exposed	Symptoms	Incubation	Resolution	Medical Attention/ Hospitalization	Vehicle	Risk Factor
Picnic[14]	351/631 (56%)	D (95%), C (82%), N (68%), V (61%), HA (41%), F (27%)	16 hr (4-42 hr)	4 days (<1-10 days)	60%/2%	Steamed crab	Cross-contamination, unrefrigerated food
Chronic hospital[14]	24/100 (24%)	D (100%), C (89%), N (72%), V (44%), HA (56%), F (33%)	18 hr (4-60 hr)	3 days (<1-7 days)	No data available	Crab salad	No data available
Shrimp boil[49]	~600/1200 (50%)	D, C, V, HA, F	23 hr (5-92 hr)	(few hr-1 wk)	1%/0%	Boiled shrimp	Storage temperature
International flight[43]	12/134 (9%)	D, C, V	(8-20 hr)	No data available	40%/25%	Cooked crab	Cross-contamination
Parish dinner[11]	~1000/1700 (59%)	D (95%), C (92%), N (72%), HA (47%), F (47%), V (12%)	16 hr (3-76 hr)	4.6 days (<1-8 days)	26%/7.4%	Shrimp	Cross-contamination, storage temperature
Pacific Northwest[47]	209 ill	D (99%), C (88%), N (52%), V (39%), F (33%)	15 hr (4-96 hr)	3 days mean	2 hospitalized, 1 death	Raw oysters	Uncooked oysters

C, cramps; D, diarrhea; F, fever; HA, headache; N, nausea; V, vomiting.

United States were associated with O3:K6.[19,56] By 2005, this pandemic clone was found in patients from Europe, South America, and Africa,[2,28,43] and other clones that genetically diverged from O3:K6, such as O4:K68 and O1:KUT, were isolated from clinical cases.[16]

PATHOGENESIS

The ability of certain strains of *V. parahaemolyticus* to produce beta-hemolysis on Wagatsuma agar, known as the Kanagawa phenomenon (KP), was first epidemiologically associated with human pathogenicity.[46] KP is observed in 88 to 96 percent of strains from clinical specimens and in 1 to 2 percent of strains from environmental sources.[23,36,68] Thermostable direct hemolysin (TDH) produces KP.[67] TDH has a molecular weight of 42,000, consisting of two subunits of 21,000,[47] and, in contrast to other hemolysins produced by *V. parahaemolyticus*, is not inactivated by heating at 100° C for 10 minutes. It is a pore-forming toxin that causes hemolysis by binding to and disrupting erythrocyte membranes.[30] TDH also has been shown to have enterotoxic activities, such as causing accumulation of fluid in rabbit ileal loop assays, invading intestinal mucosa,[15,71] and increasing intracellular calcium concentrations that trigger secretion of chloride by intestinal cells.[61,65,66] TDH is cytotoxic, lethal to small experimental animals, and cardiotoxic.[78]

Certain KP-negative isolates from outbreaks have been shown to produce TDH-related hemolysin (TRH).[32] Although TRH is heat-labile, it shares similarities with TDH, such as hemolysis, production of fluid accumulation in the rabbit ileal loop model, and induction of chloride secretion in human colonic epithelial cells.[31,65] Likewise, some variants closely related to the original TDH by molecular analysis (Vp TDH/I and Vp TDH/II) have been isolated from KP-negative strains.[48]

When the *tdh* and *trh* genes had been cloned and sequenced, researchers realized that certain strains possess the genetic material but are phenotypically incomplete. Strains with a typical hemolysin-positive phenotype carried two chromosome gene copies, whereas *tdh* gene–positive strains with weakly positive or negative hemolysin phenotype possessed only a single chromosome gene copy.[52] Less than 50 percent of *trh* gene–positive strains produce TRH when examined by enzyme-linked immunosorbent assay.[63] Low-level expression of the *tdh* genes may be the reason for the KP-negative phenotype.[53] The expression of the *tdh* genes is controlled by the Vp-toxRS operon. The basal production of mRNA and the degree of transcriptional activation seem to be related to differences in the nucleotide sequences and strength of the promoter region.[53]

Some studies suggest that virulence mechanisms in addition to TDH and TRH exist and that the mere presence of the *tdh* or *trh* genes does not reliably correlate with virulence of a given strain.[71,76] *V. parahaemolyticus* requires intestinal colonization factors to cause disease. A variety of pili and other potential colonization factors are present, but the evidence is too poor to implicate any of the candidate adhesins in virulence.[13] Adherence of *V. parahaemolyticus* to intestinal epithelial cells of rabbits[14] and human small intestine[27,75] seems to require binding to complex carbohydrates or hemagglutinins of the host. Also, *V. parahaemolyticus* appears to disrupt epithelial barrier function, regardless of TDH and TRH production.[41]

The occurrence of cases with grossly bloody stools[33,55] is indirect evidence of either invasiveness or production of cytotoxin. Invasion of Caco-2 cells in culture has been shown in approximately 20 percent of strains.[1] KP-positive and KP-negative strains from clinical specimens can invade and colonize the mucosal cells of the rabbit ileum, producing acute inflammation, degeneration, and erosion of the villi.[7] Vibrios can be cultured from tissue specimens of spleen, liver, and heart in experimental animals, indicating spread through the lymphatic or circulatory systems.[10]

CLINICAL MANIFESTATIONS

The spectrum of intestinal disease varies from a mild gastroenteritis to a dysenteric syndrome. The incubation period typically is 15 to 24 hours (range 4 to 96 hours)[3,64]; the variability presumably is related to the number of organisms ingested. Resolution is expected to occur in approximately 3 days,[47] but it varies from several hours to more than 10 days.[3,11] Fatigue may persist for a few days. Diarrhea (96%) and abdominal pain (95%) are the most frequent and earliest symptoms, accompanied by nausea, vomiting, and headache in 40 to 70 percent of cases. Chills and moderate fever are less frequent (20%) manifestations.[3,17] Diarrhea is watery and explosive,[12] with patients having up to 15 stools during the first day. Shock caused by loss of fluid is an exceptional event.[20] Mucus is observed frequently, but grossly bloody stool is seen less commonly.[8,33,40] Small superficial ulcerations on sigmoidoscopy may be present.[8] No difference in symptoms exists in cases associated with KP-negative strains.[30]

Extraintestinal infections occur. During the Vibrio Surveillance Program that started in 1989 in four Gulf Coast states, 18 to 34 percent of *V. parahaemolyticus* isolates were found to come from wound infections, and 3 to 5 percent were found to be associated with septicemia.[18,40] Wound infection occurs after contamination of skin lacerations with seawater or after direct trauma with pieces of shellfish, fishhooks, or utensils contaminated with seawater.[9] Superficial infection can extend to deeper soft tissue and may require radical surgical débridement. Septicemia is a concern in immunocompromised patients, particularly patients with leukemia[22] and patients with liver disease.[21,29] Bacteremia may develop after either wound infections[9,22] or ingestion of seafood.[29,60] Skin bullae,[29] intravascular hemolysis,[22] and disseminated intravascular coagulation[29] may complicate wound and bacteremic infections.

COMPLICATIONS

An acute diarrhea episode requires medical attention in 25 to 50 percent of cases during an outbreak, but less frequently requires hospitalization.[11,17,40,64] Children younger than 5 years old are more likely to require hospitalization compared with individuals older than 5 years.[69] Usually, no long-term sequelae occur. Severe dehydration, shock,[33,58] and death (0.04% of cases in Japan) can occur.[7,72] Primary septicemia,[38,40,60] septicemia secondary to wound infection,[9,22,38] and septicemia secondary to gastroenteritis[29,38] have higher mortality rates, especially in immunosuppressed patients or in patients with liver diseases.[9]

DIAGNOSIS

Epidemiologic data are the basis for the presumptive diagnosis. In a patient with compatible symptoms, a history of recent consumption of seafood should suggest this diagnosis. Leukocytosis and fecal leukocytes may be found.[8,33] A positive stool culture on selective media, such as TCBS agar, can confirm the clinical impression. Routine use of TCBS agar is not cost-effective, even in coastal areas, unless an appropriate clinical setting is available.[9,40,45] The use of a transport medium, such as Cary-Blair, is necessary if a delay in processing the sample is expected. Isolation of more than 10^5 *V. parahaemolyticus* from epidemiologically implicated food supports the diagnosis and identifies the vehicle.[45] A correlation between the serotype of the food and isolates from patients is not always present because multiple strains can con-

taminate a single food.[3] Adding an enrichment broth to the processing increases the yield of isolation.

For testing blood specimens, use of routine culture media followed by selective media is appropriate.[29,60] Immunoassays (enzyme-linked immunosorbent assay, immunoprecipitation in agar medium, reversed passive latex agglutination) are available in research laboratories and commercially in Japan (KAP-RPLA, Denka Seiken, Tokyo; BT test, Nissui Pharmaceutical, Tokyo) to detect the TDH. Strains producing TRH may be detected by cross-reactions.[77] Serologic methods (slide agglutination) can detect H antigens in lateral flagella.[62] Gene probe hybridization[51] and polymerase chain reaction with a sequence of a highly conserved DNA fragment[39] or targeting the *tdh* gene can be used to detect low numbers of the organism in environmental and clinical specimens. Histologic findings from duodenal and rectal biopsy samples from patients infected with *V. parahaemolyticus* were consistent with acute inflammatory response, showing epithelial degradation, polymorphonuclear neutrophil infiltration of villi and crypt cells, and hemorrhage.[59]

TREATMENT

Only supportive therapy and careful control of the fluid and electrolyte balances are required for the management of gastroenteritis. Oral rehydration usually is appropriate, although intravenous fluids may be required if massive losses of fluid occur.[8,33,58] Antibiotic therapy is unnecessary for this short-lived disease. In the unusual protracted episode, tetracycline or a fluoroquinolone may be beneficial for adults and older children.[7,8,36]

For wound infections and septicemia, antibiotics always are indicated. *V. parahaemolyticus* usually is susceptible to tetracycline. In addition, only a few strains are resistant to chloramphenicol, trimethoprim-sulfamethoxazole, third-generation cephalosporins, aztreonam, imipenem, fluoroquinolones, and aminoglycosides.[9,22,26,29] Penicillins are ineffective because of the presence of β-lactamases in 50 percent of isolates.[26,37] The older cephalosporins also have poor activity.[37]

PREVENTION AND CONTROL

Although ensuring the lack of contamination of seafood is impossible, avoiding food-handling errors should diminish the risk of infection. A recommendation for an acceptable upper limit of 100 colony-forming units per gram of *V. parahaemolyticus* in raw shrimp has been made by the International Commission on Microbiological Specification for Foods.[34] Thorough cooking eliminates the organism.[70] Heating seafood to 60° C for 15 minutes[23] or boiling for 7 minutes[11] seems to be adequate to reduce the risk of infection. When undercooked or raw seafood is consumed, adequate prior refrigeration to preclude multiplication of organisms is important. During the preparation of seafood, special attention should be paid to possible cross-contamination. Use of the same utensils, board surfaces, or containers for fresh and recently cooked seafood should be avoided.[58,70] Raw seafood consumption should be discouraged, particularly for individuals at high risk for development of septicemia.[21,38,40]

CHAPTER 129

VIBRIO VULNIFICUS

Randall G. Fisher

BACTERIOLOGY

Vibrio vulnificus is a small, curvilinear, gram-negative rod of the family Vibrionaceae.[6] This facultative anaerobe is oxidase-positive and lysine-positive similar to other species of the genus *Vibrio*. Its major difference is that it ferments lactose, a feature that accounts for its original name, Lac + *Vibrio*. *V. vulnificus* is arginine-negative and ornithine-variable. This halophilic (salt-loving) organism grows in concentrations of sodium chloride of from 1 to 8 percent and seems to grow best at approximately 3 percent.[35]

EPIDEMIOLOGY

V. vulnificus, similar to *Vibrio parahaemolyticus*, is a marine organism that is a common inhabitant of off-shore waters, especially estuarial waters.[50] It has been isolated from sediment, plankton,

water, finfish, crabs, and oysters. Peak recovery occurs in the summer and early fall,[17] possibly because at higher water temperatures *V. vulnificus* is released and rises to surface waters. There it attaches to plankton and shore fish and then is taken up and concentrated by filter-feeding mollusks and crustaceans.

V. vulnificus has been isolated from wild and commercial oysters throughout the world. It especially is prevalent in warm coastal waters. Reports about the survival of the organism in oysters stored at low temperatures are conflicting. Nilsson and associates[48] revealed, however, that even if *V. vulnificus* is rendered nonculturable by storage at low temperatures, it can be "resuscitated" by allowing the oysters to warm up to room temperature; this cycle could be carried out twice without any reduction in bacterial count. Because of the ubiquity of the organism in the marine environment and its ability to thrive under even the most careful conditions of sanitation, storage, and transport,[16,33] ensuring that commercial shellfish do not contain viable *V. vulnificus* is very difficult.

So-called heat shock shucking, during which the internal meat temperature exceeds 50° C for 1 to 4 minutes, reduces the *V. vulnificus* and total bacterial levels in oysters 10-fold to 10,000-fold compared with conventional processing.[22] A separate study confirms that low-temperature pasteurization, which brings oyster temperatures to 50° C for 10 to 15 minutes, reduces colony counts from greater than 100,000/g of oyster meat to undetectable levels.[2] Three-hour ice immersion is ineffective at reducing *V. vulnificus* and actually increases coliform counts in oysters.[53] High-pressure processing is a promising new approach to eliminating *V. vulnificus* from oysters; in preliminary studies, *V. vulnificus* could be reduced to undetectable levels by processing at 586 MPa with a 7-minute "come up" time.[36]

Disease in humans is initiated by contact with the organism. Contact occurs either through marine contamination of a wound or in the gastrointestinal tract after ingestion of the organism in raw shellfish, most commonly oysters.[6]

PATHOPHYSIOLOGY

V. vulnificus causes three distinct diseases in humans: wound infection and gastrointestinal infection, which may be self-limited or progress to septicemia. Local infection occurs after a wound is exposed to contaminated sea water. Wound infections with *V. vulnificus* are marked by rapid spread, the formation of bullae, and necrosis of involved tissues.[6] Marked edema and vascular thromboses occur in experimental and natural infection. *V. vulnificus* elaborates a cytolysin,[20,21,35] a collagenase,[56] and a protease,[46] which enhance its rapid spread in tissues. The protease activates the plasma kallikrein-kinin system to produce bradykinin[45]; histamine also is released locally. These factors account for the intense inflammatory reaction seen in these lesions. One group of researchers constructed an isolate that lacked a flagellum and found that its ability to adhere to cells was decreased, as was its lethality in mice.[39] Hemorrhagic complications may be due to the presence of a metalloprotease that interferes with blood homeostasis through prothrombin activation and fibrinolysis.[11]

In otherwise healthy individuals, a mild, self-limited gastrointestinal illness similar to that caused by *V. parahaemolyticus* has been described.[34] The most serious infection produced by *V. vulnificus* is primary septicemia, which occurs most commonly in patients with liver disease, after they have ingested the organism in raw shellfish.[6,51,52]

For patients with hepatic disease, the risk of acquiring septicemia is 40 to 80 times greater, and the case-fatality rate is 2.5 times higher than for otherwise healthy individuals.[24] *V. vulnificus*, similar to many other gram-negative organisms, requires iron for growth and grows better in an excess of iron.[64] It is able to extract iron from hemoglobin, even if it is complexed completely to haptoglobin.[64,67] Liver damage, excess iron, and deferoxamine therapy all have been shown to decrease the median lethal dose (LD_{50}) of *V. vulnificus* in experimental animals. Deferoxamine alone decreased the LD_{50} by four orders of magnitude.[9] Iron overload almost certainly underlies *V. vulnificus* septicemia in patients who require repeated transfusions and deferoxamine therapy for anemia.[29,66] Some evidence indicates that alcoholism, even in the absence of demonstrable liver disease, is a risk factor for developing sepsis.[51] Fatal septicemia also has been reported in patients with other chronic diseases, such as diabetes mellitus and lymphomas.[52]

Virulence factors of the organism also have been described.[65] Virulent strains are resistant to the bactericidal activity of human serum,[37] probably because of the presence of a polysaccharide capsule.[1] Poor uptake of virulent strains into phagocytes[59] and opaqueness of the colony on agar have been correlated with the presence of the capsule.[55,65] No difference has been shown in the lipopolysaccharides of virulent versus avirulent strains.[5] The production of recalcitrant shock in patients with septicemia is secondary to toxins, loss of vascular tone, capillary leak, and possibly negative inotropy, as in other forms of gram-negative sepsis.

CLINICAL MANIFESTATIONS

Patients commonly present with wound infection or primary septicemia. Wound infection occurs after injury in sea water or after the contamination of a recently acquired wound with sea water. Often, the wound is caused by the shell of a crustacean or mollusk. Many patients with wound infections work in shellfish-related industries. Apparently, wound infection with *V. vulnificus* can develop from superficial wounds acquired within 24 hours of "uneventful" fish handling; the physiologic characteristics of human sweat may be conducive to the survival of the organism on the skin, allowing for later inoculation.[10] Cellulitis may develop and spread rapidly. Overlying skin often is covered with tense bullae. At débridement, the extent of necrosis may exceed presurgical expectations.[63] Primary wound infection may progress to systemic infection; for this reason, wound infection with *V. vulnificus* carries a mortality rate of 7 to 24 percent.[6,34]

Patients with primary septicemia generally give a history of recent (6 to 72 hours) consumption of raw seafood. Illness is marked by the rapid onset of fever, hypotension, and septic shock. Prodromal symptoms, such as malaise, chills, and fever, are common manifestations. Vomiting and diarrhea are seen in approximately 20 percent of patients.[7] Shock progresses quickly and is difficult to reverse. Secondary skin lesions develop in approximately half of patients[6] and may be bullous, petechial, or maculopapular. *V. vulnificus* frequently is isolated from cultures of secondary lesions, providing evidence of septicemic spread to those sites.[6] The mortality rate from primary septicemia has been reported to be 46 to 79 percent.[6,51]

In addition to causing the two above-mentioned syndromes, *V. vulnificus* has been reported as a cause of corneal ulcer,[60] myositis,[31] adult epiglottitis,[42] osteomyelitis,[61] endocarditis,[60] peritonitis,[26] tubo-ovarian abscess,[43] and meningitis.[29,51] In one case, a patient presented with endogenous endophthalmitis without systemic symptoms that developed after ingestion of raw seafood.[28] A case of fatal septicemia in which the presenting symptom was a compartment syndrome of the forearm has been described.[27]

Ninety percent of reported patients are 40 years old or older.[6,51] Childhood cases of septicemia have been associated with thalassemia major,[28] for which frequent transfusions and deferoxamine therapy are required. Wound infections in previously healthy children and adolescents have been reported. *V. vulnificus* also has been isolated from a premature infant's stool sample obtained on the infant's first day of life; the infant's mother worked as an oyster shucker.[4]

DIAGNOSIS

The diagnosis of *V. vulnificus* infection is made by isolating the organism from blood or tissue culture. It also may be recovered from stool specimens.[4,52] Agars designed specifically to aid in the growth and identification of *V. vulnificus* have been developed; cellobiose-colistin agar outperforms thiosulfate citrate bile salts sucrose agar (TCBS) for recovery of *V. vulnificus* from environmental samples.[25] From a practical standpoint, however, most hospital microbiology laboratories do not stock cellobiose-colistin agar. Of the commercially available media, *V. vulnificus* tends to grow best in thiosulfate citrate bile salts sucrose agar (TCBS),[6] but it also may be recovered from ordinary blood agar plates[3,54] or MacConkey plates.[6]

A very sensitive nested polymerase chain reaction technique that is capable of detecting 1 pg of bacterial DNA and one colony-forming unit of *V. vulnificus* has been described; it was positive in 94 percent of clinical samples that grew the bacteria in culture and was positive in 42 percent of culture-negative samples from patients with suspected *V. vulnificus* infection.[40] An enzyme immunoassay also has been developed.[59] Both of these methods are experimental and not yet available for routine clinical use.

The diagnosis of *V. vulnificus* wound infection or septicemia can be suspected on clinical grounds and appropriate therapy initiated while awaiting culture results. A history of ingestion of raw shellfish or contamination of a wound with either sea water or brackish inland waters[57] should be sought. *V. vulnificus* infection should be given high consideration in patients with hemosiderosis, anemia with transfusion therapy, liver disease, or other chronic diseases.

TREATMENT

For severe wound infections, performing surgical therapy as rapidly as possible is paramount. For primary septicemia, support of the patient's airway, along with aggressive pressor support and other adjunctive therapies for severe septic shock, is of primary concern. Secondarily, appropriate antibiotic treatment for *V. vulnificus* should be started as early as possible.

In vitro, the organism is susceptible to many antibiotics, including ampicillin, third-generation cephalosporins, tetracycline, chloramphenicol, and gentamicin.[6] Bowdre and associates[8] reported that, in mice, the minimum inhibitory concentrations obtained in the laboratory did not seem to correspond with response to therapy. In particular, the organism seemed to be exquisitely sensitive to cefotaxime in vitro (minimum inhibitory concentration 0.06 μg/mL); however, 9 of 10 mice treated with cefotaxime died of overwhelming infection. Anecdotal evidence indicates that this puzzling phenomenon may occur in humans as well; four of five patients reported by Chuang and associates[14] died, despite receiving therapy with third-generation cephalosporins at appropriate dosages. Similarly, although the organism is almost universally sensitive to gentamicin in the laboratory, case reports show a lack of response to this antibiotic. Of all the antibiotics to which the organism was sensitive in vitro, only tetracycline led to survival of mice in Bowdre's study; all 12 of the mice treated with tetracycline survived the infection.[8]

Case reports also show favorable outcomes with tetracycline or doxycycline[14] and chloramphenicol[14] and ciprofloxacin.[41] More recently, the combination of minocycline and cefotaxime has been shown to be synergistic in vitro, with the combination reducing the growth of *V. vulnificus* by six orders of magnitude compared with either drug alone.[13] Enhanced survival of mice infected with *V. vulnificus* and treated with minocycline plus cefotaxime provides an in vivo correlate of the in vitro results.[15] No data are available comparing the activity of minocycline versus that of tetracycline; nonetheless, the aforementioned evidence is sufficiently strong to suggest that either tetracycline or minocycline together with cefotaxime should be the treatment of choice for known or suspected *V. vulnificus* infection. Fluoroquinolones also may have a role in treatment. In vitro synergy studies show that the combination of ciprofloxacin and cefotaxime is synergistic for *V. vulnificus*,[32] and in a murine model, the newer fluoroquinolones (e.g., moxifloxacin) worked as well as combination therapy at preventing lethality in mice.[12] As yet, no human clinical data are available regarding the efficacy of third-generation fluoroquinolones.

The addition of modified Dakin solution (0.025% sodium hypochlorite) may have some utility in the treatment of skin and wound infections. An in vitro study of eight different topical antibiotic preparations showed that *V. vulnificus* was most sensitive to modified Dakin solution.[44] Although no controlled trial has been performed, a series of 10 patients with culture-proven *V. vulnificus* wound infections treated with doxycycline and topical modified Dakin solution, none of whom experienced progression of infection or required surgical débridement, has been reported.[62]

PREVENTION

Patients with severe anemia, liver disease, hemosiderosis, or other debilitating chronic diseases and patients on deferoxamine therapy should be advised against eating raw seafood of any kind. Patients with open wounds probably should avoid contact with sea water or brackish inland waters.

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 130

Miscellaneous Non-Enterobacteriaceae Fermentative Bacilli

Randall G. Fisher

This chapter discusses fermentative bacilli that are not of the family Enterobacteriaceae. Specifically, it examines *Chromobacterium violaceum*, *Plesiomonas shigelloides*, and *Pasteurella* organisms other than *Pasteurella multocida*.

CHROMOBACTERIUM VIOLACEUM

C. violaceum is a facultatively anaerobic, gram-negative rod that is a saprophyte of soil and water, especially in tropical and sub-

tropical climates. It causes occasional illness in animals and, rarely, in humans. Infection with *C. violaceum*, when it does occur, is a serious disease with a high mortality rate.

BACTERIOLOGY

C. violaceum is a long, motile, gram-negative bacillus that appears singly or in pairs on Gram stain. It has a polar flagellum and one to four subpolar or lateral flagella, which antigenically are distinct from the polar flagellum.[73] Most isolates produce an insoluble pigment, violacein. This pigment is intense and makes colonies appear dark purple to black, especially on blood agar. Violacein induces apoptotic death in certain cell types in vitro, including leukemia and lymphoma cells.[57] The therapeutic potential of violacein and structural analogues is being explored. Violacein also has antibacterial, anti-trypanosomic, and weak antiviral effects.[7] *C. violaceum* grows readily on standard agar (any medium that contains tryptophan supports growth). The colonies are low convex, violet, smooth, and not gelatinous. Colonies produce hydrogen cyanide, so a faint almond odor may be present.[73]

C. violaceum is catalase-positive and oxidase-positive, although the latter may be difficult to interpret because of the production of pigment. Growing the organism anaerobically inhibits pigment formation.[45] Pigment also may be lost on subculture[65] or as effective treatment is initiated. *C. violaceum* has a fermentative, not oxidative, attack on carbohydrates. *C. violaceum* produces antimicrobial agents that have been shown to have activity against bacteria and trypanosomes.

EPIDEMIOLOGY

C. violaceum commonly is found in soil and water of areas with tropical or subtropical weather patterns. It also has been recovered from soil as far north as New Jersey.[17] Ten of the first 12 cases reported in the United States occurred in Florida; the other two were in Louisiana. Subsequently, one case from New Jersey[61] and one from Ohio[75] have been reported, along with more from southeastern states. All but one case occurred during summer.[65] Patients tend to be young, with a median age of 14 years.[65]

PATHOPHYSIOLOGY

Although *C. violaceum* is a common inhabitant of soil and water, human infection is rare. Disorders of neutrophil function are important risk factors. A disproportionately high number of *C. violaceum* infections have occurred in patients with chronic granulomatous disease.[52] *C. violaceum* infection in a child with another disorder of neutrophil function, polymorphonuclear leukocyte glucose-6-phosphate dehydrogenase deficiency, has been reported.[53] Organisms may show variable virulence, and differences in endotoxin activity, resistance to phagocytosis, and production of catalase and hydrogen peroxide have been observed between clinical and soil isolates.[58] An elastase activity, expressed through the entire life cycle and produced by a zinc metalloproteinase, may account for the propensity of *C. violaceum* to cause abscesses.[87] Because *C. violaceum* is a free-living organism that is exposed to diverse environmental conditions, it exploits a wide range of energy resources and is able to thrive in aerobic and anaerobic conditions.[16] It is equipped to be tolerant of harsh conditions, including acid and ultraviolet stress, temperature stress, heavy metal exposure, and antibiotic exposure.[37] The complete sequencing of its genome has allowed researchers to identify putative virulence genes that are likely involved in host cell adhesion, cell invasion, and cytolysis.[11]

The organism usually gains entrance to the body through cuts or abrasions that come in contact with contaminated soil or water. After entrance, a localized infection usually develops at or around the site of entry, which is commonly followed by dissemination of infection via the bloodstream to distant sites. Rapid débridement and appropriate antibiotic therapy may arrest the infection at the wound stage.[48] Two cases of systemic infection occurred in near-drowning victims. One case report describes fulminant infection and death in an immunocompetent host from *C. violaceum* sepsis that began as conjunctivitis after a fall that splattered mud into the patient's eye.[22] Numerous microabscesses are found in multiple organs, especially liver, lung, and kidneys. Spread to bone, joints, and the central nervous system also has been described.

CLINICAL MANIFESTATIONS

The pattern of illness in all reported patients is similar, with a contaminated inoculation site, localized disease, regional lymphadenopathy, and hematogenous spread to visceral organs. Progression of symptoms tends to be rapid after a variable incubation period.

Most patients have cutaneous lesions,[52] which are described as being nodular or pustular and sometimes with surrounding cellulitis.[80] They may progress to suppuration and drainage, or ulceration. Occasionally, classic ecthyma gangrenosum lesions have been described.[12] Regional lymphadenopathy is common; some of the nodes suppurate and require surgical drainage or removal.

Severe disease is heralded by high fever (39° C to 41° C), confusion or lethargy, abdominal pain, headaches, nausea and vomiting, and sometimes myalgias. Patients with systemic illness appear toxic. Hepatosplenomegaly develops frequently, and jaundice may be present. Progression from high fever and moderate toxicity to septic shock with disseminated intravascular coagulation and multisystem organ failure is precipitous. After the liver, the lung is the most common site of dissemination of infection, and evidence of pneumonia often is found. Adult respiratory distress syndrome is rare.[49] Brain and liver abscesses have been noted.[59] The overall mortality rate is 65 percent.[52] Rarely, there may be recurrence, which can prove fatal.[45,65] A review of all 25 pediatric cases reported between 1971 and 2005 revealed, counterintuitively, that the case-fatality rate was 12 of 16 (75%) in patients without chronic granulomatous disease and 0 of 9 in patients with a known diagnosis of chronic granulomatous disease.[71] Disseminated infection, bacteremia, and initiation of ineffective antibiotic therapy were associated with mortality.[71]

DIAGNOSIS

Diagnosis is made by recovery of the organism from blood, lymph nodes, skin lesions, or abscesses. Gram-negative bacilli sometimes can be seen in smears of material from skin lesions. Laboratory values reveal either very low or very high white blood cell counts with marked left shifts. Mild to moderate anemia is common. There may be elevated liver enzymes; evidence of early renal failure sometimes is present. The organism grows readily and is easy to identify if it produces the characteristic violet pigment. Nonpigmented forms exist in soil and have similar virulence in mice[72] but are recovered only rarely from clinical specimens.[75] Other cases may have been missed, however, because the nonpigmented forms often are misidentified as *Aeromonas hydrophila* or as pseudomonads.[72] Reports that *C. violaceum* infection causes a melioidosis-like illness were probably due to misidentification of *Burkholderia pseudomallei* by the API 20NE system.[38]

A clinical history of contamination of a wound with water or soil, especially in the southeastern United States or in Southeast Asia, with subsequent local infection, lymph node suppuration, and lack of response to conventional antibiotic therapy, should arouse suspicion of *C. violaceum* infection. The clinician particularly should be aware of the possibility of *C. violaceum* infection in patients with chronic granulomatous disease.

TREATMENT

C. violaceum is sensitive in vitro to chloramphenicol, gentamicin, fluorinated quinolones, tetracyclines, imipenem, trimethoprim-sulfamethoxazole, and semisynthetic penicillins. *C. violaceum* often is resistant to cephalosporins, penicillin, ampicillin, and the antistaphylococcal penicillins. All isolates are resistant to vancomycin and rifampin.[4] Some strains have been shown to elaborate a β-lactamase, which is chromosomal and inducible in vitro.[21] At least one case report gives in vivo evidence of inducible resistance to ceftazidime.[80] Laboratory evidence of susceptibility to erythromycin cannot be relied on. In vitro, the fluorinated quinolones have the highest activity.[4] Clinical experience with the fluoroquinolones in *C. violaceum* infection is scarce; an impressive case of a 4-month-old infant with severe disseminated *C. violaceum* infection who survived after therapy with trimethoprim-sulfamethoxazole and ciprofloxacin has been reported.[59] The review of 25 cases mentioned earlier found that all survivors had been given one or a combination of the following agents: ciprofloxacin, trimethoprim-sulfamethoxazole, chloramphenicol, or imipenem.[71]

Because infection with *C. violaceum* is rare and often rapidly fatal, optimal antimicrobial therapy is unknown. Duration of therapy also is unknown, but because of late recurrences, some authors recommend 3 to 4 weeks of intravenous therapy followed by 1 month or more of oral trimethoprim-sulfamethoxazole.[65]

PLESIOMONAS SHIGELLOIDES

Plesiomonas shigelloides is the only species for the genus *Plesiomonas*. These organisms are facultatively anaerobic, motile, gram-negative rods that are common inhabitants of surface water and fish. They have been implicated in gastrointestinal infections and, rarely, have been recovered from extraintestinal sites.

BACTERIOLOGY

These facultatively anaerobic, gram-negative rods are members of the family Vibrionaceae, although some authorities suggest they are related more closely to Enterobacteriaceae.[51] They are motile by means of a polar flagellum. They are lysine-positive, ornithine-positive, and arginine decarboxylase–positive. They can be distinguished from Enterobacteriaceae by oxidase positivity. They also are catalase-positive and indole-positive. They grow well on MacConkey agar but not on thiosulfate citrate bile salts sucrose. Growth may be enhanced by the use of selective media, such as trypticase soy broth with ampicillin[66] and inositol brilliant green–bile salts agar. Growth is maximal at 40° C to 44° C and completely inhibited at 8° C. Usually within 24 hours, 1- to 1.5-mm grayish, shiny, opaque colonies with a slightly raised center and a smooth surface are visible. A few isolates of *P. shigelloides* share a common O antigen with *Shigella sonnei*.

EPIDEMIOLOGY

The organism is a ubiquitous fresh-water inhabitant at temperatures greater than 8° C. It sometimes also is found in estuarial waters in temperate or tropical climates and can exist in sea water during the summer. It has been cultured from finfish, shellfish, pigs, birds, and dogs.[84] Although infection with *P. shigelloides* has been associated with ingestion of raw or improperly cooked fish (especially oysters), it is unknown what role, if any, other animals play in the ecology of the organism. Asymptomatic carriage of *P. shigelloides* is rare in developed countries,[68] but may be 15 percent in some parts of China.[84]

PATHOPHYSIOLOGY

Despite the ubiquity of the organism in nature, human infection is uncommon and has been recognized only more recently. Most often, infection is associated with gastroenteritis. Evidence for the role of *P. shigelloides* in the production of gastrointestinal symptoms is that it has been isolated much more frequently from patients with diarrhea than from healthy controls[35]; there have been some outbreaks, especially in Japan; it often is the only organism detected in the stools of patients with gastroenteritis[56]; and patients who have *P. shigelloides* growing from a stool culture recover more quickly with than without antibiotic therapy.[42] Acquisition of disease has been linked specifically to consumption of raw seafood or untreated water and to foreign travel, especially to Mexico.[33,55]

The mechanism by which the organism produces disease has been elusive. It is not enteroinvasive by laboratory tests, most investigators fail to find either a Shiga toxin or an enterotoxin,[1,33] no animal model of gastrointestinal disease has been found,[10] patients in the recovery phase do not show serologic evidence of infection, and inoculation of volunteers fails to produce illness.[33] In a suckling gnotobiotic piglet model in which the animals became septic, histology of the gastrointestinal tract showed neither destruction of cells nor invasion of tissues.[33] Neonatal BALB/c mice became chronically infected with *P. shigelloides*, however, and histopathologic findings included some cases of necrosis of the mucosal surface of the ileum and colon.[83]

Some potential virulence factors (i.e., a cholera-like toxin, a weak cytolysin, serum resistance, and a large [>150-kd] plasmid) have been described, but their exact roles in pathogenesis are uncertain; attempts to correlate these features with virulence have been fruitless.[1] Investigators have characterized a cytotoxin derived from *P. shigelloides* using strains from patients with a diarrheal illness. The cytotoxin is a complex of three lipopolysaccharide-binding proteins and lipopolysaccharide in a 6 : 5 ratio.[63] Cytotoxic activity was inhibited 80 percent in vitro by proteinase K or when incubated with anti-cholera toxin antibody. This cytotoxin produced a positive reaction in the suckling mouse assay, whereas the purified lipopolysaccharide exhibited almost no cytotoxicity.[63]

Transmission electron microscopy has provided investigators with the first definitive proof that *P. shigelloides* can adhere to and invade eukaryotic intestinal cells. Organisms attached to microvilli and plasma membranes of the cells; they also were seen within vacuoles in the cell cytoplasm, suggesting a phagocytotic entry mechanism.[78] In one in vitro system using Caco-2 cells, adherence occurred within 10 minutes, and internalization occurred within 60 minutes. Cytotoxicity was due to the induction of apoptosis.[81] In vitro, cell-free and cell-associated hemolysis is demonstrable,[29] and low levels of elastase, proteinase, histidine decarboxylase, and moderate levels of triacylglycerol lipase activity have been found.[15] Culture filtrates are capable of inducing vacuolation of a variety of mammalian cells in vitro.[20]

P. shigelloides rarely, but more clearly, is a pathogen in extraintestinal sites. Osteomyelitis, endophthalmitis, cholecystitis, pseudoappendicitis, spontaneous peritonitis,[3] meningitis,[77] and septicemia have been reported sporadically.[10] Most patients with septicemia have been immunocompromised hosts, but the organism has been isolated from blood cultures in otherwise healthy individuals.[39,64] The mode of infection in extraintestinal sites is unclear, but most cases are thought to arise from the gastrointestinal tract. The case of a newborn with *P. shigelloides* meningitis, septicemia, and endophthalmitis who was born to a mother who reported severe diarrhea after eating raw oysters 2 weeks before delivery raises the possibility of transplacental transmission.[54]

CLINICAL MANIFESTATIONS

Patients with *P. shigelloides* gastroenteritis complain of diarrhea, crampy abdominal pain, nausea and vomiting, headache, and fever. Symptoms usually begin 24 hours to 4 days after contact with the organism.[35] Diarrhea tends to be secretory, although some patients have symptoms more consistent with colitis.[42] Passage of blood, mucus, or both in the stools is a common manifestation, as is the presence of white blood cells by Wright stain.[35] Patients with *P. shigelloides* gastroenteritis tend to have disease that is more acute, associated with more severe abdominal pain, and of longer duration than patients with diseases caused by other enteropathogens.[42]

In one case-control study, 76 percent of patients were sick for more than 2 weeks, and 32 percent were sick for more than a month.[42] In contrast, a large Japanese study of returning travelers suggested that for most patients, the symptoms abated within approximately 3 days.[70] In a series of 38 pediatric cases in Bangladesh, 84 percent had secretory diarrhea and 71 percent had associated emesis. Only three patients (8%) had fever, and only five (13%) had diarrhea for 14 days or longer.[47] In a separate report, one child developed migratory polyarthritis during an otherwise typical case of culture-proven gastrointestinal infection. All symptoms and signs of arthritis disappeared when the gastrointestinal infection was treated with antibiotics.[30]

Localized extraintestinal infections have been reported but are rare. Two cases of severe polymicrobial endophthalmitis resulting from fishhook trauma progressed to enucleation.[13] Two cases of peritonitis associated with continuous ambulatory peritoneal dialysis were reported from Hong Kong. Both patients recovered with 10 days of receiving intraperitoneal cefazolin and tobramycin.[85] In one odd case, a woman presented with pyosalpinx from *P. shigelloides*, thought to have been acquired by swimming in contaminated water.[69]

Septicemia, meningitis, or both usually occur in immunocompromised hosts. Severe, rapidly progressive sepsis complicated by disseminated intravascular coagulation, adult respiratory distress syndrome, renal insufficiency, hepatic dysfunction, adrenal hemorrhage, and splenic abscess has occurred in patients with hemoglobinopathies and absence of splenic function, including thalassemia intermedia and sickle-cell disease.[6,82] Unusual sites of infection sometimes are noted in immunocompromised individuals, such as epididymo-orchitis in a patient with human immunodeficiency virus infection.[86] Newborns constitute most of the reported cases of *P. shigelloides* meningitis, in whom the mortality rate is 80 percent.[1] Septicemia also has a high mortality rate in adults, although otherwise well patients may recover with appropriate antimicrobial therapy.

DIAGNOSIS

A clinical history of foreign travel or of ingestion of raw seafood or untreated water should raise suspicion of possible *P. shigelloides* infection, especially when the clinical illness matches the description just mentioned. Oxidase tests should be done on any predominant or solitary organisms to distinguish them from Enterobacteriaceae.[35] The organisms can be shown not to be aeromonads or pseudomonads by production of ornithine decarboxylase and fermentation of inositol. Selective medium can be used if the index of suspicion is high.

TREATMENT

Most strains of *P. shigelloides* produce a β-lactamase,[67] which seems to be specific for the penicillins. In one study, all isolates were resistant to ampicillin, ticarcillin, carbenicillin, and piperacillin.[26] *P. shigelloides* is universally susceptible to trimethoprim-sulfamethoxazole, the fluoroquinolones, most cephalosporins, carbapenems,[76] tetracycline,[76] and chloramphenicol. It is variably susceptible to the aminoglycosides and mostly resistant to erythromycin.

P. shigelloides gastroenteritis resolves without therapy, but the illness may be prolonged. Treatment seems to shorten the course.[42] Extraintestinal infections carry a poor prognosis and should be treated aggressively. For meningitis, the cephalosporins have good cerebrospinal fluid penetration and are effective therapy against most isolates.

OTHER *PASTEURELLA* ORGANISMS

The genus *Pasteurella* consists of a group of pleomorphic, gram-negative coccobacilli that are part of the normal flora of many animals. These organisms are frequent animal pathogens. *P. multocida* is a common human pathogen; it is discussed elsewhere (see Chapter 126). The other species of the genus *Pasteurella* are rare but occasionally serious causes of infection in humans.

BACTERIOLOGY

These organisms, similar to *P. multocida*, grow readily on most common laboratory media, including blood agar. Most of the species do not grow on MacConkey agar. They are non–spore-forming, nonmotile, aerobic, and facultatively anaerobic. These glucose-fermenting organisms all are oxidase-positive. Most are nitrate-positive and catalase-positive, and all except *Avibacterium gallinarum* (formerly *Pasteurella gallinarum*, see later) produce indole. They are small, coccoid or rod-shaped bacilli that may show prominent bipolar staining on Gram stain. Colonies are small, translucent, and gray. They may be smooth or rough. A browning discoloration may develop around them. Colonies are nonhemolytic. They have a distinctive musty or "mushroom" odor.[14]

The taxonomy of these organisms is confusing and continues to be revised. *Pasteurella ureae* and *Pasteurella pneumotropica* have been moved into the genus *Actinobacillus*. *Pasteurella haemolytica* has been reclassified into a new genus, *Mannheimia*.[8] *Pasteurella dagmatis* is the name now given to what formerly was called *P.* new species, or *P.* gas.[60] *Pasteurella gallinarum*, *Pasteurella avium*, and *Pasteurella volantium* have 96.8 percent sequence similarity and are phenotypically separate from other *Pasteurella* spp.; this feature has led to a proposal that they be moved into a new genus, *Avibacterium*.[9] Most experts agree that the genus *Pasteurella sensu stricto* should include *P. multocida*, *Pasteurella canis*, *Pasteurella stomatis*, *P. dagmatis*, and *Pasteurella* spp. B.[43] Clinically recovered species other than *P. multocida* include *Actinobacillus ureae*, *Mannheimia haemolytica*, *Actinobacillus pneumotropica*, *P. dagmatis*, *P. canis*, *Pasteurella aerogenes*, *Pasteurella bettyae*, *P. "SP"* group,

and *P. stomatis*. *Pasteurella caballi* has caused wound infections after horse bites.[18] *A. gallinarum* is an extremely rare pathogen in humans.

PATHOPHYSIOLOGY

Infection with *Pasteurella* spp. has been divided clinically into three types: infection (1) from animal bites, (2) from animal contact,[25] and (3) without known animal contact.[16] Infections from animal bites include cellulitis, abscesses, tenosynovitis, and bone and joint infection, but infection can become generalized, especially in patients who are immunocompromised. Infections caused by animal contact can be similar to infections described earlier and are caused by animals licking broken skin or wounds. Sometimes pulmonary infections occur, possibly related to aerosolization of organisms. In some cases, these organisms have been reported as respiratory flora in patients with pets, but at present no proof exists that such colonization is an antecedent of infection.[23] Cases without known animal contact history constitute 3 to 30 percent[36,40] of all cases.

Infection usually occurs when the organisms are inoculated into deeper tissues either on animal teeth that break the skin or in animal saliva that comes in contact with nonintact skin. Bite wound infections often are polymicrobial. Infection in cases without known animal contact is harder to explain but definitely happens.[44] Most cases of serious infection occur in patients with underlying diseases, such as diabetes mellitus, chronic alcoholism, and other types of liver disease.[62] Central nervous system infection with these organisms has occurred after head trauma or neurosurgery in 10 of 11 reported cases.[44] One intrauterine death of the fetus of a 20-year-old woman who worked at a pig farm has been attributed to *P. aerogenes*.[79] Case reports of unusual infections with rare species of *Pasteurella*, such as fatal sepsis and meningitis in a 4-day-old infant caused by *A. (Pasteurella) gallinarum*,[2] should be considered doubtful unless molecular identification methods have been used.[32]

CLINICAL MANIFESTATIONS

Pasteurella infections produce pain, swelling, pus, and sometimes abscess formation at the site of inoculation, beginning within 24 to 36 hours. Clinically, these infections are indistinguishable from wound infections with *Staphylococcus aureus* or other gram-positive organisms. Gram stain may show the characteristic pleomorphic bacilli with bipolar staining. Growth on standard agar is rapid.

Patients with peritonitis,[62] meningitis,[44] osteomyelitis,[26] or infectious endocarditis[3] have symptoms typical of these diagnoses. Risk factors, such as household pet exposure, animal contact, animal bites, and comorbid conditions, should heighten suspicion of possible *Pasteurella* infection.

DIAGNOSIS

Establishing the diagnosis of *Pasteurella* infection can be difficult, not because the organism is fastidious or slow-growing, but because it often is misidentified. Other organisms of the same family (i.e., *Actinobacillus* spp. and *Haemophilus* spp.) have similar biochemical profiles and can be misidentified by commonly used systems, such as API. Lester and associates[50] reported that of 30 species firmly identified as *Pasteurella* by biochemical means, only three were identified correctly by the API 20E system. *Haemophilus aphrophilus* and *Actinobacillus actinomycetemcomitans* are sometimes misidentified as *P. gallinarum* by commercial systems.[24] Additionally, Hamilton-Miller[31] reported that four strains of *Haemophilus influenzae* and three strains of *Haemophilus parainfluenzae* were identified falsely as *Pasteurella* spp. by API, and suggested that if the clinical history renders *Pasteurella* infection unlikely, tests for X and V factor requirements should be performed (see Chapter 145). Clinical case reports corroborate these laboratory observations.[19,62,74] Notifying the bacteriology laboratory of suspicion of *Pasteurella* infection is helpful.

TREATMENT

Penicillin has been considered the drug of choice for *Pasteurella* infection in the past and, despite some reports of penicillin resistance, still is effective against most strains. *Pasteurella* spp. also are susceptible to ampicillin, β-lactamase inhibitor combination drugs, tetracycline, and chloramphenicol. Truncated but fully functional tetracycline resistance genes have been identified in isolates from animal sources.[46] The aminoglycosides, erythromycin, clindamycin, cefadroxil, and cefaclor are not recommended. Dicloxacillin and cephalexin have poor activity against *Pasteurella* spp. and should not be used as monotherapy for animal bite wounds.[27] In one study of bite wound infections, ertapenem was found to be active against all *Pasteurella* spp.[28] Of fluoroquinolones tested in vitro against 75 clinical isolates of *Pasteurella* spp., levofloxacin was the most active.[34]

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 131

ACINETOBACTER

Armando G. Correa

First recognized as a human pathogen in 1908,[66] the ubiquitous organism *Acinetobacter* has emerged as a rather common cause of nosocomial infections in immunocompromised hosts.[6] Some of the confusion regarding this organism may be attributed to the many changes in nomenclature that the members of this genus have undergone over the years. Names used in the past to identify this genus include *Herellea*, *Bacterium*, *Mima*, *Achromobacter*, *Alcaligenes*, *Neisseria*, *Micrococcus*, *Diplococcus*, *Moraxella*, and *Cytophaga*. Treatment of infection caused by *Acinetobacter* is complicated by its widespread multidrug resistance and the difficulty encountered in eradicating the organism.

THE ORGANISM

The genus *Acinetobacter* belongs to the family Neisseriaceae, which also includes the *Neisseria*, *Moraxella*, and *Kingella* genera. *Acinetobacter* is a gram-negative bacterium that typically appears as a rod 0.9 to 1.6 μm in diameter and 1.5 to 2.5 μm in length, but it may become spherical in the stationary phase of growth. It frequently occurs in pairs or short chains. Many strains are encapsulated. The organism has a strictly aerobic respiratory metabolism and does not grow under anaerobic conditions. It does not form spores or exhibit swimming mobility. *Acinetobacter* grows well in all common complex media between 20° C and 30° C, with optimal growth occurring between 33° C and 35° C, and it has no growth factor requirements.

Convex, grayish-white colonies 1 to 2.5 mm in diameter are typical findings. The colonies may appear mucoid if the strain is encapsulated. *Acinetobacter* is catalase-positive and may be differentiated readily from other closely related genera by virtue of its negative reaction to oxidase.

Formerly, the genus *Acinetobacter* contained the single species *Acinetobacter calcoaceticus* subdivided into two subspecies or biovars: *anitratus* and *lwoffii*.[31] However, in 1986, the taxonomy of the genus *Acinetobacter* was changed extensively on the basis of DNA hybridization studies,[10] and at least 32 genomic species have been proposed, of which 17 have been assigned species names.[17] Ten of these nomenspecies have been isolated from human specimens: *Acinetobacter baumannii*, *A. calcoaceticus*, *Acinetobacter haemolyticus*, *Acinetobacter johnsonii*, *Acinetobacter junii*, *Acinetobacter lwoffii*, *Acinetobacter radioresistens*, *Acinetobacter parvus*, *Acinetobacter schindleri*, and *Acinetobacter ursingi*.[17] Several unnamed genospecies also have been isolated from human clinical samples and include genomic species 3, 13TU, 10, and 11.[17] These species may be difficult to differentiate in the clinical laboratory on the basis of their growth characteristics and biochemical activity. Because of their clinical relevance and antimicrobial resistance, four of these species, *A. baumannii*, *A. calcoaceticus*, and genomic species 3 and 13TU, are grouped under the term *A. baumannii-calcoaceticus* complex. Under the new classification, most *A. baumannii* strains represent organisms that were classified formerly as biovar *anitratus*, whereas *A. junii* and *A. lwoffii* previously were listed under the biovar *lwoffii*.

EPIDEMIOLOGY

Acinetobacter strains are distributed widely in nature and can be found in soil, fresh water, and sewage.[8,28] *Acinetobacter* also can be isolated from many animals, fresh meats, poultry, contaminated milk, and frozen foods.[8,28] The organism can be part of the bacterial flora of the skin in healthy individuals,[8,12] and the skin frequently becomes a reservoir for *Acinetobacter* in hospitalized patients and the health care staff.[6,8] It occasionally forms part of the normal flora of the oral cavity and the upper respiratory, genital, and lower gastrointestinal tracts.[8,12] Colonization by *Acinetobacter* is particularly common in patients who have undergone a tracheostomy.[52] The organism frequently can be found in the hospital environment, particularly in moist areas, such as in humidifiers, water sinks, and ventilators.[8] Nosocomial outbreaks have been linked to colonized medical equipment such as ventilator tubing and other respiratory equipment,[1,26] intravenous catheters,[8] gloves,[46] and mattresses.[59]

The frequency of occurrence of nosocomial infections by *Acinetobacter* is not easy to assess because the pathogenic role of this organism often has been underestimated. However, a national surveillance study conducted from 1974 to 1977 identified *Acinetobacter* as a pathogen in 0.76 percent of nosocomial infections.[49] The estimated rate of nosocomial infections caused by this organism was 3.11 per 10,000 patients discharged, and approximately 15 percent of 1372 reported episodes occurred in the pediatric age group.[49] By 1978, this rate increased by 14 percent and accounted for 1 percent of the bacterial isolates associated with nosocomial infections.[12] An unusual seasonal pattern was observed, with most infections occurring in late

summer.[12,49] The cause of this increase is unknown. Pneumonia, tracheobronchitis, and infections of the urinary tract and surgical wounds were the entities observed most frequently.[49] In a national prospective survey of U.S. hospitals from 1995 through 2002, *Acinetobacter* spp. accounted for 1.3 percent of all nosocomial bloodstream infections and was associated with a crude mortality rate of 34 percent.[70] Data from SENTRY, an international surveillance program that monitors the frequency of occurrence and antimicrobial susceptibility of bacterial pathogens, revealed a significantly greater frequency of *Acinetobacter* infections in Latin America than in all other regions.[22] A higher prevalence rate of *Acinetobacter* infections was noted in patients ranging in age from birth to 10 years.[22] In the pediatric age group, neonates appear to be particularly susceptible to nosocomial infection with this organism (Table 131–1).[42]

More recently, *Acinetobacter* emerged as a particularly important pathogen in unusual situations such as earthquakes and war zones.[30] This prevalence was illustrated by reports of outbreaks of multidrug-resistant *Acinetobacter* infections associated with the U.S.-Iraq conflict.[56]

PATHOGENESIS

Limited information is available regarding the pathogenesis of *Acinetobacter* infections. The lipopolysaccharide of *Acinetobacter*, a normal constituent of the outer membrane of gram-negative bacteria, is capable of eliciting multiple pathogenic host responses. Strains producing exopolysaccharide have been shown to be more pathogenic than are nonproducers.[30] Nonspecific adherence factors, such as fimbriae, also have been described in *Acinetobacter*.[30] The role of quorum sensing as a regulatory mechanism for autoinduction of multiple virulence factors in *Acinetobacter* is currently under investigation.[30]

In animal models, *Acinetobacter* can enhance the virulence of other bacteria in mixed infections, perhaps by slime-induced inhibition of neutrophils.[44] Researchers have speculated that the ability of this organism to grow in an acidic pH at lower temperatures may enhance its ability to invade devitalized tissue.[2] The organism also may survive in a dry environment for as long as a week.[14]

CLINICAL MANIFESTATIONS

Acinetobacter can cause suppurative infection of virtually any organ, and the clinical manifestations typically are similar to those seen with other bacterial infections because no unique features are suggestive of *Acinetobacter* infection. The clinical manifestations also may depend on the underlying immune status of compromised hosts. Infections caused by *Acinetobacter* are rare occurrences in normal children.[18]

INTRACRANIAL INFECTION

Most cases of *Acinetobacter* meningitis are the result of a penetrating injury or occur after a neurosurgical procedure, although sporadic cases of meningitis have been reported in the absence of these factors. A cluster of eight children in whom *Acinetobacter* meningitis developed after the administration of intrathecal methotrexate was reported.[32] All patients had fever, headache, nausea, and vomiting, and lumbar puncture revealed cerebrospinal fluid (CSF) pleocytosis.

The earlier literature contains several reports of *Acinetobacter* meningitis developing in apparently normal children.[15,16,29,63,67] CSF pleocytosis with a predominance of segmented forms occurred commonly.[16] Because as many as 30 percent of these patients had a petechial rash and gram-negative diplococci on CSF smears, the diagnosis of meningococcal meningitis was made erroneously in most of these cases, thereby leading to a delay in the institution of appropriate therapy and possibly contributing to a mortality rate as high as 27 percent.[16]

Siegman-Igra and associates,[60] in a review of 25 cases of *Acinetobacter* meningitis secondary to invasive procedures that included some children, found that fever, leukocytosis, and neck stiffness, along with other clinical signs of central nervous system (CNS) infection, were common features. The CSF in these patients showed pleocytosis with a predominance of polymorphonuclear leukocytes, elevated protein concentration, and a low glucose level. Most of the infections were associated with indwelling ventriculostomy tubes or a fistula into the CSF space. Filka and colleagues[20] reported 10 cases of *Acinetobacter* meningitis that occurred over the course of a 7-year period in children who had undergone ventriculoperitoneal shunt insertion.

Researchers have suggested that an inherited or acquired complement deficiency may be associated with meningitis caused by *Acinetobacter*[19] because it is seen with *Neisseria meningitidis* and other related species. Treatment of CNS infections caused by *Acinetobacter* requires a minimum of 3 weeks of parenteral antibiotics.

BACTEREMIA

Acinetobacter bacteremia may occur as an isolated event or may be secondary to a primary infected site, such as the respiratory or urinary tract or a wound. Primary bacteremia appears to occur

TABLE 131–1 Illustrative Nosocomial Clusters of *Acinetobacter* Infection in Pediatric Patients

Country	Year	Type of Unit	Infected Children	Colonized Children	Presentation	Mortality (%)	Suspected Source
United Kingdom[42]	1981	NICU	4	0	Meningitis	0	None identified
United Kingdom[61]	1983	NICU	9	1	Pulmonary infection	22	Ambu bag
Japan[64]	1983-1986	NICU	19	52	Sepsis	11	Multiple sources
India[32]	1988	Oncology	8	N/A	Meningitis	38	Intrathecal needle
Germany[55]	1988	NICU	3	41	Sepsis	100	Humidifier
Israel[48]	1988-1990	NICU	9	N/A	Sepsis	44	None identified
United Kingdom[43]	1989	NICU	7	N/A	Sepsis	0	Intravenous fluids
Bahamas[40]	1996	NICU	8	1	Sepsis	37	Air conditioner
South Africa[47]	1997	NICU	9	N/A	Sepsis	22	Suction catheters
India[41]	1995	NICU	79	N/A	Sepsis	14	None identified
India[13]	1986-1990	NICU	26	N/A	Sepsis	42	None identified

N/A, data not available; NICU, neonatal intensive care unit.

more commonly in immunocompromised neonates, and clinical manifestations can vary from an absence of clinical signs of infection to fulminant septic shock and disseminated intravascular coagulation.[33,55] Thrombocytopenia has been reported to be a prominent feature in these neonates.[43,48] Pneumonia has been seen more commonly in early-onset sepsis.[41] Predisposing factors include low birth weight,[53,55] previous antibiotic therapy,[48,53,55] and the presence of indwelling catheters.[40,53]

Acinetobacter bacteremia in children with malignant diseases also has been noted to occur rarely. Fuchs and colleagues[21] reported 29 episodes of sepsis caused by this organism over the course of a 12-year period in an oncology center. All these children were febrile and appeared ill at the time of diagnosis, and a high association of *Acinetobacter* sepsis with the presence of intravascular catheters was noted. Surprisingly, no connection was found with the level of neutropenia.[21]

RESPIRATORY TRACT

Because *Acinetobacter* may be a transient colonizer of the pharynx in 7 percent of healthy children[5] and adults[23] and this rate is increased in hospitalized patients, the relative importance of *Acinetobacter* in comparison with other potential pathogens isolated from sputum is difficult to ascertain. The tracheobronchitis and pneumonia attributed to *Acinetobacter* are mostly nosocomial infections associated with the presence of an endotracheal tube or tracheostomy.[23] Pneumonias frequently are multilobar and occasionally may lead to cavitary destruction or pleural empyema.[23]

Community-acquired pneumonia caused by *A. baumannii* has been reported to occur in adults in the Northern Territory of Australia and other tropical regions.[4] This entity generally is seen in patients with diminished host defenses caused by alcoholism, cigarette smoking, or underlying pulmonary disease and is characterized by the rapid onset of fever, dyspnea, pleuritic chest pain, and purulent sputum. The mortality rate has been as high as 53 to 64 percent.[4]

MISCELLANEOUS

Urinary tract infections occur almost exclusively in patients with indwelling bladder catheters, usually are limited to the bladder, and generally are mild.[23] Burns, as well as traumatic and surgical wounds, frequently become colonized by *Acinetobacter* as a result of the ability of this organism to thrive on compromised tissue and foreign material.[23] Bacteremia may occur as a consequence of this colonization, which is often polymicrobial. *Acinetobacter* is a prominent cause of peritonitis in children undergoing peritoneal dialysis when gram-negative organisms are involved.[68]

Other rare infections caused by *Acinetobacter* that have been reported include suppurative otitis media,[50,63] cellulitis (frequently in association with trauma, a foreign body, or an animal bite),[23,50] synergistic necrotizing fasciitis,[3] native-valve and prosthetic-value endocarditis,[25] septic arthritis,[50] osteomyelitis,[63] and liver abscesses.[23] Ocular infections also have been documented.[38] A case of osteomyelitis occurring after a hamster bite in a child has been described.[39]

DIAGNOSIS

The diagnosis of *Acinetobacter* infection is made by culture of appropriate body fluids or tissue specimens. No serologic or antigen-detection tests are available. A selective medium containing MacConkey agar with cephaloridine has been used to culture skin specimens during investigation of outbreaks[61] because of its ability to inhibit most of the skin flora but not *Acinetobacter*.

Biotyping, phage typing, electrophoretic analysis of isoenzyme and cell wall proteins, plasmid analysis, polymerase chain reaction–based DNA fingerprinting, and restriction endonuclease digestion of DNA have been used for investigation of nosocomial outbreaks.[7] Antibiogram typing no longer is considered an effective method in the investigation of *Acinetobacter* epidemics because the susceptibility pattern may change rapidly within the same outbreak.[7,11]

TREATMENT

As with many other opportunistic gram-negative organisms, treatment of infections caused by *Acinetobacter* spp., particularly those of the *A. baumannii-calcoaceticus* complex,[57,65] have become more complicated by the rapid increase in resistance to the antibiotics used commonly in hospitals. Selection of an antibiotic regimen should be based on in vitro susceptibility testing and ideally should include both a β-lactam and an aminoglycoside, which may have synergistic activity[23] and prevent the emergence of resistance.[6]

Species of the *A. baumannii-calcoaceticus* complex have shown decreased susceptibility to ampicillin, broad-spectrum penicillins, cephalosporins, aminoglycosides, and ciprofloxacin.[22,57] Resistance to extended-spectrum cephalosporins may be the result of the presence of cephalosporinases (particularly the chromosomally encoded cephalosporinase AmpC),[9] other broad-spectrum β-lactamases, or changes in the outer-membrane porins and penicillin-binding proteins.[9,45] Resistance to aminoglycosides is mediated by aminoglycoside-modifying enzymes.[65] The carbapenems imipenem and meropenem appear to be the most active agents against *A. baumannii*,[60,65] but reports have found more than 10 percent of such strains to be resistant to these antibiotics in some areas,[22,37] and increasing numbers of nosocomial outbreaks of carbapenem-resistant *Acinetobacter* infections have been reported.[24,64,72] The incidence of carbapenem-resistant *Acinetobacter* strains has been particularly high in Latin America (11.4% of all isolates versus 4.8% in the United States).[22] Resistance to the carbapenems has been associated with the presence of serine and metallo-β-lactamases (carbapenemases). Of particular concern are the numerous carbapenem-hydrolyzing OXA enzymes that have emerged in *A. baumannii*.[9] Caution should be exercised when using imipenem at high dosage in children for the treatment of meningitis (i.e., 100 mg/kg/day) because of an unusually high rate of seizures.[71] Thus, meropenem is recommended for this indication. Ertapenem, a newer carbapenem antibiotic, has poor in vitro activity against *Acinetobacter*[35] and should not be used for the treatment of these infections. Combinations of a β-lactam antibiotic with a β-lactamase inhibitor, such as ampicillin-sulbactam, piperacillin-tazobactam, or ticarcillin-clavulanate, have been used for infections caused by carbapenem-resistant strains.[64,72]

The fluoroquinolones, in particular ciprofloxacin, have been used successfully to treat infections caused by multidrug-resistant *Acinetobacter* in children[41,47] and adults. Although ciprofloxacin has been approved for the treatment of complicated urinary tract infections in children, the other systemic fluoroquinolones are not approved for use in children younger than 16 years of age because of the theoretic concern for damage to growth cartilage. Of the quinolones currently available, gatifloxacin exhibits the best in vitro activity against *A. baumannii*, followed by levofloxacin and trovafloxacin.[27] Although 76 to 86 percent of sporadic isolates of *A. baumannii* are susceptible to the fluoroquinolones, only 32 to 55 percent of outbreak-related strains remain susceptible to this antibiotic class.[27] Topoisomerase mutations in both *gyrA* and *parC* have been identified in quinolone-resistant *A. baumannii*.[9] In some cases, the polymyxin drugs polymyxin B and colistin are the only therapeutic options for the treatment of multidrug-resistant *Acinetobacter*

infection.[24,34] Efflux pumps capable of conferring resistance to multiple antibiotic classes have been identified in *Acinetobacter* spp.[9,51]

Tigecycline is the first member of the glycylcycline antimicrobial class to gain approval in the United States. Because this agent demonstrates in vitro activity against multidrug-resistant strains of *A. baumannii*, its potential use as an alternative therapy for severe infections caused by this organism is being investigated.[51] Data regarding the use of this agent in pediatric patients are lacking.

Imipenem, meropenem, amikacin, ciprofloxacin, ceftazidime, and ceftriaxone have exhibited good in vitro activity against isolates identified as species other than the *A. baumannii-calcoaceticus* complex.[57] In addition to antimicrobial therapy, prompt drainage of focal suppurative sites and removal of infected indwelling catheters are essential. Intraventricular administration of amikacin has been used in the treatment of CNS infections caused by this organism.[69]

PROGNOSIS

Because *Acinetobacter* strains often are resistant to the antibiotics used commonly, prompt recognition of the specific cause and institution of effective antibiotic therapy are critical to achieving a successful outcome. The reported mortality rate in a series of pediatric patients ranged from 0 percent to more than 50 percent (see Table 131–1), and the outcome appeared to correlate more closely with the underlying condition than with other factors such as polymicrobial bacteremia.[62] In a series of 58 infections caused by this organism that occurred over the course of a 2-year period from 1973 through 1974 at the Massachusetts General Hospital in Boston, the mortality rate was 23 percent.[23] A 1999 prospective study in the Slovak Republic revealed that the case-fatality rate for 157 episodes of *A. baumannii* bacteremia was significantly higher in adults than in children (34% vs. 12%).[33]

The nosocomial acquisition of multiresistant *A. baumannii-calcoaceticus* complex has been associated with high mortality rates and prolonged hospitalization in adult patients in intensive care units,[36,54] in contrast to the more benign clinical outcome usually seen with other species of *Acinetobacter.*[58]

PREVENTION

Nosocomial acquisition of *Acinetobacter* by high-risk compromised hosts can be prevented by placing emphasis on the control measures routinely used for endemic infections, such as careful handwashing by personnel, limitation of the frequency and duration of use of devices, proper isolation of colonized and infected patients, application of strict techniques for invasive procedures, and restricted use of antibiotics.[14,36,60]

CHAPTER 132

ACHROMOBACTER (ALCALIGENES)

Randall G. Fisher

Organisms of the genus *Achromobacter* are gram-negative bacilli that live in aqueous environments. Originally considered commensals, they increasingly are recognized as important, although rare, hospital pathogens. *Achromobacter* can be especially problematic in immunocompromised patients and in neonates, in whom infection can be life-threatening. These organisms have been isolated from such diverse clinical specimens as sputum, urine, feces, blood, cerebrospinal fluid, cornea, and peritoneal and pleural fluids.

BACTERIOLOGY

Achromobacter spp. are gram-negative, motile, indole-negative, obligate aerobes that are oxidase- and catalase-positive. They are considered to be nonfermenters because of their extremely limited action on carbohydrates. Most ferment xylose, and some ferment glucose. All reduce nitrate to nitrite. They are urease-, lysine-, and ornithine-negative. They grow well on both blood and MacConkey agar and produce colonies that are smooth and glistening and have a distinct edge. They alkalinize organic salts and amides, a property that led to the name *Alcaligenes*, which means *alkali producing*. *Alcaligenes faecalis* has a distinct, sweet odor that has been described as resembling that of green apples.[27]

Bacteriologically, these bacilli may be confused with other nonfermenting gram-negative organisms, especially *Pseudomonas* spp. Morphologically, however, they can be distinguished easily from pseudomonads by the presence of peritrichous flagella: *Pseudomonas* spp. have polar flagella.[23]

The taxonomy of these organisms is confusing and undergoes frequent changes. They were classified as *Achromobacter* spp., then reclassified as *Alcaligenes*; they have been reassigned the name *Achromobacter*. The genera *Achromobacter* and *Alcaligenes* are closely related and comprise many species, but clinically important ones are as follows: (1) *Achromobacter xylosoxidans*, which has two subspecies: *xylosoxidans* and *dentrificans*, the former of which is the most common cause of clinically recognizable infection; (2) *Alcaligenes faecalis*, which is a less common pathogen but has a distinct antimicrobial susceptibility pattern[5]; (3) and *Achromobacter piechaudii*, which has been isolated from clinical specimens[35] but is of doubtful significance. In the discussion that follows, the abbreviation *A. xylosoxidans* refers to *Achromobacter xylosoxidans* subspecies *xylosoxidans*.

EPIDEMIOLOGY

Like *Pseudomonas* spp., *Achromobacter* are water organisms and prefer aqueous environments and moist soil. They do not survive long on porous surfaces or fomites or if they become desiccated.[39] They also may be part of the normal flora of the ear and of the gastrointestinal and respiratory tracts of some people. These organisms establish a niche within the hospital environment and have been recovered from ventilators, humidifiers, "sterile" saline, intravenous fluids, and irrigation and dialysis solutions. *Achromobacter* spp. also have been recovered from infant formula,[16] children's soap bubbles,[32] well water,[45] and swimming pools.[25] Organisms also survive many disinfectants and have been cultured from chlorhexidine,[42] 1 percent eosin,[6] and alcohol- or quaternary amine–containing compounds.[39,42] Shigeta and associates[42] reported an outbreak of *A. xylosoxidans* ventriculitis secondary to contaminated chlorhexidine used on a surgical ward. Foley and colleagues[19] reported an outbreak accompanied by deaths in a neonatal intensive care unit secondary to contamination of saline used as an eyewash. Boukadida and coworkers[6] reported a neonatal death caused by meningitis contracted by dissemination after treatment of a diaper rash with 1 percent eosin. An outbreak of 37 cases (with 2 fatalities) that was caused by bacterial contamination of deionized water in a hemodialysis system was described by Reverdy and associates[36]. Surgical wound infection also has occurred wherein infection was suspected to be secondary to contaminated irrigation fluids used in surgery.[50] One outbreak of four cases in a hemodialysis unit was linked to an atomizer of 2.5 percent chlorhexidine used to disinfect the skin.[47] Three different kinds of pseudo-outbreaks have been described: in one, seven patients in a pediatric hospital were infected with *A. xylosoxidans*, but restriction fragment-length polymorphism analysis proved they all were genetically unrelated[4]; in another, *A. xylosoxidans* was isolated from three different clinical specimens but was later proven to be a contaminant of the saline used in their processing[22]; in a third, blood cultures were positive when drawn on the night shift because the nurses were cleaning the top of the blood culture bottles with a contaminated disinfectant.[44]

Studies have documented that *A. xylosoxidans* colonization of patients with cystic fibrosis is on the rise. In one large study, *A. xylosoxidans* was isolated from the sputum culture of 52 of 595 patients (8.7%).[7] In other studies, isolates of *A. xylosoxidans* at a single cystic fibrosis center were not genetically related, a finding implying no common source of infection and little or no patient-to-patient spread within the center.[14,49] However, colonization of multiple patients with identical strains also is well documented.[37] Environmental cultures at one cystic fibrosis center were positive for *A. xylosoxidans* only 0.8 percent of the time, whereas 22.8 percent of such cultures were positive for *Pseudomonas aeruginosa*.[18]

PATHOPHYSIOLOGY

Achromobacter spp. are weakly virulent bacteria. Medical care commonly provides the conduit through which organisms are introduced into their host, by way of indwelling catheters, endotracheal tubes, and so forth. The bacteria may take advantage of a weakened immune system and disseminate, causing sepsis, meningitis, and death. Preterm or small-for-gestational-age term infants are at particular risk for acquiring such severe *Achromobacter* infections.[19] Although most neonatal infections are considered to be nosocomial, vertical transmission from mother to baby may occur.[23] An increased incidence of infection has been reported for patients with neoplasms[28] and those receiving long-term steroid therapy.[26] Sporadic cases of *Achromobacter* infection in patients with idiopathic immunoglobulin M (IgM) deficiency,[15] Waldenström macroglobulinemia,[46] and systemic lupus erythematosus have been reported.[38] My colleagues and I have seen one boy with hyper-IgM syndrome in whom 14 separate episodes of *Achromobacter* bacteremia occurred; an exhaustive environmental search for a source was fruitless. The source was eventually proven to be deep infection of a cervical lymph node, and the episodes ceased when the node was removed.[51] *Achromobacter* infections occur in patients with acquired immunodeficiency syndrome (AIDS),[8,21] but whether this syndrome is an independent risk factor for infection is unclear.

In one study, patients with cystic fibrosis and colonized with *A. xylosoxidans* tended to be older (mean age, 20 years) and at baseline had worse lung function than did noncolonized controls; however, over the course of the study, the rate of decline of lung function did not differ between cases and controls.[10] In a second similar case-control study, lung function decline and growth parameters generally were not affected by colonization; however, a subset of patients had rapidly increasing antibody titers against *A. xylosoxidans*, and this group did experience more accelerated decline.[37]

In unusual circumstances, patients with neither overt underlying disease nor obvious immune deficiency will develop infection with *Achromobacter* spp. Most of these cases involve penetrating trauma. One case of corneal infection complicating epidemic keratoconjunctivitis in a normal host has been described.[33]

CLINICAL MANIFESTATIONS

Signs of sepsis or meningitis caused by *A. xylosoxidans* in the newborn are difficult to differentiate from other causes of bacterial sepsis. However, some babies may develop a distinctive rash in association with this infection, in which 1- to 2-cm, sharply demarcated red patches appear, especially in the head and neck region. This rash was noted in 29 of 33 newborns with *A. xylosoxidans* infection reported by Doxiadis and associates in 1960[12] and was seen again in a case reported in 1993.[6] *A. xylosoxidans* sepsis/meningitis tends to manifest later in life than do infections with the usual vertically acquired pathogens and may have a more insidious onset.[30] In some cases, cerebrospinal fluid profiles may resemble those usually associated with viral meningitis, with white blood cell counts in the hundreds and with monocytic predominance.[40] Neonatal *Achromobacter* sepsis or meningitis has an extremely poor prognosis; one series noted a mortality rate that approached 75 percent, and 36 percent of survivors had severe neurologic deficits.[19] The incidence of intracranial hemorrhage also was high.

Three large series of bloodstream infections with *A. xylosoxidans* all revealed a similar story: most cases are nosocomial, most patients have an underlying malignant disease, many are neutropenic or receiving high-dose steroids, and many patients have indwelling vascular catheters.[2,20,41] Polymicrobial bacteremia was not rare in these series. Mortality rates ranged from 15 percent[20]

to 48 percent.[41] Risk factors for mortality were age greater than 65 years at diagnosis, neutropenia, nosocomial acquisition, and polymicrobial bacteremia. An earlier review of reported cases revealed that the case-fatality rate was lowest in patients with catheter-associated bacteremia and highest (65%) in those with pneumonia, meningitis, or endocarditis.[13]

One child developed osteomyelitis caused by *A. xylosoxidans* after stepping on a nail through old sneakers (a clinical situation classically associated with *Pseudomonas* infection)[24,25]; another developed *Achromobacter* infection as a consequence of a gunshot wound.[9] In the setting of a patient with an artificial heart valve, *A. xylosoxidans* endocarditis has been described.[34] In another case, endocarditis was associated with an abandoned pacemaker lead.[1] A case series of liver abscesses included three patients from whom *A. xylosoxidans* was isolated, all of whom shared a clinical pattern: history of cholecystectomy, "coral-like" multilobulated appearance on computed tomographic scanning, and epithelioid granulomas at the periphery of the abscesses.[3] *A. xylosoxidans* infection in older patients usually is not suspected on clinical grounds but rather in the context of a common-source outbreak or because of microbiologic clues. *A. faecalis* infection is less common and usually is part of a polymicrobial process.

DIAGNOSIS AND TREATMENT

Generally, the diagnosis of *Achromobacter* infections rests on recovery of the organism from clinical samples, although newer methods sometimes have been employed. In one case of culture-negative endophthalmitis, fluid obtained from the anterior chamber was subjected to polymerase chain reaction using a 16S rDNA primer set, finding a 214 base pair sequence from *A. xylosoxidans*.[48] These organisms often are mistaken for pseudomonads, and the clinician should suspect *A. xylosoxidans* when the laboratory reports an organism as a *Pseudomonas* spp. that is resistant to all aminoglycosides.[39] Key differentiation features include the antibiogram and the morphology of the organism, with its distinctive peritrichous flagella.

Achromobacter spp. typically are resistant to a large number of antibiotics, including ampicillin, aztreonam, aminoglycosides, first- and second-generation cephalosporins, tetracyclines, and rifampin. They variably are resistant to chloramphenicol, fluoroquinolones, macrolides, ureidopenicillins, and β-lactamase combination drugs.[5] *Achromobacter* spp. have been shown to produce β-lactamases, some of which are chromosomal, constitutive, and inducible[11] and some of which are on plasmids.[29] Some isolates overproduce β-lactamase,[11] which stoichiometrically can render β-lactamase inhibitors useless. In addition, their porins are small, thus rendering antibiotic entry difficult. Although there is no antibiotic to which all isolates have been shown to be sensitive,[34] most are sensitive in vitro to trimethoprim-sulfamethoxazole, imipenem, ceftazidime, and cefoperazone. Imipenem-resistant strains also have been discovered. These strains produced VIM-2, OXA-30, and a chromosomal AmpC β-lactamase.[43] Two case reports describe treatment failures of ceftazidime[31] and piperacillin[11] in clinical isolates that were sensitive at the time of isolation but developed resistance during the course of therapy.

Because resistance patterns vary from isolate to isolate, the combination of a third-generation cephalosporin, piperacillin, or imipenem with trimethoprim-sulfamethoxazole is reasonable empiric therapy for suspected *Achromobacter* infection, pending susceptibility results. In general, in vitro susceptibilities seem to correlate well with in vivo results,[28] but the risk of inducible resistance to β-lactam antibiotics should be acknowledged. One report described synergy in microbial killing with an aminoglycoside, even though the isolate was resistant to the same aminoglycoside when it was tested alone.[8] This phenomenon was confirmed by two-disk Kirby-Bauer approximation methods using 11 clinical blood culture isolates; all were resistant to gentamicin, but 10 of 11 were inhibited synergistically when gentamicin was added to ticarcillin/clavulanate, and 9 of 11 displayed synergy when gentamicin was added to piperacillin or ceftazidime.[13]

Removal of infected catheters may speed recovery, although some patients have been treated successfully through indwelling lines.[8] Because of a high recurrence rate, experts in the care of patients with renal failure treated with continuous ambulatory peritoneal dialysis recommend removal of peritoneal catheters in patients who develop peritonitis with *A. xylosoxidans*.[17]

Acknowledgments

I would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 133

EIKENELLA CORRODENS

Randall G. Fisher

Eikenella corrodens is a facultatively anaerobic, fastidious gram-negative rod that is part of the normal flora of the mouth and the gastrointestinal and genitourinary tracts. Long regarded as a commensal, its pathogenicity no longer is in doubt. It frequently is a pathogen of periodontitis in both adults and children and is a common isolate from wounds that have been contaminated by oral secretions. It also has been recovered from pleuropulmonary infections, central nervous system infections, orbital cellulitis, peritonsillar abscesses, abdominal infections, osteomyelitis, and bloodstream infections, including endocarditis.

BACTERIOLOGY

In 1948, Hendriksen[17] described the organism and called it the *corroding bacillus* because it pitted the agar. It was characterized more fully in 1958 by Eiken,[10] who named it *Bacteroides corrodens*. In 1972, Jackson and Goodman[19] separated two species of corroding bacteria; the strict anaerobe kept the name *B. corrodens* (now called *Bacteroides ureolyticus*), and the facultative anaerobe was classified as *Eikenella*. It is a small, straight, nonmotile gram-negative rod that occasionally is coccobacillary. It is oxidase-positive and catalase-negative. Most strains are lysine- and ornithine decarboxylase-positive. The organism is nonfermentative, reduces nitrate to nitrite, and is urease- and indole-negative. *E. corrodens* cell surface components vary from isolate to isolate; these differences probably relate to virulence.[6]

E. corrodens will grow either aerobically or anaerobically, but its growth is not rapid. Growth can be enhanced by 3 to 10 percent carbon dioxide. It grows on blood or chocolate agar but poorly or not at all on MacConkey agar. Selective medium, which contains clindamycin, may increase the yield. Colonies are small and grayish. They look slightly yellow when they are old. Although *E. corrodens* is nonhemolytic, a faint green appearance may be seen on blood agar. Approximately 50 percent will produce the characteristic pitting. They elaborate an odor that resembles that of bleach or hypochlorite.[18]

E. corrodens is a member of the so-called HACEK family of organisms, which have the following in common: (1) slow growth, (2) a requirement for carbon dioxide, and (3) a predilection for infecting heart valves. The other members of the family are *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, and *Kingella kingae*.

EPIDEMIOLOGY

Infection with *E. corrodens* occurs when mucosal or skin barriers are disrupted and the organism gains access to deeper tissues. Puncture of the skin with forks[32] or toothpicks[38] may result in

deep-seated infections. One case of vertebral osteomyelitis that occurred after a woman accidentally inoculated the organism into the paravertebral space by penetration of a fish bone through the posterior pharynx has been reported.[28] In a similar case, a fish bone stuck in the throat for 2 months eventually led to a spinal epidural abscess.[21] Infection commonly occurs after clenched-fist injury as a result of fistfighting.[13] Hand infections in children are more likely to be secondary to digital biting or sucking.[15] Intravenous drug abusers are at risk for injection site and soft tissue abscesses,[14] bacteremia, and endocarditis.[9,31] Elderly persons and patients with advanced carcinomas are the other high-risk groups. However, children are at particularly high risk for serious *E. corrodens* infections.[37] Reports of thyroid abscesses[7,46] and purulent thyroiditis[36] all have been in children. In one review,[23] more than 20 percent of *E. corrodens* pleuropulmonary infections occurred in children younger than 14 years of age, and more than 50 percent of abdominal infections were reported in patients younger than 25 years of age.[8] *E. corrodens* orbital cellulitis,[16] empyema,[41] peritonsillar abscess,[25] paronychia,[1] and osteomyelitis[34,40] have been observed in children. A review of 54 cases of *E. corrodens* infection in children and adolescents revealed that 41 percent of pediatric infections occurred in the head and neck. The most common single site was the thyroid gland.[32]

PATHOPHYSIOLOGY

E. corrodens infections often are polymicrobial[44] and may include other anaerobes or gram-negative rods. However, *E. corrodens* is accompanied most frequently by recovery of alpha-hemolytic streptococci. In most reports, the streptococci were not speciated further, but Jacobs and associates[20] made a case for the *Streptococcus anginosus* group because of similarities between the two organisms (i.e., both are found in the mouth and gastrointestinal tract, both produce local suppurative infection, and both thrive in carbon dioxide-rich, oxygen-poor environments). Brooks and colleagues[4] also reported synergy of the two organisms in a rabbit model of skin infection. In vitro studies of *E. corrodens* co-cultivated with members of the *S. anginosus* group showed that a significant degree of co-aggregation occurs. Additionally, exponential growth of *Streptococcus constellatus* and *Streptococcus intermedius* occurs 6 hours into incubation when these species are grown in the presence of *E. corrodens*; in its absence, exponential growth does not occur until 25 hours after inoculation.[48]

The possible role of *E. corrodens* in periodontitis has not been delineated precisely. However, soluble products of *E. corrodens* induce gene expression and protein production of vascular endothelial growth factor and cause phosphorylation of mitogen-activated protein kinase in vitro, a process that leads to increased production of interleukin-8 and adhesion molecules.[49] This cascade of inflammatory responses could promote chronic periodontitis.

E. corrodens has a propensity toward formation of an abscess in any location, whether alone or in concert with other organisms. Such formation is a hallmark of central nervous system infection.[3] Of intra-abdominal infections reported by Danziger and associates,[8] 15 of 19 patients had abscesses. In two cases of orbital cellulitis reported by Hemady and coworkers,[16] both patients had subperiosteal abscesses. Deep or superficial skin abscesses reported in drug addicts[14] or in clenched-fist injury from fistfighting[13] often recur, even after presumed adequate drainage.[35]

CLINICAL MANIFESTATIONS

Infections with *E. corrodens* are indolent. The time from inoculation to onset of symptoms generally is 1 week or longer.[4] Many cases show initial improvement with treatment but relapse days later, even with appropriate therapy.[15,25,33,37] The head and neck are the most common sites of infection at all ages.[32]

Infection of periodontal sites may be associated with rapid progression and bone resorption thought to be secondary to surface-associated materials of *E. corrodens* and other organisms of periodontitis.[29] Craniofacial and neck infections tend to have prolonged morbidity; many require repeated drainage procedures and long courses of antimicrobial agents.[37] Central nervous system infections often are preceded by sinus infections but also have been seen in children with congenital heart disease.[2,45]

Pleuropulmonary infections are marked by fever, cough, and chest pain. Necrotizing pneumonia with multiple abscesses sometimes is seen. Effusions or empyema are noted in 30 percent, and cavitation is seen in 8 percent. Children with a predisposition toward aspiration may be at higher risk.[23] In one case, a bedridden 16-year-old girl developed a bronchopleural-cutaneous fistula complicating necrotizing pneumonia with empyema.[47]

Endocarditis is associated with large, friable vegetations and frequent emboli and often requires valve replacement.[11] Intravenous drug use has been implicated in approximately half of reported cases.

Abdominal *E. corrodens* infections are seen most commonly as complications of ruptured appendicitis but also have been associated with abdominal trauma and surgery. The clinical course is protracted.[8]

Chorioamnionitis leading to premature delivery has been documented infrequently. In one case, the infection precipitated the birth of twins at 23 weeks' gestation and led to the demise of one twin.[22,24,43]

Soft tissue infections tend to be severe. Many require wide débridement and skin grafting. Infection of underlying joints, tendons, or bones is not infrequent and can be necrotizing and even lead to amputation.[35]

DIAGNOSIS

Definitive diagnosis rests on recovery of *E. corrodens* in culture, which can be a difficult task because of the organism's slow growth. *Eikenella* tends to be overgrown by hardier species when it is part of a polymicrobial process and may be missed, especially if the isolate does not pit the agar. All the HACEK organisms can pit agar,[5] although not with the regularity of *E. corrodens*.

Many bacteriology laboratories have difficulty identifying and separating catalase-negative, oxidase-positive, gram-negative rods. Not surprisingly, one report noted that of 100 isolates of *E. corrodens* identified by the National Collection of Type Cultures, only 21 were sent in as probable *E. corrodens*.[5] Organisms that *E. corrodens* may be mistaken for include the other HACEK organisms, *H. paraphrophilus*, *Moraxella atlantae*, and *Actinobacillus ureae*.

TREATMENT

E. corrodens has a very unusual antimicrobial susceptibility pattern, in that although most isolates are sensitive to penicillin and ampicillin, they are resistant to semisynthetic penicillins, such as methicillin and nafcillin.[42] Additionally, these organisms uniformly are resistant to clindamycin and metronidazole,[18] drugs commonly used to treat anaerobic infections. They also variably are resistant to aminoglycosides.

Most isolates are sensitive to piperacillin, second- and third-generation cephalosporins, and tetracycline. In one report, all of 31 *Eikenella* isolates derived from normal oral flora were sensitive to azithromycin in vitro.[30] Although penicillin often is cited as the drug of choice, some strains produce β-lactamases. One

report associated the β-lactamase with a transposon[26] and another with a plasmid[39]; one report found a chromosomal enzyme that was not inducible.[27] In addition, there are reports of intermediate resistance to penicillin, even in isolates that do not produce a β-lactamase.[12]

Incision and drainage of abscesses and débridement of necrotic tissue are essential to recovery from these infections. Therapy should be prolonged after patients apparently have recovered because early cessation of antibiotic therapy tends to be associated with relapse. If patients continue to have fever or other signs of infection days after appropriate therapy has been started, reimaging of the infected area may be prudent to detect early reaccumulation of purulence.

Acknowledgments

I would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 134

Elizabethkingia and *Chryseobacterium* Species

Randall G. Fisher

Members of the genus *Chryseobacterium* (formerly *Flavobacterium*) seldom are associated with human infection. Most disease occurs after exposure to a contaminated environmental source. In 1944, Shulmann and Johnson[50] reported a case of meningitis caused by a previously unidentified, gram-negative bacillus isolated from a 9-day-old premature infant. The term *Flavobacterium meningosepticum* was proposed for this organism by King[30] in 1959, based on her studies of bacterial isolates associated primarily with neonatal meningitis and septicemia. Although neonatal meningitis is the most common manifestation of human disease caused by this genus,[15,55] sepsis,[14,23,42,52] endocarditis, pneumonia,[44] septic arthritis with penetrating trauma or prosthesis,[22,31] and skin infection[19] (including one case of necrotizing fasciitis)[32] occur in individuals beyond the newborn period.[3]

BACTERIOLOGY

The taxonomy of these organisms is confusing because of frequent changes. All but one of the clinically relevant species of the original genus *Flavobacterium* were reclassified to the new genus *Chryseobacterium* in 1994.[59] Phylogenetic analysis based on 16S rRNA sequencing demonstrated that the organisms formerly classified as *Chryseobacterium meningosepticum* and *Chryseobacterium miricola* represent a separate lineage. Researchers proposed that these two organisms be moved to a new genus, named *Elizabethkingia* after the microbiologist who first described them.[29] The former *Flavobacterium odoratum*, rarely responsible for human disease, has been divided into two species (*odoratus* and *odoratimimus*) reclassified as members of the genus *Myroides*.[58] *Chryseobacterium indologenes* is the species isolated most frequently from human specimens, but it usually is not associated with significant disease. Therefore, this chapter focuses mainly on *Elizabethkingia meningosepticum*, which can cause severe infections, especially in newborns. These organisms are long, thin, catalase-positive, gram-negative rods with slightly swollen ends; they are nonmotile, oxidase-positive, weakly fermentative, and proteolytic and grow on solid agar as 1- to 2-mm, convex, glistening colonies of buttery consistency.[30] Yellow pigmentation is seen occasionally. Colonies do not demonstrate hemolysis on blood agar but may produce a lavender-green color in the surrounding media as a result of extensive proteolytic enzyme activity. *Elizabethkingia* is unable to grow on Salmonella-Shigella agar or Simmons citrate and lacks motility. These characteristics distinguish *Elizabethkingia* from *Pseudomonas*, with which it often is confused.[15] Similarly, utilization of glucose in an open tube of oxidation-fermentation media distinguishes *Elizabethkingia* from *Achromobacter faecalis*.[15] The clinically relevant species *E. meningosepticum* (also referred to interchangeably in the current literature by its old name *Chryseobacterium meningosepticum* and in the older literature as *Flavobacterium meningosepticum*) and *Flavobacterium IIB* (renamed *Flavobacterium balustinum*) are differentiated by the former's consistent liquefaction of gelatin and early utilization of mannitol and maltose and the latter's lack of these abilities.[30] *Myroides odoratus* and *Myroides odoratimimus* (*F. odoratum*), which have been identified most commonly as saprophytes in skin wounds,[26] characteristically are nonsaccharolytic and produce a fruity odor when they are grown on standard media.

EPIDEMIOLOGY

Elizabethkingia spp. and *Chryseobacteria* are distributed widely as saprophytes in fresh and salt water, as well as in the soil. *E. meningosepticum* has been identified as a pathogen in birds.[57] In hospitals, these organisms have been found to be ubiquitous colonizers of the patient's environment and have been isolated from flower vases,[54] ice machines,[52] vials of intravenous drugs,[42] and nebulizers.[16] In addition, tap water,[16] eyewashes,[45] tube feedings,[16] sink traps,[8] and hand cultures of hospital personnel[16] have yielded this organism. In some instances, these reservoirs have been implicated in nosocomial outbreaks of patient colonization and invasive disease.

Neonatal infection caused by *E. meningosepticum* has been reported frequently in the literature, often in association with nursery epidemics.[2,7,47] As with other neonatal pathogens, infants who are premature and small for gestational age seem to be at particular risk of infection. More than 50 percent of infected infants weigh less than 2500 g. Almost all cases occur within 3 weeks of birth, and more than 50 percent of these infants manifest illness before they are 7 days old.[15]

Nosocomial epidemics have occurred sporadically since the nursery outbreak reported by Brody and colleagues in 1958.[2,5,7,8] Cabrera and Davis[8] reported such an outbreak in detail in 1960. During a 3-month period, the bacteria were isolated from a total of 44 infants, of whom 14 had overt infection. Most colonized infants had organisms isolated from the nasopharynx. The only reservoir of infectious bacteria discovered was a faulty sink trap, beneath which cleaning materials for the nursery were stored. Repair of the defective trap and thorough cleansing and repainting of the nursery coincided with termination of the epidemic. More recently, clusters of neonatal and adult systemic infections caused by atypical strains of *E. meningosepticum* were reported from Taiwan. These strains initially were identified erroneously as *Aeromonas salmonicida*.[12]

Nursery outbreaks of *E. meningosepticum* have been traced to saline used to flush infants' eyes after administration of silver nitrate,[45] and organisms have been recovered from washbasins sinks, disinfectants, and suction devices in other epidemics.[8] Colonization of patients in a surgical intensive care unit was associated with tap water, sinks, ice machines, and washbasins yielding the bacteria.[16] Ribotyping and random amplified polymorphic DNA fingerprinting (RAPD) offer promise for more precise characterization of epidemics.[12,13]

PATHOPHYSIOLOGY

Elizabethkingia spp. and *Chryseobacterium* spp. generally are of low virulence. Rabbits administered 1-mL intravenous infections of 24-hour-old broth cultures demonstrated no mortality or morbidity; death rates were less than 30 percent in mice inoculated intracerebrally with "barely turbid" preparations.[30]

Most cases of invasive human disease are thought to be caused by environmental contamination with high numbers of *E. meningosepticum*, with spread to the compromised newborn or debilitated older patient. Some neonatal infections may be caused by colonization of the infant during passage through the birth canal of a colonized mother.[13] Intrapartum infection is supported by

occurrence of symptoms as early as 10 hours after birth.[15] However, only 0.3 percent of genital swabs submitted from patients with suspected venereal disease yielded the organism.[41] Continuing reports of *E. meningosepticum* as a cause of neonatal infection in developing countries have been speculated to be related to use of contaminated groundwater for bathing of newborn infants and feminine genital hygiene.[15] The propensity for this organism to produce meningitis in the newborn is not understood, but infection may occur in association with heavy nasopharyngeal colonization, leading to subsequent bacteremia and seeding of the meninges.

Cases in older children have been related to insulin-dependent diabetes mellitus,[9] thalassemia major with splenectomy,[43] and oncologic disease with indwelling catheters.[40] Peritonitis in patients undergoing continuous ambulatory peritoneal dialysis, including a case series of 30 patients, also has been reported.[44]

In older individuals, *E. meningosepticum* and chryseobacteria primarily play the role of opportunists.[38,91] Heavy nosocomial colonization combined with a blunted immune response probably accounts for the immunocompromised patient's poor capacity to handle this otherwise noninvasive bacterium.

CLINICAL MANIFESTATIONS

Neonatal sepsis and meningitis caused by *E. meningosepticum* share signs and symptoms in common with other forms of neonatal bacterial infection. However, the development of meningitis may be insidious, and several days of illness often pass before its presentation[15,47]; this factor is consistent with the low virulence of *E. meningosepticum* in comparison with other agents of neonatal sepsis. Prognosis is extremely poor, and mortality rates may exceed 60 percent.[33] Fifty percent of survivors develop significant neurologic complications, often in association with hydrocephalus.[34]

These organisms are uncommon pathogens in adults, and childhood disease occurring beyond the newborn period is extremely rare. Among the 24 initial isolates of *E. meningosepticum* identified by King,[30] organisms were identified in a throat culture from an adult patient and in cerebrospinal fluid (CSF) from an 8-month-old infant. Bacteria formerly classified as *Flavobacterium IIB* (now known as *F. balustinum*) were isolated from the blood and CSF of several adult patients without clinical information.[27] Since their initial identification in 1959, these agents have been implicated as causes of meningitis,[38,47] postoperative bacteremia,[3,41] bacterial endocarditis,[61] pneumonia,[53,54] catheter-associated infection, septic arthritis, and skin infection.[19] *E. meningosepticum* is the clinically relevant species most commonly isolated, but *C. balustinum*, *M. odoratus* and *M. odoratimimus* (*F. odoratum*), and other *Chryseobacterium* spp. have been implicated in human disease. *Elizabethkingia* and *Chryseobacterium* spp. accounted for 0.25 percent of infections in a large consecutive series of patients with human immunodeficiency virus infection. Risk factors included low CD4 counts and leukopenia.[37]

E. meningosepticum meningitis beyond the neonatal period typically occurs in immunocompromised patients. Adults with preexisting leukemia,[47] glomerulonephritis,[38] and squamous cell carcinoma[23] have been described as having meningitis caused by this organism. In a 56-year-old woman, meningitis with *E. meningosepticum* developed after she underwent transsphenoidal hypophysectomy[10]; in an 8-month-old male child with preceding severe neurologic damage, meningitis developed with bacteria designated by the Centers for Disease Control and Prevention as *Flavobacterium*-like organisms (IIE). In a 6-week-old infant, *E. meningosepticum* bacteremia and meningitis developed in association with a strangulated hernia.[15]

Elizabethkingia and *Chryseobacterium* spp. were isolated frequently from tracheal aspirates of patients in intensive care during a 70-month observation period; yet during that time, none of more than 2000 critically ill patients developed pneumonia attributable to these microbes.[16] However, true respiratory tract infection was identified in an intubated pediatric patient and in adults receiving aerosolized medications.[6,54]

Sporadic cases of bacteremia have been reported in adult patients.[23,35] Infection in immunocompromised patients can occur as a complication of relatively benign invasive procedures or as a localized infection.[35,51] Endocarditis was documented in intravenous drug abusers and in patients undergoing dialysis.[18,61] Postoperative bacteremia in eight adult patients was linked to contaminated intravenous medications infused during anesthesia.[42] Contaminated arterial catheters were implicated in an epidemic of *Chryseobacterium* bacteremia.[52] Four patients, including a 7-year-old boy, became bacteremic in an outbreak associated with contamination at the time of intracardiac surgery.[3] This organism also has been associated with bacteremia in pediatric burn patients.[49]

Chryseobacterium spp. also have been isolated from infected skin lesions manifesting as papules, sheet-like lesions, plaques, and deep panniculitis.[19] One fatal case of necrotizing fasciitis in a patient with diabetes mellitus and chronic heart failure was reported.[32] Infection may have been related to wound contamination during repair of an orthopedic injury. Chryseobacteria have been isolated from amputation stumps, but the bacteria may play a largely saprophytic role at these sites.[26]

DIAGNOSIS

Rapid identification of infection with these organisms is urgent, not only to ensure providing proper therapy for the patient, but also to hasten initiating appropriate infection control measures to forestall epidemic outbreaks. Identification of *E. meningosepticum* is hindered by characteristically long periods required for oxidation of carbohydrates and weak or delayed indole production. Cultures may be misidentified as species of *Achromobacter* or *Pseudomonas*.[15] Clinical isolation of an unidentified gram-negative rod that is catalase- and oxidase-positive and that shows multiple antibiotic resistance should raise suspicion of *E. meningosepticum* infection. Cultures should be kept for several days for observation for typical carbohydrate reactions, which confirm the diagnosis.[15,46] Pulse-field gel electrophoresis of DNA was used successfully to identify recurrence of intravenous catheter-associated infection in a 6-year-old boy with non-Hodgkin lymphoma.[4,48]

TREATMENT

Unfortunately, treatment of *E. meningosepticum* meningitis represents an especially difficult challenge for the physician. The organism is paradoxically likely to be sensitive to drugs commonly employed against gram-positive organisms (rifampin, vancomycin, clindamycin, trimethoprim-sulfamethoxazole) and resistant to those used to treat gram-negative infections (aminoglycosides, cephalosporins, tetracyclines, carbapenems). Most *Elizabethkingia* and *Chryseobacterium* spp. produce broad-spectrum metallo–β-lactamases. In *E. meningosepticum*, the enzyme is highly efficient at hydrolyzing carbapenems. Inactivation of cephalosporins displays a remarkable variability that is based on the affinity of the enzyme for the different compounds.[60] Delay in establishing a specific identification of the organism occurs commonly, so the physician knows only that the organism is gram-negative, often resulting in prolonged periods of suboptimal therapy because recommended empiric antimicrobial treatment of gram-negative neonatal meningitis usually consists of a third-generation cephalosporin or ampicillin and an aminoglyco-

side, drugs to which *E. meningosepticum* almost uniformly is resistant. Moreover, antimicrobial susceptibilities determined by disk diffusion must be interpreted with caution. Aber and associates[1] found clinical isolates in which specific strains were sensitive to gentamicin and rifampin by disk diffusion but were resistant by agar gel dilution susceptibility testing. Therefore, more direct methods of measuring the minimal inhibitory concentration than disk diffusion sensitivity should be used to determine the optimal microbial agents for therapy.

Probably as a consequence of difficulties encountered in providing rapid and effective antibacterial therapy, these organisms frequently persist for prolonged periods in CSF. Average persistence of *E. meningosepticum* in CSF is 19 days,[15] as compared with the 3.9 days described by McCracken[39] for most cases of gram-negative neonatal bacterial meningitis.

Studies of in vitro susceptibility data forced a reappraisal of the idea that vancomycin is a good first-line choice for the treatment of chryseobacterial infection. In one report, a literature review showed that only 65 percent of historic isolates were susceptible to vancomycin[4]; in another, a thorough search for a susceptible organism among 58 clinical isolates met with utter failure.[20] Ninety-seven percent of *E. meningosepticum* isolates were susceptible to rifampin. Clinically, drugs that have been used alone or in combination with some success have included erythromycin, vancomycin, trimethoprim-sulfamethoxazole, fluoroquinolones (especially sparfloxacin and levofloxacin), and rifampin.[56] Some of these agents have the potential disadvantage of poor penetration of CSF. Combined use of many of these drugs renders interpreting therapeutic response difficult. The 3 survivors among the 12 patients reported by George and associates[21] all received vancomycin intravenously, intrathecally, or both, as a part of their regimen. Hawley and Gump[24] reported a case of *E. meningosepticum* meningitis in a neonate who responded to systemic vancomycin after unsuccessful treatment with multiple antibiotics, including erythromycin.

Intraventricular erythromycin[17,47] or rifampin[11,33,34,47] has been used in conjunction with systemic administration of these drugs. In particular, Lee and associates[34] reported no deaths in seven infants with *E. meningosepticum* meningitis who were treated with intraventricular rifampin through an Ommaya reservoir at a dose of 2 to 5 mg every 24 hours combined with 40 mg/kg/day administered intravenously. Intraventricular administration continued until the CSF was sterile. However, colonization of the Ommaya reservoir was a common finding, and formation of a porencephalic cyst occurred in one patient. Chandrika and Adler[11] reported sterilization of ventricles in one afflicted neonate within 48 hours after institution of therapy with intraventricular and intravenous rifampin. Erythromycin has been used intraventricularly with limited success at 5 to 10 mg/day.[17,47] Rios and Associates[47] reported the successful addition of intraventricular rifampin to a failing regimen of intravenous and intraventricular erythromycin. Development of resistance during therapy has been demonstrated with erythromycin and rifampin[17,47]; persistence of organisms in the CSF despite administration of presumably adequate therapy should alert the physician to test for this possibility. Addition of trimethoprim-sulfamethoxazole may be of benefit with such an occurrence; this agent effected a bacteriologic cure in eight of nine infants with meningitis.[36] This agent usually is not recommended in the neonatal period because of possible displacement of bilirubin from albumin-binding sites. Bacterial eradication was achieved in 48 hours in two patients with meningitis who were treated with clindamycin, rifampin, and cefotaxime systemically and rifampin intraventricularly.[7]

As with other types of gram-negative meningitis, antimicrobial therapy should be continued for at least 2 weeks after sterilization of ventricular fluid has been achieved. Complications of hydrocephalus and the potential use of intraventricular therapy render the neurosurgeon an essential part of the management team. Historically, mortality has been in excess of 70 percent, no doubt in part because of delays in identifying the organism and the limited antibiotic spectrum available for effective therapy. More recent series of patients, although small, suggest some improvement in this statistic, but the rate of morbidity of hydrocephalus and neurologic deficits remains high.

Recovery has been the rule in immunocompetent older individuals infected with contaminated materials, often despite treatment with antibiotics to which the organism was insensitive, a finding highlighting the very low virulence of these organisms in immunocompetent adults.[38] However, significant mortality and morbidity often occur in immunocompromised individuals with bacteremia or meningitis. Use of chloramphenicol, vancomycin, levofloxacin, erythromycin, or rifampin has achieved some success in these patients, but the choice of antibiotic must be based on a detailed examination of the organism's susceptibility.[25,49]

Acknowledgments

I would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 135

PSEUDOMONAS AND RELATED GENERA

Michael T. Brady

The original classification of the genus *Pseudomonas* described a wide variety of aerobic gram-negative rods divided into five rRNA homology groups (homology groups I to V). The genus since has undergone extensive revision, with four of the five homology groups being reclassified into separate genera (Table 135–1).[83] This reclassification was accomplished by using DNA-rRNA hybridization, DNA-DNA hybridization, and 16S rRNA sequencing techniques.

Pseudomonas and related genera are aerobic, motile, non–spore-forming, nonfermentative, gram-negative bacilli that live in soil, in water, and on plants and animals. Most organisms of these genera are ubiquitous and rarely pathogenic in humans. Although the pseudomonads may produce disease in any individual, they usually are opportunists that more commonly cause disease in patients with burns, cystic fibrosis, malignant diseases, and immunodeficiency conditions; in recipients of immunosuppressive therapy; or in malnourished persons. The most important of the opportunistic pseudomonads is *Pseudomonas aeruginosa*. However, numerous other pseudomonads cause specific clinical syndromes in children.

TABLE 135–1 Recent Toxignomic Changes and Reclassification of *Pseudomonas* Homology Groups I to V That Cause Disease in Humans

Homology Group	Previous Designation	Current Designation
I		*Pseudomonas aeruginosa*
		Pseudomonas fluorescens
		Pseudomonas putida
		Pseudomonas stutzeri
		Pseudomonas mendocina
		Pseudomonas pseudoalcaligenes
		Pseudomonas alcaligenes
		Pseudomonas (CDC group 1)
	Chryseomonas luteola	*Pseudomonas luteola*
	Flavimonas oryzihabitans	*Pseudomonas oryzihabitans*
II	*Pseudomonas cepacia*	*Burkholderia cepacia*
	Pseudomonas gladioli	*Burkholderia gladioli*
	Pseudomonas mallei	*Burkholderia mallei*
	Pseudomonas pickettii	*Ralstonia pickettii*
	Pseudomonas pseudomallei	*Burkholderia pseudomallei*
III	*Pseudomonas acidovorans*	*Delftia acidovorans*
	Pseudomonas testosteroni	*Comamonas testosteroni*
	Pseudomonas delafieldii	*Acidovorax delafieldii*
	Hydrogenomonas facilis	*Acidovorax facilis*
IV	*Pseudomonas diminuta*	*Brevundimonas diminuta*
	Pseudomonas vesicularis	*Brevundimonas vesicularis*
V	*Xanthomonas maltophilia*	*Stenotrophomonas maltophilia*
		Stenotrophomonas africana

CDC, Centers for Disease Control and Prevention.
Data from Gilligan, P. H., and Whitier, S.: Burkholderia, Stenotrophomonas, Ralstonia, Brevundimonas, Comamonas, and *Acidovorax. In Murray, P. R., Baron, J., Pfaller, M. A., et al. (eds.): Manual of Clinical Microbiology. 7th ed. Washington, D.C., ASM Press, 1999, pp. 526-538.*

ETIOLOGY

Pseudomonas spp. usually are gram-negative obligate aerobes (oxygen as the terminal electron acceptor), but they can grow anaerobically in the presence of nitrates or arginine (terminal electron acceptors). They lack the phosphoenolpyruvate-hexose-phosphotransferase system and catabolize carbohydrates by the Entner-Doudoroff pathway. Because pseudomonads can use a wide variety of carbon sources (simple and complex carbohydrates, alcohols, and amino acids), they can survive and multiply in almost any moist environment containing minimal amounts of organic compounds.

P. aeruginosa is the most clinically important species of the genus *Pseudomonas*. It is an oxidase-positive, gram-negative rod varying in size from 0.5 to 0.8 μm by 1.5 to 3.0 μm. Most strains are motile by one or more polar, monotrichous flagella and display fine projections (pili or fimbriae). *P. aeruginosa* grows readily on standard laboratory media. It grows optimally at 37° C but not at 4° C. Clinical *Pseudomonas* isolates are oxidase-positive (except for *Pseudomonas luteola* and *Pseudomonas oryzihabitans*) and catalase-positive. On MacConkey agar, *Pseudomonas* spp. are identified as nonlactase fermenters. They do not ferment carbohydrates but do oxidize monosaccharides such as glucose and xylose, but not maltose. Strains from clinical specimens may produce beta-hemolysis on blood agar. More than 90 percent of *P. aeruginosa* organisms produce a bluish-green phenazine pigment (pyocyanin-blue pus), as well as fluorescein, a yellow-green fluorescent pigment. Occasional *Pseudomonas* strains also produce dark red (pyorubin) or black (pyomelanin) pigment. These pigments diffuse into and color the medium surrounding the colonies. Strains of *P. aeruginosa* can be differentiated from one another for epidemiologic purposes by serologic typing, phage typing, ribotyping, and pyocin (bacteriocin) typing.

EPIDEMIOLOGY

P. aeruginosa is a ubiquitous environmental organism found in soil, in water, and on vegetation, including the surface of many raw fruits and vegetables. It was recognized first as a pathogen when Gessard recovered it from green pus in 1882. Its minimal nutritional requirements and ability to grow in a wide variety of physical environments enhance the organism's ability to survive in numerous ecologic niches. *P. aeruginosa* is found infrequently as normal microflora of healthy humans. The gastrointestinal (GI) tract is the most frequent site of human colonization. As many as 5 to 30 percent of normal persons have *P. aeruginosa* in their GI tract, although it rarely is the predominant organism. The large intestine is the most frequent site of transient colonization after ingestion. Other moist body sites that may become colonized include the throat, nasal mucosa, axillae, perineum, and the respiratory tract of patients who have been hospitalized for extended periods, have foreign bodies in place (endotracheal tubes or tracheostomies), have poor mucociliary clearance, and have received broad-spectrum antibiotics or chemotherapy. In general, *P. aeruginosa* is an opportunistic and not a frank pathogen. Despite the ability to colonize skin and mucosal surfaces, it rarely results in persistent colonization, it does not produce specific toxic factors that damage host tissues, and it is not capable of invading normal skin or mucosa. *P. aeruginosa* proves most effective as a pathogen in situations in which the host's immune defenses are diminished or lacking (e.g., poor mucociliary clearance in children with cystic fibrosis, neutropenia in children receiving chemotherapy for cancer, damaged skin barriers in burned patients).

P. aeruginosa frequently enters the hospital environment on the clothes, skin, respiratory tract, or shoes of patients or hospital personnel; colonization of any moist environment ensues. Thus, these organisms may be found growing in distilled water, hospital kitchens and laundries, mops, shower heads, whirlpools, antiseptic solutions, eyedrops, irrigation fluid, dialysis fluid, and equipment used for dialysis and respiratory care or inhalation therapy. Transmission of *P. aeruginosa* from patient to patient or from hospital personnel to patient often is assumed but rarely is documented.[54,242] In hospitalized patients, the likelihood of *Pseudomonas* colonization increases with the duration of hospitalization.

Sources of *Pseudomonas* outside the hospital that may result in colonization with subsequent infection include swimming pools, water slides, hot tubs, contact lens solutions, cosmetics, illicit injectable drugs, and the inner soles of sneakers. *P. aeruginosa* commonly is found on the surface of many types of raw fruits and vegetables. Consumption of these foods by profoundly immunosuppressed children can result in GI colonization and potentially can lead to invasive disease.

The environmental distribution of most of the other *Pseudomonas* spp. and related genera is similar to that of *P. aeruginosa*. *Pseudomonas pseudoalcaligenes* has one of the more unusual habitats. This organism has been identified in metalworking fluid (a mixture of water and petroleum products) at concentrations as high as 10^8 organisms per milliliter or higher. Metalworkers are exposed to aerosols containing high concentrations (10^5 organisms per milliliter) of *P. pseudoalcaligenes*.[138] Despite the development of high antibody levels to *P. pseudoalcaligenes*, these metalworkers with long-term exposure do not have clinical evidence of any acute or chronic respiratory or systemic disease.

Burkholderia, formerly *Pseudomonas cepacia*, is a plant pathogen that is ubiquitous in nature and can be found in water, soil, and decaying organic matter.[124] *Burkholderia cepacia* is an obligate aerobic, gram-negative rod that is intrinsically resistant to a wide range of antimicrobial agents, including aminoglycosides and carboxypenicillins (e.g., ticarcillin, azlocillin, and piperacillin). Historically, it was regarded as an organism with low pathogenicity. However, *B. cepacia* has been identified increasingly as a cause

of sporadic nosocomial outbreaks of infection in medical intensive care units. Outbreaks are far less common than with *P. aeruginosa*. When they occur, they have been traced to contaminated automated peritoneal dialysis machines, blood gas analyzers, povidone-iodine, and chlorhexidine.[20,21,88,215] *B. cepacia* can survive for extended periods in moist environments and even in the presence of disinfectants, including povidone-iodine.[6] Colonization of the respiratory tract, sometimes associated with endobronchial infection in patients with cystic fibrosis, is becoming a more common occurrence and is associated with increased morbidity and mortality. This organism also has become more important as a cause of infection and complications in patients with chronic granulomatous disease[219] and sickle-cell hemoglobinopathies.[22]

Stenotrophomonas maltophilia (formerly *Xanthomonas maltophilia*) is an aerobic gram-negative rod that grows readily on most bacteriologic media. *S. maltophilia* is being isolated with increasing frequency in hospitalized patients. Colonization of nonsterile sites such as the respiratory tract and wounds in the absence of clinical disease occurs commonly in hospitalized patients receiving long-term or broad-spectrum antibiotics. However, clinical illnesses such as pneumonia, urinary tract infections, endocarditis, bacteremia, meningitis, and peritonitis have been reported.[16,61,73,149,231] Isolation of *S. maltophilia* from the respiratory tract of patients with cystic fibrosis is increasing; in some centers, it is the second most frequent gram-negative bacterium isolated from sputum.[13,117]

Burkholderia pseudomallei is most prevalent in the tropical and subtropical areas of Southeast Asia and northern Australia. *B. pseudomallei* has been recovered frequently from rice paddy surface water in rice-growing areas of northern Thailand.[47,216]

PATHOGENESIS

The pathogenesis of *Pseudomonas* infections is multifactorial.[17,133] Although *P. aeruginosa* is not uncommonly a human saprophyte, it usually causes disease as an opportunistic pathogen. *P. aeruginosa* is a significant cause of infection in compromised hosts. Its ability to adapt to a variety of environments, its minimal nutritional requirements, and its propensity for the development of antibiotic resistance allow *P. aeruginosa* to survive in compromised patients. The requirement of oxygen for growth may account for the lack of invasiveness of these organisms after they have colonized and even infected the skin. *P. aeruginosa* possesses a variety of virulence factors, including an endotoxin, an enterotoxin, numerous extracellular enzymes, and cell-bound organelles such as flagella and pili. *P. aeruginosa* endotoxin is not as potent as are the endotoxins produced by other gram-negative organisms (2 to 3 mg needed to kill a 20-g mouse). However, *P. aeruginosa* endotoxin does protect the organism from the effects of complement and triggers cytokine pathways that lead to the sepsis syndrome and shock. This endotoxin may produce a diarrheal syndrome. A *Pseudomonas* enterotoxin also has been described, but its role in causing diarrhea in humans remains unclear.

The extracellular enzymes of *P. aeruginosa* include lecithinase, collagenase, lipase, elastase (LasA and LasB), caseinase, gelatinase, fibrinolysin, hemolysin, alkaline protease, phenazines, phospholipase C, exoenzyme S, exoenzyme U, and exotoxin A. The proteolytic enzymes may be responsible for localized necrosis of the skin or lung and for corneal ulceration. Exotoxin A is an adenosine-5′-diphosphate ribosyltransferase enzyme that inhibits the synthesis of eukaryotic cell protein (same mechanism as diphtheria toxin). Specific exotoxin A–deficient mutants of *P. aeruginosa* have reduced virulence in producing infection of the cornea or lung in mice and rats.[161,245] Exotoxin A also diminishes the activity of host phagocytes. Passive or active immunization against exotoxin A significantly protects against experimental infection with exotoxin-producing strains of *P. aeruginosa*. Phospholipase C degrades phospholipids, which are plentiful in eukaryotic but not prokaryotic cell membranes. The hemolysis produced by *P. aeruginosa* may be caused by heat-labile phospholipase C and by a heat-stable moiety. Exoenzyme S is another virulence factor.

In patients with burn injuries, *P. aeruginosa* growing in the burned area produces exoenzyme S; *P. aeruginosa* on intact skin does not.[158] In burned patients in whom *Pseudomonas* sepsis develops, exoenzyme S can be found in the blood before the bacteria can be detected. *P. aeruginosa* strains that lack exoenzyme S production are less able to cause invasive disease.[198]

The various proteases also can degrade numerous plasma proteins such as complement and coagulation factors.[246] Solubilization and destruction of lecithin (surfactant) may play a role in the atelectasis seen in pulmonary infections caused by *P. aeruginosa.* A leukocidin also has been described that may in part be capsular material. The purified slime from *Pseudomonas* is nontoxic. Pigments produced by *P. aeruginosa* also are nontoxic.

Surface structures such as pili and fimbriae are involved in attachment of *P. aeruginosa* to the epithelial cells of mucosal surfaces. *P. aeruginosa* that lack flagella are less capable of dissemination from wounds and of causing bacteremia and pneumonia in animal models.[8,55,65] *P. aeruginosa* preferentially binds to normal respiratory mucin, in contrast to some members of the family Enterobacteriaceae.[234] Fibronectin may protect epithelial cells from bacterial attachment, but the ability to do so is reduced in patients with cystic fibrosis (high levels of protease in respiratory secretions) and after cellular injury (trauma after intubation and viral infection of the lower respiratory tract, especially influenza virus). The glycocalyx (extracellular slime layer) is important in allowing *P. aeruginosa* organisms to adhere to each other and form microcolonies, which impair phagocytosis and antibody and antibiotic activity.

The pathogenicity of *P. aeruginosa* also depends on its ability to resist phagocytosis. Fick and Reynolds[69] noted that in patients with cystic fibrosis, the opsonic function of immunoglobulin G (IgG) was reduced as a result of a molecular change in the Fc portion of the IgG molecule. This deficit was magnified in the lungs of patients with cystic fibrosis infected with *P. aeruginosa* because bacterial proteases can fragment IgG and further impair its opsonic activity, which already may be marginal. The persistent presence of *P. aeruginosa* in the lungs of patients with cystic fibrosis also may be related to the presence of one or more factors in their sputum that interfere with the bactericidal activity of fresh normal human serum against *P. aeruginosa*. These blocking factors have been shown to be IgG antibody that blocks the normal bactericidal IgM activity of human sera.[170,203]

Concentrations of IgG subclass immunoglobulins have been studied in patients with cystic fibrosis and compared with values obtained in age-matched healthy children and adults. Pressler and associates[176] noted that in 52 percent of patients with cystic fibrosis, at least one of the four IgG subclasses had an elevated serum concentration in comparison to controls. A significant correlation of elevated serum concentrations of IgG2 (and, to a lesser extent, IgG3) with decreased forced expiratory volume at 1 second was noted. Moss[147] found that patients with cystic fibrosis who were infected with *P. aeruginosa* had markedly elevated serum concentrations of IgG antibodies to the opsonic immunodeterminant, type-specific lipopolysaccharide. This elevation was distributed among all four IgG subclasses, with a significant shift toward IgG3. Sera from patients with cystic fibrosis who were colonized with *P. aeruginosa* had diminished opsonic capacity, but complement-dependent human neutrophil phagocytosis was not impaired. Serum concentrations of IgG4 but not IgG1, IgG2, or IgG3 were correlated inversely with opsonic capacity. On the basis of these data, Moss[147] suggested that high levels of IgG4

antibody to opsonic immunodeterminants may inhibit normal pulmonary clearance of *P. aeruginosa* by pulmonary macrophages in vivo.

P. aeruginosa produces two elastolytic enzymes: LasA and LasB. These enzymes are virulence factors produced during infection. They probably cause direct damage to lung tissue (elastin accounts for 30% of the protein of lung tissue) and interfere with immune clearance of *P. aeruginosa* from the lungs. Berger and associates[18] noted that elastase treatment of isolated polymorphonuclear leukocytes severely impaired the ability of the cells to kill opsonized *P. aeruginosa*. These investigators demonstrated proteolytic degradation of C3b receptors and suggested that it may contribute to the inability of patients with cystic fibrosis to eradicate *P. aeruginosa* from their lungs. Because several cell types, including macrophages, monocytes, B lymphocytes, and some T lymphocytes, all carry the same C3b receptor, the proteolytic activity may cleave this molecule from all these cells, thereby decreasing the phagocytic activity of monocytes and macrophages in these patients. Berger and colleagues[18] demonstrated that optimal interaction between the complement-derived opsonic ligands C3b and iC3b and their respective receptors does not occur in the milieu of the lungs of patients with cystic fibrosis who are infected with *Pseudomonas*. These workers suggested that both *Pseudomonas* and host proteases may contribute to the initiation of a cycle of events in which neutrophils entering the infected lung actually impair phagocytosis rather than eradicate the source of these infections. Breakdown of elastin in the walls of blood vessels possibly may be responsible for the intrapulmonary hemorrhage noted in individuals with cystic fibrosis.

The mucoid strains of *P. aeruginosa* isolated from the respiratory secretions of patients with cystic fibrosis produce large quantities of alginate (composed of acetylated D-mannuronic acid and L-glucuronic acid).[39,220] This polysaccharide polymer not only gives *P. aeruginosa* a mucoid appearance on agar but also has antiphagocytic activity. Alginate also can elicit a significant inflammatory immune response in the lungs of patients with cystic fibrosis that may contribute to the lung damage present after chronic *P. aeruginosa* lung infection.[140] Because of its viscous nature, alginate contributes to the thick bronchial secretions in the lungs of children with cystic fibrosis; these secretions obstruct small airways and impair mucociliary clearance and movement of phagocytic cells. Production of alginate by *P. aeruginosa* is regulated and inducible. Mucoid *P. aeruginosa* loses the mucoid trait when it is serially cultured on laboratory media. Nonmucoid isolates convert to the mucoid (alginate-producing) phenotype when they are inoculated into the lung in a rat model.[198]

The role of lipopolysaccharide in the virulence of *P. aeruginosa* also has been studied. The virulence of several strains of *P. aeruginosa* in burned mice was found to be related directly to lipopolysaccharide integrity.[44] Deficiency of the O side chain of lipopolysaccharide reduced virulence markedly.

S. maltophilia and *B. cepacia* are opportunistic organisms with virulence factors that include intrinsic resistance to many antimicrobials effective in treating infection with *Pseudomonas* spp., an ability to adhere to plastic materials,[111] and elaboration of exoenzymes such as elastase and gelatinase.[152] *B. cepacia* also resists nonoxidative neutrophil killing.[219] For both *S. maltophilia* and *B. cepacia*, the following factors increase the risk of colonization occurring with these organisms, as well as progression from colonization to infection: (1) prolonged hospitalization, especially in intensive care settings[138]; (2) administration of broad-spectrum antibiotics[221]; (3) malignant disease, particularly if associated with immunosuppressive therapy and neutropenia[112,221]; and (4) breaks in mucocutaneous defense barriers, chiefly by instrumentation or the use of invasive devices.[112]

CLINICAL MANIFESTATIONS

P. aeruginosa can produce disease in healthy, immunocompetent children.[64] Generally, when disease occurs in previously healthy children, the organism has been introduced into a minor wound contaminated with water, soil, or vegetative material. This contamination is followed by the development of localized cellulitis that typically progresses to an abscess that exudes green or blue pus. The skin lesions (whether caused by direct inoculation or secondary to septicemia) begin as pink macules that progress to small cutaneous hemorrhagic nodules and eventually to areas of necrosis with eschar formation surrounded by an intense red areola (ecthyma gangrenosum; Fig. 135–1). In addition to skin infections, previously healthy children may experience a number of localized and systemic infections, including septicemia, endocarditis, corneal infection, otitis externa, dacryocystitis, mastitis, mastoiditis, meningitis, pneumonia, diarrhea, necrotizing fasciitis, peritonitis, and urinary tract infection. *Pseudomonas* osteochondritis/osteomyelitis may develop after puncture wounds, particularly of the foot.[72] Systemic *P. aeruginosa* infections in healthy children can be life-threatening, with mortality rates reported as high as 55 percent.[232]

Outbreaks of dermatitis (folliculitis), plantar nodules (*Pseudomonas* hot-foot syndrome), otitis externa, mastitis, and urinary tract infections caused by *P. aeruginosa* have been reported in normal, healthy children after the use of community swimming pools, water slides, recreational whirlpools, or family-owned hot tubs.[63,64,71,85,197,214,236] Pruritic or painful skin lesions (5 to 30 mm) develop several hours to 5 days or longer (mean, 48 hours) after contact with these water sources. Skin lesions may be erythematous, macular, or pustular. In some cases, very tender nodules have been observed.[71] Illness may vary from a few scattered lesions in some patients to extensive truncal involvement in others. The rash is most severe in areas occluded by snug-fitting bathing suits. In some children, malaise, fever, otitis externa, vomiting, sore throat, conjunctivitis, rhinitis, pyuria, abdominal cramps, and swollen breasts may be associated with the dermal lesions.

Multiple serotypes of *P. aeruginosa* have been associated with these outbreaks. The use of whirlpool baths usually involves soaking in water for variable periods. Superhydration of skin and exposure to *P. aeruginosa* result in primary cutaneous infection.[92] Whirlpool water is heated to temperatures higher than 37.8° C (100° F) and frequently is not filtered, thereby allowing for the persistence of desquamated skin. Both these factors are conducive to growth of *P. aeruginosa*.

Otitis externa caused by *P. aeruginosa* has been reported in healthy competitive swimmers who swim repetitively in a pool contaminated with *P. aeruginosa*.[182] The organism also has been associated with a more malignant form of otitis externa manifested by high fever, necrosis of portions of the external ear, facial nerve paralysis, mastoiditis, and osteomyelitis of the temporal bone and basilar skull.[95,154] Rarely, *P. aeruginosa* meningitis results from progression of this infection.[173] Malignant otitis externa usually is associated with predisposing factors such as malnutrition, leukopenia (a disorder of leukocyte function), malignant disease, or diabetes mellitus. Successful management of this condition requires aggressive surgical débridement in addition to appropriate systemic antibiotic therapy.

P. aeruginosa is a common agent of chronic suppurative otitis media (with or without cholesteatoma) and acute and chronic mastoiditis.[33,109,159] Chronic suppurative otitis media is a complication of inadequately treated acute otitis media and is manifested by a perforated tympanic membrane with persistent otorrhea. Chronic suppurative otitis media also occurs in children with surgically induced perforations of the tympanic membrane by

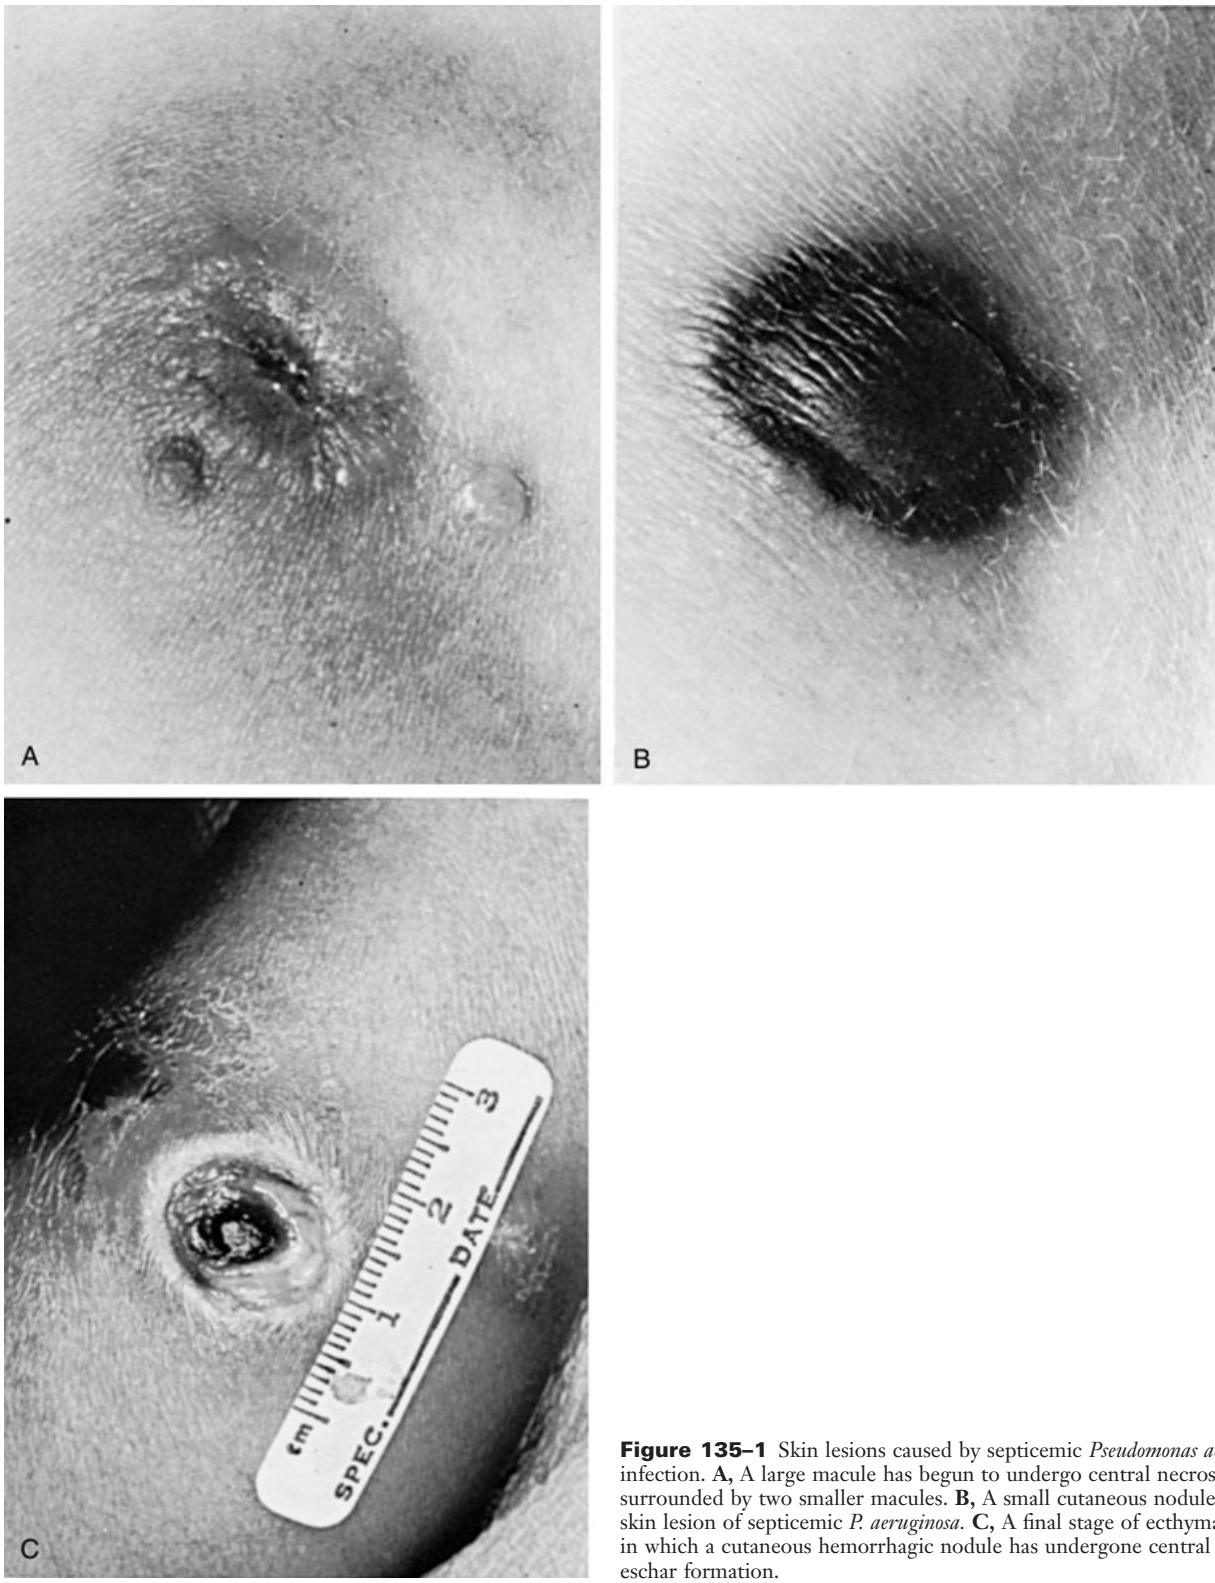

Figure 135–1 Skin lesions caused by septicemic *Pseudomonas aeruginosa* infection. **A,** A large macule has begun to undergo central necrosis and is surrounded by two smaller macules. **B,** A small cutaneous nodule representing the skin lesion of septicemic *P. aeruginosa*. **C,** A final stage of ecthyma gangrenosum in which a cutaneous hemorrhagic nodule has undergone central necrosis and eschar formation.

tympanostomy tubes and incompletely or inadequately treated otitis media. The etiologic microbial agents of acute otitis media in children with tympanostomy tubes differ from those in children with intact tympanic membranes. *P. aeruginosa* has been recovered from 12 percent of children with acute otitis media and tympanostomy tubes.[190] When tympanostomy tubes become colonized with *P. aeruginosa*, eradication of the infection may be complicated by the production of a biofilm.[26] The presence of a biofilm reduces the effectiveness of conventional systemic and topical antimicrobial therapy. Outpatient therapy with oral anti-

biotics frequently is unsuccessful because of the lack of oral antimicrobial agents with antipseudomonal activity. Topical ciprofloxacin with or without dexamethasone has been shown to be effective and superior to oral amoxicillin/clavulanic acid in the treatment of acute otitis media in children with otorrhea through tympanostomy tubes.[53] Intravenous antibiotics targeting the bacterial agents isolated from middle ear aspirates may be needed to cure chronic suppurative otitis media. This therapy may preclude the necessity of performing tympanomastoid surgery, which becomes essential in patients with extensive granulation tissue and osteitis in the mastoid.

P. aeruginosa ear infections were reported after commercial ear piercing.[107] In these patients, upper ear cartilage was involved more commonly than was lobe piercing. Re-use of a "single-use" disinfectant bottle contaminated at a sink harboring *P. aeruginosa* was implicated.[107]

P. aeruginosa infection of the eye usually occurs after trauma or surgery, after deposition of a large inoculum topically, or by hematogenous spread. Using contaminated contact lens solution, using tap water during contact lens care, and endotracheal suctioning without covering the eyes of sedated or comatose patients have been implicated.[91,94] Infection of the cornea can result in ulceration, which may progress to more invasive disease, including endophthalmitis. Loss of vision may result, even if appropriate antimicrobial therapy is administered promptly.

P. aeruginosa may produce serious infections during the neonatal period. Septicemia may be noted in the earliest hours of life and is associated with high morbidity and mortality rates. In utero acquisition of the organism resulting in intra-amniotic infection, neonatal sepsis, and death has been described.[160,194,252] The clinical course is similar to that of any other form of gram-negative septicemia, with hypotension, respiratory distress, and skin lesions the predominant manifestations. Mortality rates may be as high as 80 percent.[102] Late-onset neonatal *P. aeruginosa* infection usually occurs as a nosocomial infection (bacteremia, urinary tract infection, and pneumonia) associated with a foreign body (e.g., indwelling urinary or vascular catheter or endotracheal tube) in hospitalized infants. An outbreak in a neonatal intensive care unit of *P. aeruginosa* pneumonia and bloodstream infection was determined to be associated with intermittent otitis externa in a health care worker.[253] Maternal colonization after the use of a hot tub for relaxation during labor was responsible for *P. aeruginosa* meningitis and bacteremia in an 11-day-old infant.[235]

Increasing use of implantable devices has created new opportunities for health care–associated *Pseudomonas* infections. Infections of intrathecal baclofen pumps used to manage spasticity has been associated with wound infections and meningitis caused by *P. aeruginosa*.[248] Delayed infections in cochlear implant recipients with *P. aeruginosa* have been reported.[79] In these cases of device-associated *Pseudomonas* infection, removal of the device is important for successful management of the infection.

Other pseudomonads (except *B. pseudomallei*) rarely cause disease in healthy persons. Reports in normal, healthy children, particularly when these children had been hospitalized in an intensive care unit,[24,204] include the following: pneumonia, keratitis,[129] and abscesses caused by *B. cepacia*; otitis media caused by *Shewanella putrefaciens*; abscesses caused by *Pseudomonas fluorescens*; otitis media, pneumonia, and osteomyelitis[34,192] caused by *Pseudomonas stutzeri*; post-traumatic leg ulcers[169] and brain abscess[227] caused by *Sphingomonas paucimobilis*; and cellulitis, pneumonia, septicemia, endocarditis, peritonitis, and meningitis caused by *S. maltophilia*. *S. maltophilia* septicemia and endocarditis have been associated with intravenous abuse of illicit drugs.[256] Peritonitis and septicemia caused by *B. cepacia*, *S. putrefaciens*, and *S. paucimobilis* have been associated with contamination of equipment used for peritoneal dialysis.[11,20,46,84]

BURNS AND WOUND INFECTION

The surface of wounds or burns frequently is populated by pseudomonads and other gram-negative organisms.[64] Colonization does not imply infection necessarily, but it is a prerequisite to development of invasive disease. Septicemia with *P. aeruginosa* is a major problem in burned patients; the mortality attributed to *Pseudomonas*-associated burn wound sepsis approaches 78 percent.[141] Systemic involvement may be related to the multiplication of organisms in devitalized surface areas, followed by invasion, or it can be associated with the prolonged intravenous or urinary catheterization required for the care of these persons. Antibiotics may diminish the susceptible microbiologic flora but permit more resistant selected strains of *P. aeruginosa* to flourish. In addition, the hydrotherapy that commonly is provided to burned patients promotes colonization of the burned area, as well as other sites.[228]

In burn patients, abnormalities in neutrophil function that precede the onset of septicemia have been described.[3] Killing of *Pseudomonas* by neutrophils is impaired. Burn injury also is associated with abnormal responses to antigens, delayed rejection of homografts, abnormal vascular responses, impaired delayed hypersensitivity responses, diminished uptake of particles by the reticuloendothelial system, and altered antimicrobial pharmacokinetics. Contamination of wounds with high concentrations of bacteria ($>10^5$ colony-forming units [CFUs] per gram of tissue) impedes contraction and healing of the wound.[167] In addition, *P. aeruginosa* produces numerous substances that can further inhibit the natural healing process of burns and wounds. Secretion of exogenous plasminogen activators and proteases breaks down proteins such as fibrin and halts the contraction process.[172] *P. aeruginosa* exotoxin A, a protein synthesis inhibitor, is also a potent cause of retardation of wound healing.[87]

BONE AND JOINT INFECTIONS

P. aeruginosa is the most common cause of osteomyelitis after puncture wounds of the foot and is responsible for more than 90 percent of cases.[27,62,144] The calcaneus or metatarsal bones commonly are affected.[43] Symptoms may be present for 2 to 40 days (mean, 9 days) before diagnosis is established and hospitalization is needed.[43] Pain and swelling are the most common symptoms; fever and wound drainage rarely are noted. Leukocytosis (white blood cell count >10,000/mm^3) and an elevated erythrocyte sedimentation rate are present in most patients. Radiographs of the affected foot usually show evidence of osteomyelitis at some time during the period of evaluation and treatment. Bone scan results almost universally are abnormal and frequently yield evidence of osteomyelitis before positive findings on radiographs. The inner pad of sneakers has been implicated as a possible source of *P. aeruginosa* in these patients.[72] However, *P. aeruginosa* osteomyelitis of the foot bones has developed when the puncture occurred through other types of footwear or while the child was barefoot.

Other *P. aeruginosa* infections of bones and joints are uncommon findings in children. When they do occur, they are the result of hematogenous spread of *P. aeruginosa* in patients who are intravenous drug abusers or who have urinary tract or pelvic infections. Although any bone or joint may be affected as a result of *P. aeruginosa* bacteremia, *P. aeruginosa* has a unique predilection for the vertebrae, sternoarticular joints, pelvis, and symphysis pubis. The clinical course of *P. aeruginosa* osteomyelitis or septic arthritis is more indolent than that occurring after infection with *Staphylococcus aureus*. Contiguous spread can occur after penetrating trauma, surgery, or overlying soft tissue infections, especially decubitus ulcers.

CYSTIC FIBROSIS

Cystic fibrosis is one of the most common lethal inherited diseases of children.[64] It is a generalized disorder of salt and water transport that affects the exocrine glands and is caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene.[118,191] The course and prognosis are determined largely by chronic infections of the airways with opportunistic bacteria. Death usually results from chronic obstructive pulmonary disease. *P. aeruginosa* can be recovered from cultures in most children with cystic fibrosis. Colonization with *P. aeruginosa* occurs more frequently in children with cystic fibrosis who require pancreatic enzyme supplementation. Recovery of *P. aeruginosa* from the sputum of a child with cystic fibrosis does not imply necessarily infection and the destructive pneumonitis related to this organism. Mucociliary clearance is impeded in patients with cystic fibrosis; as a consequence, they fail to cleanse the bronchopulmonary epithelium of inhaled particles, including bacteria.[118,146] Adherence of *P. aeruginosa* to the airways of children with cystic fibrosis may be enhanced by acidic environment that results from the hyperacidification of the trans-Golgi network caused by the dysfunctional CFTR in cystic fibrosis lung epithelial cells.[175] Colonization of the sputum of patients with cystic fibrosis may reflect the use of mist tents, inhalation therapy, exposure to colonized individuals in health care facilities, cystic fibrosis camps, or at home, and continuous use of broad-spectrum antibiotic therapy.[254] Colonization of the respiratory tract of patients with cystic fibrosis by mucoid strains of *P. aeruginosa* can be correlated with the patient's age, clinical score, extent of pulmonary function abnormalities, severity of changes on chest radiographs, and serum immunoglobulin levels.[68,70] Once *P. aeruginosa* is in the respiratory tract, it rarely is eradicated by antibiotic therapy.

Some observations, however, suggest that the relationship between *Pseudomonas* and patients with cystic fibrosis is more specific. Patients with cystic fibrosis almost always harbor an unusual mucoid *P. aeruginosa* phenotype that produces an excessive amount of capsular slime.[184] The tracheobronchial tree of 70 to 80 percent of these patients is colonized chronically, and the organism infrequently is eradicated either spontaneously or by antibiotic therapy.[80,210] The peculiar lung environment of a patient with cystic fibrosis is thought to trigger a switch to a cluster of genes that code for abundant production of the mucoid polysaccharide (alginate), thereby giving rise to the mucoid phenotype.[39,220] In contrast, mucoid strains of *P. aeruginosa* are recovered from only 0.5 to 1.7 percent of patients without cystic fibrosis. Chronic infection of the lungs in patients with cystic fibrosis causes additional genetic adaptations by *P. aeruginosa*. Chronic, persistent infection results in the loss of genes responsible for virulence factors required for initiation of acute infections.[213] The loss of these virulence factors is presumed to be beneficial for immune evasion. The immune system can recognize these virulence factors, thus leading to effective immune response. Loss of the virulence factors inhibits the immune response from eradicating *P. aeruginosa* from the airways.

Persistence of *P. aeruginosa* within the respiratory tract is aided by growth of the organism in microcolonies embedded in a biofilm of alginate.[93,168] This biofilm allows nutrients to pass while protecting the organism from host defense mechanisms, antibodies, and probably antibiotics.[118] In addition, investigators have noted that rabbit alveolar macrophages fail to phagocytize and kill the organism in the presence of serum from patients with cystic fibrosis. This phenomenon suggests that these patients have a specific, local defect in pulmonary resistance to *P. aeruginosa*.

A clustering of *P. aeruginosa* serotypes also occurs in isolates obtained from patients with cystic fibrosis. Homma type 8 strains may be recovered from 50 to 93 percent of patients with cystic fibrosis.

Bacterial infection in patients with cystic fibrosis is limited almost entirely to the respiratory tract, and pulmonary exacerbations with endobronchial disease are common findings. Infection of the pulmonary parenchyma rarely occurs. Rather, the epithelium of the airways and the submucosa are edematous and contain infiltrates of chronic inflammatory cells. Documentation of a pulmonary exacerbation in cystic fibrosis relies heavily on clinical impression (e.g., increase in the frequency of productive cough, increase in volume or a change in characteristics of the sputum, increase in the respiratory rate or dyspnea, and decrease in appetite, activity, or exercise tolerance). Fever and leukocytosis are present in a minority of patients and are associated with poorer pulmonary function test results and a worse prognostic score.[212] Concentrations of *P. aeruginosa*, DNA (derived from polymorphonuclear leukocytes and, to a lesser extent, from respiratory epithelial cells), and total protein in sputum are increased during pulmonary exacerbations and decrease significantly after administration of antimicrobial therapy.[212] Pulmonary infection in patients with cystic fibrosis generally is chronic. Bronchitis, bronchiolitis, and bronchiectasis can occur. Eventually, local necrotizing pneumonitis may be noted, in contrast to the overwhelming generalized necrotizing pneumonitis seen in immunosuppressed patients. Septicemia is a rare occurrence. However, bacteremia may develop in patients with indwelling venous catheters.

B. cepacia complex has emerged as an increasingly frequent agent of asymptomatic colonization, pneumonia, and septicemia in patients with cystic fibrosis. At least 10 distinct *Burkholderia* spp. are in the *B. cepacia* complex.[131] *Burkholderia cenocepacia* (genomovar III) is the most prevalent species, responsible for nearly half of all clinical isolates in the United States. This species is responsible for most of the cases of the "cepacia syndrome."[130] *Burkholderia multivorans* (genomovar II) accounts for approximately one third of clinical isolates in the United States and generally is thought to be less virulent than is *B. cenocepacia*.[105] A less common species, *Burkholderia dolosa* (genomovar IV), is associated with a rapid deterioration in lung function and decreased rates of survival.[105] Rates of colonization have been as high as 40 percent in some centers.[196] The increased frequency of colonization of the respiratory tract with *B. cepacia* in patients with cystic fibrosis has been associated with increased morbidity and mortality rates in some cystic fibrosis centers since the 1980s. The risk of colonization with *B. cepacia* complex increases with the severity of underlying disease and increasing age.[225] The source or mode of transmission of the organism has not been defined adequately.[131,226] However, more recent information supports person-to-person transmission.[103] Nosocomial transmission (patient-to-patient and contaminated inhalation therapy equipment) within cystic fibrosis centers and social contact, particularly at summer camps, appear to be important in the acquisition of new infection with *B. cepacia*. Once colonization with *B. cepacia* has been identified in patients with cystic fibrosis, three distinct clinical patterns have been noted: (1) chronic asymptomatic carriage (usually in association with *P. aeruginosa*); (2) progressive deterioration over the course of many months, with recurrent acute pulmonary exacerbations accompanied by fever, progressive weight loss, leukocytosis, and an elevated erythrocyte sedimentation rate; and (3) rapid, usually fatal, deterioration in pulmonary function associated with necrotizing pneumonia and, at times, bacteremia (cepacia syndrome).[98,130] The last complication can occur even in patients who were affected only mildly before acquiring *B. cepacia* infection.

B. cepacia has numerous important virulence factors, some of which may play a specific role in the clinical syndromes seen in patients with cystic fibrosis. *P. aeruginosa* enhances subsequent adhesion to epithelial surfaces by *B. cepacia*,[195] a property that may suggest a synergistic relationship between the two bacterial

pathogens, particularly in patients with cystic fibrosis.[218] Additionally, *B. cepacia* strains from patients with the most severe progression of cystic fibrosis bind most avidly to mucin.[196]

S. maltophilia was reported first in respiratory cultures of patients with cystic fibrosis in 1975.[76] Since that time, the prevalence of isolation of *S. maltophilia* from patients with cystic fibrosis has been increasing; rates in the United States range from 1.8 to 8.7 percent,[51,148] and many European centers report higher rates. One center in Spain reported a prevalence rate of 30 percent.[12] The prognostic significance of *S. maltophilia* colonization in patients with cystic fibrosis is not certain. In general, new acquisition of *S. maltophilia* does not seem to be associated with an adverse clinical outcome.[51] However, prolonged colonization with *S. maltophilia*, particularly with high bacterial counts in excess of 10^5 to 10^6 CFUs/mL of sputum, may be associated with progressive deterioration in pulmonary function.[12,106]

MALIGNANCY

Children with leukemia, particularly those receiving immunosuppressive therapy and those who are neutropenic, are extremely susceptible to septicemia caused by *P. aeruginosa* and other pseudomonads.[64] Most pseudomonads, including *Pseudomonas putida*, have been reported as causes of septicemia in children with malignant disease.[4] Generally, infection results from invasion of the bloodstream by a colonizing *Pseudomonas* organism (e.g., from the GI tract). Anorexia, malaise, nausea, vomiting, diarrhea, and fever may be noted. Generalized vasculitis develops, and hemorrhagic necrotic lesions can be found in all organs, including the skin, where the lesions appear as purple nodules or ecchymotic areas that become gangrenous.[181] Other invasive *P. aeruginosa* infections noted in children receiving immunosuppressive chemotherapy include hemorrhagic gangrenous perirectal cellulitis or abscess, typhlitis, pre-septal cellulitis, and necrotizing fasciitis.[134,142,233]

Children undergoing treatment of malignant diseases are particularly vulnerable to bacterial infection. Chemotherapy and radiation therapy can disrupt mucocutaneous barriers and result in moderate to severe immunosuppression. Fergie and associates[66] described 98 children and adolescents with cancer in whom *P. aeruginosa* bacteremia developed; the rate of bacteremia was highest in patients with leukemia. Most cases occurred when patients had absolute neutrophil counts of less than 100/mm^3. Mortality associated with *P. aeruginosa* bacteremia was higher in patients with solid tumors, an absolute neutrophil count of less than 100/mm^3, perineal skin lesions, and bacteremia during remission or induction therapy rather than during a relapse.

The single most important factor that predisposes children with cancer to development of infection is granulocytopenia. The bactericidal capacity of children with leukemia and other neoplasms also may be impaired. Heat-stable opsonins specific for *P. aeruginosa* similarly may fall precipitously in children with acute leukemia who are receiving intensive combination chemotherapy. Fatal infections with *P. aeruginosa* may be related in part to a deficiency of this specific opsonin.

IMMUNOSUPPRESSION

Immunosuppressive agents may be used in the management of malignant diseases, transplantation, or collagen vascular disease. The location of the infectious process and the type of causative organisms depend somewhat on the underlying disease. Infection by *P. aeruginosa*, particularly pneumonia and septicemia, occurs more commonly in children receiving immunosuppressive therapy than in the normal, healthy population.

OTHER CONDITIONS THAT PREDISPOSE TO *PSEUDOMONAS* INFECTION

P. aeruginosa is a major cause of hospital-acquired infections in children. It is the leading cause of nosocomial respiratory tract infection in children undergoing mechanical ventilation or receiving inhalation therapy. Asymptomatic colonization of the upper and lower airways occurs commonly and should be distinguished from respiratory tract disease, tracheitis, and pneumonia. A predominance of gram-negative bacilli with an abundance of polymorphonuclear leukocytes on Gram stain of lower respiratory tract secretions, in conjunction with a positive culture for *P. aeruginosa*, strongly supports the role of *P. aeruginosa* as the causative agent for the lower respiratory tract infection. Absence of *P. aeruginosa* from lower respiratory tract secretions markedly reduces the likelihood that *P. aeruginosa* is in the lower respiratory tract.

P. aeruginosa septicemia occurs with increased frequency in children with indwelling vascular or urinary catheters.[223] In addition, septicemia may occur in children with congenital or acquired neutropenia or in persons with a functional deficit in polymorphonuclear leukocyte function. Urinary tract infections also have been associated with cystoscopic examination. *Pseudomonas* is a common cause of abscesses and meningitis in children with dermoid sinus tracts or dermoids extending down to or communicating with the meninges or neural tissue and in children with meningomyeloceles. *P. aeruginosa* may produce acute or subacute endocarditis in children with congenital cardiac lesions before or after they undergo cardiac surgery and in adolescents who inject illicit drugs intravenously. *P. aeruginosa* supraglottitis was reported in a 6-month-old child with severe combined immunodeficiency syndrome.[122]

Severe *P. aeruginosa* infections have been reported in children infected with human immunodeficiency virus (HIV), primarily after severe immunodeficiency has developed.[74,189] Risks for acquiring *P. aeruginosa* infection in HIV-infected individuals include hospital exposure, declining CD4$^+$ cell count, and the use of dapsone or trimethoprim-sulfamethoxazole; azithromycin use was reported to be protective.[217] Bacteremia may occur with or without the presence of an indwelling vascular catheter. Fever, hypotension, skin lesions (papules or ecthyma gangrenosum), and pneumonia are common manifestations.[74] Mortality rates can be high, particularly when empiric antimicrobial therapy is inadequate for the treatment of severe, invasive *Pseudomonas* infection.

P. aeruginosa causes endocarditis on both native and prosthetic heart valves. Fortunately, it is an uncommon occurrence in children because its usual setting is in intravenous drug users. Obviously, *P. aeruginosa* needs to be considered in adolescents, particularly those with a history of intravenous drug use or at risk for acquiring HIV infection, and in infants, children, and adolescents with prosthetic valves or other intracardiac synthetic material. Tricuspid valve involvement occurs most commonly, but involvement of multiple valves is possible with *P. aeruginosa*; the manifestations are typical of subacute endocarditis. When the left side of the heart is involved (aortic or mitral valves), the patient has acute and more fulminant disease. Fever and heart murmur are almost universal findings.

DISEASE CAUSED BY OTHER PSEUDOMONADS

In addition to causing respiratory tract infection in patients with cystic fibrosis, *B. cepacia* can result in other infections, primarily in hospitalized or immunocompromised patients. Nosocomial pneumonia in ventilated patients, bacteremia, wound infections, urinary tract infections, meningitis, endocarditis, and skin lesions

may be caused by *B. cepacia*. Fortunately, all these infections are uncommon occurrences in children.

S. maltophilia has been reported with an ever-expanding spectrum of clinical manifestations, most notably bacteremia, endocarditis, lower respiratory tract infection, urinary tract infection, wound infection, meningitis, conjunctivitis, keratitis, dacryocystitis, otitis media, and bone and joint infections. Lower respiratory tract colonization, at times associated with symptomatic disease, is the most common manifestation in children. In addition to its occurrence in children with cystic fibrosis, *S. maltophilia* may be isolated from the respiratory tract of hospitalized children, especially those with endotracheal tubes or tracheostomies. Although colonization usually is asymptomatic, occasionally, lower respiratory tract infection with *S. maltophilia* can result in respiratory deterioration, pneumonitis, and an increased risk of mortality.[119,145]

Bacteremia with *S. maltophilia* usually results from the presence of an intravascular device or an infection of the respiratory, GI, or urinary tracts. Pseudobacteremia with *S. maltophilia* arising from contamination of blood cultures that were performed with blood used to fill nonsterile tubes designed for coagulation studies has been reported.[99] Other infections with *S. maltophilia* in children occur primarily after trauma or instrumentation.

Melioidosis is a rare disease of Southeast Asia and northern Australia that increased in frequency in the United States when Americans returned from Vietnam, Honduras,[37] or El Salvador,[36] and, rarely, after immigration by Southeast Asians.[47,163] The causative agent is *Burkholderia pseudomallei*, an environmental saprophyte of soil and water in the tropics, particularly in rice paddies. *B. pseudomallei* is a small, motile, pleomorphic gram-negative rod without a capsule that exhibits bipolar staining. It is an obligate aerobe that grows best at pH 7 and 37.0° C (98.6° F). Infection occurs after contact of abrasions or wounds with contaminated soil or water, inhalation of contaminated dust, or ingestion of contaminated water. Patients with poorly controlled diabetes, renal disease, or immunocompromised conditions caused by collagen vascular disease, hematologic malignant diseases, or immunosuppressive therapy appear to have an increased risk for development of disease after infection with *B. pseudomallei*.

Transmission most commonly occurs following percutaneous inoculation. Inhalation and ingestion are less common modes of transmission. Hematogenous spread occurs following local infection. Transmission from animals to humans has not been reported. The rat flea and the *Aedes aegypti* mosquito have been reported to infect animals with *B. pseudomallei*, but this route of infection has not been documented in human cases.[164] Human-to-human transmission has occurred during sexual or prolonged close contact.[121] Two cases of mother-to-child transmission of *B. pseudomallei* occurred through breast milk.[179] One mother had obvious mastitis.[179] An outbreak of melioidosis in Australia was traced to a potable water source from a water treatment plant that had irregularities in purification.[96]

Most infections with *B. pseudomallei* remain subclinical. Melioidosis can have a broad spectrum of clinical signs, and symptoms may be latent for months or years before the disease becomes clinically apparent. The initial clinical finding may be a single primary skin lesion (vesicle, pustule, bulla, urticaria) in a patient with no underlying disease. Septicemia occasionally occurs, and multiple abscesses may be noted in every organ of the body. The mortality rate associated with fulminant sepsis approaches 90 percent.[120] Meningitis, encephalitis, arthritis, nodular pulmonary densities, abscesses of liver,[7] lung, spleen, kidney, and bones, and endophthalmitis have been observed in both normal and compromised hosts after or concomitant with an episode of septicemia. The acute septicemic illness is indistinguishable from other types of septicemia caused by gram-negative organisms.

B. pseudomallei can cause myocarditis, pericarditis, endocarditis, intestinal abscess, cholecystitis, acute gastroenteritis, urinary tract infection, septic arthritis, paraspinal abscess, osteomyelitis, hilar lymphadenopathy, and cervical lymphadenopathy. Parotitis was documented in 38 percent of 126 children with melioidosis in Thailand.[48] None of the 126 children with melioidosis had any apparent predisposition to infection.

Subacute melioidosis generally is characterized by an illness lasting weeks to months. Pulmonary infection in this form of disease is a common occurrence and may mimic tuberculosis. The disease can vary from mild bronchitis to severe, fulminant pneumonitis.[120] Consolidation and cavitation occur frequently.

Neonatal melioidosis has been reported in Thailand.[135] Infants with neonatal septicemia, meningitis, or both, caused by *B. pseudomallei*, have been described. The mode of transmission of this organism to these newborn infants is not always clear. A clear case of mother-to-child transmission of *B. pseudomallei* was reported.[1] The mother had acute melioidosis treated with ofloxacin at 32 weeks' gestation. Consolidation of the right lung of the infant occurred, and an abscess eventually developed. Postpartum cultures of the mother's cervix yielded *B. pseudomallei*.

Chronic melioidosis occurs more frequently in whites than in Asians.[139] Chronic melioidosis may involve every organ in the body, including the brain.[120] Melioidosis may become dormant, with exacerbations occurring years after primary infection when host defenses are impaired as a result of steroid use, burns, diabetes mellitus, or other processes. The longest latent period (24 years) was reported by Kingston.[113]

Melioidosis should be considered in any person who has been to Southeast Asia or northern Australia at any time and has fever of unknown origin, overwhelming sepsis, single or multiple abscesses, or any tuberculosis-like illness. The diagnosis is established by culture of blood, skin lesions, or purulent material from an abscess cavity or from other sites of infection.[125] The organism grows in media commonly used for isolation of gram-negative bacteria. On solid media, the colonies develop slowly (over a week) and have a characteristic daisy-head appearance. Alpha-hemolysis is noted on sheep blood agar. A selective medium (Ashdown medium) can increase the recovery rate of *B. pseudomallei* from clinical specimens containing mixed bacterial flora, such as throat, rectal, and sputum specimens.[9] *B. pseudomallei* produces a dry, wrinkled, and violet-purple colony with a pungent, earthy odor on Ashdown medium.[81]

Serologic tests are more useful in establishing the diagnosis of melioidosis in latent or asymptomatic forms of this disease.[2,136,156] Hemagglutination (HA), indirect HA, complement-fixation (CF) tests, and an enzyme-linked immunosorbent assay (ELISA) are available. Diagnostic titers are 1:40 or greater for the HA test and 1:10 or greater for the CF test. Because the sensitivity of these serologic tests varies, both should be performed. HA antibodies generally are present within 7 to 14 days after onset of the illness; the CF test yields positive results in 4 to 6 weeks. Maximal titers for both tests are reached in 4 to 6 months. Both HA and CF antibodies persist for 9 months to 2 years after the onset of disease. In the United States, the indirect HA test is used by the Centers for Disease Control and Prevention for the diagnosis of melioidosis. An ELISA that detects specific IgG and IgM antibody to *B. pseudomallei* was developed.[10] This assay proved more suitable than was an IgG indirect fluorescent antibody test in screening for melioidosis and also was more sensitive than was the indirect HA test for melioidosis. Gold blot detection of IgM- and IgG-specific antibodies has been developed[122] and allows serodiagnosis of melioidosis to be made more rapidly. *B. pseudomallei* can be detected in serum by an ELISA method.[244]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of *Pseudomonas* infection depends on recovery of the organism from blood, cerebrospinal fluid (CSF), and urine

obtained in a manner that avoids contamination by cutaneous flora (suprapubic aspiration or urethral catheterization is usually required for young children) and from joint fluid, peritoneal dialysis fluid, or purulent material obtained by aspiration of subcutaneous abscesses or areas of cellulitis. A diagnosis of *Pseudomonas* pneumonia can be made by needle aspiration of the lung and, less convincingly, by recovery of the organism from sputum obtained by postural drainage of a child with cystic fibrosis. Recovery of the organism from the surface of the skin or the throat, a tracheal aspirate, or bronchial secretions may reflect colonization and is not necessarily diagnostic of infection. The validity of a positive culture is enhanced when it is associated with a typical clinical syndrome (e.g., *P. aeruginosa* recovered from a skin lesion typical of whirlpool folliculitis). Isolation of *P. aeruginosa* from the respiratory tract, particularly when the specimen is obtained from an endotracheal tube in an intubated patient, is not an unusual occurrence. Differentiating colonization from infection is clinically important. Gram stain of respiratory secretions obtained by endotracheal suction typically reveals abundant gram-negative rods and polymorphonuclear leukocytes in the setting of a true lower respiratory tract infection caused by *P. aeruginosa* (tracheitis or pneumonitis). An absence of gram-negative rods or the presence of squamous epithelial cells, rather than polymorphonuclear leukocytes, indicates that either the patient does not have a lower respiratory tract infection or, if an infection is present, the etiologic agent is not likely to be *P. aeruginosa*.

Isolation of *Pseudomonas* spp. other than *P. aeruginosa* from clinical specimens occurs far less frequently. Recovery of these *Pseudomonas* spp. from sites that normally are sterile, such as blood or blood product containers, always should be considered clinically significant unless proved otherwise.

Pseudomonas and *Burkholderia* spp. are nutritionally versatile and grow well on most standard laboratory media (such as 5% sheep blood or chocolate agar). They grow optimally at 37° C and also at 42° C, but not at 4° C. All members of both genera grow in broth blood culture systems.[81] Isolation of *Pseudomonas* and *Burkholderia* from specimens with mixed bacterial flora is enhanced by using selective media such as MacConkey agar. Cetrimide, acetamide, nitrofurantoin, and 9-chloro-9[4-(diethylamino)phenyl]-9,10-dihydro-10-phenylacridine hydrochloride (C390) can be used for the isolation of *P. aeruginosa* from clinical as well as environmental specimens. Two media, PC (for *P. cepacia*)[81] and OFPBL (for oxidative-fermentative base-polymyxin B-bacitracin-lactose)[239] agar, inhibit *P. aeruginosa* and are useful for recovery of *B. cepacia* from the sputum of patients with cystic fibrosis.

P. aeruginosa usually is recognized easily on laboratory media by its characteristic colony morphology, diffusible pigment (when present), and odor (resembling sweet grapes or corn tacos). Colonies generally are spreading (sometimes overrunning other organisms in mixed infections) and flat. They usually have a metallic sheen. However, patients with cystic fibrosis typically have *P. aeruginosa* isolates with mucoid colony formation. *P. aeruginosa* can be identified reasonably by the presence of the following: (1) positive oxidase test, (2) triple sugar iron agar reaction of alkaline over no charge, (3) growth at 42° C, and (4) production of a bright blue to blue-green (and, to a lesser extent, red or brown) diffusible pigment on non–dye-containing agar such as Mueller-Hinton. Many laboratories rely on commercial systems for identifying *P. aeruginosa*. For pigmented *P. aeruginosa*, these systems are accurate 70 to 100 percent of the time (average, >90%).[77,186,188] The accuracy with nonpigmented *P. aeruginosa* is significantly less.[115]

The bluish, nodular skin lesions and the ulcers with ecchymotic and gangrenous centers and bright areolae (ecthyma gangrenosum) have been considered to be virtually pathognomonic of *P. aeruginosa* infection. Rarely, skin lesions that are clinically indistinguishable from those caused by *P. aeruginosa* develop after septicemia secondary to *Aeromonas hydrophila*.[208] Cutaneous or disseminated infections with *Aspergillus* and *Fusarium* in immunocompromised patients also can cause the necrotic skin lesions of ecthyma gangrenosum.

Immunoglobulin antibodies to *P. aeruginosa* surface antigens in serum have been detected reliably by ELISA.[28] Detection of specific IgG and IgA antibodies is not clinically useful for establishing the diagnosis of acute *P. aeruginosa* infection. However, antibody titer increases were associated with active disease caused by *P. aeruginosa* in patients with cystic fibrosis. Antibody titers returned to baseline when *Pseudomonas* infection was controlled by effective antimicrobial therapy. Thus, this assay appears to help in differentiating between early infection and colonization. Antibodies to *P. aeruginosa* also may be detected by immunoblotting (Western blotting).[209] These methods may be sensitive and useful for determining the onset of *P. aeruginosa* infection in patients with cystic fibrosis.

TREATMENT

Systemic infections with *Pseudomonas* should be treated promptly with antibiotics to which the organism is susceptible in vitro.[23,185] Community-acquired *P. aeruginosa* infections typically are sensitive to antipseudomonal penicillins, aminoglycosides, ciprofloxacin, ceftazidime, meropenem, and imipenem. Susceptibility is less predictable for aztreonam, a monobactam. Nosocomially acquired *P. aeruginosa* is more likely to be antibiotic-resistant than are community-acquired strains. Response to treatment may be impaired, and prolonged treatment may be required when systemic infection occurs in an immunocompromised host. Unfortunately, *P. aeruginosa* has been developing resistance to many of the classes of drugs that previously were used to treat this organism. Multidrug-resistant and panresistant *P. aeruginosa* are occurring with increasing frequency, especially in critical care settings. *Multidrug resistance* may be defined when *P. aeruginosa* has diminished susceptibility to more than one of the following five drug classes: aminoglycosides, antipseudomonal cephalosporins, antipseudomonal carbapenems, antipseudomonal β-lactam–β-lactamase inhibitor combinations, and antipseudomonal fluoroquinolones.[165] *Panresistance* may be defined when *P. aeruginosa* has diminished susceptibility to antipseudomonal cephalosporins, antipseudomonal carbapenems, antipseudomonal fluoroquinolones, and antipseudomonal β-lactam–β-lactamase inhibitor combinations.[165] If *P. aeruginosa* organisms retain susceptibility to aminoglycosides while being resistant to the other drug classes, they still should be considered panresistant because aminoglycoside monotherapy in serious infections, especially in critically ill or immunocompromised patients, has a high failure rate.

Prior use of a specific antibiotic may predict the development of resistance to that antibiotic.[60,165] However, use of fluoroquinolones and, to a lesser extent, antipseudomonal β-lactam antibiotics predisposes to multidrug-resistant *P. aeruginosa*.[50,165] Combination therapy has been suggested as a means of reducing the development of resistance while the patient is receiving treatment. Some studies supported the benefit of combination therapy to reduce the development of resistance.[56,237] However, other studies found that antipseudomonal β-lactam antibiotics alone are as effective as is an antipseudomonal β-lactam antibiotic-aminoglycoside combination for preventing the emergence of antibiotic resistance.[166]

Pseudomonas spp. not only exhibit intrinsic resistance to numerous antibiotics but also have the ability to acquire genes encoding resistance determinants. Mechanisms of resistance include production of β-lactamases [AmpC cephalosporinases, PSE β-lactamases, OXA β-lactamases, TEM β-lactamases, SHV-type β-lactamases, PER-1 β-lactamases, and metallo-carbapene-

mases] and aminoglycoside modifying enzymes [AAC (6′)-I and APH (3′)-II], mutations in topoisomerases II and IV, up-regulation of efflux pumps, and diminished expression of outer-membrane proteins (porin).[165]

Table 135–2 provides dosages of some of the more commonly prescribed antipseudomonal antibiotics.[151] These dosages are only guidelines because the doses of some of these antibiotics may vary with different clinical situations and patient populations. Once-daily administration of aminoglycoside is being evaluated as a way to decrease nephrotoxicity and improve clinical efficacy. Aminoglycoside doses must be decreased, preferably by increasing the dosing interval, in patients with diminished creatinine clearance (e.g., renal impairment, neonates). Significantly higher doses (e.g., 7 to 12 mg/kg/day for gentamicin or tobramycin) may be required for patients with increased total plasma clearance, such as those with cystic fibrosis and burns. Therefore, aminoglycoside therapy must be individualized and doses guided by pharmacokinetic information. Extended-infusion (4-hour infusion every 8 hours) of β-lactam antibiotics (piperacillin-tazobactam) has been considered to enhance the duration of drug concentration that remains in excess of the minimal inhibitory concentration (MIC) of *P. aeruginosa*.[134]

Invasive infections, including septicemia caused by proven or suspected *P. aeruginosa* infection, should be treated with a β-lactam antibiotic (antipseudomonal penicillin, third- or fourth-generation cephalosporin, or carbapenem) combined with an aminoglycoside (gentamicin, tobramycin, netilmicin, or amikacin). The combination of an aminoglycoside and a β-lactam antibiotic may be synergistic against the organism. Rifampin (synergistic in vitro with anti-*Pseudomonas* penicillins and aminoglycosides) may be added to the combination therapy if the clinical response is not adequate. Monotherapy with the cell wall–active β-lactam antibiotics, as well as the fluoroquinolones, frequently leads to the development of antibiotic resistance during therapy as a result of a mutation.[15,205]

P. aeruginosa may be responsible for lower respiratory tract infections in neonates, infants, and children. Involvement of the airways in patients with cystic fibrosis and nosocomial tracheitis or pneumonitis in intubated patients are the most common manifestations. In patients with cystic fibrosis and in critically ill intubated patients, previous use of antimicrobial therapy results in a high frequency of antibiotic-resistant *P. aeruginosa.* Combination therapy with a β-lactam antibiotic and an aminoglycoside is synergistic in vitro and has superior clinical efficacy when compared with monotherapy, particularly with aminoglycosides alone.[89] Quinolones do not appear to be synergistic with either β-lactam antibiotics or aminoglycosides. However, in postpubertal children, quinolones can be used in combination therapy when antibiotic resistance reduces the potential benefit of either the β-lactam antibiotic or the aminoglycoside.

For empiric treatment of *P. aeruginosa* lower respiratory tract disease before antibiotic susceptibility test results are available, the choice of which β-lactam antibiotic and which aminoglycoside will be used should be based on the patient's previous antibiotic experience and knowledge of the usual pattern of antibiotic susceptibility and resistance in the patient's clinical environment. Once susceptibility testing has been completed, at least two effective antibiotics should be included in the patient's regimen. The dose and pharmacotherapeutics of the chosen antibiotics should be optimized. If the patient fails to respond to therapy or if clinical deterioration is noted, acquisition of antibiotic resistance should be anticipated. If antibiotic failure is likely, more than one new antibiotic should be substituted. Selection of the new antibiotic should be guided by previous susceptibility testing and the probable changes that resulted in antibiotic resistance.

The route of administration also may be important with aminoglycoside antibiotics. Penetration of aminoglycosides from blood into respiratory secretions is poor.[19] Topical application of aminoglycosides by aerosolization, particularly through an endotracheal tube, provides much higher concentrations in respiratory

TABLE 135–2 Dosages of Commonly Prescribed Antipseudomonal Antibiotics

Generic Name	Dosage (mg/kg/day)	Route	Interval	Pediatric Precaution
Antipseudomonal Penicillins				
Carbenicillin indanyl sodium	30-50	PO	q6h	SNE
Ticarcillin disodium	200-300	IV	q4-6h	
Ticarcillin/clavulanate	200-300 (ticarcillin)	IV	q4-6h	
Piperacillin	200-300	IV	q4-6h	PDNE
Piperacillin/tazobactam	240 (piperacillin)	IV	q4-6h	PDNE
Cephalosporins				
Ceftazidime	200-300	IV, IM	q6-8h	
Cefepime	100-150	IV, IM	q8-12h	
Aminoglycosides				
Gentamicin sulfate	3-7.5	IV, IM	q8h or q24h	
Tobramycin sulfate	3-7.5	IV, IM	q8h or q24h	
Netilmicin sulfate	3-7.5	IV, IM	q8h or q24h	
Amikacin sulfate	15-22.5	IV, IM	q8h or q24h	
Quinolones				
Ciprofloxacin	20-30	PO, IV	q12h	>18 yr*
Monobactams				
Aztreonam	90-120	IV, IM	q6-8h	SNE
Carbapenems				
Imipenem/cilastatin sodium	60-100	IV, IM	q6h	SNE
Meropenem	60 (meningitis: 120)	IV	q8h	

**Safety in children younger than 18 years is not completely established, and use is recommended for specific infections (complicated urinary tract infections, pyelonephritis, and postexposure treatment of inhalation anthrax) and in circumstances in which the benefit outweighs the risk.*

IM, intramuscular; IV, intravenous; PDNE, pediatric dose not yet established; PO, oral; SNE, safety in children not yet established.

Data from Bradley J. S., and Nelson J. D.: Nelson's Pocket Book of Pediatric Antimicrobial Therapy. 16th ed. Buenos Aires, Alliance for World Wide Editing, 2006-2007, pp. 94-112.

secretions. This approach results in faster bacteriologic eradication, but clinical efficacy varied in different studies.[30] Administration of aerosolized aminoglycosides to patients with cystic fibrosis resulted in improvement in pulmonary function tests, decreased concentrations of *P. aeruginosa* in sputum, and no significant apparent toxicity. This aerosol treatment did not increase the isolation of *B. cepacia*, *S. maltophilia*, or *Alcaligenes xylosoxidans*; however, isolation of the fungi *Candida albicans* and *Aspergillus* did increase.[31]

Aztreonam, a monobactam antibiotic, has excellent antipseudomonal activity but is not approved for use in pediatric patients. Fluoroquinolones are approved for use in patients younger than 18 years of age to treat complicated urinary tract infections and pyelonephritis and for post-exposure treatment for inhalation anthrax. Polymyxin B and colistin (polymyxin E), used previously, have been superseded largely by less toxic agents, but they may be useful in selected patients who are infected with strains resistant to the other agents. However, all *Burkholderia* spp. are resistant to polymyxin B.

Ciprofloxacin and the other quinolones have been evaluated for the treatment of acute and chronic *P. aeruginosa* infections in teenagers and adults with cystic fibrosis.[100,193,222,224] These antibiotics, which may be given orally or intravenously, proved to be effective, as judged by clinical scores and results of pulmonary function tests. In the United States, quinolone (ciprofloxacin, ofloxacin, norfloxacin, enoxacin, levofloxacin, lomefloxacin, sparfloxacin, and trovafloxacin) use is limited to specific infections until after puberty because these antibiotics may bind cartilage and arrest growth. The information available from clinical trials in Europe suggests that ciprofloxacin and the other quinolones may not be as harmful in children as they are in other juvenile animal species.[41,200,201] However, pefloxacin, a fluoroquinolone that had been used extensively in France, does cause arthropathy in children and adults. In addition, two other quinolones, alatrofloxacin and trovafloxacin, cause acute liver failure, and some cases resulted in patients' deaths. Ciprofloxacin may be considered in selected children when the risks associated with the use of this antibiotic are outweighed by the potential benefits associated with its clinical efficacy (e.g., multiresistant strains of *Pseudomonas*, substitution of an oral quinolone to avoid long-term intravenous therapy requiring an indwelling catheter). If ciprofloxacin is used in a patient younger than 18 years of age for infections other than those for which it is approved, the balance of the risks and benefits of administering ciprofloxacin and alternatives should be explained to the patient and parents or guardians. Ciprofloxacin may be administered in a dosage of 15 mg/kg every 12 hours orally or 10 to 15 mg/kg twice a day intravenously. The oral dosage should not exceed 1000 mg/day in patients who weigh less than 40 kg or 1500 mg/day in patients who weigh more than 40 kg.

Determining the optimal antibiotic therapy for patients with cystic fibrosis may be very problematic. Respiratory cultures may yield *P. aeruginosa* with many different colony morphotypes. These different morphotypes may have significantly different antibiograms. The accuracy of susceptibility testing is improved when different morphotypes are tested individually. However, it is labor-intensive and expensive.

After years of antibiotic exposure, patients with cystic fibrosis commonly are infected with *P. aeruginosa* that is resistant in vitro to all available antimicrobial agents. For these patients, aerosolized tobramycin may be used to yield tobramycin concentrations in the range of 100 to 200 μg/mL of respiratory secretion. Some of these panresistant *P. aeruginosa* strains may be susceptible in vivo when concentrations of tobramycin reach these high levels in respiratory secretions. Susceptibility testing of these panresistant organisms should be performed by either determining MICs or performing an E-test to ascertain whether the organism is susceptible at these higher levels, 100 to 200 μg/mL.[82] In addition to management of resistant *P. aeruginosa*, aerosolized tobramycin given over a prolonged period (>1 year) may have the potential to eradicate *P. aeruginosa* temporarily from patients with cystic fibrosis who have newly acquired this organism.[180] Confirmation of the efficacy of prolonged antibiotic aerosol therapy may prove valuable because data indicate a poor outcome in children with cystic fibrosis who acquire *P. aeruginosa* by the age of 7 years.[157]

P. aeruginosa endocarditis requires aggressive medical and surgical therapy. Despite combination therapy with maximal β-lactam and aminoglycoside antibiotics, valve replacement (native and prosthetic) frequently is required for cure. When gentamicin or tobramycin is administered in three divided doses per day, peak concentrations should be maintained at 12 to 15 μg/mL. Quinolones should be reserved for patients intolerant of aminoglycosides or whose bacteria are resistant to aminoglycosides or for long-term suppression of *P. aeruginosa* prosthetic valve endocarditis.

Although fortunately uncommon, *P. aeruginosa* infection of the eye can be serious and sight-threatening. *P. aeruginosa* corneal ulcerations or keratitis may be seen in contact lens wearers or in intubated, sedated patients in intensive care units. Topical therapy with ticarcillin, piperacillin, tobramycin, gentamicin, amikacin, ciprofloxacin, or ofloxacin may be used and is effective. Clinical efficacy is improved by frequently clearing inflammatory debris and applying topical antibiotics. Initially, antibiotic solutions should be administered every 15 to 30 minutes. The frequency can be decreased gradually to four to six times a day when clinical improvement is apparent.

P. aeruginosa endophthalmitis frequently occurs after invasive eye surgery or penetrating injuries. Systemic, topical, and intraocular (anterior chamber and vitreous cavity) routes all are required. Even with aggressive medical intervention, return of retinal function seldom is achieved. The prognosis is worse when initiation of therapy is delayed. Ceftazidime, imipenem, and ciprofloxacin have greater intraocular penetration than do the aminoglycosides.[251]

P. aeruginosa meningitis or brain abscess should be treated with ceftazidime (200 mg/kg/day in four divided doses every 6 hours), and an aminoglycoside should be given intravenously. The initial empiric choice of the aminoglycoside should be guided by local susceptibility patterns. Concomitant intraventricular or intrathecal treatment with gentamicin may be required if initial intravenous therapy fails to sterilize the CSF. Gentamicin can be placed into the ventricular or lumbar CSF in a total dose of 1 to 5 mg once each day (the dose is independent of body weight). Meropenem has good penetration into CSF and can be used when the *P. aeruginosa* is ceftazidime-resistant. Meropenem is the preferred carbapenem because the high doses of imipenem required to treat central nervous system (CNS) infections may be associated with CNS toxicity. Fluoroquinolones such as parenteral ciprofloxacin or pefloxacin and aztreonam are possible alternatives in the treatment of *P. aeruginosa* CNS infections if more conventional therapy has failed. However, experience with these agents for CNS infections is limited.[112,127,158,207]

Skin abscesses or abscesses in other locations caused by *P. aeruginosa* should be incised and drained.[181] Failure to do so may result in a poor response despite prolonged systemic antibiotic treatment. Osteomyelitis of foot bones requires surgical débridement in every case. A course of 10 to 14 days of appropriate antibiotics appears to be adequate if surgery has removed the infected tissue effectively.[98] The adequacy of surgical débridement and clinical improvement can be monitored by serial sedimentation rates.[43] *P. aeruginosa* infection of foreign bodies (vascular, peritoneal, and CNS catheters) may require removal of the foreign material to cure the infection, particularly if a tunnel or exit-site infection exists.

Pseudomonas folliculitis and plantar nodules generally are self-limited and do not usually require specific antimicrobial therapy.

More severe cases can be treated by the topical application of any of the following: 2.5 percent acetic acid compresses (vinegar is 5% acetic acid), gentamicin ointment, topical 0.1 percent polymyxin B, or silver sulfadiazine (Silvadene).

The β-lactam antibiotics (antipseudomonal penicillins, cephalosporins, carbapenems), monobactams, and ciprofloxacin are rapidly bactericidal to *P. aeruginosa*.[75] The combination of an aminoglycoside with any of these antibiotics is unlikely to have a significant effect on the initial clinical response rate. However, a reduction in the emergence of drug-resistant *P. aeruginosa* clones is the major potential benefit of combination therapy that includes an aminoglycoside. Combination therapy with two β-lactam antibiotics is inappropriate for serious *Pseudomonas* infections because the induction of β-lactamase may result in resistance to both antibiotics.

Antibiotic resistance is an important factor in patients with serious *Pseudomonas* infections that do not respond to antibiotic therapy. As the quintessential opportunist, *Pseudomonas* has acquired various means to resist the activity of antibiotics. *P. aeruginosa* produces numerous different β-lactamase enzymes. Plasmid-mediated β-lactamases are responsible for resistance to antipseudomonal penicillins but not to the cephalosporins or carbapenems.[42] The most clinically relevant β-lactamases produced by *P. aeruginosa* are encoded primarily chromosomally rather than located on plasmids. Cephalosporinases, classified as class I β-lactamases,[187] produced by *P. aeruginosa* increase on exposure to any of the β-lactam antibiotics (de-repression of the β-lactamase gene).[199] However, the propensity to induce β-lactamase varies among the β-lactam antibiotics.[45] Imipenem and cefoxitin are strong inducers of β-lactamase.[57] All antipseudomonal penicillins, cephalosporins, and aztreonam are susceptible to the class I β-lactamase produced by *P. aeruginosa*.[155]

Clavulanate and tazobactam are β-lactamase inhibitors effective against plasmid-encoded class III and class V β-lactamases and the chromosomally encoded class II β-lactamases found in *P. aeruginosa* and some other gram-negative bacteria. However, these β-lactamase inhibitors not only are ineffective against the common class I β-lactamase of *Pseudomonas* but also are potent inducers of the β-lactamase gene. Use of these β-lactamase inhibitors will not enhance the activity of ticarcillin (Timentin) or piperacillin (Zosyn) against *Pseudomonas* and may actually increase the likelihood of emergence of resistant strains.

Pseudomonas strains with chromosomally encoded class I β-lactamase may not produce detectable β-lactamase until they are exposed to β-lactam antibiotics. These β-lactamase–encoded strains may appear sensitive to β-lactam antibiotics on in vitro sensitivity testing before antibiotic use. However, administration of β-lactam antibiotics to patients colonized or infected with these strains results in the induction of β-lactamase production and emergence of resistance. For this reason, repeat in vitro sensitivity testing of clinical isolates of *Pseudomonas* a few days after the administration of β-lactam antibiotics may reveal reduced sensitivity to β-lactams.

Whereas imipenem and meropenem resist the β-lactamases commonly produced by *Pseudomonas*, resistance to carbapenems can result through the loss of an outer-membrane porin that allows carbapenems to enter *Pseudomonas*.[32] The permeability of other β-lactam antibiotics also may be reduced when this outer-membrane porin is lost. Although chemically distinct from imipenem or meropenem, fluoroquinolones such as ciprofloxacin may induce decreased permeability to both antibiotics.[178] Plasmid-mediated metallo-β-lactamases that confer resistance to imipenem have been described.[143,206,238] Fortunately, these metallo-β-lactamases are identified only rarely in *P. aeruginosa*. Continued use of carbapenems may pressure an increase in these β-lactamases in the future. *S. maltophilia* is resistant innately to imipenem.

Tobramycin is the most active aminoglycoside against *P. aeruginosa*, whereas amikacin induces the lowest frequency of resistant strains. Resistance to aminoglycosides usually results from enzyme-mediated antibiotic modification.[52] The various aminoglycoside-modifying enzymes have different substrate affinities. Therefore, resistance to one aminoglycoside through aminoglycoside-modifying enzymes does not predict resistance to others necessarily. Resistance is less common to amikacin than to other aminoglycosides.[78,250] Aminoglycoside-modifying enzymes usually are coded by plasmid-mediated genes, but they occasionally can be coded by genes on the bacterial chromosome.[52] Plasmid-encoded resistance supports rapid transference among strains within an institution. *P. aeruginosa* also can become resistant to aminoglycosides by decreasing the intracellular uptake of aminoglycosides or by modification of intracellular ribosomal attachment.[49,57] These mechanisms of resistance generally cause cross-resistance for all aminoglycosides.

Ciprofloxacin, a bacterial DNA gyrase inhibitor, is the most effective of the quinolones used against *P. aeruginosa*. Alteration of the binding site of DNA gyrase and decreased penetration of ciprofloxacin through the *Pseudomonas* cell membrane can result in resistant strains.[57,127]

Multidrug resistance is not an unusual occurrence in *P. aeruginosa*, and it may arise after treatment with a single antibiotic. The induction and production of β-lactamase may act synergistically with diminished outer-membrane permeability.[251] In addition, facilitation of energy-dependent efflux of antibiotics by *P. aeruginosa* can result in simultaneous resistance to quinolones, β-lactams, tetracycline, and chloramphenicol.[174,251]

In addition to antibiotic resistance, other clinical factors can adversely affect aminoglycoside activity against *Pseudomonas*. The acidic environment in tissue infected with *P. aeruginosa* can inactivate aminoglycosides.[25] Aminoglycosides may fail to reach therapeutic tissue levels because of poor penetration into bronchial secretions and lung tissue.[19] For patients with tracheitis (e.g., intubated patients) or endobronchial disease (e.g., cystic fibrosis), aminoglycosides and, less frequently, colistin have been administered by aerosol.[202] This route of delivery allows for greater availability of the antibiotic at the site of the infection, with enhanced safety because of negligible absorption into the systemic circulation. Doses of gentamicin and tobramycin of 2.5 to 8 mg/kg can be given safely by aerosol three times a day, with a maximum of 300 mg/dose. Resistance may emerge after prolonged courses.

Antibiotic therapy for *B. cepacia* infection is very challenging and should be guided by results of in vitro susceptibility testing. Unfortunately, *B. cepacia* frequently is resistant to many commonly used antipseudomonal antibiotic agents, particularly the aminoglycosides. Antibiotics that may have activity against *B. cepacia* include ceftazidime, cefoperazone, ureidopenicillins, quinolones, trimethoprim-sulfamethoxazole, and chloramphenicol. Susceptibility to carbapenems and minocycline varies; meropenem has greater in vitro activity against *B. cepacia* than does imipenem.[58] Typically, *B. cepacia* isolates from patients with cystic fibrosis are more antibiotic-resistant than are isolates from other patient populations. Combination therapy with two or three antibiotics may be required to achieve a clinical response. Combinations of β-lactam agents with aminoglycosides may provide synergy clinically, even when the *B. cepacia* strain isolated is aminoglycoside-resistant. *B. cepacia* may be sensitive to minocycline.[119] Minocycline may be considered to have an adjunctive role in the management of *B. cepacia* infection in patients with cystic fibrosis. However, resistance to minocycline commonly develops with prolonged therapy (3 to 13 months).[119]

S. maltophilia also exhibits significant antibiotic resistance to the common antipseudomonal agents. Trimethoprim-sulfamethoxazole, chloramphenicol, ceftazidime, cefoperazone, ticarcillin plus clavulanic acid, and ciprofloxacin may be active

against this organism whether these drugs are used alone or in combinations. *S. maltophilia* is resistant to antipseudomonal penicillins, imipenem, and aminoglycosides. A combination of trimethoprim-sulfamethoxazole and ticarcillin-clavulanate has been recommended as the most appropriate initial therapy for serious infections that are suspected or known to be caused by *S. maltophilia*.[230] For patients with catheter-related infections, removal of the catheter offers the greatest opportunity for cure.[61]

The most active antibiotics against *B. pseudomallei* are imipenem, piperacillin-tazobactam, piperacillin, ceftazidime, ticarcillin-clavulanate, ampicillin-sulbactam, tetracycline, and chloramphenicol.[216] Piperacillin, ceftazidime, and imipenem are not bactericidal in vitro.[216] Ciprofloxacin seems to be of limited value because of a high rate of resistance.

Chronic melioidosis can be treated with chloramphenicol over a period of many months or with tetracycline. Trimethoprim-sulfamethoxazole was recommended previously, but most strains currently are resistant.

For acute systemic melioidosis, ceftazidime (120 mg/kg/day) or chloramphenicol (50 to 75 mg/kg/day) plus an aminoglycoside (amikacin, 15 to 20 mg/kg/day) and sulfisoxazole (120 to 150 mg/kg/day) should be administered for a period of 4 weeks. When third-generation cephalosporins have been used, cefoperazone and ceftazidime have shown greater activity against *B. pseudomallei* than have other third-generation cephalosporin agents. Ceftazidime was compared with chloramphenicol, doxycycline, and trimethoprim-sulfamethoxazole for the treatment of severe melioidosis.[241] Ceftazidime, in a dosage of 120 mg/kg/day intravenously in three divided doses every 8 hours, was associated with a 50 percent lower overall mortality rate when compared with other forms of therapy. These results suggest that ceftazidime combined with an aminoglycoside and sulfisoxazole now should be considered the treatment of choice for severe melioidosis.

Soft tissue infections should be treated for 4 to 6 months with tetracycline (in children older than 8 years) provided in a dosage of 50 mg/kg/day in four divided doses. In younger children, trimethoprim-sulfamethoxazole (8 mg/kg/day of trimethoprim and 40 mg/kg/day of sulfamethoxazole) in two divided doses may be used. Most penicillins are ineffective.[59,216] The duration of therapy must be guided by clinical and laboratory findings; therapy for 4 weeks to many months may be required in patients with osteomyelitis. Relapses are common occurrences and should be treated as one would treat the first episode.[38]

PREVENTION

Prevention of infection with pseudomonads depends, in part, on a continuous surveillance program of the hospital environment that is designed to identify and subsequently eradicate sources of pseudomonads as quickly as possible. Transmission of health care–associated *P. aeruginosa* frequently can be traced back to colonization of the water distribution system of the health care institution. Biofilm colonization of faucets can be particularly problematic. However, eradication of *P. aeruginosa* from the water distribution system has not been successful, even after using high water temperatures, copper and silver ionization, or microfilters at faucets or after removing colonized faucets. Because *P. aeruginosa* cannot be eradicated from the environment, other infection control measures, especially good hand hygiene and the use of sterile water to wash patients and patient supplies, should be emphasized. Pseudomonads can grow to a concentration of 10^6 organisms per milliliter in distilled water that appears to be perfectly clear. Growth of pseudomonads in distilled water, disinfectants, and medications is the factor most commonly incriminated in single-source outbreaks of *Pseudomonas* infection in hospitals. Prevention of the follicular dermatitis caused by *P. aeruginosa* contamination of whirlpools or hot tubs should be possible by maintaining the pool water at a pH of 7.2 to 7.8 and free allowable chlorine concentrations at 0.4 to 1.5 ppm.[35]

Outbreaks of *Pseudomonas* infection in newborn nurseries have been reported.[24] Generally, infection has been transmitted by the hands of personnel from washbasin surfaces and by suction catheter rinse solution to the newborn infants. Strict attention given to handwashing, particularly with a liquid iodophor handwashing agent before and between contact with newborn infants, may prevent or interdict epidemic disease. Growth of *Pseudomonas* on suction catheters can be prevented by rinsing the catheter in an acetic acid solution.

Daily replacement of all apparatus used for intravenous administration greatly reduces the hazard of extrinsic contamination by *Pseudomonas* and other gram-negative organisms. When intravenous administration is indicated, a small metal needle is preferable to a plastic catheter because these needles have been associated with a lower rate of septicemia and phlebitis. Meticulous care is required in the preparation of solutions for total parenteral alimentation and in the insertion and care of catheters.

The risk of developing *Pseudomonas* infection in a burned patient also can be minimized by careful protective isolation and by the topical application of silver nitrate (0.5%) solution or 10 percent mafenide acetate cream. Débridement for removal of devitalized tissue also is imperative.

Pseudomonas infection of dermal abnormalities that communicate with the cerebrospinal axis can be prevented by careful evaluation and early surgical repair. Providing antibiotic prophylaxis of *Pseudomonas* urinary tract infection is difficult without a suitable oral antipseudomonal antibiotic for children. Identification and surgical correction of obstructive lesions of the urinary tract minimize or prevent the development of *Pseudomonas* infection of the urinary tract.

Cohorting plus isolation of patients with cystic fibrosis who are colonized with multiresistant strains of *P. aeruginosa* or *B. cepacia* has been suggested as a means of reducing nosocomial transmission of these organisms.[67] However, the proper manner of handling patients with these organisms has not been established. Any attempt to reduce transmission should be based on measures with proven efficacy and must also consider the potential consequences of strict isolation or segregation on this population, which spends so much time at health care facilities.

In patients with cystic fibrosis and in certain immunocompromised patients, high rates of *P. aeruginosa* colonization and infection and ever-increasing antibiotic resistance render active or passive immunization (or both) against *P. aeruginosa* desirable. Since the 1980s, an understanding of the human immune response to *P. aeruginosa* and the immune responses that may provide protection against infection or disease has increased considerably. Naturally occurring immunity generally is ineffective. Certain naturally generated antibodies may even be detrimental.[240] These antibodies may form antigen-antibody complexes that increase pulmonary inflammation and direct lung damage. Even if neutralizing antibodies could be administered passively or developed after vaccine administration, the large quantities of mucoid exopolysaccharide produced by *P. aeruginosa* could possibly mask many of the antigens targeted for antibody neutralization or opsonization.

Despite the aforementioned difficulties, numerous investigations of candidates for *P. aeruginosa* vaccines are ongoing. Purified bacterial proteins, including flagellar antigen, outer membrane proteins, lipopolysaccharide-O, several inactivated bacterial toxins, high-molecular-weight polysaccharide antigen and glycoconjugate, and killed whole-cell vaccine preparations, have been tested. Many of the candidate vaccines have been shown to be safe, immunogenic, and capable of generating protective immunity in various animal systems.[177] To date, evidence of protective

efficacy in humans has not been established definitively for any of these vaccines. Some studies have demonstrated the efficacy of active immunization of burned patients with specific strains of *Pseudomonas* or the administration of hyperimmune globulin in the prevention of *Pseudomonas* septicemia.[3,103] *P. aeruginosa* vaccine also has been suggested as a possible method for preventing or delaying this disease in patients with acute leukemia or cystic fibrosis.[124,171]

The route of vaccine delivery may be important in creating the optimal immune response. Data from experimental animals suggest that vaccine antigens administered parenterally stimulate IgG and IgM antibodies; antigens administered orally induce IgA and IgG at mucosal surfaces. For patients whose disease occurs after mucosal colonization (e.g., cystic fibrosis), oral administration of a *P. aeruginosa* vaccine could be the preferred route of administration to develop the optimal immune response at the site of *P. aeruginosa* infection.

Purified bacterial proteins and lipopolysaccharide from *B. cepacia* are in the initial vaccine research and development stages. Whether these *B. cepacia* vaccine candidates will enter preclinical or phase I clinical trials is yet to be determined.

PROGNOSIS

The prognosis depends largely on the nature of the underlying disease process. Septicemia is the leading cause of death in children with leukemia; *Pseudomonas* is responsible for half of these deaths. Four variables independently influence the outcome of *Pseudomonas* septicemia: (1) the development of septic shock, (2) inappropriate antibiotic therapy, (3) granulocyte counts less than 500/mm^3, and (4) the development of septic metastases.[17] Most deaths in children with cystic fibrosis are caused by pulmonary insufficiency. *Pseudomonas* can be recovered from the lungs of almost every one of these patients, and, in many, it has been responsible for their deaths.

CHAPTER 136

Stenotrophomonas (Xanthomonas) maltophilia

Carlos A. Sattler

Stenotrophomonas maltophilia is a gram-negative bacillus that previously belonged to the *Pseudomonas* and subsequently the *Xanthomonas* genus. In 1993, the new genus *Stenotrophomonas* was proposed, resulting in the most recent reclassification of this bacterium.[75] *S. maltophilia* is an opportunistic pathogen that has emerged as a significant cause of nosocomially acquired infection. It rarely is a cause of infection in healthy, immunocompetent children.

BACTERIOLOGY

S. maltophilia is an aerobic, nonfermentative, gram-negative bacillus that is oxidase-negative and lysine decarboxylase-positive. In addition, key features that allow identification of *S. maltophilia* include oxidation of glucose and maltose, as well as a positive DNase reaction.[40] Optimal growth occurs at 35° C; on sheep blood agar, colonies appear rough and lavender green and have a distinct ammonia-like odor. Morphologically, the organism is a straight bacillus, 0.7 to 1.8 μm long, that is motile by means of multiple polar flagella. It grows well on standard culture media, including blood agar and chocolate agar, as well as in broth blood culture systems, within the standard 5-day incubation period. Because of the hardy nature of this organism, standard collection, transport, and storage procedures are sufficient. The use of selective media such as MacConkey agar allows for *S. maltophilia* to be isolated from polymicrobial specimens, although for highly contaminated samples such as feces, the addition of antibiotics such as imipenem, vancomycin, and amphotericin B to the media should be considered.[54]

EPIDEMIOLOGY

S. maltophilia is a free-living, ubiquitous organism, the natural habitats for which include water, soil, and plants. The ability to survive in an aqueous milieu has allowed *S. maltophilia* to occupy a niche in the hospital environment. It has been cultured from dialysis fluids,[9] ventilators and other respiratory equipment,[24,55,81] and preoperative surgical brushes.[74] Several reports have linked nosocomial outbreaks of *S. maltophilia* to contamination of hospital water sources such as faucet aerators,[96] taps, and sinks,[55] as well as disinfectant solutions.[99] Intestinal colonization with *S. maltophilia* has been described in hospitalized oncology patients with diarrhea and could represent a potential source of nosocomial infection.[4] Other reports have described cases of nosocomial cross-infection occurring in neonatal and pediatric intensive care units.[36,44,59] In addition, cases of "pseudoinfection" caused by contamination of blood collection tubes have been described.[84]

Infection with *S. maltophilia* generally is hospital acquired.[37,83] Predisposing factors associated with colonization and infection by *S. maltophilia* include the presence of a severe, debilitating underlying illness, particularly malignancy; immune suppression (including human immunodeficiency virus infection); exposure to

broad-spectrum antibiotics (particularly to carbapenems, quinolones, or broad-spectrum cephalosporins); prolonged exposure to antibiotics; the presence of a central venous catheter; neutropenia; severe mucositis; prolonged hospital stay; stay in an intensive care unit; tracheostomy; mechanical ventilation; chronic obstructive pulmonary disease; or a combination of these factors.[5,12,13,21,30,65,72,73,89,94] Among children, predisposing factors are similar to those found in adults.[83] *S. maltophilia* is being isolated from clinical samples with increasing frequency.[5,29,56,64,68,83] This increase probably is related to advances in medical care that allow for a rise in the survival rate of severely ill patients, who are at highest risk for acquiring infection with this organism and who require more frequent use of invasive medical equipment, including indwelling lines, as well as broad-spectrum antimicrobials to which the organism is not susceptible.

PATHOPHYSIOLOGY

Like many pseudomonads, *S. maltophilia* is an organism with low virulence and limited invasiveness. An intact host immune system is an important deterrent to acquisition of a severe and even life-threatening infection; septicemia and death occur in patients with underlying debilitating illnesses. *S. maltophilia* elaborates a wide range of extracellular enzymes, including DNase, RNase, fibrinolysin, lipase, hyaluronidase, protease, and elastase, which may play a role in the pathogenesis of disease processes associated with *S. maltophilia*.[23] The pathogenesis of *S. maltophilia* infection also may be related to the development of cytotoxic activity.[33] In addition, *S. maltophilia* has been found to adhere to plastic materials, including intravenous catheters, and to produce biofilm, properties that may account for the relatively high incidence of catheter-related bloodstream infections caused by this organism.[20,23,31] *S. maltophilia* is inherently resistant to several classes of antibiotics. Colonization with *S. maltophilia*, especially in the respiratory tract, is not an uncommon finding. In debilitated patients, exposure to broad-spectrum antimicrobials, many of which are ineffective against this bacterium, may allow overgrowth of colonizing organisms that subsequently gain access to sterile body sites and cause infection. Portals of infection include indwelling devices such as central venous catheters, peritoneal dialysis or urinary tract catheters, the respiratory tract, and the gastrointestinal tract.

CLINICAL MANIFESTATIONS

S. maltophilia once was regarded as a microorganism with very limited pathogenicity that was unlikely to cause infection except in the most debilitated patients.[37] However, not only the incidence but also the severity of infection and the spectrum of clinical manifestations caused by this bacterium have increased. The most common site of isolation of *S. maltophilia* is the respiratory tract, particularly in hospitalized, mechanically ventilated patients. Attributing a causative role to *S. maltophilia* occasionally is difficult when the organism is isolated only from respiratory secretions, particularly as part of a mixed culture. Most critically ill, mechanically ventilated patients have abnormal chest radiographs, and differentiating infectious from noninfectious infiltrates may be very difficult. Nonetheless, *S. maltophilia* has unequivocally been associated with pneumonia, which may be severe and which may occur in patients who are not receiving mechanical ventilation.[1,34,39] Occasionally, the pathogen may be associated with massive, fatal pulmonary hemorrhage in adult patients with malignant disease,[28] and it is a cause of ventilator-associated pneumonia.[62] In adults with pneumonia, the development of secondary bacteremia signals a grave prognosis.[29]

S. maltophilia bloodstream infections usually are catheter-associated.[10,55,57,58,69,93] In a series of 32 episodes of bacteremia in children, all were related to the presence of a central venous catheter, although in 10 episodes, the primary source was not the catheter.[83] In a series of 217 episodes of *S. maltophilia* bloodstream infections occurring in patients with cancer who had central venous catheters, secondary bacteremia generally occurred in patients who were neutropenic, had concurrent pneumonia, or were critically ill, and it was associated with a worse outcome compared with patients who had central venous catheter–related bacteremia.[10] Frequently, *S. maltophilia* is isolated as part of a polymicrobial bloodstream infection, particularly when the central venous catheter is the origin of the infection. In children, the severity of illness appears to be similar regardless of whether *S. maltophilia* is isolated in a monomicrobial or mixed blood culture.[83] Malignant disease is the most common underlying illness in patients with bacteremia, and many patients have concomitant neutropenia. Bloodstream infections caused by *S. maltophilia* can be severe. In a pediatric series, 31 percent of the patients initially were seen in septic shock, and the attributable mortality rate was 6.3 percent.[83] In another pediatric series of 32 episodes of bacteremia occurring in 31 children, the crude mortality rate was 40.6 percent.[100] However, the death rate associated with *S. maltophilia* bloodstream infection is, in general, higher in adults.[55,56,66,69]

S. maltophilia endocarditis is a rare occurrence. It has been associated with intravenous drug abuse and frequently occurs after replacement of a prosthetic valve.[6,46,70,101] Surgical therapy often is required, although cure with medical treatment alone has been reported. No cases of endocarditis caused by this organism in children have been reported.

Urinary tract infections caused by *S. maltophilia* almost invariably occur in patients with structural abnormalities of the urinary tract, indwelling urinary catheters, or underlying illnesses. Infection may be severe and associated with sepsis and septic shock.[91]

Skin and soft tissue infections caused by *S. maltophilia* have occurred in patients who have had work-related injuries and wounds contaminated with soil and plant material, such as occur in injuries associated with use of lawn mowers.[18,27,41] In the hospital setting, *S. maltophilia* frequently is cultured from wounds and surgical sites, although determining the clinical significance of this organism in children, particularly when it is isolated in mixed culture, often is difficult.[83] In adult patients with cancer, tender, erythematous nodular skin lesions have been described in association with *S. maltophilia* bacteremia and probably represent metastatic infectious foci.[92] In 2006, the first reported cases of metastatic soft tissue involvement, including nodular skin lesions and pyomyositis, in pediatric patients with bacteremia were described.[87,100] All these patients had severe underlying diseases, particularly hematologic malignancies, associated with neutropenia.

S. maltophilia has been implicated as a cause of conjunctivitis and keratitis in the setting of ocular surface compromise resulting from trauma, the use of soft contact lenses, or previous infection with human herpes simplex virus.[79] Endophthalmitis occurring after ophthalmologic surgical interventions also has been described.[15,48,51]

Meningitis caused by *S. maltophilia* is an extremely rare occurrence and usually is nosocomial and associated with neurosurgical procedures and infection of intraventricular devices.[78] However, spontaneous meningitis in four infants was reported.[61,71,82]

S. maltophilia is the fourth most common organism isolated from the bronchial secretions of patients with cystic fibrosis, after *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Haemophilus influenzae*.[88] The incidence and prevalence of *S. maltophilia* isolated from the respiratory secretions of patients with cystic fibrosis are increasing,[53,86] although they are not uniform across all

cystic fibrosis centers.[21] *S. maltophilia* is recovered from the sputum of an estimated 10 percent of patients with cystic fibrosis in the Untied States and from as many as 25 percent of such patients in Europe.[95] The origin of the bacterium is uncertain; evidence suggests that it may be acquired both in the hospital and in the community.[21] Colonization may be transient or persistent, with chronic colonization occurring more frequently in older patients.[88] Case-control studies identified greater exposure to antipseudomonal antibiotics, oral ciprofloxacin, inhaled aminoglycosides, and oral corticosteroids, as well as more hospitalization days, and isolation of *Aspergillus fumigatus* from the sputum as risk factors for colonization with *S. maltophilia*.[26,63,86] Unlike with *Burkholderia cepacia* infection, no evidence of patient-to-patient transmission of *S. maltophilia* has been found, nor does the organism appear to be associated with rapid deterioration of pulmonary function in patients with cystic fibrosis.[25,42] Cases of *S. maltophilia* bacteremia have not been reported in patients with cystic fibrosis, with the exception of one patient who died of sepsis caused by this bacterium on the first day after undergoing lung transplantation.[52] The clinical significance of isolation of *S. maltophilia* from the sputum of patients with cystic fibrosis and its role in the deterioration in lung function is uncertain. Its presence may represent more a marker of severe, advanced disease than causally related respiratory deterioration.[22,43]

Other infections caused by *S. maltophilia* include peritoneal catheter exit-site infections and peritonitis in patients undergoing peritoneal dialysis,[19,85] as well as cholangitis,[76] osteochondritis,[7] mastoiditis,[47] bursitis,[77] sinusitis,[45] liver abscess,[80] osteomyelitis,[58] and necrotizing ulcerative gingivitis.[67]

DIAGNOSIS

The diagnosis of infection is established by isolating the organism from normally sterile sites in the presence of a compatible clinical picture. However, growth of *S. maltophilia* from normally sterile samples actually may represent an episode of pseudoinfection caused by the ability of this organism to contaminate and survive in hospital equipment such as blood collection tubes and antiseptic solutions. Because *S. maltophilia* is a common colonizer of hospitalized patients, isolation from nonsterile sites such as sputum or wounds is more difficult to interpret, particularly when the organism is isolated in mixed culture. Because nosocomial outbreaks have been reported, isolation of *S. maltophilia* from other patients in a hospital setting should alert the physician to the possibility of *Stenotrophomonas* infection. Infection control offices should be notified after the organism has been isolated.

Occasionally, *B. cepacia* is misidentified as *S. maltophilia*, especially in patients with cystic fibrosis.[11] *S. maltophilia* is oxidase-negative and DNase-positive. These tests should be repeated when identification of the organism is in doubt. Because of the serious clinical implications of misidentification in this group of patients, molecular analysis of the isolates should be considered if results remain uncertain.[98]

TREATMENT

Providing antibiotic therapy for *S. maltophilia* is difficult for several reasons. This organism displays multiple resistance mechanisms that confer broad antibiotic resistance, including resistance to β-lactam antibiotic agents. Mechanisms of resistance include the production of two chromosomally encoded, inducible β-lactamases designated L1 and L2. The former is a β-lactamase inhibitor–resistant metalloenzyme that hydrolyzes a broad range of β-lactam antibiotics, including carbapenems such as imipenem and meropenem. L2 is a cephalosporinase and, unlike L1, is susceptible to β-lactamase inhibitors.[23] Other mechanisms of resistance include reduced antibiotic uptake, the main mechanism providing aminoglycoside resistance, and an antibiotic efflux system that confers multidrug resistance.[3,103] In addition, in vitro antibiotic susceptibility testing is plagued by numerous methodologic problems. Several factors, including the time of incubation and the composition of the medium, affect the interpretation of test results. Furthermore, poor reproducibility among different testing methods has been described.[14] The Clinical and Laboratory Standards Institute (CLSI, formerly the National Committee for Clinical Laboratory Standards) has established standards for antibiotic susceptibility testing, including testing by both disk diffusion and broth or agar dilution (minimum inhibitory concentration [MIC] evaluation).[17] For the disk diffusion method, the CLSI recommends testing only trimethoprim-sulfamethoxazole, levofloxacin, and minocycline. In the case of broth or agar dilution, the CLSI recommends testing trimethoprim-sulfamethoxazole (susceptible: 2/38 μg/mL; resistant: 4/76 μg/mL), ceftazidime (susceptible: 8 μg/mL; intermediate: 16 μg/mL; resistant: 32 μg/mL), chloramphenicol (susceptible: 8 μg/mL; intermediate: 16 μg/mL; resistant: 32 μg/mL), levofloxacin (susceptible: 2 μg/mL; intermediate: 4 μg/mL; resistant: 8 μg/mL), minocycline (susceptible: 4 μg/mL; intermediate: 8 μg/mL; resistant: 16 μg/mL), and ticarcillin-clavulanate (susceptible: 16/2 μg/mL; intermediate: 32/2-64/2 μg/mL; resistant: 128/2 μg/mL). However, no controlled clinical studies have determined the most effective antibiotic regimen or duration of treatment.

Antibiotic susceptibility studies and clinical observation suggest that the most active antibiotic against *S. maltophilia* is trimethoprim-sulfamethoxazole, and most authorities agree that it is the drug of choice. It is bacteriostatic, however, a property that may have clinical implications in immunosuppressed patients. In addition, resistant strains are being identified with increasing frequency.[2,66,90] Other antibiotics that have shown good in vitro activity include ticarcillin-clavulanate, doxycycline, minocycline, and tigecycline, although clinical experience with the latter three drugs is limited.[23,49] The activity of early fluoroquinolones such as ciprofloxacin and ofloxacin varies widely, and emergence of resistance during treatment has been reported.[16] Newer quinolones, including levofloxacin and gatifloxacin, appear to have better activity in vitro against *S. maltophilia*,[32,50,60,97] but their activity decreases against multiresistant strains, and the development of resistance during the course of treatment has been described.[8,58] In addition, geographic variations in antibiotic resistance rates have been reported.[35]

Bloodstream infections can be severe, particularly in immunosuppressed patients. Combination antibiotic therapy with trimethoprim-sulfamethoxazole and ticarcillin-clavulanate for bloodstream infections by isolates that are susceptible has been advocated by some authorities and is supported by in vitro pharmacodynamic model data.[69,90,102] Other combinations have shown varying efficacy and correlation between in vitro and in vivo findings, which have not always been consistent.[23] In cases of catheter-related bloodstream infection, removal of the catheter has been associated with improved outcome, irrespective of the appropriateness of antibiotic therapy.[29,83] Nonetheless, successful treatment without removal of the catheter,[69] as well as an association of inappropriate antibiotic therapy and death,[66] has been described. In cases of serious infection such as bacteremia or severe pneumonia, combination antibiotic therapy should be considered when in vitro and in vivo evidence suggest that rapid emergence of resistance may occur during treatment.[38]

Appropriate management of patients from whom *S. maltophilia* is isolated from nonsterile sites, particularly in mixed culture, is not always clear because some isolates may represent colonization or contamination of the sample. In a pediatric study describing nonrespiratory infections in children, 6 of 16 patients with *S. maltophilia* that was cultured from sites other than the

bloodstream were treated with antibiotics not active in vitro, and 5 of these children were "cured."[83] Nonetheless, in adults, *S. maltophilia* has been associated unquestionably with severe infection at sites other than the bloodstream, and death caused by *S. maltophilia* infection has been associated with inappropriate initial antibiotic therapy.[72]

SUBSECTION 5

Gram-Negative Coccobacilli

CHAPTER 137

ACTINOBACILLUS ACTINOMYCETEMCOMITANS

Suzanne Whitworth ❂ Richard F. Jacobs

Actinobacillus actinomycetemcomitans is a fastidious, non–spore-forming, nonmotile, facultatively anaerobic gram-negative rod that frequently complicates actinomycosis caused by *Actinomyces israelii*. In addition to being associated with actinomycosis, it has been implicated as a pathogen in periodontal disease and is part of the oral flora. Infection by this bacterium often is not resolved by the normal host, possibly because of inefficient phagocytosis and a weak oxidative burst response of neutrophils.[7] In addition, the bacterium has several virulence factors, including induction of apoptosis and tissue destruction.[3] This organism is characterized by slow growth in culture and a requirement for incubation in an atmosphere enhanced with carbon dioxide.[4] Other bacterial species concomitantly isolated in human actinomycosis are *Eikenella corrodens*, *Fusobacterium*, *Bacteroides*, *Capnocytophaga*, *Staphylococcus*, *Streptococcus*, and members of Enterobacteriaceae.

*A. actinomycetemcomitan*s is a pathogen in at least 30 percent of actinomycotic infections[4] (see Chapter 161). Failure to recognize this organism and to treat it adequately has resulted in clinical relapse and deterioration in patients infected with actinomycosis.[5,13] Severe forms of periodontitis, particularly localized aggressive periodontitis, also are associated with this pathogen, and studies have shown that this organism is related strongly to children in the 10- to 19-year age group.[9] This type of periodontitis is characterized by rapid loss of attachment and bone around the permanent incisors and permanent molars. Treatment consists of local débridement and antibiotic therapy, usually metronidazole alone or in combination with amoxicillin. *A. actinomycetemcomitan*s also is an important pathogen in Papillon-Lefèvre syndrome, an autosomal recessive disorder characterized by prepubertal periodontitis and palmar-plantar hyperkeratosis.[8] Additionally, it is one of the HACEK (HACEK also includes *Haemophilus aphrophilus*, *Cardiobacterium hominis*, *E. corrodens*, and *Kingella kingae*) organisms that have a propensity for infecting heart valves. The endocarditis caused by this organism usually is insidious, with fever occurring in fewer than 50 percent of cases.[4] This organism also has been reported to cause pericarditis, meningitis, brain abscess, parotitis, synovitis, osteomyelitis, urinary tract infection, pneumonia, and empyema.[4] Cases of endophthalmitis[1,11] and cavernous sinus infection also have been reported.[12]

A. actinomycetemcomitans can be cultured on blood and chocolate agar, but it grows poorly on MacConkey agar. Cultures require incubation in an enhanced carbon dioxide atmosphere. Growth of the organism in a blood culture may take as long as 9 days in patients with endocarditis, and thus cultures should be held longer. On Gram stain, the organism appears coccoid to coccobacillary. Molecular techniques based on non-amplification nucleic acid probes or on polymerase chain reaction can provide rapid and accurate identification of *A. actinomycetemcomitans*.[10] Because of the frequency of co-infection with this organism in cases of actinomycosis, attempts always should be made to isolate this organism in these patients.

A. actinomycetemcomitans is susceptible to the newer cephalosporins, rifampin, trimethoprim-sulfamethoxazole, aminoglycosides, quinolones, tetracycline, azithromycin, and chloramphenicol. It is susceptible also to penicillin and ampicillin in vitro, but test results do not necessarily correlate with clinical outcome. Vancomycin, erythromycin, and clindamycin have very little activity against this organism. Treatment of aggressive periodontal disease consists of local débridement and antibiotic therapy with metronidazole and amoxicillin, which appear to be effective at suppressing *A. actinomycetemcomitans* to less than the level of detection.[2] Endocarditis caused by this organism has been treated successfully with a combination of ampicillin and gentamicin.[6] Cefotaxime or ceftriaxone is also acceptable.

CHAPTER 138

Bartonellosis

Barbara W. Stechenberg

Bartonellosis is a term that has been used to describe a geographically distinct disease caused by *Bartonella bacilliformis*. Recent advances in molecular biology have led to the reclassification of several bacterial pathogens, and the family Bartonellaceae, genus *Bartonella*, has expanded from a single species, *B. bacilliformis*, to include 16 validated species, 8 of which have been known to be pathogenic in humans. Of the members of the genus *Rochalimaea* that have been reclassified as *Bartonella* spp., *Bartonella henselae* is the cause of cat-scratch disease (see Chapter 151). Manifestations of *Bartonella* infection other than classic bartonellosis seldom occur in children and are discussed briefly.

BARTONELLOSIS (CARRIÓN DISEASE)

Bartonellosis is a disease unusual in its manifestations and rich in its history. The organism, *B. bacilliformis*, causes two illnesses that are both clinically and temporally distinctive. Besides producing subclinical asymptomatic infection, this organism can cause Oroya fever, a disease characterized by severe febrile hemolytic anemia, or verruga peruana, an eruption of hemangioma-like lesions. The eponym *Carrión disease* is used to designate the two forms collectively. The disease is restricted in its distribution to an area in South America that includes parts of Peru, Ecuador, and Colombia.

The origin of this disease in the history of the region probably considerably precedes the first written documentation of the disorder. The first written account of bartonellosis is attributed to Gago de Vadillo, who published a treatise on the subject in 1630, a century after the arrival of the first Spaniards. In 1764, Cosme Bueno first described the vector of this disease and of cutaneous leishmaniasis as the uta or sandfly.[13] The era of the mid-1800s was a period of increasing wealth in Peru because of a new industry, the mining of guano, or bird manure. With this increase came the building of a railroad from Callao to Oroya and nearly 10,000 workers from Chile, Bolivia, and China, none of whom had previous contact with or immunity to Carrión disease.[17] An epidemic that took the lives of hundreds of workers ensued. A cavalry unit of black soldiers sent to round up deserters quickly fell ill with the disease. A physician caring for them was so impressed with the rapidity and the profound anemia of the disease that he said, "It turned the blacks to whites," a remark henceforth frequently associated with the disease.[30]

In 1885, a Peruvian medical student (Carrión) was collecting data on the geographic distribution and clinical features of verruga peruana. Because of concern about the difficulty in diagnosing the pre-eruption period of verruga, he inoculated himself with material taken from a patient with verruga. He experienced his first symptoms 21 days after inoculation and then went on to exhibit the classic signs and symptoms of Oroya fever. Carrión realized the significance of his experiment 3 days before he died; he had proved the unitary origin of the two illnesses. In 1905, Alberto Barton, a Peruvian physician, described the etiologic agent *(B. bacilliformis)*, but several years passed before this organism was accepted as the cause of Oroya fever and was named in his honor.

THE ORGANISM

B. bacilliformis is small, 0.2 to 1.0 μm wide by 0.3 to 2.0 μm long. It stains easily with Giemsa (purple) and is a gram-negative and motile organism, with a brush of 10 or more unipolar flagella. In tissues, the organism stains black with silver-impregnated stains, such as Warthin-Starry stain. On electron microscopy, the contrast between *B. bacilliformis* and other members of the genus *Bartonella* is striking. Cultured *B. bacilliformis* organisms show the retracted cytoplasm and cell walls typical of bacteria.[22] They are rod shaped in young culture and become mostly coccoid in older culture. These organisms are obligate aerobes that grow best at 28° C in semisolid nutrient agar with 10 percent rabbit serum and 0.5 percent rabbit hemoglobin. Growth is subsurface, usually occurring in 7 to 10 days. The organism is pathogenic only for human beings and other primates, and only one antigenic type exists. Analysis of 16S rRNA sequences shows that *B. bacilliformis* is in the alpha$_2$ subgroup of proteobacteria and that its closest relatives are *Bartonella quintana* and *Brucella abortus*.[5]

EPIDEMIOLOGY

The distribution of the disease historically has been restricted to the mountain valleys of the Andes Mountains in Peru, Ecuador, and Colombia. Within these regions, the disease usually is seen only between the altitudes of 500 and 3200 m above sea level and primarily in valleys that are at right angles to the prevailing wind. This interesting geographic distribution reflects the habits of *Lutzomyia verrucarum*, the sandfly vector, which is seen only at these altitudes. One usually acquires the disease at twilight or soon thereafter because of the feeding habits of the insects. Within the region, the disease is endemic, with sporadic epidemic outbreaks that continue to occur.[12] Recent outbreaks have occurred in nonendemic populations in the surrounding area.[16] Several isolated reports of anemia with *Bartonella*-like organisms have been reported: three cases from Thailand in 1966 and one case from the Sudan in 1969.

PATHOPHYSIOLOGY

After inoculation by the sandfly, *Bartonella* organisms enter the endothelial cells of the blood vessels, where they proliferate during the incubation period. Microscopically, masses of organisms may be noted within the cytoplasm of the cells lining the blood vessels and lymph channels, and their numbers cause them to bulge into the lumen of the vessel. The organisms may be found within reticuloendothelial cells, particularly in the lymph nodes, but also in the liver, spleen, bone marrow, kidneys, adrenals, pancreas, and, more rarely, the skin, heart, and lungs.[11]

The organisms then re-enter the bloodstream and parasitize erythrocytes (red blood cells [RBCs]). Binding of *B. bacilliformis* to RBCs causes indentations and deformation of the membrane; membrane fusion is induced, and the organisms then enter the intracellular vacuoles, where they replicate.[4] The resulting anemia is caused primarily by destruction of these parasitized cells. Because as many as 90 percent of cells may be infected, profound, rapid anemia is a common symptom; the life span of infected RBCs is markedly shortened, particularly in the first few days. All parasitized cells are not destroyed, and no hemolysins or agglutinins have been recovered.[27] *B. bacilliformis* can be demonstrated easily with Giemsa stain. In earlier studies, considerable controversy ensued regarding whether the parasites were within or on the surface of RBCs; Cuadra and Takano[9] showed that they are located predominantly within the cells. In the recovery phase

of the anemia, the rod-shaped organisms change to a more coccoid form and rapidly disappear from the blood.

A patient who survives the acute phase of Oroya fever may or may not experience cutaneous manifestations of the disease, which appear as nodular, hemangiomatous lesions ranging in size from a few millimeters to several centimeters. Light microscopy reveals angioblastic and histiocytic hyperplasia of the dermis. Numerous newly formed small vessels with endothelial cell proliferation are found. Mast cells, lymphocytes, and macrophages are present.[1] Electron microscopy demonstrates that the bacterial organisms are located in the verruga, extracellularly in the fine fibrous interstitium. Two types of histiocytic cells are found in the verruga: a more numerous one, which is clear and has many lysosomes, ribosomes, mitochondria, and cytoplasm, and a darker one, with numerous lamellar membranous structures in the cytoplasm.[26] Studies have substantiated the presence of activity in *B. bacilliformis* that stimulates endothelial cells in vitro and is angiogenic in vivo. This finding may explain the similar pathogenesis of verruca and bacillary angiomatosis produced by other *Bartonella* spp.[1]

CLINICAL MANIFESTATIONS

The incubation period varies from 2 to 14 weeks, with a mean of 3 weeks. The difficulty in determining the duration of the incubation period results from the variable symptoms of the disease. Some patients are totally asymptomatic, and disease is detected only by blood culture or on serologic survey.[16] In a population-based cohort study, 0.5 percent of participants had asymptomatic bacteremia.[7] Other patients are not anemic, but symptoms such as headache, malaise, and occasional fever develop, and *B. bacilliformis* is recovered from blood cultures. Still others have severe anemia (Oroya fever). Patients with hemolytic anemia are febrile, and organisms may parasitize the RBCs. The anemia develops rapidly. Patients are deeply apathetic and have a peculiar discoloration of their skin and sclerae secondary to the combination of slight icterus and severe anemia.[28] Tachycardia and soft hemic murmurs are noted; occasionally, peripheral vascular collapse occurs. Headache, vertigo, restlessness, tinnitus, and occasionally angina pectoris may be present. Clouding of the sensorium and delirium are rather common findings; these effects usually are mild but may progress to overt psychosis. The temperature usually fluctuates between 37.5° C and 38.5° C (99.5° F and 101.3° F); higher elevations in temperature may be caused by intercurrent infection. Physical examination discloses generalized lymphadenopathy and nonpainful hepatomegaly.[18]

The anemia is macrocytic and usually hypochromic, with anisocytosis and poikilocytosis. The RBC count may drop to as low as 500,000/mm^3 in the first 2 to 4 weeks of illness. Reticulocytes may increase to 50 percent. The pathognomonic sign of the disease is the presence of *B. bacilliformis* within Giemsa-stained RBCs as red-violet rods. The leukocyte count may be normal, low, or elevated.

The "critical stage" of the anemia is the period of transition when the organism suddenly disappears from the RBCs.[28] During this time, *Bartonella* organisms change from the rod shape to more coccoid forms, the number of parasitized RBCs decreases, and the degree of anemia decreases; accordingly, the RBC count increases, and less hyperbilirubinemia is present. Clinically, fever decreases, and the patient stabilizes.[28] In some cases, the illness may become more severe, a finding that suggests the development of intercurrent infection (usually with *Salmonella*). Although this complication may occur at any time, it does so most commonly during the transitional period and may be noted in as many as 40 percent of patients.[8]

In the pre-eruptive stage, patients may complain of pain in their joints, bones, and muscles, as well as cramps and paresthesias. Inflammatory reactions such as phlebitis, parotitis, pleuritis, erythema nodosum, and encephalitis may occur. The anemia and lymphadenopathy of the invasive stage disappear.

The appearance of red cutaneous nodules, or verruga, is pathognomonic of the disease in the eruptive stage. Usually, these lesions are present in the skin, but they may be found in mesenchymatous tissue. They vary greatly in number and size, from small nodules to disfiguring zonular (hemangioma-like) lesions. They rarely cause symptoms; however, larger lesions may require surgical excision. This stage may last from several months to a year and may be the sole manifestation of the disease, particularly in school-aged children in endemic areas.

DIAGNOSIS

The diagnosis is based on clinical manifestations, in conjunction with a Giemsa-stained blood smear showing typical organisms, or on blood cultures. In the pre-anemic stage or in patients without the typical anemia who reside in an endemic area, the diagnosis can be based on blood culture alone. The presence of typical verruga in patients from an endemic area is pathognomonic of the disease. Immunoglobulin M antibody may be present in both stages of the disease, as well as in some healthy persons.[12,14] Persons with typical Oroya fever who are treated with antibiotics may not have an antibody response.[12,14] More recently, an indirect fluorescent antibody assay has shown promise for evaluating patients in both the acute and convalescent phases of the disease.[6] The differential diagnosis in the initial phase includes typhoid fever, malaria, tuberculosis, leptospirosis, brucellosis, and meningitis, as well as hematologic malignant disease and aplastic or hemolytic anemia. The eruptive phase may resemble hemangiomata, bacillary angiomatosis, Kaposi sarcoma, and other nodular diseases.

TREATMENT

B. bacilliformis is sensitive to many antibiotics, including penicillin, tetracycline, streptomycin, and chloramphenicol. With treatment, the fever usually abates by 24 hours; the rod-shaped organisms change to more coccoid forms and soon disappear from the blood.

The choice of antibiotic may be guided by considerations other than simple eradication of *B. bacilliformis*, including the risk of developing intercurrent infection. Chloramphenicol is considered the drug of choice because it also is useful in the treatment of salmonellosis.[33] Occasional patients need the addition of another antibiotic, usually a β-lactam.[29] Blood transfusions may be helpful during the period of severe anemia, especially if blood is obtained from patients who have recently recovered from the disease.[27]

Treatment of verruga peruana usually is not necessary unless particularly large zonular lesions interfere with function; in these persons, surgery may be necessary. Treatment is considered when patients have more than 10 cutaneous lesions, if the lesions are particularly erythematous or violaceous, or if the onset of lesions was less than 1 month before presentation.[18] Oral rifampin, ciprofloxacin (not approved for children), or tetracycline may be used to aid in healing of the cutaneous lesions.[17,29]

PROGNOSIS

The mortality rate in untreated bartonellosis was estimated in the past at approximately 40 percent. However, the more recent fatality rate has been approximately 9 percent in patients admitted to the hospital.[17] Intercurrent *Salmonella* infection increases

the mortality rate. In one population-based study, the fatality rate was 0.7 percent.[14,16] With the use of chloramphenicol, the prognosis is much improved. Permanent immunity develops in most patients.

PREVENTION

Dichlorodiphenyltrichloroethane (DDT) has been effective in controlling the disease by eliminating the vector *Lutzomyia verrucarum*. Persons can protect themselves by leaving endemic areas at night and using insect repellents. No vaccine of demonstrable efficacy has been developed.

TRENCH FEVER (*BARTONELLA QUINTANA*)

Trench fever was described first in Russia and was recognized as causing a severe epidemic during World War I, with more than a million troops infected.[3] The human body louse, *Pediculus humanus* variety *corporis*, is the vector, and humans are the only known reservoir.

The incubation period is extremely variable (from 4 to 35 days, with an average of 22 days). Symptoms also are highly variable. Four major fever patterns have been described: (1) a single febrile episode; (2) a single febrile period lasting 4 to 5 days; (3) three to eight recurrent febrile episodes, each lasting 4 to 5 days (sometimes for a year or more); and (4) persistent fever lasting 2 to 6 weeks.[10,31] Associated signs and symptoms may include conjunctival injection, retro-orbital pain, myalgias, arthralgias, headache, bone pain (especially in the shins), and splenomegaly. Chronic bacteremia following clinical improvement is common.[10]

In a non-epidemic situation, establishing the diagnosis of trench fever is impossible because the manifestations are not distinctive. The relapsing form can mimic malaria or *Borrelia recurrentis* relapsing fever. A history of body louse infestation or association with an epidemic should heighten suspicion. *B. quintana* can be cultured from blood by using a modification that includes culturing on epithelial cells. Serologic testing is available; however, cross-reactions with *B. henselae* occur. No controlled trials of treatment have been performed, but dramatic defervescence has been noted with the use of tetracycline and chloramphenicol.[15,31]

BACILLARY ANGIOMATOSIS AND BACILLARY PELIOSIS HEPATIS

Both *B. henselae* and *B. quintana* can cause disease in immunocompromised persons, primarily adults with acquired immunodeficiency syndrome (AIDS) or cancer or recipients of organ transplants. Lesions of bacillary angiomatosis are the most easily recognized form of *Bartonella* infection in immunocompromised patients. They are seen predominantly in patients with AIDS and with very low CD4 counts.[13,15] The vasoproliferative lesions may be cutaneous or subcutaneous and pathologically resemble the verruga of *B. bacilliformis*. Most characteristically, these lesions are red with a collarette of scale, but the clinical findings can be diverse. The differential diagnosis includes Kaposi sarcoma, pyogenic granuloma, and verruga peruana, and deep soft tissue masses may develop. Trauma may result in ulceration or bleeding. Osseous lesions occur in the long bones and can be very painful. A 12-year-old child with lymphocytic leukemia and bacillary angiomatosis has been reported.[19]

Bacillary peliosis hepatis was described first in 1990.[21] It is seen primarily in patients infected with human immunodeficiency virus (HIV) who have fever and abdominal pain. Vascular proliferative lesions develop, primarily in the liver and spleen. The differential diagnosis includes hepatic Kaposi sarcoma, lymphoma, extrapulmonary pneumocystosis, and infection with *Mycobacterium avium-intracellulare*. Both bacillary angiomatosis and bacillary peliosis hepatis have been treated successfully with antimicrobial therapy, including erythromycin, newer macrolides such as azithromycin or clarithromycin, or, as an alternative, doxycycline.[15,21,31]

ENDOCARDITIS

B. henselae, *B. quintana*, and *Bartonella elizabethae* all have been reported to cause bacteremia or endocarditis. The symptoms and signs are similar to those of other causes of endocarditis, although prolonged fever, night sweats, and profound weight loss may occur.[32] Many of the immunocompetent patients reported have been homeless. Cases also have been described in immunocompromised persons, particularly HIV-infected patients. *Bartonella* organisms may be a significant cause of culture-negative endocarditis.[2,23,24,32] Two children have been reported with central nervous system infection associated with *B. quintana*.[20]

Special culturing techniques, including the use of Isolator tubes, and prolonged incubation, as well as serology, histopathology of valvular tissue, and polymerase chain reaction, may be helpful.[34] Initial treatment of culture-negative endocarditis with ceftriaxone and gentamicin is effective for *Bartonella* organisms. A retrospective analysis of 101 patients with endocarditis[25] showed a benefit with the use of an aminoglycoside as part of a treatment regimen for a minimum of 14 days. If *Bartonella* is proven, doxycycline with gentamicin are recommended.

CHAPTER 139

Brucellosis

Edward J. Young

Brucellosis is a disease of animals (zoonosis) that is transmittable to humans.[76] Humans are accidental hosts, and human-to-human transmission rarely occurs. Brucellosis is distributed worldwide, and an estimated 500,000 human cases occur annually.[78] Programs to eradicate the disease in animals have reduced the incidence of human infection in many countries; however, brucellosis remains enzootic in large parts of the world.[117] Although brucellosis was once considered a rare occurrence in children, it now is recognized that persons of all ages are susceptible, especially in areas where *Brucella melitensis* is endemic.[38]

HISTORY

Brucellosis was one of many indistinguishable fevers until 1859, when J. A. Marston, a Royal Army Medical Corps physician, provided the first accurate description of the disease among troops stationed on Malta during the Crimean War.[62] During the 19th century, brucellosis was known by various names, including Malta fever, Mediterranean fever, and undulant fever.[72] Although the disease caused considerable morbidity and mortality in British military personnel stationed throughout the Mediterranean, the cause was not immediately apparent. In 1886, David Bruce,[16] another Royal Army Medical Corps surgeon, isolated a microorganism from spleen tissue of victims of Malta fever. Termed *Micrococcus* (later renamed *Brucella*) *melitensis*, the organism could be found in the blood, urine, and feces of patients with Malta fever. Between 1904 and 1907, Bruce headed the Mediterranean Fever Commission, which studied aspects of the disease in Malta. Themistocles Zammit, a Maltese physician working with the Commission, first identified native goats as the reservoir of brucellosis and their unpasteurized milk as the vehicle of transmission to humans.[108] When fresh goat's milk was replaced with tinned condensed milk in the military mess, the incidence of brucellosis among military personnel declined precipitously.[97] In 1897, Almroth Wright applied the newly devised agglutination assay to the serologic diagnosis of Malta fever.[112]

Unlike *B. melitensis* that was initially isolated from human tissue, other *Brucella* spp. were recognized for the disease they caused in animals. In 1897, Bernhard Bang,[13] a Danish veterinarian, isolated the "abortion bacillus" (later, *Brucella abortus*) from placental tissue of cattle suffering contagious abortions. *Brucella suis* was isolated around 1914 by F. M. Hayes and J. Traum[45] at the Bureau of Animal Industry. The bacteriologist Alice Evans[36] finally recognized the relatedness of these disparate bacteria in 1918. After Evans' work was confirmed, K. F. Meyer and E. B. Shaw proposed the name *Brucella* for the genus to honor Bruce.[43]

Additional *Brucella* spp. were isolated from sheep (*Brucella ovis*) and from desert wood rats (*Brucella neotomae*), but to date they have not been shown to cause illness in humans. *Brucella canis* was isolated from kennel-bred dogs in 1968 by Carmichael and Brunner,[19] although it appears to be a rare cause of human brucellosis.[102,109] Since the late 1990s, at least two previously unrecognized species of *Brucella* have been isolated from marine mammals.[15,47] Tentatively named *Brucella cetaceae* (from cetaceans) and *Brucella pinnepediae* (from pinnepeds),[23] their role as human pathogens remains to be clarified.[63,91]

ETIOLOGY

The brucellae are small, fastidious, nonmotile, non–spore forming, gram-negative coccobacilli that lack native plasmids. The outer cell membrane resembles other gram-negative bacilli with a dominant lipopolysaccharide (LPS) component. Their metabolism is oxidative, and all strains are aerobic. Some strains require carbon dioxide for growth, especially for primary isolation. Brucellae are always catalase-positive, but oxidase activity varies among biovars. Most strains reduce nitrate to nitrite, but some do not. Production of hydrogen sulfide also varies, as does urease activity.[28] Various media, including chocolate, trypticase soy, and serum dextrose agars, support the growth of brucellae. Growth in vitro characteristically is slow, and when brucellosis is suspected, cultures should not be discarded before 28 days.

Brucellae belong to the alpha-2 subdivision of the Proteobacteria phylogenetically related to plant pathogens and symbionts, such as *Agrobacterium* and *Rhizobium*, and to intracellular animal parasites, such as *Bartonella* and *Rickettsia*.[22] On the basis of DNA-DNA hybridization and genome sequencing, the genus *Brucella* comprises a single species.[31,44,79] Despite genetic homology greater than 90 percent, the *Brucella* nomen species show a remarkable preference for certain natural hosts. Consequently, the traditional nomen species classification is retained for epidemiologic purposes (Table 139-1).

TABLE 139–1 Nomen-Species Classification of *Brucella* Species

Species	Biovars	Natural Hosts	Pathogenicity for Humans
B. abortus	1-6, 9	Cattle, other Bovidae	Yes
B. melitensis	1-3	Goats, sheep	Yes
B. suis	1-3	Swine	Yes
	4	Reindeer, caribou	Yes
	5	Rodents	Yes
B. canis	—	Dogs, other canines	Yes
B. neotomae	—	Desert wood rats	No
B. ovis	—	Sheep	No
*B. maris**			
*B. pinnipediae**		Pinnipeds	?
*B. cetaceae**		Cetaceans	?

**Tentative designations.*
?Still unresolved.

EPIDEMIOLOGY

Historically in the United States, brucellosis was linked to the livestock industry, and *B. abortus* was the predominant species causing human illness. Farmers, ranchers, meat inspectors, and veterinarians were at highest risk of acquiring infection, usually through direct contact with infected animals. With the virtual elimination of bovine brucellosis by way of test-and-slaughter practices and immunization of susceptible cattle, the epidemiology of brucellosis changed, especially in states that border Mexico. *Brucella melitensis* replaced *B. abortus* as the major cause of human disease, and foodborne transmission replaced direct contact with animals as the primary mode of infection.[20,105] On the Mexican border, human brucellosis occurs at a rate eight times higher than the national average in the United States,[33] and unpasteurized goat's milk cheese is a common vehicle of transmission.[104,121] Human infection caused by *B. suis* traditionally has been an abattoir-associated infection,[18] but in recent years, the hunting of feral swine has become a risk when hunters are contaminated with the blood of infected animals.[99] Personnel working in clinical or research laboratories also are at risk, and brucellosis continues to be the most commonly reported laboratory-associated bacterial infection.[85,113]

Brucellosis once was thought to be an uncommon or mild disease in children, but susceptibility now is recognized in persons of all ages.[90] Conditions for the transmission of brucellosis from animals to humans vary among countries and cultures. Where farm animals traditionally are raised in the home, contact with children occurs frequently. Moreover, foodborne infection is not limited to any age or sex and can occur without direct contact with animals. Childhood brucellosis occurs more commonly in locations where *B. melitensis* is enzootic.[38,60]

The clinical manifestations of brucellosis in children do not differ from those in adults,[101] although unfamiliarity with the disease can delay diagnosis.[3,21] Human-to-human transmission of brucellosis is a rare occurrence, but evidence of venereal transfer has been documented.[88,98] Rare cases associated with bone marrow transplantation have been reported.[35] Few cases of brucellosis have been reported in patients infected with the human immunodeficiency virus.[68]

Spontaneous abortion is a common manifestation of brucellosis in animals in which brucellae localize within the reproductive organs of both sexes. Brucellosis in pregnant women can lead to abortion if the infection is unrecognized and untreated.[75] In a retrospective study from Saudi Arabia, intrauterine death and spontaneous abortion occurred in 46 percent of 92 women with brucellosis.[52] This rate was significantly higher than the rate of spontaneous abortion in women without brucellosis. When the infection is diagnosed early, pregnant women can be treated successfully without compromising their ability to carry the pregnancy to term or to conceive again. On rare occasions, transplacental transmission can lead to neonatal brucellosis.[69]

PATHOGENESIS

The incubation period for brucellosis varies; however, symptoms generally appear within 2 to 3 weeks after acquisition of infection. Disease caused by *B. melitensis* and *B. suis* tends to be more severe than is illness caused by *B. abortus* or *B. canis*.[105] Morbidity can be considerable, but death occurs in only approximately 1 percent of cases, usually from complications such as neurobrucellosis or endocarditis.[117] Although no racial or genetic differences in susceptibility are known in humans, innate immunity has been demonstrated in various animals.[103] Normal human serum has limited bactericidal activity against brucellae, but complement opsonizes the organism for phagocytosis by neutrophils.[122] Brucellae are facultative intracellular pathogens that are able to survive and multiply within phagocytic cells of the host. The mechanisms by which brucellae evade killing by neutrophils is not completely understood; however, virulent strains contain a potent superoxide dismutase enzyme and nucleotides (adenine and guanosine monophosphate) that inhibit phagolysosome fusion, degranulation, and activation of the myeloperoxidase-halide system.[29] Brucellae that survive neutrophils killing enter the lymphatics, where they are ingested by monocytes and fixed macrophages of the reticuloendothelial system (RES). Survival within mononuclear phagocytes appears to depend on specific proteins, including stress proteins that block tumor necrosis factor-α (TNF-α), increase cyclic adenosine monophosphate, and prolong the life of the host cell by inhibiting apoptosis.[49,56] Intracellular killing of brucellae occurs when macrophages become "activated" by specifically committed T lymphocytes. This T-helper (T_H1) response involves cytokines, including interleukin-2, interferon-?, and TNF.[114]

CLINICAL MANIFESTATIONS

The spectrum of human brucellosis ranges from subclinical (diagnosed by serology) to chronic (characterized by recurrent symptoms over many years).[120] The disease is characterized by a plethora of nonspecific somatic complaints, such as fatigue, anorexia, nausea, weight loss, sweats, and depression. In contrast, there is a paucity of physical findings, notably fever, and occasionally hepatosplenomegaly. The infection can involve any organ or organ system of the body. Sometimes, symptoms related to a single organ predominate, in which case the disease is termed *localized*.[26] Not unexpectedly, localization often involves organs rich in elements of the RES.

Osteoarticular complications are the most frequent localized manifestations of brucellosis, and in children monoarticular arthritis involving the hips, knees, and sacroiliac predominates.[12,41,59,71] Spondylitis, osteomyelitis, and inflammatory arthropathy also have been described, but they occur less often in children than in adults.[53,93] Brucella is a rare cause of prosthetic joint infection.[110]

Neurobrucellosis comprises a variety of nervous system complications including meningitis/encephalitis, myelitis, radiculitis, peripheral and cranial neuropathies, and demyelinating syndromes.[64] Although most patients complain of headache and weakness, direct invasion of the central nervous system occurs in less than 5 percent of cases.[14,70] Analysis of cerebrospinal fluid (CSF) in cases of *Brucella* meningitis reveals lymphocytic pleocytosis, elevated protein, and normal or low glucose. Organisms are rarely seen on Gram stain or culture from CSF; however, anti-

bodies to *Brucella* are present, and their finding in CSF is diagnostic.[7]

Gastrointestinal complaints frequently reported include anorexia, nausea, vomiting, abdominal discomfort, and weight loss.[67,90] Rare cases of ileitis,[81] colitis,[48,100] and peritonitis[2] have been reported.

The liver is the largest organ of the RES, and it probably always is involved in brucellosis, even when transaminase levels are normal or only slightly elevated.[25] Rarely, acute hepatitis occurs with hepatic enzyme levels resembling viral hepatitis.[57] The liver histology in patients infected with *B. abortus* is characterized by epithelioid granulomas indistinguishable from sarcoidosis.[96] In contrast, infection with *B. melitensis* can result in a spectrum of lesions ranging from diffuse hepatitis to granulomas.[115,118] Infection with *B. suis* (and *B. melitensis*) also can result in suppurative abscess that may become chronic.[11,27,107]

Genitourinary tract involvement usually manifests as orchitis or epididymo-orchitis and can be mistaken for testicular cancer.[74] Rare cases of interstitial nephritis, membranous nephropathy, and glomerulonephritis also have been reported.[106]

Respiratory tract localization of brucellosis is reported in approximately 7 percent of cases.[77] Lung lesions attributed to brucellosis include hilar adenopathy, lobar pneumonia, lung nodules, pleural effusion, and thoracic empyema.[58]

Cardiovascular lesions of brucellosis include endocarditis, myocarditis, pericarditis, and aneurysms of the aorta and cerebral blood vessels.[84] Both native valve endocarditis and prosthetic valve endocarditis have been described, and the aortic valve is involved most often. Delays in establishing a diagnosis can result in life-threatening complications such as valve rupture, myocardial abscess, and sinus of Valsalva fistula. Treatment of *Brucella* endocarditis generally requires the combination of antibiotics in addition to valve surgery.[46,51]

Ocular lesions, most notably uveitis, have been described in patients with brucellosis. Other eye lesions that have been reported include endophthalmitis, optic neuritis, episcleritis, nummular keratitis, and chorioretinitis. The pathogenesis of some of the lesions is a matter of conjecture because brucellae rarely are isolated from the eye.[5,34,50]

Cutaneous lesions attributed to brucellosis include contact dermatitis, rashes, abscess, and vasculitis.[66] On occasion, brucellae have been cultured from subcutaneous papules.[60]

Hematologic abnormalities such as anemia, leukopenia, and thrombocytopenia are common occurrences in the course of brucellosis.[30] These changes generally are mild and resolve promptly with antimicrobial therapy. On occasion, thrombocytopenia can be severe, resulting in hemorrhage into the skin and from mucosal sites.[123] The origin of this complication likely is multifactorial, including hypersplenism, disseminated intravascular coagulation, bone marrow suppression and hemophagocytosis, and immune mechanisms.

DIAGNOSIS

The symptoms of brucellosis are nonspecific. Therefore, the importance of obtaining a detailed history including occupation, avocations, travel, animal exposure, and food habits cannot be overemphasized. Routine laboratory tests generally are not helpful; however, characteristic hematologic findings (normal or low white blood cell count) can suggest the possibility of brucellosis.[4]

A definitive diagnosis of brucellosis is made by isolating a *Brucella* sp. from blood, bone marrow, or other tissue. The rate of positive blood cultures varies from 15 to 70 percent depending on the methods used and the period of in vitro incubation.[42] Bone marrow culture was reported to be more sensitive than blood culture before the introduction of newer isolation techniques.[32,65] Nucleic acid amplification tests using a variety of gene sequences are being applied with some success to the rapid diagnosis of brucellosis.[73,83,111]

In the absence of bacteriologic confirmation, a presumptive diagnosis can be made by measuring the titer of specific antibodies in serum.[116] Human brucellosis is characterized by an initial production of immunoglobulin M (IgM) antibodies followed by a switch to IgG synthesis within the second week of infection. Treatment results in a gradual decline in both antibody isotypes; however, the persistence of IgG antibodies is associated with relapse or chronic infection.[80] Consequently, the pattern of immunoglobulin isotypes is important in differentiating active from treated disease[39,116] This distinction is made by performing the serum agglutination test with and without 2-mercaptoethanol or dithiothreitol, agents used to destroy the agglutinability of IgM while preserving agglutination by IgG.[17] Alternatively, a more direct way to measure IgM and IgG antibodies is the indirect enzyme-linked immunosorbent assay (ELISA) employing anti-IgM and anti-IgG conjugates.[61]

Most serologic tests for brucellosis employ smooth LPS (S-LPS), the immunodominant cell wall antigen capable of detecting antibodies to all smooth species (*B. abortus*, *B. melitensis*, *B. suis*). Because *B. canis* is naturally rough and lacks S-LPS, antibodies against this organism are detected with antigen prepared from rough species (*B. canis* or *B. ovis*).[82] Various cell wall and cytoplasmic proteins have been studied as potential serodiagnostic antigens.[40] However, none has proved superior to LPS-based assays. More recently, a latex agglutination assay using S-LPS has been shown to be simple to run and rapid and to have good sensitivity and specificity.[1]

TREATMENT

Antimicrobial therapy lessens morbidity, shortens the course of illness, and reduces the incidence of complications of brucellosis.[119] Numerous drugs are active against *Brucella* spp., but the results of in vitro sensitivity tests do not always correlate with clinical effectiveness. Because the rate of relapse with single-drug therapy is high, successful treatment of brucellosis requires combination therapy for prolonged periods of time.[93,94] The tetracyclines remain the most effective antibiotics against brucellae with minimal inhibitory concentrations (MICs) lower than 1 μg/mL. Aminoglycosides (streptomycin and gentamicin) have been shown to enhance the killing of brucellae in vitro by numerous antibiotics.[89] Traditionally, the combination of tetracycline HCl administered for 6 weeks and streptomycin given for 2 to 3 weeks provided the highest cure rates in patients with brucellosis.[10] Currently, the preferred regimen is doxycycline (for adults 200 mg/day orally for 45 days) in combination with gentamicin (5 mg/kg/day as a single daily dose intramuscularly for the first 7 days).[86,92]

Rifampin also shows good in vitro activity against *Brucella* spp., and in 1986 the World Health Organization recommended the combination of doxycycline (200 mg/day orally for 45 days) and rifampin (600 to 900 mg/day orally for 45 days) as the treatment of choice. Although this regimen has been used successfully, subsequent studies have shown the superiority of the combination of doxycycline and an aminoglycoside.[95]

Children who are older than 8 years can be treated as adults. Because tetracycline is contraindicated for children younger than 8 years old and for pregnant women, alternative treatments have been sought. A regimen of trimethoprim-sulfamethoxazole (TMP-SMZ; co-trimoxazole) in a fixed combination (80 mg TMP, 400 mg SMZ twice daily for 45 days) in addition to gentamicin (5 mg/kg/day as a single daily dose for 7 days) has yielded satisfactory results.[90] Alternatively, the combination of TMP-SMZ and rifampin (15 mg/kg once daily) administered for either 6 or 8 weeks gave comparable results.[87] Similarly,

pregnant women can be treated successfully with TMP-SMZ in combination with rifampin without causing adverse drug effects in the newborn.[52]

The quinolones are active against *Brucella* spp. in vitro, but the MIC values vary for each compound and to some extent for *Brucella* isolates.[37] In clinical practice, however, results have been disappointing.[54,119] Consequently, quinolones are not recommended alone for treating brucellosis, and their role in combination therapy awaits well-designed clinical trials.

The optimal treatment for complications of brucellosis such as meningitis and endocarditis has not been defined with certainty. Doxycycline crosses the blood-brain barrier more effectively than does generic tetracycline, and it has been used in combination with other drugs (e.g., rifampin, TMP-SMZ) for neurobrucellosis.[64,70] Third-generation cephalosporins achieve high concentrations in CSF, but the sensitivity of brucellae varies, and in general, β-lactam drugs are not effective when they are used alone.[55] On occasion, patients with *Brucella* endocarditis have been treated successfully with antimicrobial therapy alone; however, most patients have required valve replacement surgery.[6]

RELAPSE AND CHRONIC BRUCELLOSIS

Most patients with brucellosis recover completely within a few weeks to months after receiving adequate therapy. Despite receiving appropriate treatment, some patients suffer a relapse characterized by recurrence of symptoms and re-isolation of brucellae from their blood.[9] Obviously, relapse occurs more frequently if the full course of treatment is not completed, and taking oral antibiotics for 6 weeks can tax a patient's compliance. With few exceptions, relapse is *not* caused by antibiotic-resistant strains of *Brucella*.[8]

Even with appropriate treatment, some patients experience delayed recovery and continue to have nonspecific complaints, notably fatigue. Such patients have no objective evidence of infection, such as fever, and their antibody titers decline as expected. Whether this condition represents a variant of the chronic fatigue syndrome is not clear, but additional antibiotic therapy does not improve their recovery.[24] Rarely, chronic brucellosis results from a persisting focus of infection such as osteomyelitis or a deep tissue abscess. Such patients have fever or other objective signs of infection, and levels of IgG antibodies in the serum remain elevated. Scanning techniques (e.g., technetium 99m bone scan, gallium 67 scan, computed tomography, or magnetic resonance imaging) can be useful in localizing an occult focus of infection.

CHAPTER 140

Pertussis and Other *Bordetella* Infections

James D. Cherry ✪ Ulrich Heininger

Pertussis (whooping cough) is an acute infectious illness of the respiratory tract caused by *Bordetella pertussis* and, less frequently, by *Bordetella parapertussis*.[49,55,68,174,257] The illness occurs worldwide and affects all age groups, but it is recognized primarily in children; it is most serious in young, unprotected infants.[85,168,257]

HISTORY

Unlike other severe epidemic infectious diseases of children (e.g., smallpox, poliomyelitis, and measles), pertussis lacks an ancient history.[184] The first observation of pertussis occurred in France in 1414, and the first epidemic was noted in Paris in 1578.[68,77,221] This epidemic and the clinical characteristics of the cases were described in 1640 by Guillaume de Baillou.

Pertussis was noted as *the kink* (a Scottish term synonymous with *fit* or *paroxysm*) and *kindhoest* (a Teutonic word meaning *child's cough*) in the Middle Ages.[58,184] In 1669, Sydenham named the illness *pertussis* (meaning *violent cough*).[221] Isolation of *B. pertussis*, the main causative agent of pertussis, was reported by Bordet and Gengou in 1906.[30,31]

Vaccines consisting of killed whole *B. pertussis* organisms were developed shortly after the bacterium was isolated, and the first results of protection were reported by Madsen in 1925.[246] The mouse protection test, developed and reported by Kendrick and collaborators[209] in 1947, allowed vaccine production to be standardized. Comprehensive studies conducted by the British Medical Research Council[264] in the 1940s and 1950s demonstrated a correlation between the potency of pertussis vaccines as determined by the mouse protection test and their clinical efficacy in children. As a consequence, immunization against pertussis, most commonly in combination with diphtheria and tetanus toxoids (DTP), became part of routine vaccination programs in many countries throughout the world.

Concern about a relationship between pertussis vaccination and temporally associated serious adverse events (e.g., sudden infant death syndrome and a variety of neurologic illnesses) led to a sharp decline in vaccination rates in Japan and several European countries during the 1970s.[49,55,68,213] This concern, along with well-documented high rates of unpleasant local and systemic reactions, led to the development of new acellular vaccines. These vaccines cause reactions less frequently and have been used in Japan since 1981 and in many developed countries since the mid 1990s.[162,213,391,408]

B. bronchiseptica, which causes cough illnesses in a number of animals as well as humans, was first isolated some time around 1910 by Ferry[115], McGowan, and perhaps others who were studying dogs with distemper.[257,260] *B. parapertussis* was isolated first from children with pertussis in the 1930s, and *Bordetella holmesii* was noted in nasopharyngeal specimens from patients with pertussis-like illnesses in Massachusetts during the period from 1995 through 1998.[32,104,105,258,427]

MICROBIOLOGY

The genus *Bordetella* contains nine species: *B. pertussis*, *B. parapertussis*$_{hu}$ (adapted to humans), *B. parapertussis*$_{ov}$ (ovine-adapted *B. parapertussis*), *B. bronchiseptica*, *Bordetella avium*, *Bordetella hinzii*, *B. holmesii*, *Bordetella trematum*, and *Bordetella petrii*.[81,174,210,257] *B. pertussis* infects exclusively humans. *B. parapertussis* also is a human pathogen, but it has been recovered from sheep ("ovine") as well.[322] Both *B. pertussis* and *B. parapertussis* are respiratory pathogens. *B. bronchiseptica* primarily is an animal pathogen that causes atrophic rhinitis and pneumonia in pigs, kennel cough in dogs, pneumonia in cats, and respiratory illnesses in other animals.[81,132,377] This organism also is the occasional cause of respiratory illness in humans.[72,89,143,299,344,361,377,378,423] *B. avium* is an important cause of respiratory illness in turkeys and other birds.[211]

Three additional species of *Bordetella* have been recognized to infect humans: *B. holmesii* and *B. hinzii* have been isolated from blood cultures, primarily in patients with underlying chronic illness.[80,234,380,414] *B. holmesii* also has been isolated from the human respiratory tract, and *B. trematum* has been found in wounds and ear infections.[258,395,427] *B. petrii* has been isolated from the environment and is capable of anaerobic growth.[403]

The genus *Bordetella* consists of gram-negative, pleomorphic, aerobic bacilli that are grouped together on the basis of genotypic characteristics, and species are differentiated by phenotypic characteristics. Selected differential characteristics of the four *Bordetella* spp. that cause respiratory illnesses in humans are presented in Table 140–1. All species have relatively simple requirements, but *B. pertussis* is quite fastidious and is inhibited by constituents in common laboratory media such as fatty acids, metal ions, sulfides, and peroxides.[239,394] For laboratory growth, *B. pertussis* requires the addition of "protective substances" such as charcoal, blood, or starch, whereas the other species are less fastidious and may grow in blood or MacConkey agars.

TABLE 140–1 Selected Differential Characteristics of *Bordetella* Species That Cause Respiratory Illnesses in Humans

Rights were not granted to include this table in electronic media. Please refer to the printed publication.

From Loeffelholz, M. J.: Bordetella. In Murray, P. R., Baron, E. J., Jorgensen, J. H. (eds.): Manual of Clinical Microbiology. 8th ed. Washington, D.C., American Society for Microbiology, 2003, pp.780-788.

The genomes of representative strains of *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* have been sequenced.[312,324] The genome sizes are as follows: *B. pertussis*, 4,086,186 bp; *B. parapertussis*, 4,773,551 bp; and *B. bronchiseptica*, 5,338,400 bp. *B. pertussis* has 3816 predicted genes, whereas *B. parapertussis* and *B. bronchiseptica* have 4404 and 5007 predicted genes, respectively. Pseudogenes occur most commonly in *B. pertussis* (358) and *B. parapertussis* (220) and are uncommon in *B. bronchiseptica* (18). *B. pertussis* has three insertion sequence elements (IS): IS 481 (238 copies), IS 1002 (6 copies), and IS 1663 (17 copies). *B. parapertussis* has IS 1001 (22 copies) and IS 1002 (90 copies). The sequenced RB50 *B. bronchiseptica* strain contained no IS elements, but studies of other *B. bronchiseptica* strains found strains with IS 481, IS 1001, and IS 1663.[95,122,328]

ETIOLOGY OF PERTUSSIS (WHOOPING COUGH)

B. pertussis and *B. parapertussis* are the etiologic agents of pertussis, but approximately 95 percent of illnesses are caused by *B. pertussis*.[133,174,325] In rare instances, *B. bronchiseptica*, which normally is enzootic in pigs, dogs, cats, rodents, and other animals, has been isolated from humans with pertussis-like cough illnesses.[72,89,143,299,344,361,377,378,423] From 1995 to 1998, *B. holmesii* was isolated from the nasopharynx of 33 individuals in Massachusetts suspected of having pertussis, most of them adolescents and young adults.[258] In contrast to all other *Bordetella* spp., this organism is susceptible to cephalexin, an antibiotic that frequently is added to *Bordetella* culture media.[302] This addition may explain why the organism has not been noted in patients with pertussis in other laboratory studies.

Adenoviruses have been isolated from children with pertussis, and some researchers have suggested that several adenoviral types on occasion may cause a pertussis-like illness.[14,76,78,295] However, the data of Nelson and associates[295] and Baraff and coworkers,[14] as well as our own observations, lead us to suggest that mixed infections are occurring and that the classic symptoms are caused by *B. pertussis* and not infection with an adenovirus. At variance with our view are data presented by Wirsing von König and associates.[421] These investigators noted pertussis-like illnesses caused by viral or *Mycoplasma pneumoniae* infections in 83 patients in whom pertussis laboratory studies were performed and were negative. These authors serologically identified 33 adenoviral illnesses, 18 illnesses caused by parainfluenza viruses, 15 illnesses caused by *M. pneumoniae*, and 14 caused by respiratory syncytial virus (RSV). In young infants, co-infection with an adenovirus and perhaps RSV may lead to more severe disease.[20,227] Infection with human bocavirus also may cause an illness with a paroxysmal cough.[9] Of 54 children with laboratory confirmed bocavirus infections, 85 percent had cough, and 19 percent had paroxysmal coughing episodes.

Physicians often suggest that *Chlamydia trachomatis* can cause a pertussis-like illness. However, in our opinion, the repetitive cough of *C. trachomatis* is distinctly different from the paroxysmal cough of *B. pertussis* infection, and thus illnesses caused by the two agents usually should not be confused clinically. Infections with *Chlamydia pneumoniae* and *M. pneumoniae* also cause long-lasting illness with cough.[87,149,421] Although infection with these agents in older children and adults can be confused with *B. pertussis* infection, true paroxysms typical of pertussis rarely occur.

ANTIGENIC AND BIOLOGICALLY ACTIVE COMPONENTS OF *BORDETELLA PERTUSSIS*

B. pertussis contains a variety of components that are antigenic or biologically active (Table 140–2).* With the exception of tracheal cytotoxin (TCT), all known virulence factors produced by *B. pertussis* are regulated by the single genetic locus *bvgAS*.[81] Under certain conditions, such as an environmental temperature of 37° C, *bvgAS* is active, toxins and adhesins are produced, and the organism is virulent in a mouse model (*bvg*$^+$ phase). In the *bvg*$^-$ phase, a different set of genes (*vrg*, *vir* repressed genes) are expressed, and *B. pertussis* is avirulent in mice in this phase.[411] The switch from *bvg*$^+$ to *bvg*$^-$ is a phenomenon common to all *Bordetella* spp. and is associated with a change in phenotype. An intermediate phase with reduced virulence and expression of specific proteins also has been characterized. Although still speculative, the intermediate phase may have some function in transmission of the organism.[81,367]

Fimbriae

Fimbriae (FIM) are protein projections on the surface of *B. pertussis*.[257,279,281,325,334,335] They are highly immunogenic, and antibody to them, as well as to other antigens, causes agglutination of the organism. Two fimbrial antigens (FIM 2 and 3) are the main agglutinogens; endotoxin and pertactin (PRN) also are agglutinogens.[52,334]

In the past, typing of *B. pertussis* strains was based on the agglutination patterns noted with specific antisera.[57,106,325,334] Six specific agglutinogens were recognized, and typing was based on the presence or absence of agglutination by each specific antiserum. More recently, researchers recognized that two of the agglutinogens (agglutinogens 2 and 3) are fimbrial in location (FIM 2 and 3) and that agglutinogens 4, 5, and 6 are minor antigens.[325,334] All *B. pertussis* strains contain agglutinogen 1. The nature of this agglutinogen is not known.[334] It could be lipopolysaccharide (LPS) or PRN, but because the original serotyping scheme was based on heat-labile antigens, it probably was not LPS.[33,229,382]

FIM function as adhesins, but some studies suggest that in infection they are not the primary adhesins but serve to sustain the attachment established by other attachment factors.[68,335,387,412] An in vitro study by Rodriguez and associates[336] suggested that the effect of FIM on attachment was the result of bacterial agglutination. In the mouse model system, immunization with purified FIM resulted in protection against infection when challenged with *B. pertussis*.[206] Data from two trials in which serologic correlates of immunity were studied indicated that antibody to FIM was important in protection.[69,372]

TABLE 140–2 Biologically Active and Antigenic Components of *Bordetella pertussis*

Component	Characteristic
Adhesions	
Fimbriae (FIM)	Two serologic types (types 2 and 3); antibody to specific types causes agglutination of the organism; organisms may contain fimbriae 2, fimbriae 3, fimbriae 2 and 3, or neither fimbriae 2 nor fimbriae 3
Filamentous hemagglutinin (FHA)	220-kd surface-associated and secreted protein; highly immunogenic
Pertactin (PRN)	A 69-kd outer-membrane protein that is the most important adhesin; antibody to pertactin causes agglutination of the organism
Vag8	95-kd outer-membrane protein
BrkA	73-kd surface-associated N-terminal passenger domain with 30-kd outer-membrane C-terminal protein; confers serum resistance and protection against antimicrobial peptides in *B. pertussis*
SphB1	Subtilisin-like Ser protease/lipoprotein required for FHA maturation
Tracheal colonization factor (TcfA)	60-kd secreted protein
Toxins	
Pertussis toxin (PT; also called lymphocytosis-promoting factor)	A classic bacterial toxin with an enzymatically active A subunit and a B oligomer-binding protein; effects in an animal model system include histamine sensitization, promotion of lymphocytosis, stimulation of insulin secretion, and adjuvant and mitogenic activity; it is an envelope protein that is also an important adhesin; it adversely affects host immune cell function
Adenylate cyclase toxin (ACT)	Calmodulin-activated RTX family toxin with dual adenylate cyclase/hemolysin activity; acts as an antiphagocytic factor during infection
Dermonecrotic toxin (DNT)	160-kd heat-labile secreted toxin; induces necrosis in vitro
Tracheal cytotoxin	Disaccharide-tetrapeptide monomeric byproduct of peptidoglycan synthesis; causes mitochondrial bloating, disruption of tight junctions, damage to cilia, and interleukin-1α and nitric oxide production
Lipopolysaccharide (LPS) (endotoxin)	An envelope toxin with activities similar to endotoxins of other gram-negative bacteria; a significant cause of reactions to whole-cell pertussis vaccines; antibody to LPS causes agglutination of the organism

Filamentous Hemagglutinin

Filamentous hemagglutinin (FHA) is a component of the cell wall of all *Bordetella* spp.[25,68,81,214,248,257,387] It is highly immunogenic and is the dominant attachment factor for *Bordetella* in animal model systems.[257,345,354] However, because FHA is released in large amounts from the cell surface, its role as an adhesin must be questioned. Adhesins typically remain associated with the bacterial surface to promote maximum attachment. FHA is a component of most acellular component (DTaP) vaccines.[102] However, the importance of antibody to FHA and protection from disease is not clear. Some data indicate that a vaccine containing both pertussis toxin (PT) and FHA had an efficacy greater than that of a vaccine containing only toxoided PT.[370] However, in two studies in which serologic correlates of immunity were evaluated, researchers found that FHA made no contribution to protection.[69,372] Finally, one whole-cell component DTP vaccine in which vaccinees did not mount an antibody response to FHA was, nonetheless, highly efficacious.[166,362]

Pertactin

PRN is a 69-kd outer-membrane protein that is, in our opinion, the most important adhesin of *B. pertussis*.[25,225,302,303] Antibody to PRN has a strong protective effect in aerosol-challenge studies in mice.[48,355] In the two vaccine efficacy trials in which serologic correlates of immunity were evaluated, researchers found that antibody to PRN was most important in protection.[69,372] In addition, the vaccine efficacy trials conducted in the 1990s, in which mild disease and typical disease were evaluated, revealed that DTaP vaccines that contained PRN in addition to PT and FHA clearly were significantly more effective.[56,65,145,257] Another study revealed that anti-PRN antibodies were required for efficient phagocytosis of *B. pertussis* by host immune cells.[176]

Other Autotransporters

In addition to PRN are several other surface-associated proteins (Vag8, BrkA, SphB1, and TcfA) that are considered to belong to the autotransformer family.[257] All likely contribute to attachment to host cells, but their potential adhesive functions have not been investigated directly.

Pertussis Toxin

PT is an adenosine diphosphate–ribosylating toxin synthesized and secreted exclusively by *B. pertussis*. It is an A-B toxin with an enzymatically active A subunit (S_1) and a B oligomer ($S_{2\text{-}5}$) binding portion.* PT inactivates G proteins, a process resulting in disruption of signaling pathways and leading to histamine sensitization, enhancement of insulin secretion in response to regulatory signals, and both suppressive and stimulatory immunologic effects in animal model systems.[257] The various effects of PT in animal model systems and in humans were reviewed in depth previously by one of us (J. D. C.).[68,257] In contrast to animal studies, histamine sensitization does not appear to happen in children, but PT does cause an increase in plasma insulin levels.[68,257] PT also is responsible for leukocytosis with lymphocytosis in *B. pertussis* infections. PT is a strong adjuvant in several immunologic systems in animals, but in DTP-vaccinated persons (DTP vaccines contain small amounts of active toxin), only the enhancement of serum antibody responses to antigens of other vaccines has been demonstrated. In mouse and rat models, PT inhibits chemotaxis and migration of neutrophils, monocytes/macrophages, and lymphocytes to infection sites, and PT also functions as an adhesin in the adherence of *B. pertussis* to human macrophages and ciliated respiratory epithelial cells.

In 1979, researchers suggested that pertussis was a single-toxin disease, a suggestion that led to the idea that pertussis could be prevented by a PT vaccine in a manner similar to the success achieved with diphtheria toxoid in diphtheria.[52,319,320] Although convincing arguments to the contrary have been presented, this idea persists.[332] The most compelling evidence that pertussis from *B. pertussis* infection is not a PT disease is as follows: identical illness results from *B. parapertussis* infection, and this organism does not express PT.[52,174]

PT does contribute to morbidity in *B. pertussis* infections, as indicated by the severity of illness, which tends to be greater than

*See references 7, 8, 68, 81, 125, 196, 225, 257, 319, 320, 389.

that caused by *B. parapertussis* infection. In particular, the frequent finding of extreme leukocytosis caused by PT in neonates and young infants with fatal pertussis is noteworthy.

Adenylate Cyclase Toxin

Adenylate cyclase toxin (ACT) is an extracytoplasmic enzyme that impairs host immune cell function and may contribute to local tissue damage in the respiratory tract.[68,81,181,212,257,413] ACT enters phagocytic cells (particularly polymorphonuclear neutrophils) and, once inside, is activated by calmodulin and catalyzes the production of supraphysiologic amounts of cyclic adenosine monophosphate from adenosine triphosphate, which intoxicates these cells.[257]

Dermonecrotic Toxin

Dermonecrotic toxin (DNT) is a heat-labile toxin described by Bordet and Gengou[31] in 1909. This cytoplasmic protein causes skin necrosis in laboratory animals,[293] and it may contribute to local tissue damage in the respiratory tract.

Tracheal Cytotoxin

TCT is a disaccharide-tetrapeptide monomer of peptidoglycan.[81,130] It causes local damage to respiratory epithelium and may affect host neutrophil function adversely.[86,130] The cytopathology caused by TCT probably is the result of increases in nitric oxide.[81]

Lipopolysaccharide (Endotoxin)

The LPS of *B. pertussis* is similar to the endotoxins of other gram-negative bacteria.[46,68,81] Its function in disease is unknown, but it may act as an adhesin.[89] LPS is a major cause of reactions to whole-cell pertussis vaccines.[13] LPS is a significant agglutinogen. Antibody to LPS reduces colonization of *B. pertussis* in the lungs and trachea of mice after aerosol challenge.[289]

EPIDEMIOLOGY

Today, considerable misinformation is circulating with regard to the epidemiology of pertussis. The main reason for misinformation is the failure to recognize the significant differences in the dynamics of reported pertussis compared with the dynamics of *B. pertussis* infections.[60,61] The two different epidemiologies are the (1) epidemiology of reported clinical pertussis and (2) the epidemiology of *B. pertussis* infection.

OBSERVED (REPORTED PERTUSSIS)

Pertussis is one of the most highly communicable diseases; when it has been introduced into a susceptible population, attack rates of 100 percent in susceptible individuals have been recorded.[220] Infants and young children have the highest risk of acquiring the disease.

Incidence

The incidence of reported pertussis and its mortality are affected markedly by the use of pertussis vaccine. In the prevaccine era in the United States, the average attack rate of reported pertussis was 157 per 100,000 population, versus 230 per 100,000 population in England and Wales.[49] Previous studies, however, suggested that reported cases represent only between 15 and 25 percent of cases that actually occur.[159,203,205,368]

With the introduction and widespread use of pertussis vaccines, the attack rate in the United State fell approximately 150-fold from 1943 to 1976. For the 7-year period from 1976 to 1982, the attack rate in the United States remained between 0.5 and 1.0 per 100,000 population (Fig. 140–1). From 1982 to 2005, the attack rate curve shifted modestly upward and reached a rate of 8.9 per 100,000 in 2004.[61] Possible reasons for the resurgence of reported pertussis that have been suggested are (1) increased vaccine failures resulting from genetic changes in *B. pertussis*, (2) increased vaccine failures related to vaccines of lessened potency, (3) greater awareness of pertussis, and (4) the availability of better laboratory tests.[60,61,65,74,138,145] Of these possibilities, it is our opinion that greater awareness is the most important. Also of probable importance is that, in general, DTaP vaccines are less efficacious than are DTP vaccines, which, in particular, may be a contributing factor relating to the increase in reported pertussis in older children and adolescents.

Pertussis epidemics in the prevaccine era occurred at 2- to 5-year intervals (average, 3.2 years), and these cycles have continued in the vaccine era. As noted by Fine and Clarkson,[116,118] this continuation of the same cycles today as occurred in the prevaccine era indicates that, although immunization has controlled disease, it has not reduced transmission of the organism in the population.[49,54,57]

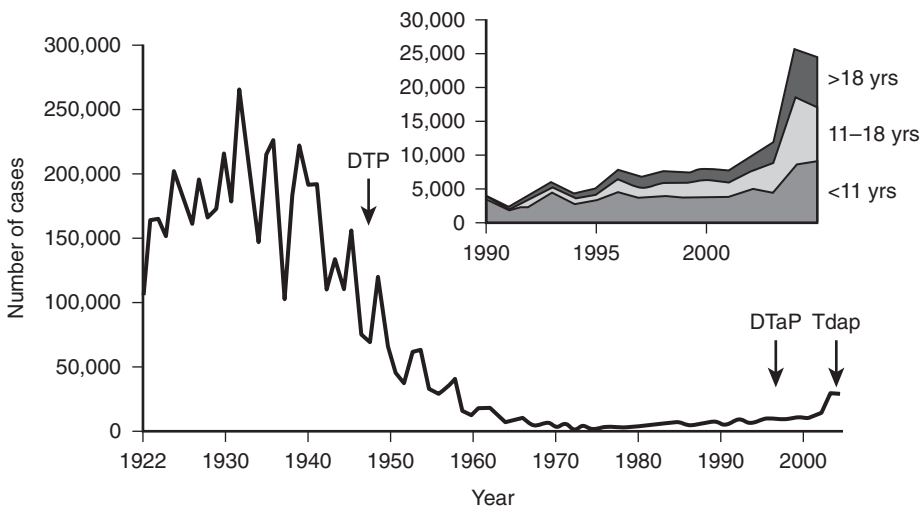

Figure 140–1 Number of reported cases of pertussis by year, United States, 1922 to 2005. DTaP, diphtheria-tetanus-acellular pertussis; Tdap, tetanus-diphtheria-acellular pertussis component vaccine. *(Data from Centers for Disease Control and Prevention, Atlanta.)*

In the prevaccine era, the following percentages of cases by age were noted in Massachusetts: younger than 1 year, 7.5 percent; 1 to 4 years, 41.1 percent; 5 to 9 years, 46.0 percent; 10 to 14 years, 4.1 percent; and 15 years and older, 0.9 percent.[30] Associated with the marked reduction in reported cases of pertussis in the United States resulting from widespread pediatric immunization, a major shift occurred in the percentages by age category.[30] During the period from 1978 to 1981, the age distributions were as follows: younger than 1 year, 53.5 percent; 1 to 4 years, 26.5 percent; 5 to 9 years, 8.2 percent; 10 to 14 years, 5.4 percent; and 15 years or older, 6.5 percent. In contrast, U.S. data for 2005 revealed the following: younger than 1 year, 16 percent; 1 to 4 years, 9 percent; 5 to 9 years, 10 percent; 10 to 19 years, 31 percent; and 20 years or older, 28 percent (unknown age, 6%). Today, pertussis in adolescents and adults is an important source of *B. pertussis* infection in unimmunized or partially immunized children.* Disease in adolescents and adults usually is not recognized as pertussis, even though the cough frequently is paroxysmal and the illness persists for weeks.[57,251,323,352]

In a study in university students, members of our group found that 26 percent of students with a cough illness of 6 days' duration or longer had *Bordetella* infections, none of which had been diagnosed correctly clinically.[278] The findings in this study led to the suggestion that *B. pertussis* infections are endemic in adults and are responsible for cyclic outbreaks in susceptible children. More recent studies in the United States, Germany, and elsewhere support this hypothesis.†

Morbidity and Mortality

During the first 30 years of the 20th century, pertussis was an important cause of death in the United States.[221] The number of deaths from pertussis in the United States between 1926 and 1930 was 36,013,[133] and most of these deaths occurred in children younger than 1 year of age. The pertussis death rate curve in the United States declined throughout the 20th century. In infants, the mortality rate decreased approximately fivefold from 1900 to 1944. During the next 35 years, it declined more than 85-fold.[286,287] Today, most of the deaths caused by pertussis occur in unimmunized infants younger than 6 months of age.[144,257] During 1990 to 1996, 57 deaths attributed to pertussis were reported in the United States.[144] Of these 57 patients, 49 were younger than 6 months old. Young maternal age and preterm delivery were risk factors for fatal disease. Currently in the United States, approximately 10 to 20 deaths are reported each year.[39,42,144,402,425]

Of importance is that deaths caused by pertussis frequently are misdiagnosed as deaths from other respiratory infectious illnesses.[49,171,300] For example, in England and Wales during the epidemic from 1977 to 1979 and at the beginning of the epidemic in 1982, 32 deaths were reported to be caused by pertussis.[49] However, when the excess deaths from other respiratory infectious illnesses were examined, approximately 362 additional deaths appeared to be caused by pertussis.

The morbidity caused by pertussis in recent years can be gleaned from numerous reports. The numbers of pertussis-related hospitalizations, complications, and deaths in the United States during 1990 to 1996 were reviewed in 1999 by Güris and colleagues.[144] Of the 31,837 cases analyzed, 31.7 percent of these patients were hospitalized, 9.5 percent had pneumonia, 1.4 percent had seizures, 0.2 percent had encephalopathy, and 0.2 percent died. The most severe morbidity occurred in infants younger than 6 months of age. Of this group, 72.2 percent were hospitalized, 17.3 percent had pneumonia, 2.1 percent had seizures, 0.5 percent had encephalopathy, and 0.5 percent died. During the period from 2000 to 2004, 12,174 cases in infants were reported.[44] Of this group, 62.8 percent were hospitalized, 55.8 percent had apnea, 12.7 percent had pneumonia, 1.5 percent had seizures, and 0.8 percent died.

In adolescents with reported pertussis, 0 to 2 percent are hospitalized, and 2 percent have pneumonia.[45] In a review of data from seven studies of reported adult pertussis, the following findings were noted: hospitalization, 3 to 12 percent; seizures, 0 to 0.6 percent; rib fracture, 0 to 4 percent; and pneumonia, 0.6 to 8 percent.[44]

A pertussis surveillance system was introduced in conjunction with a large pertussis vaccine efficacy trial in several regions of Germany in 1990. The initial results of this ongoing surveillance study were published in 1993.[164] Of 601 culture-proven cases, 12.3 percent occurred in infants, and 86.2 percent occurred in children younger than 6 years of age. Serious complications were reported in 22 of 275 patients with follow-up. These complications included pneumonia in 5.5 percent, apnea in 2.2 percent, and cardiorespiratory failure in 0.4 percent.

In a follow-up report of the same study, 1 of 185 culture-confirmed cases in infants was fatal.[168] In another German study from 1993 to 1996, Herzig and associates[178] noted 116 hospitalized pertussis patients with the following complications: pneumonia in 81 percent, apnea requiring assisted ventilation in 15 percent, seizures in 14 percent, encephalopathy in 5 percent, and death in 2 percent. In Canada from 1991 to 1997, Halperin and colleagues[156] analyzed the complications of pertussis in 1082 hospitalized children younger than 2 years of age and noted that 9.4 percent had pneumonia, 3 percent had atelectasis, 2.3 percent had seizures, 0.59 percent had encephalopathy, 0.8 percent had inguinal or umbilical hernias, 1.3 percent had more than a 5 percent weight loss, and 0.9 percent died.

Season, Geography, and Sex

Pertussis occurs throughout the world.[68] Historically, epidemic pertussis had no seasonal pattern.[49] However, in the present vaccine era in North America, pertussis usually occurs in the summer and fall.[110,134,144,257,294] In the past, the incidence of pertussis was greater in female than in male patients.[49,133,409] Between 1980 and 1996, this female preponderance was observed again, but only in older age groups.[110,144] In 2004, 25,827 cases were reported in the United States, and of these patients, 11,199 (45%) were male and 13,879 (55%) were female (sex not identified in 749 cases).[41] In the large study in Germany, 1263 (50.7%) of the 2493 subjects were female.[168]

Transmission

Transmission is thought to occur by droplets from a coughing patient that reach the upper respiratory tract of a susceptible person. Indirect spread also possibly occurs. A symptomatic patient could contaminate the environment with respiratory secretions. The hands of the new host-to-be make contact with the secretions and then may inoculate the respiratory tract.[68] Attack rates in susceptible household contacts range from 70 to 100 percent.[49,68] Antibody studies indicate that asymptomatic infections also occur in contacts.[91,240,241] These asymptomatic infections are likely to be short-lived and probably are not important with regard to contagion. Transmissibility is greatest early in the illness, that is, during the catarrhal and early paroxysmal phases.

BORDETELLA PERTUSSIS INFECTION

The cyclic pattern of reported pertussis is similar today to what it was in the pre-vaccine era.[257] This pattern is different from that

*See references 27, 44, 57, 60, 61, 66, 219, 236, 237, 285, 294, 392.
†See references 26, 57, 60, 61, 91, 94, 280, 352, 420, 426.

seen with other diseases that have been brought under control by universal immunization.[57,60,61,278] An example is measles. As this disease was brought under control, the interepidemic cycle lengthened because circulation of the measles virus in the population had been reduced. In contrast, with pertussis, immunization controlled disease but did not decrease the circulation of *B. pertussis*.[118,119] In the 1970s, Nelson[294] noted that the source of *B. pertussis* infection in hospitalized infants most often was an adult. This observation led many investigators to suspect that *B. pertussis* infections were endemic in adolescents and adults.[57,278] Sporadic infection in the adolescent and adult reservoir is the major source of *B. pertussis* infections in nonimmune children. The cyclic pattern occurs because it takes a few years for a significant number of susceptible members of the population to develop so that an outbreak will result from the sustained transmission.

Our present understanding of the importance of adolescent and adult *B. pertussis* infections has been the result of the ability to diagnose infection serologically by measuring immunoglobulin G (IgG) and IgA antibodies to PT by enzyme-linked immunosorbent assay (ELISA).[60,61,257,278] During the last 20 years, numerous studies in adolescent and adult populations have contributed to our understanding of *B. pertussis* epidemiology.

Studies of prolonged cough illnesses in adolescents and adults suggest that between 13 and 20 percent of the illnesses are caused by *B. pertussis* infection.* Many studies have looked at overall infection rates by determining significant IgG or IgA titer rises to PT in persons who have two or more serum samples collected over extended periods.[60,61,83,94,182,257,407] These studies suggest that between 1 and 6.7 percent of adolescents and adults have a *B. pertussis* infection each year. In another large study in the Netherlands, which used a combination of serologic surveys, an incidence of infection of 6.6 percent per year for persons between the ages of 3 and 79 years was estimated.[92] The incidence in children 3 to 4 years of age was 3.3 percent. It then increased gradually to a peak of 10.8 percent in those 20 to 24 years of age. Other age-specific incidences were 6.5 percent in persons 25 to 55 years old and 4.0 percent in those older than 55 years of age.

The specific rates of cough illnesses caused by *B. pertussis* were determined in two prospective specific population-based studies.[373,406] In the first study, the rate was 500 per 100,000 (0.5%), and in the second, it was 370 per 100,000 (0.37%). In addition, the retrospective serologic analysis of a respiratory disease study in adults older than 65 years suggested a rate as high as 1.5 percent.[182] This high value assumes that all respiratory illnesses with cough during the 4-month periods of seroconversion were the result of *B. pertussis* infection.

PATHOLOGY

Data on pathology of *B. pertussis* infections have been determined mainly by postmortem study in fatal cases.[49,68,73,221,235,249,311,358] However, information relating to uncomplicated pertussis can be gleaned from experiments using rhesus and ringtail monkeys.[221,347] In these studies, pure cultures of *B. pertussis* have been obtained from between the cilia of the smaller bronchi and bronchioli. Endobronchitis and peribronchitis are noted, and the bronchi contain leukocytes, mucus, and debris.

In a recent study of autopsy material from is infants (≤4 months old), the consistent histopathologic features were necrotizing bronchiolitis and pneumonia, intra-alveolar hemorrhage and fibrinous edema, and abundant intra-alveolar macrophages.[311] Angiolymphatic aggregates of mixed leukocytes in the intralobular septa and pleurae were seen in 86 percent of the specimens. Intact *Bordetella* were noted in cilia of the trachea, bronchi, and bronchioles and within airways and alveoli. They also were noted intracellularly in alveolar macrophages and respiratory epithelium. Six of the respiratory specimens had evidence of co-infections with one or more other agents (cytomegalovirus, 1 child; RSV, 2 children; *Streptococcus pneumoniae*, 2 children; *Streptococcus pyogenes*, 2 patients; *Moraxella catarrhalis*, 1 child; and viridans streptococci, 1 child).

Pathologic changes in the brain and liver also have been described. Microscopic or gross cerebral hemorrhage may be noted, and cortical atrophy has been observed. These changes most likely are the result of anoxic brain damage. In some studies of pertussis encephalopathy, findings suggested meningoencephalitis, with perivascular cuffs of lymphocytes within cerebral gray matter and pleocytosis.[422] However, the studies in which inflammation was demonstrated were performed before modern virologic techniques became available. Probably, the neurologic findings in these instances were caused by interactions with neurotropic viruses or other infectious agents and were not the result of *B. pertussis* infection.[68] Fatty infiltration of the liver has been noted in patients with pertussis encephalopathy.

PATHOGENESIS AND IMMUNITY

After the patient is exposed to *B. pertussis*, the pathogenesis of infection depends on four important steps: attachment, evasion of host defenses, local damage, and systemic disease.* The biologically active antigenic components of *B. pertussis* listed in Table 140–2 have various roles in pathogenesis.

Infection is initiated in the respiratory tract by the attachment of *B. pertussis* organisms to the cilia of ciliated epithelial cells.[412] Adhesins (FHA, PT, FIM, LPS, TcfA, Vag8, BrkA, and PRN) facilitate this attachment.[81,210,291,325,387,412] Because of the redundancy of protein adhesins, determining the importance of the individual proteins and ascertaining a primary adhesin or adhesins have been difficult.[257] In animal model systems, FHA is an important adhesin; however, data from two vaccine efficacy trials in which serologic correlates of immunity were studied suggested that FHA may not be necessary if other adhesins are present.[69,372] Data from one of these efficacy trials noted that a DTP vaccine that contained a minimal amount of FHA and generated a minimal anti-FHA response had greater efficacy than did a DTaP vaccine that contained a large amount of FHA and generated a vigorous antibody response to FHA.[166,362] However, in a study in which a PT toxoid vaccine was compared with a two-component PT/FHA vaccine, researchers found that the two-component vaccine was more efficacious.[1,369-371] This finding suggests that in the absence of antibody to other adhesins, antibody to FHA contributes to protection.

Of the other attachment proteins, data relating to human infection are available for PRN and FIM only. In the two trials that looked at serologic correlates of immunity, researchers found in both that antibody to PRN was most important and that antibody to FIM was also important.[66,372] Studies suggest that FHA and PRN may act synergistically.[25,214,225] Because the FIM of some gram-negative bacteria are important for attachment, researchers have assumed that *B. pertussis* FIM are important in attachment. However, in one tissue culture study, FIM did not mediate the attachment of organisms to cells.[390] In a more recent study, investigators found that FIM played a role in attachment in persistent infection.[281] Furthermore, antibodies against FIM were shown to provide protection against colonization with *B. pertussis* in the murine respiratory tract.[417]

*See references 26, 60, 61, 127, 202, 257, 278, 297, 338, 352, 373, 401, 420, 426.

*See references 68, 81, 130, 179, 257, 289, 291, 293, 325, 412.

Both ACT and PT adversely affect immune cell function and, therefore, allow infection, once initiated, to continue.[68,181,291] PT prevents migration of lymphocytes and macrophages to areas of infection and adversely affects phagocytosis and intracellular killing. ACT enters phagocytic cells and catalyzes excessive production of cyclic adenosine monophosphate, which intoxicates neutrophils and results in a decrease in phagocytosis.

TCT, DNT, and ACT all have been implicated as contributors to local tissue damage in the respiratory tract.[68,130,293] Of these toxins, TCT is likely to be the most important.[130] In hamster tracheal organ cultures, TCT selectively destroys ciliated cells in a manner similar to that seen in *B. pertussis* infection, and the pathologic process is similar to that noted in human pertussis autopsy studies. As noted in Table 140–2, several other *Bordetella* virulence factors have been described and have been characterized to some extent in mouse models.[81,114,120,210,257,428] Determination of their precise roles, however, requires further investigation.

Pertussis is a unique illness in that it has only one manifestation of systemic disease in uncomplicated infection: leukocytosis with lymphocytosis caused by PT.[68,174,194] T and B lymphocytes increase to a similar extent in the circulation.[24] In contrast to the situation in *B. pertussis* infection, lymphocytosis is not a characteristic of *B. parapertussis* infection because this organism does not liberate PT. The most important systemic complication of pertussis is encephalopathy, the mechanism for which is not known. The most likely explanation is anoxia associated with coughing paroxysms.

Some investigators have suggested that pertussis is a toxin-mediated disease caused by PT.[319,320] Although some researchers continue to entertain this idea,[332] little evidence supports it. Undoubtedly, PT is a fascinating protein with multiple activities in experimental animals, such as histamine sensitization, promotion of lymphocytosis, effects on glucose metabolism, and induction of adjuvant and mitogenic activity.[68,125,257,291] However, in infections in humans, the main effects that appear to be caused by PT are lymphocytosis and mild, compensated hyperinsulinemia. PT has been suggested to be the cause of the prolonged cough in pertussis. However, because persistent cough is a major manifestation of *B. bronchiseptica* infection in dogs and of *B. parapertussis* infection in children, and because neither organism liberates PT, this hypothesis should be refuted.[174,257,302]

Cell-mediated immune function is altered by *B. pertussis* infection. In some studies, cell-mediated immunity was depressed, whereas in others it was augmented.[307]

Various antibodies develop after exposure of the human host to infection with *B. pertussis*. The development of agglutinins, hemagglutination-inhibiting antibodies, and bactericidal antibodies has been described.[49] ELISA techniques have demonstrated class-specific antibodies (IgA, IgE, IgG, and IgM) to many of the specific proteins of *B. pertussis*.[161,250,308] These antibodies develop after infection and, with the exception of IgA antibodies, also after immunization. Neutralizing antibody to PT likewise develops after both infection and immunization.[152,308] Specific IgA antibodies to PT and FHA also can be demonstrated in nasopharyngeal secretions and saliva.[136,429]

At present, both *B. pertussis* infection and immunization with whole-cell or acellular pertussis vaccines clearly elicit protection of varying degree and duration against pertussis. The prevailing opinion throughout the last century was that immunity acquired from having *B. pertussis* infection is lifelong, whereas vaccine-induced immunity is relatively short-lived. Although the latter clearly is true,[118] studies performed by members of our research group suggest that the former opinion regarding infection-induced immunity is wrong.[55,58,67,257,352,399] Proceeding from the knowledge that IgA antibodies to pertussis antigens (PT, FHA, and PRN) result from infection and not from primary vaccination, our group studied the prevalence of these antibodies in the sera of young German and American men of similar ages.[67] In Germany, routine childhood immunization was not carried out during the 1970s and 1980s, and pertussis was epidemic. To our surprise, the rate and mean values of IgA antibodies in the two populations were similar, thus suggesting that adult infection rates were similar. In another study in Germany, we found that *Bordetella* infections were common occurrences in adults, often in persons with a known history of childhood pertussis.[352]

The nature of immunity in pertussis is not known. The consensus has been that serum antibodies greater than some unknown concentration to one or more of the pertussis antigens are responsible for protection.[91] Antibodies to PT, FHA, and PRN have been shown to be protective in animal model systems.[25,82,225,345,355] However, no serologic correlates of immunity had been established until recently, although several large vaccine trials have been performed since the late 1980s.[1,138,145,231,357,362,385] In a nested household contact study, our group was able to evaluate the roles of IgG antibodies to PT, FHA, PRN, and FIM 2 by determining pre-exposure imputed values in children at the time of household exposure to *B. pertussis* infection by using both classification tree and logistic regression methods.[69] The imputed geometric mean antibody values to PT, PRN, and FIM 2 were higher in non-cases than in cases. In the classification tree analysis, however, only antibodies against PRN contributed significantly to protection. Specifically, subjects with an imputed PRN value of less than 7 EU/mL had a 67 percent likelihood of infection. Logistic regression analysis also found that PRN values of 8 EU/mL or more were associated with prevention of illness after household exposure. In accordance with our findings, data from a Swedish study indicate that antibody values of 5 EU/mL or more to PRN and FIM 2/3 correlated with protection.[372]

In addition to humoral responses to several *B. pertussis* antigens, evidence exists that cell-mediated immune responses to PT, FHA, and PRN also occur.[10,247,275-277,340,341,384,415,431] Studies in a murine respiratory infection model suggest that cellular immunity plays an important role in bacterial clearance and augments the effects of antibody by predominantly T-helper 1 (T_H1) cell stimulation.[275,276] Studies in humans demonstrate a cellular immune response shortly after natural infection with *B. pertussis*, with PT, FHA, and PRN preferentially inducing the synthesis of T_H1 cells.[415] Immunization with a whole-cell pertussis vaccine results in a T_H1 response, whereas the response to acellular vaccines is more heterogeneous and involves both T_H1 and T_H2 cells.[315] Persistent memory T and B cells and anamnestic antibody responses are important in long-term immunity.[247]

Immunity developed after having *B. pertussis* infection or receiving vaccination with a whole-cell pertussis vaccine does not protect against illness caused by *B. parapertussis*, and, similarly, infection with *B. parapertussis* does not induce protection against disease caused by *B. pertussis*.[222,381] However, in our vaccine efficacy trial in Germany, the results showed some evidence that the acellular pertussis multicomponent vaccine, which contained a large amount of FHA, offered some protection against *B. parapertussis* infections, whereas the whole-cell vaccine, which contained minimal amounts of FHA, did not.[172] Although *B. pertussis* infection is a localized infection involving ciliated cells of the respiratory track, bacteremia has been noted in immunocompromised adults.[40,201,386]

CLINICAL MANIFESTATIONS

The *clinical* manifestations of *B. pertussis* infection have considerable variation that depends on age, previous immunization or infection, the presence of passively acquired antibody, and perhaps other factors such as the degree of exposure, host genetic and acquired factors, and the genotype of the organism. The

incubation period for pertussis generally varies between 6 and 20 days; most cases have an onset 7 to 10 days after exposure. However, after household exposure, 22 percent of secondary cases were noted to have an onset more than 4 weeks after the onset of illness in the primary case.[166]

CLASSIC ILLNESS

Classic illness occurs as a primary infection in unimmunized children between the ages of 1 and 10 years.[58,68,133,307] The illness usually lasts 6 to 12 weeks and has three stages: catarrhal, paroxysmal, and convalescent. The initial illness is characterized by rhinorrhea, lacrimation, and mild cough suggesting a common cold. Body temperature usually is normal. The severity of the cough gradually increases over a period of 1 to 2 weeks, but pertussis usually is not suspected until the cough becomes paroxysmal.

After the catarrhal period, the coughs increase in severity and number. Repetitive series of 5 to 10 or more forceful coughs during a single expiration can be noted. These paroxysms are followed by a sudden massive inspiratory effort, and a characteristic whoop may occur as air is forcefully inhaled through a narrowed glottis. Cyanosis, bulging eyes, protrusion of the tongue, salivation, lacrimation, and distention of neck veins occur during paroxysms. Several paroxysmal coughing episodes with their associated massive inspiratory effort may occur sequentially until the child succeeds in dislodging the obstructing mucus. The production of purulent sputum does not occur. Post-tussive vomiting is a common occurrence. Paroxysms may strike several times per hour, and they occur during both day and night.

The paroxysmal episodes are exhausting, and patients frequently appear dazed and apathetic. Weight loss may occur as a result of vomiting and also because eating and drinking may be resisted, given that they trigger attacks. Attacks also may be triggered by yawning, sneezing, or physical exertion. Between attacks, the patient may appear normal and usually is in no distress.

Common and important complications of classic pertussis include pneumonia, otitis media, seizures, and encephalopathy. Pneumonia may be caused by *B. pertussis* or secondary bacterial invaders. Atelectasis may develop as a result of the mucus plugs. The forcefulness of the paroxysms can cause rupture of the alveoli and can produce interstitial or subcutaneous emphysema.

Otitis media is a common occurrence and frequently is caused by *S. pneumoniae*. Pertussis also has been associated with activation of latent tuberculosis. Convulsions and coma may be observed. These findings may be a reflection of cerebral hypoxia related to asphyxia. Rarely, subarachnoid and intraventricular hemorrhage may occur. Tetanic seizures may be associated with the severe alkalosis that results from the loss of gastric contents caused by persistent vomiting.

Other complications that have been noted include ulcer of the frenulum of the tongue, epistaxis, melena, subconjunctival hemorrhage, subdural hematoma, spinal epidural hematoma, rupture of the diaphragm, umbilical hernia, inguinal hernia, rectal prolapse, dehydration, meningoencephalitis, the syndrome of inappropriate antidiuretic hormone secretion, apnea, rib fracture, and nutritional disturbances.[37,58,198,256,323,359,410]

The convalescent stage, which usually lasts 1 to 2 weeks, is characterized by a decreasing frequency and severity of coughing episodes, whooping, and vomiting. All patients with classic pertussis caused by primary infection have leukocytosis secondary to lymphocytosis. Fever and pharyngitis are not usual manifestations in pertussis, and, therefore, a search for a secondary cause should be undertaken when these findings occur. Except for the observation of typical paroxysms, physical examination in pertussis usually is unrewarding. Diffuse rhonchi may be noted on auscultation.

Infection with *B. parapertussis* causes an illness that is similar to that caused by *B. pertussis*, but generally it is less severe and of shortened duration.[174]

MILD ILLNESS AND ASYMPTOMATIC INFECTION

Mild, nonclassic illness is common in *B. pertussis* infection.[91,164,168,348] It occurs in previously vaccinated children and also as a primary infection in nonvaccinated children. In a study in which physicians sent nasopharyngeal specimens from children with cough illness, regardless of whether the illness was typical of pertussis, to our laboratory,[164] 247 culture-positive cases were noted. Of these patients, 47 percent had a total duration of cough illness of 28 days or less. In 26 percent, the duration of cough was less than 3 weeks. Most of these cases occurred in unvaccinated children. In a 6-year, similar study involving 2592 culture-positive, previously unvaccinated children, 38 percent had a duration of cough illness of 28 days or less, and in 17 percent, the duration was 21 days or less.[168] In a study in which both culture and polymerase chain reaction (PCR) were used for establishing the diagnosis of *B. pertussis* infection, many mild cases were found to be PCR-positive and culture-negative.[348] Of these cases, only 68 percent had a cough illness lasting 4 weeks or longer, and only 57 percent and 32 percent had paroxysmal cough and whoop, respectively.

In studies of household contacts, asymptomatic infections in family members are common occurrences.[91,240,241] Deen and associates[91] found that 52 (46%) of 114 household contacts who remained well had laboratory evidence of *B. pertussis* infection. In another study, 21 of 399 healthy infants who were controls had PCR-positive nasopharyngeal samples.[167]

INFANTS

Pertussis in infancy is a unique experience.[257] Its spectrum of clinical manifestations varies by age, immunization, and the presence or absence of transplacentally acquired antibody.* Most deaths resulting from *B. pertussis* infection occur in neonates and early infancy, and morbidity is most severe in infants.† From 1997 through 2000, 8276 cases of pertussis were reported in infants in the United States.[39] Of this group, 59 percent were hospitalized, 11 percent had pneumonia, 1 percent had seizures, 0.2 percent had encephalopathy, and 0.7 percent died. Eighty-seven percent of these infant cases occurred in children younger than 6 months of age.

The source of infection in infants usually is a family member.[16,27,85,91,107,217] In a study of 616 infant cases, the source was identified in 43 percent.[27] A family member was the source 75 percent of the time, and the mother was the most common source (32%). Of the source persons, 56 percent were adults, and 20 percent were 10 to 19 years of age.

B. pertussis infection in neonates is particularly severe, with a death rate of between 1 and 3 percent.[20,73,144,171,173,189,233,261] A common initial finding is apnea, and typical coughing is not observed. Seizures in association with apnea caused by hypoxia occur frequently. Severe pulmonary hypertension is a relatively common problem in pertussis in the first 4 months of life.[88,97,135,142,148,311,317,360,416] The severity of disease and the risk of death correlate directly with the white blood cell count and, in particular, the number of lymphocytes.[20,73,88,142,171,261,269,311,317] White blood cell counts in the range of 30,000 to more than 100,000 cells/mL are common findings. Co-infection with

*See references 20, 49, 68, 73, 107, 110, 171, 217, 261, 294, 300.
†See references 16, 20, 73, 84, 85, 88, 129, 135, 142, 144, 147, 148, 167, 171, 173, 189, 227, 257, 259, 261, 269, 294, 300, 311, 317, 321, 337, 358, 360, 379, 402, 416.

respiratory viruses (RSV, adenovirus, influenza viruses) and respiratory bacterial pathogens (*S. pneumoniae*, *Haemophilus influenzae*) are relatively frequent.[20,85,227,311,358]

Whoop is a rare manifestation of illness in infants, and other respiratory manifestations frequently are confused with those caused by respiratory viruses.[49] *B. pertussis* infection has been noted in association with sudden infant death syndrome (SIDS), but whether a cause-and-effect relationship exists is not clear.[167,173,233,300] Nichol and Gardner,[300] in a study in England, found that many deaths attributed to SIDS were, in fact, related to *B. pertussis* infection. Using PCR, we found *B. pertussis* DNA in nasopharyngeal specimens from 9 (18%) of 51 infants who had sudden, unexpected deaths.[173] In a subsequent study, we collected specimens for PCR from 254 infants who experienced sudden, unexplained deaths and from 441 healthy matched controls.[167] The rate of PCR-positive results in the sudden death cases was 5.1 percent; it was 5.3 percent in the controls. In a careful follow-up histopathologic study with unique immunohistochemical staining of specimens from a subset of these fatal cases, we could find no evidence of specific *B. pertussis* pulmonary infection or pathologic features.[310]

ADULTS

Increased awareness of adult pertussis has occurred since the 1970s.* Unrecognized pertussis cases in adults often are the source from which infants and children become infected.[20,27,57,73,171,261,294,352] All adults previously have been exposed to *B. pertussis* antigens by immunization, infection, or both,[67,91,94,257] and this exposure tends to modify their illness. In a U.S. study, the following cough characteristics were noted in 31 university students with laboratory evidence of *Bordetella* infection: the median duration was 21 days before initial evaluation, 94 percent had one or more coughing episodes per hour, and 90 percent of the coughs had a staccato or paroxysmal quality.[278] Despite these findings, pertussis was not suspected in any of the students, and clinical diagnoses by the primary care providers included upper respiratory tract infection (39%), bronchitis (48%), and other diagnoses (16%). Although specific records were not available, most of these students probably were vaccinated as children and almost certainly had previous, unrecognized infections.[67,91]

In contrast to these findings in the United States, in a study in Germany, adults were found to be more likely to have typical pertussis, even though the epidemiologic data suggested that all had a previous infection, and 26 percent of 64 patients with laboratory evidence of infection recalled having had pertussis during childhood.[67,352] Rates of clinical manifestations in the 64 laboratory-confirmed cases were as follows: paroxysms, 70 percent; whoop, 38 percent; post-tussive phlegm, 66 percent; and post-tussive vomiting, 17 percent. The clinical diagnosis in 39 percent was definite or probable pertussis; only 14 percent were thought not to have pertussis. Of note is that the clinical diagnosis was not made by primary care physicians but by a small team of specially trained central investigators with high awareness for pertussis.

In a German household contact study, similar findings were noted: 80 percent of 79 adults with laboratory-confirmed *B. pertussis* infection coughed for 3 or more weeks, and 63 percent had spasmodic cough for 3 or more weeks.[323] In addition, in 53 percent of patients, coughing was followed by choking or vomiting. However, only 8 percent of the adults in this study had whoops. Complications that were observed included pneumonia, rib fracture, inguinal hernia, and severe weight loss. Unique sweating episodes are reported in approximately 5 percent of adults, and fainting can occur in association with coughing.[93,323]

*See references 26, 27, 41, 42, 44, 45, 57, 60, 61, 91-94, 110, 127, 144, 182, 200, 202, 219, 257, 278, 280, 294, 297, 323, 333, 338, 352, 373, 383, 407, 420, 426.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

In typical pertussis, the clinical diagnosis should be apparent based on the paroxysmal cough with post-tussive vomiting and whooping and lack of significant fever. However, the cause of the illness can be *B. pertussis* or *B. parapertussis*. A history of contact with a known case (laboratory confirmed) will help to establish the diagnosis in a patient with mild or atypical illness. The presence of leukocytosis with lymphocytosis in a child with a cough illness or the presence of apnea in an infant is a strong indication that the illness is caused by *B. pertussis* and not *B. parapertussis*. In a matched-control comparison, none of 11 children with culture-proven *B. parapertussis* infection versus 7 of 22 (32%) with *B. pertussis* infection had lymphocytosis of 10,000 or more cells/mL.[174] Lymphocytosis of 10,000 or more cells/mL is observed in few other diseases.

Many other infectious agents cause illnesses with prolonged and repetitive cough that can be confused with *B. pertussis* or *B. parapertussis* infections.[257] In particular, *M. pneumoniae*, *C. pneumoniae*, adenoviruses, bocavirus, and other respiratory viruses all can cause prolonged cough illnesses.* In addition, coughing episodes may be seen in children with asthma, bronchiolitis, bacterial pneumonia, cystic fibrosis, *Coccidioides immitis* infection, and other fungal pulmonary infections and tuberculosis. Another problem is the cough associated with sinusitis, which can be confused with *B. pertussis* infection. The cough associated with gastroesophageal reflux also can be confused with pertussis, as can cough associated with an airway foreign body.

SPECIFIC DIAGNOSIS

A laboratory diagnosis of pertussis caused by either *B. pertussis* or *B. parapertussis* can be made by culturing the organisms on appropriate media, by identifying their presence by direct fluorescent antibody testing (DFA) or PCR, and by demonstrating the presence of specific antibodies. *Bordetella* spp. can be recovered from nasopharyngeal specimens, with the highest rate of isolation occurring within the first 3 weeks of cough.[164,374] Specimens for culture can be collected by swabbing the nasopharynx, by nasopharyngeal washing, or by nasopharyngeal aspiration.[68,150] In general, nasopharyngeal aspiration gives the highest yield of positive cultures.

B. pertussis and *B. parapertussis* are recovered most easily by direct plating of the specimen from the patient onto selective media.[68,70,186,239] Specific swabs (calcium alginate or Dacron) and media (Regan-Lowe or Bordet-Gengou agar and modified Stainer-Scholte broth) are required, and laboratory personnel should be experienced in isolating the organisms. If cultures cannot be inoculated directly, the use of Regan-Lowe transport medium is recommended. In classic disease, the culture or a DFA study will be positive in approximately 80 percent of cases if the specimen is obtained within 2 weeks of the onset of cough and antibiotics have not been administered previously.[165,308] DFA has been used for the diagnosis of pertussis caused by *B. pertussis* or *B. parapertussis* during the last 40 years.[257,290,363] It is rapid and inexpensive, but it lacks sensitivity and specificity; it does not employ amplification for sensitivity, and it lacks specificity because

*See references 9, 14, 49, 68, 76, 78, 87, 149, 295, 421.

of cross-reactions with other organisms of the nasopharyngeal flora.[109]

Since the late 1980s, numerous PCR assays with primers derived from four different chromosomal regions have been developed for the diagnosis of *B. pertussis* and *B. parapertussis* infections, and they have been evaluated in multiple studies by comparison with culture and clinically typical pertussis.*

PCR has the advantage of having much higher sensitivity than that of conventional culture. In a prospective study in which swabs for PCR and culture were obtained simultaneously from 555 subjects with cough illnesses, the use of PCR increased the identification of *B. pertussis* infection almost fourfold, from 28 to 111.[348] Only a few studies have been reported in which the sensitivity and the specificity of PCR for the diagnosis of *B. pertussis* infection were determined by comparison with serologically identified cases.[169,230,232,329,397] In a study that our group performed, we compared PCR results with serologic diagnosis and found that PCR had a sensitivity of 61 percent and a specificity of 88 percent.[118] Similar findings have been noted in other studies.[230,232,330,397] At present, the most commonly used primers for the diagnosis of pertussis include IS 481 and IS 1001.[257] IS 481 occurs in the genomes of *B. pertussis* and *B. holmesii* but not in *B. parapertussis*. IS 1001 occurs in the genomes of *B. parapertussis* and *B. holmesii* but not in *B. pertussis*. The genome of *B. bronchiseptica* generally contains neither IS 481 nor IS 1001. However, in two recent studies, *B. bronchiseptica* strains were found to contain IS 1001 in their genomes.[122,328] False-positive results are a potential problem with the use of PCR for establishing the diagnosis of pertussis and other respiratory illnesses.[3,262,290] False-positive results can occur if specimens are opened in the pertussis laboratory before transport to the PCR laboratory.[257] False-positive results also can result from contamination of the air in a room in which the previous patient had pertussis. Moreover, as noted earlier, *B. bronchiseptica* can be mistaken for *B. parapertussis* when the IS 1001 primer is used.[122,328] Therefore, rigorous internal and external laboratory controls are necessary.

Obtaining a routine laboratory diagnosis of *B. pertussis* infection in adults or in other atypical cases is hampered by the problem that medical care usually is not sought until the third or fourth week of the illness, and antibiotics frequently have been administered before the possibility of pertussis was considered.[278,352] During the last 2 decades, the most significant advance in the diagnosis of pertussis has been the development of ELISA.[257]

Natural infection with *B. pertussis* is followed by a rise in serum concentrations of IgA, IgG, and IgM antibodies to specific antigens of the organism, as well as to preparations of the whole organism.[79,123,154,250,268,278,308,362,400] In contrast to natural infection, primary immunization of children induces mainly IgM and IgG antibodies.

Serologic testing for *B. pertussis* infection in the clinical setting is neither standardized nor widely available.[68,308] In the research setting, the use of ELISA has contributed significantly to establishing the diagnosis of *B. pertussis* infection in many patients with negative cultures.[94,151,240,241,278,280,352,426] Most useful has been the determination of IgG and IgA antibodies to PT and FHA. The most reliable proof of acute infection is the demonstration of a significant increase in antibody values between acute-phase and convalescent-phase serum specimens. Frequently, because collection of acute-phase specimens is delayed and, therefore, the acute-phase values already are elevated, significant increases between first and second serum specimens cannot be demonstrated. However, a diagnosis frequently can be established on the basis of a high value or values on a single serum specimen.[91,278,352,419,426] Because *B. parapertussis* infection induces cross-reacting antibodies to *B. pertussis* FHA, the use of this antigen alone cannot differentiate *B. pertussis* from *B. parapertussis* infection.[137,362]

Measurement of agglutinating antibodies also is useful for establishing the diagnosis of *B. pertussis* infection, and, because the test is simple, inexpensive, and accurate, it can be used in the clinical setting.[91,170,278,308,352] Unfortunately, its sensitivity is low.

Today in clinical practice, the laboratory diagnosis of pertussis should be approached as follows: In all cases in which the cough illness is of less than 2 weeks' duration in adolescents and adults or 3 weeks' duration in children, a nasopharyngeal specimen should be obtained for culture or PCR. In adults who have had cough for greater than 2 weeks' duration, single serum ELISA is the preferred method. This method also can be used in children if they have not been immunized within 2 years. At present, many commercial laboratories offer single serum diagnostic tests for *B. pertussis*, and almost all the offered tests lack specificity. Any test that employs the whole organism in the test is fraught with false-positive results. Tests that report specific IgM antibodies also are unreliable. The greatest sensitivity and specificity for the serologic diagnosis of *B. pertussis* infection are achieved by ELISA or an ELISA-like test with the measurement of IgG and IgA antibodies to PT. Single high values of IgG or IgA antibodies to PT are indicative of infection.[257] In our opinion, a sensitive and specific test is available from Focus Diagnostics, Cypress, California.[326]

Not all infected persons develop antibody responses to PT. In children, approximately 25 percent lack an adequate response, as do approximately 10 percent of adolescents and adults.[63,362]

An ELISA also has been developed for the detection of IgA antibody to *B. pertussis* in nasopharyngeal secretions and as an indicator of recent infection.[131,136,429] *B. pertussis* IgA appears in nasopharyngeal secretions during the second or third week of illness and persists for at least 3 months.[131] However, the appearance of secretory IgA may be delayed in children younger than 1 year of age.[292] This antibody is not induced by primary parenteral *B. pertussis* vaccination. Detection with the use of ELISA of *B. pertussis* IgA in secretions may be a diagnostic aid in culture-negative patients whose symptoms have persisted for longer than 3 weeks. To our knowledge, this test is not clinically available.

TREATMENT

Several antibiotics have in vitro efficacy against *B. pertussis*.[14,17-19,23,43,187,190-192] The first choice for treatment since the 1970s has been oral erythromycin; this ameliorates the symptoms if it is given early during the course of the illness and eliminates the organism from the nasopharynx within a few days, thereby shortening the period of contagiousness.[23] The dose for children is 40 to 50 mg/kg/day given every 6 hours for 14 days; the dose for adults is 2 g/day given every 6 hours for 14 days. A 7-day course of erythromycin estolate was shown in a large study in Canada to be as efficacious as 14 days of treatment.[153] The newer macrolides, azithromycin (10 mg/kg on day 1 and 5 mg/kg on days 2 to 5 as a single dose for 5 days for children and 500 mg on day 1 and 250 mg on days 2 to 5 for adults) or clarithromycin (15 to 20 mg/kg/day in two divided doses for 7 days for children and 1 g/day in two doses for 7 days for adults), also can be expected to be effective.[6,43] Although rare, the use of erythromycin in young infants is associated with hypertrophic pyloric stenosis, so parents need to be educated about the symptoms of this potential risk.[38,185,284] Because of this risk, the Centers for Disease Control and Prevention (CDC) recommends treating neonates with azithromycin rather than erythromycin.[43] Trimethoprim-sulfamethoxazole can be used as an alternative agent in those who

*See references 98, 108, 111, 128, 141, 160, 169, 193, 215, 228, 230, 232, 253, 262, 304, 329, 330, 348, 349, 396-398, 430.

cannot tolerate erythromycin.[192] The first erythromycin-resistant strain of *B. pertussis* was isolated from a 2-month-old male infant in Yuma County, Arizona, in June 1994.[227] The isolate was highly resistant, with a minimal inhibitory concentration (MIC) greater than 64 μg/mL (the usual MIC of erythromycin is 0.02 to 0.1 μg/mL). More recently, two more resistant *B. pertussis* strains were recovered from cases in California and Utah.[216,224] At present, no evidence of a pattern of emerging macrolide resistance has been seen, but because PCR rather than culture is becoming the diagnostic method of choice in many laboratories, the chance of missing resistant strains is a possible problem.

Patients infected with *B. parapertussis* and *B. holmesii* also can be treated with macrolides, but *B. bronchiseptica* usually is resistant to erythromycin so that alternative therapy is necessary.[257] *B. bronchiseptica* strains usually are sensitive to aminoglycosides, extended-spectrum, third-generation penicillins, tetracyclines, quinolones, and trimethoprim-sulfamethoxazole.

Historically, no infectious disease has a greater list of remedies lauded as beneficial but without objective evidence of effectiveness.[62] Supportive care includes avoidance of factors that provoke attacks of coughing and maintenance of hydration and nutrition. In the hospital, gentle suction to remove secretions and well-humidified oxygen may be required, particularly in infants with pneumonia and significant respiratory distress. In severe infections in neonates and young infants, assisted ventilation may be necessary.

However, infants who develop pulmonary hypertension with respiratory and cardiovascular failure respond poorly to aggressive therapy (pulmonary artery vasodilators and extracorporeal membrane oxygenation [ECMO]) and have high mortality rates. Because data suggest that the pulmonary hypertension results from the extreme leukocytosis with lymphocytosis, which is always present in fatal cases, our opinion is that leukocyte-reducing measures such as exchange transfusion should be implemented.[96,142,317,337]

The use of corticosteroids has received attention in the treatment of pertussis. Cortisone treatment in the murine model of pertussis increased the mortality rate.[195] In contrast, Zoumboulakis and associates[433] suggested that a 7-day course of steroids and erythromycin reduced the number of coughing paroxysms and episodes of vomiting significantly, in addition to shortening the duration of symptoms. Unfortunately, this study was not controlled rigorously.

The use of salbutamol has also been suggested as having some value, but definitive studies are needed to confirm the efficacy of this mode of treatment.[34] Pillay and Swingler[318] reviewed the symptomatic treatment of pertussis and found no statistically significant benefit for the use of diphenhydramine, dexamethasone, or salbutamol.

PROGNOSIS

The prognosis in pertussis is related to the patient's age. In older children and adults, the prognosis is good, but infants have a significant risk of death and development of encephalopathy.* In addition, long-term follow-up suggests that apnea or seizures at the time of disease may be associated with subsequent intellectual impairment.[376] The present availability of pediatric intensive care units and assisted ventilation has reduced the rate of mortality in infants who receive medical care.[171] Unfortunately, many deaths occur outside the hospital. No evidence has shown that pertussis impairs ventilatory function later in life.[204]

PREVENTION

VACCINE EFFICACY

Whole-Cell Vaccines

The first pertussis vaccines were developed in the 1920s, and effective vaccines have enjoyed worldwide use since the 1940s.[49,63,68,257] After World War II, extensive vaccine trials were organized by the British Medical Research Council.[263-265] Based on these studies, as well as smaller studies in England, the United States, and other countries, DTP vaccine use became routine in many countries.[119]

The pertussis attack rate was relatively constant in the United States in the pre-vaccine era between 1922 and 1942 (see Fig. 140–1). From 1943 to 1976, a 150-fold reduction in the attack rate was noted in association with widespread childhood pertussis immunization.

The existence of a relationship between vaccine use and disease control also was supported by data from England and Wales. The pertussis attack rate declined between 1958 and 1973 and increased dramatically between 1977 and 1983 after a marked decrease occurred in the number of vaccinations administered, beginning in 1974.[49] The attack rate decreased with the widespread use of vaccine and increased when vaccine use decreased. Moreover, the attack rate after the decrease in vaccine use was increased most markedly in the newly susceptible cohort of children younger than 4 years of age. Until recently, English children received their pertussis immunization only in the first year of life, and protection is not long-lasting.

In the 1980s, numerous household contact studies were performed.[91,309,313-315] In a study from 1982 to 1983 involving 440 household contacts aged 6 months to 9 years, the secondary attack rate in unvaccinated contacts was compared with the rate in children who had received three or more DTP doses. Vaccine efficacy was found to be 91.4 percent. A similar study conducted during the period 1979 to 1981 revealed an efficacy of 82.4 percent.

In another study, Onorato and associates[309] noted that the calculated efficacy varied markedly according to the clinical case definition. Efficacy against any cough illness was 63 percent, whereas it was 83 percent if a cough duration of 21 or more days was required.

In the 1990s, the most definite studies of DTP vaccine efficacy were carried out in four countries.[138,145,166,231,351,357,362] In these trials, the efficacy of the candidate DTaP vaccines was compared with the efficacy of DTP vaccines; the controls were subjects who received DT. With the exception of one lot of one DTP vaccine (Connaught, USA), which had poor immunogenicity, the DTP vaccines were more efficacious than were the DTaP vaccines. The poor efficacy of the Connaught DTP vaccine probably was the result of an unusual low potency lot of this vaccine rather than a generic problem with this vaccine.[257] In a case-control study in the United States, the efficacy of the Connaught vaccine was similar to that of the Wyeth-Lederle DTP vaccine, which, in the controlled trial in Germany, had a high level of efficacy.[28] Finally, in a large comparative trial, the DTP vaccine from England (Evans vaccine) had efficacy greater than those of the three DTaP vaccines with which it was compared.[146,306]

Acellular Vaccines

Research in the 1970s showed that three *B. pertussis* antigens (PT, FHA, LPS) were liberated into the medium during culture and that these antigens could be concentrated and separated by density gradient centrifugation.[68,179] This finding allowed for the development and production of vaccines by six manufacturers in Japan.[64,213,301,346] All six vaccines had minimal or no endotoxin but

different amounts of PT and FHA. In addition, some of the vaccines were found to contain FIM 2 and PRN.

Despite limited proof of efficacy, the six vaccines were put into routine use in Japan in 1981, and they have controlled, to some degree, epidemic pertussis during the ensuing decades. However, because adequate data were not available on any single vaccine or on vaccine use in young infants, many extensive trials were performed subsequently in Europe, Africa, and Japan.[1,288]

After extensive analysis of the data was conducted on the original efficacy trial in Sweden in the mid-1980s, calculated efficacy was found to vary significantly, depending on the clinical case definition and the laboratory methods.[1,29,151,369-371] Therefore, researchers decided that a universal primary case definition should be developed for use in all subsequent efficacy trials so that different vaccines in different trials could be compared.

A World Health Organization (WHO) committee met in Geneva in January 1991, and a primary case definition was developed.[424] This definition and minor variations of it were used in the efficacy trials in the 1990s. The WHO case definition is as follows: (1) an illness with 21 days or more of spasmodic cough and either culture-confirmed infection with *B. pertussis* or serologic evidence of infection with *B. pertussis* as indicated by a significant rise in IgA or IgG antibody by ELISA against PT or FHA in paired sera or (2) contact with a case of culture-confirmed pertussis in the household with onset within 28 days before or after the onset of cough in the study vaccinee. Not all members of the WHO committee, including one of us (J. D. C.), agreed with this primary case definition because its use results in the elimination of many laboratory-confirmed cases from efficacy calculations.[56,164,168,369-371] With this definition, vaccines that lessen the severity of disease but are poor at preventing mild disease will be overrated.

In 1994 and 1995, seven efficacy trials with candidate DTaP vaccines in four countries were completed,[138,145,231,351,357,362,385] and an additional trial in Sweden was completed in 1997.[306] As noted in Table 140–3, the nine vaccines are different in the number of antigens that they contain, as well as in the concentrations of the specific antigens. In all efficacy studies, confounding factors may affect the results. In general, double-blind studies with placebo and whole-cell vaccine controls are ideal. However, placebo control was not ethical in countries in which DTP vaccine was recommended. Therefore, studies in Germany and Senegal used various methods to obtain efficacy data in spite of the lack of a blinded diphtheria-tetanus (DT) toxoid group. Observer bias can affect the results of all studies, including those with double-blind control. For example, a less efficacious vaccine that prevents typical disease but not mild disease can be determined to be more efficacious than it actually is if the study observers believe they "know pertussis" and dismiss atypical cases as being other respiratory illnesses and do not obtain cultures or conduct prospective follow-up.[71]

In general, household contact studies, unless they are nested analyses in prospective cohort studies, also are subject to observer bias, and case-control studies result in significantly inflated efficacy percentages.[56,65,71,117,119,288] In cohort studies, observer bias by parents can be reduced by frequent prospective telephone contact with study families. Finally, serologic diagnosis, as well as diagnosis by culture, increases the identification of mild cases, which are more likely to occur in vaccinees than in control subjects.

A summary of the efficacy data for 10 acellular pertussis vaccines evaluated in the 8 trials performed in the 1990s and the earlier 1980s Swedish trial is presented in Table 140–4. The data

**Efficacy against typical pertussis based on positive culture without serologic analysis.*
†Significant observer bias occurred in this trial.[56]
‡Laboratory diagnosis based on culture only; 80 percent efficacy was against cough illness of 21 or more days, and 93 percent efficacy was against the World Health Organization (WHO) case definition.
§Thirty-one percent efficacy based on 21 days or more of cough illness; 74 percent efficacy was against the WHO case definition.

in this table indicate that three- and four-component vaccines (vaccines containing PRN and FIM as well as PT and FHA) have greater efficacy against *B. pertussis* illness (mild and typical) than do the PT or PT/FHA vaccines. The apparent high efficacy of the two-component vaccine (Tripedia) in the Munich study[231] can be explained by the type of study (case-control study), significant observer bias, and the lack of serologic diagnosis. However, in the post-licensure effectiveness case-control study done in the United States from 1998 to 2001, investigators found that the two-component vaccine (Tripedia) was slightly more effective than the four-component vaccine (Acel-Immune).[28] This finding suggests that a vaccine without PRN was more effective than was a vaccine that contained PRN. However, it is our understanding that this "two-component" vaccine also contained some PRN and perhaps some fimbrial protein as well. The final study, done in Stockholm, was a comparative study without a DT control group.[305] In this trial, in which vaccines were administered to children at 3, 5, and 12 months of age, the efficacy of CCL DTaP5 (five-component) was significantly better than that of Acelluvax (three-component vaccine) and was not significantly different from that of the comparative DTP vaccine (Evans vaccine). Acelluvax had greater efficacy than did the two-component vaccine SKB-2.

Follow-up studies of the various efficacy trials have been done in Sweden, Italy, and Germany, and all suggest sustained protection.[146,242,305,342,343] Of particular importance in this regard is the most recent report by Gustafsson and associates,[146] in which the large cohort vaccinated at 3, 5, and 12 months in the 1993 to 1996 trial were followed from October 1997 to September 2004. Overall, good protection lasted for approximately 5 years. The tabular data in this report suggest that Acelluvax (three-component vaccine) had efficacy similar to that of CCL DTaP5 (five-component vaccine). However, when all the data from the original trial and the present follow up data are combined, the overall attack rate in those children who had received the five-component vaccine was lower (47.5/100,000) than that in children who had received the three-component vaccine (59.7/100,000). This difference was not significantly different, however. Most notable is that the Evans DTP vaccine had greater sustained efficacy than did either Acelluvax or CCL DTaP5. In summary, it appears that DTaP vaccines that contain PRN have relatively good efficacy for approximately 5 years, but that (with the exception of one lot of one DTP vaccine), in general, DTP vaccines are more efficacious.[138,145,146,231,306,342,351,357,362]

In recent years, two acellular pertussis component, diphtheria, and tetanus toxoid vaccines (Tdap vaccines) have been developed for use in adolescents and adults.[44,45,59,112,113,163] These two vaccines are Adacel and BOOSTRIX, and their components are presented in Table 140–5. Both these vaccines elicit vigorous antibody responses to the antigens that they contain after a single dose. These responses are significantly greater than those observed in infants at 7 months of age after they have received three doses of the DTaP vaccines (Daptacel and INFANRIX) of the two manufacturers.

TABLE 140–5 Antigenic Composition of Adacel and BOOSTRIX per 0.5 mL

Antigen	Adacel	BOOSTRIX
Diphtheria toxoid	2 Lf	2.5 Lf
Tetanus toxoid	5 Lf	5 Lf
Pertussis toxin toxoid (PT)	2.5 µg	8 µg
Filamentous hemagglutinin (FHA)	5 µg	8 µg
Pertactin (PRN)	3 µg	2.5 µg
Fimbriae 2/3 (FIM 2, 3)	5 µg	—

Lf, flocculation units.

In a double-blind efficacy trial in adolescents and adults, an acellular pertussis vaccine (without diphtheria and tetanus toxoids) with the same concentrations of PT, FHA, and PRN as BOOSTRIX had an efficacy of 92 percent.[406] No similar efficacy trial was done with Adacel or its acellular pertussis components. However, extensive epidemiologic data from Canada, where Adacel has been used since 2003, show a marked reduction of pertussis in adolescents.[207]

ADVERSE EVENTS

Whole-Cell Vaccines

Local reactions and relatively mild systemic complaints are frequent occurrences after pertussis immunization. Less commonly, severe neurologic illness and death have been noted in temporal association with DTP immunization.

The largest study in the United States designed to assess the risk of relatively common and uncommon reactions to pertussis vaccine was performed by Baraff and associates.[11-13,75] This study was conducted between January 1978 and December 1979. Reactions in children who received either DTP or DT immunization were compared. A total of 15,752 DTP immunizations and 784 DT immunizations were given to children aged birth to 6 years of age. These children were evaluated for reactions that occurred within 48 hours of vaccine administration. All common local and systemic reactions occurred more frequently in the DTP recipients than in the DT group. Differences between the common reactions in the two groups were all highly significant ($p < .005$).

Redness at the injection site occurred in 37.4 percent of DTP recipients and in 7.6 percent of DT vaccinees. Fever (≥38° C [100.4° F]) was noted in 46.5 percent of DTP recipients. A temperature of 39° C (102.2° F) or higher occurred in 6.1 percent of DTP recipients, but in only 0.7 percent of DT recipients. Drowsiness, fretfulness, vomiting, anorexia, and persistent crying were other reactions recorded in 3.1 percent (persistent crying) to 53.4 percent (fretfulness) of DTP recipients versus 0.7 percent (persistent crying) to 22.6 percent (fretfulness) of DT vaccinees. In general, rates of local reactions, but not those of systemic reactions (except fever), increase from dose to dose in an immunization series.

In addition to these reactions, 0.1 percent of DTP recipients in this study were reported by the parents to have a high-pitched, unusual cry; 0.06 percent had convulsions, and 0.06 percent had hypotonic-hyporesponsive episodes (shock, collapse). No children in the control group (DT recipients) had similar reactions; however, the control group was of modest size (784 DT recipients), so statistical significance could not be assigned to any of these relatively uncommon events.

Because convulsions in young children are the result of many different etiologic factors, the cause-and-effect relationship with pertussis vaccine is less clear. However, inasmuch as fever develops in almost half of all DTP vaccinees and febrile convulsions are not uncommon events, a reasonable assumption is that many convulsions that occur in temporal association with DTP vaccination are induced by the immunization. Three studies have noted a significant association between pertussis immunization and febrile convulsions.[15,356,404] Approximately 1 per 1000 vaccinees older than 6 months of age will have a first febrile seizure after receiving pertussis immunization. The concomitant use of acetaminophen (15 mg/kg per dose at the time of immunization and every 4 hours for 24 hours) and DTP vaccine has been suggested as a means of reducing the incidence of febrile convulsions in vaccinees.[226]

Neurologic disease and death occurring in temporal association with pertussis immunization have been of major concern

throughout the vaccine era. During the last 60 years, several case series and individual cases of neurologic illness occurring after receipt of pertussis immunization were reported; by 1979, more than 1000 cases of alleged neurologic damage induced by pertussis vaccine were reported.[22,36,47,49,218,252,418] Few of these reports had evidence of an adequate search for other possible causes of the neurologic disease, and in none were data available for rate calculations.

From 1967 to 1980, several attempts were made to determine the frequency of neurologic disease after receipt of pertussis immunization.[2,49,100,101,121,158,366,375] However, because controls were not included in any of the population evaluations, all rate estimates included children with temporally related events that had other causes.

A carefully designed prospective case-control study (National Childhood Encephalopathy Study [NCES]) of all hospital admissions of children aged 2 to 35 months with acute serious neurologic disorders in England, Wales, and Scotland was undertaken between 1976 and 1979.[4,21,245,270-273] The results of this study for the first time revealed an apparent statistical association between pertussis immunization and neurologic illness. Researchers found that a child who had received DTP vaccine within the previous 3 to 7 days was two to five times more likely to have neurologic disease than was a child who was not immunized during the same interval. The causal relationship between DTP immunization and neurologic illness noted in this study must be questioned, however, because both cases and controls had an equal frequency of immunization during the month preceding the index date. A more appropriate interpretation of the results is that they do not indicate cause and effect; rather, the DTP immunization calls attention to or brings out something that will occur anyway, but just moves it forward in time ("trigger effect").[50,51]

Infantile spasms, an identifiable seizure disorder of infancy, usually has its onset in the 6-month period from 2 to 7 months of age; therefore, that some cases occur after DTP immunization is not surprising. Simple calculations indicate that approximately 12 percent of all patients destined to have infantile spasms between 2 and 7 months of age will have an onset of illness within 7 days after receiving DTP immunization. The temporal association between DTP immunization and infantile spasms has led many people to assume a cause-and-effect relationship. However, controlled data from the NCES in Great Britain provide strong evidence against a causative role for pertussis vaccine in infantile spasms.[21] In another study, Melchior[266] in Denmark noted that the time of onset of infantile spasms was not altered when the time of pertussis immunization was changed from 5, 6, 7, and 15 months of age to 5 weeks, 9 weeks, and 10 months of age. In both periods, 42 percent of patients had their onset during the first 4 months of life.

Data from the NCES were reanalyzed with the exclusion of cases of infantile spasm.[271,273] From these analyses, the risk of permanent brain damage occurring from pertussis immunization has been suggested to be 1 per 330,000 vaccine doses, and the risk of any encephalopathy has been estimated to be 1 per 140,000 vaccinations. However, a review of the NCES data by other investigators indicates that both rate estimates are incorrect. Specifically, Stephenson[365] showed that the 1 per 140,000 rate for all encephalopathy is an artifact resulting from the inclusion of 9 children with febrile convulsions. Similarly, MacRae[244] noted that the increased relative risk that was observed within 7 days of receiving immunization (which was used to calculate the risk of brain damage of 1 per 330,000 immunizations) was offset by a decreased relative risk over the subsequent 3-week period. This finding, similar to the original study data and the infantile spasm data, indicates not a cause-and-effect relationship but rather a redistribution of events over time.

In the United States, the major neurologic illness that was noted in temporal association with DTP immunization was the first seizure of what turned out to be severe epilepsy. By chance alone, this association may occur 400 times a year in the United States. Four carefully performed studies that included approximately 330,000 children and 1 million immunizations have examined the possibility that pertussis immunization is a causative factor in epilepsy; no evidence of a causative role has been found.[51,126,140,356,404] More recently, two large studies in the United States and Canada found no evidence of a causal association with DTP immunization and encephalopathy.[282,327]

Similar to infantile spasms, SIDS also occurs in early life; therefore, that cases are noted to occur after administration of DTP immunization again is not surprising. Hoffman and associates[183] performed an extensive prospective case-control study of risk factors in SIDS from October 1978 through December 1979. In this study of 800 cases, investigators found that DTP immunization was not a risk factor for development of the syndrome. Other good, controlled studies have yielded similar results.[68,139] No evidence has demonstrated that DTP vaccinees have an increased risk of developing asthma later in life.[177]

Acellular Vaccines

An extensive amount of reactogenicity information has been generated in phase II and phase III studies with all licensed DTaP vaccines.[90,138,145,231,331,350,388] Because endotoxin has been removed from all DTaP vaccines, one is not surprised that all are less reactogenic than are DTP vaccines. In a double-blind study, the reactogenicity of 13 DTaP vaccines was presented and was compared with the reactogenicity of a DTP vaccine.[90] This study involved 2200 infants; 113 to 217 received an acellular product, and 370 received the whole-cell vaccine. Study participants received three doses of vaccine at 2, 4, and 6 months of age. Overall, all monitored reactions except vomiting occurred less frequently and were less severe in DTaP recipients than in DTP recipients. Specific results from this study are presented in Table 140–6. As can be seen, local redness and swelling and fever increased in frequency from the first to the third dose, whereas the complaint of drowsiness decreased.

In our efficacy trial in Germany with Acel-Immune, we monitored reactions in more than 8000 children after receipt of four doses of vaccine at 3, 4½, 6, and 15 to 18 months.[353,388] For the first three vaccine doses, the findings were similar to those noted in Table 140–6. After the fourth dose, the frequency of occurrence of local erythema and induration and fever increased considerably in comparison with their frequencies after the third dose. Ten percent of DTaP recipients had local erythema of 2.4 cm or greater, and 28 percent had temperatures of 38° C or higher. Other investigators also noted an increased frequency and severity of local reactions occurring after administration of the fourth and fifth doses of DTaP vaccines.[165,199,316,331,350] Of particular concern is the observation of extensive swelling of the thigh with booster doses of some DTaP vaccines.[331,350] Rennels and associates[331] found that this swelling occurred more commonly after immunization with DTaP vaccines containing high amounts of diphtheria toxoid. With Acel-Immune, a vaccine with a low diphtheria toxoid content, we noted that 15.4 percent of subjects had induration of more than 5 cm but less than 10 cm after receiving a fifth dose; swelling of the entire limb was not noted.[165]

In five of the 1990s efficacy trials, the occurrence of less common, more severe events (persistent crying, seizures, and hypotonic-hyporesponsive episodes) was monitored. A summary of these data is presented in Table 140–7. As can be seen, temporally related persistent crying, hypotonic-hyporesponsive episodes, and seizures were rare events after receipt of immunization with DTaP vaccines. In a large active surveillance program (IMPACT), researchers found that risks of having febrile seizures and hypotonic-hyporesponsive episodes after receiving pertussis-

containing vaccines decreased significantly after the introduction of DTaP vaccines in Canada.[223]

SCHEDULES AND CONTRAINDICATIONS

Immunization schedules with whole-cell vaccines have varied throughout the world and to great measure were determined by concern relating to true and perceived reactions.[49,68] An immunization schedule involving only three doses given to infants at 2, 3, and 4 months of age has been quite effective in controlling pertussis-related morbidity and mortality in the United Kingdom.[393] However, the five-dose schedule used in the United States resulted in lower attack rates in preschool- and school-aged children.[49,68]

The recommendation for the DTaP vaccine in the United States is that it be given in the same five-dose schedule as recommended for DTP vaccines.[391] However, follow-up data from the 1990s efficacy trials, as well as reactogenicity data, suggest that administration of this "one size fits all" approach could be modified.[138,145,146,305,342,343,350,382,385] Our findings with Acel-Immune suggest that the present five-dose schedule is appropriate.[242,362] Conversely, data from other trials suggest that administration of the fourth dose of some vaccines can be postponed until the child is 4 to 6 years of age, or the third dose can be moved back to the child's second year of life.[146,305,306,342,343,382,385] These changes would not be expected to decrease efficacy but would decrease troubling local reactions with booster doses.

Acellular pertussis component quadrivalent (DTaP, IPV), pentavalent (DTaP, IPV, HBV; DTaP, IPV, Hib), and hexavalent (DTaP, IPV, HBV, Hib) vaccines have been developed and are available in many countries. In the United States, the following multicomponent vaccines are available: DTaP/Hib (TriHIBit for the fourth dose of DTaP and Hib series), DTaP/IPV/HBV (PEDIARIX), and DTaP, IPV, Hib (Pentacel). In general, multicomponent vaccine use should be encouraged to reduce the number of injections that a child receives.

In addition to providing childhood immunization, the availability of adolescent and adult Tdap vaccines allows the vaccination of adolescents and adults to be conducted.* At present, the schedule for the use of Tdap vaccines varies in different countries.[112,113,163] The most common recommendation is for universal immunization of preadolescents and adolescents and the selective immunization of adults. However, our opinion is that a universal program involving all preadolescents or adolescents and adults every 10 years will be necessary to prevent the transmission of *B. pertussis* effectively to unimmunized infants and to prevent the continued circulation of *B. pertussis* in a population.

Over the years, pertussis vaccine recommendations have undergone many changes. In particular, contraindications to vaccine are evolving continually. An important note, however, is that few scientific data support any of the present contraindications. The primary goal of national immunization programs is to vaccinate all infants and children. If excessive contraindications and their overinterpretation lead to a large number of unimmunized children, the programs will fail, and the children in greatest need of protection will contract pertussis. In the United States, the most recent recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics generally should be followed. However, individual case-by-case decisions often need to be made.

ISOLATION AND PROPHYLACTIC MEASURES

Erythromycin, azithromycin, or clarithromycin treatment in the index case shortens the duration of communicability of the organisms and thus limits spread of the disease. During the first few days of treatment, contact with susceptible persons should be avoided. In general, close contacts (household members, those in daycare centers, playmates) of the index case should be protected from infection. Such protection can be implemented by the prophylactic use of erythromycin for 14 days, azithromycin for 5

*See references 44, 45, 53, 54, 57, 59-61, 112, 113, 155, 163, 208, 257, 339.

days, or clarithromycin for 7 days.[6,43,257,364] Active immunization of all exposed persons (children, adolescents, and adults) who are not adequately vaccinated also should be conducted.

The use of prophylactic antibiotics in adolescents and adults in exposure situations such as classrooms and hospital settings frequently is recommended. This approach often involves many people and considerable expense.

In our experience, the side effects of erythromycin and other macrolides are such that adult compliance is poor. Therefore, our opinion is that erythromycin and other macrolides should not be used prophylactically but only for treatment at the first sign of respiratory illness in those exposed.

OTHER *BORDETELLA* INFECTIONS

BORDETELLA PARAPERTUSSIS

B. parapertussis infection in children can cause unrecognized infection, mild pertussis, or typical pertussis.[257] We studied 38 children with *B. parapertussis* illnesses and compared their illnesses with those occurring in 76 children with *B. pertussis* illnesses.[174] The results were as follows (*B. pertussis/B. parapertussis)*, in percentages: cough for longer than 4 weeks, 57 percent/37 percent ($p = .06$); whooping, 80 percent/59 percent ($p = .07$); whooping for longer than 2 weeks, 26 percent/18 percent ($p = .05$); paroxysms, 90 percent/83 percent; post-tussive vomiting, 47 percent/42 percent; and mean leukocyte and lymphocyte counts, 12,500 per mm^3 and 7600 per mm^3/7800 per mm^3 and 3500 per mm^3 ($p < .0001$), respectively. In another study in Italy, children with *B. parapertussis* infection had the following rates of findings: cough, 100 percent; paroxysms, 76 percent; whooping, 33 percent; post-tussive vomiting, 42 percent; apnea, 29 percent; and cyanosis, 12 percent.[254] All of these rates except cough and paroxysms were lower in children with *B. parapertussis* infections than in children with *B. pertussis* infections. Concomitant infections with *B. pertussis* and *B. parapertussis* are not rare.[188,197,267]

Before and during the early pertussis vaccine era, pertussis caused by *B. parapertussis* was considerably less common than that caused by *B. pertussis*.[257] For example, during a 16-year period in the Grand Rapids area of Michigan, 4483 cases of pertussis were caused by *B. pertussis*, and 106 cases were caused by *B. parapertussis*.[103] More recently, during the DTaP vaccine efficacy trials in Europe, the comparative rates of illness caused by *B. pertussis* or *B. parapertussis* were examined. In our trial in Germany, the rate of pertussis caused by *B. parapertussis* infection in control children was 0.9 cases per 100 person years.[362] Of 130 culture-confirmed cases, 21 percent were caused by *B. parapertussis*. The percentage of cases caused by *B. parapertussis* in five other trials varied from 2.1 to 20 percent.[254]

During the last 30 years in the United States, pertussis caused by *B. parapertussis* has been an uncommon occurrence. However, during 2004 and 2005, 493 culture-positive cases of pertussis were noted by the Wisconsin State Laboratory of Hygiene.[298] Of these cases, 14 percent were caused by *B. parapertussis*.

BORDETELLA BRONCHISEPTICA

In 1911, McGowan[260] observed that laboratory workers exposed to various animals with *B. bronchiseptica* infections on occasion had respiratory illness. In 1926, a 5-year-old girl with a pertussis-like illness was found to be infected with *B. bronchiseptica*.[35] Her illness commenced about 10 to 12 days after she had been given a rabbit with mild "snuffles." Otherwise healthy children who became infected with *B. bronchiseptica* after being exposed to farm animals or pets usually have pertussis-like illnesses.[257]

B. bronchiseptica causes respiratory infections in at least 18 different mammals.[81] Most notable are atrophic rhinitis in pigs, kennel cough (rhinotracheitis) in dogs, and bronchopneumonia in rabbits and other laboratory animals. Occasional infections in humans have been noted during the last 35 years, with the majority occurring in immunocompromised adults.[5,99,423] Most recent reports have noted *B. bronchiseptica* infections in patients with acquired immunodeficiency syndrome (AIDS). Respiratory infections have ranged from mild upper respiratory illnesses to pneumonia. In patients with AIDS, the pneumonia frequently is cavitary. Sinusitis and bronchitis also occur.

BORDETELLA HINZII

B. hinzii has been recovered from an adult patient with cystic fibrosis during pulmonary exacerbations throughout a 3-year period.[124] Bacteremia has been noted in a patient with AIDS.[80]

BORDETELLA HOLMESII

B. holmesii has been isolated from the nasopharyngeal specimens of 33 patients suspected of having pertussis.[427] Twenty-three of the cases were investigated further, and 19 (82%) of these patients were adolescents, 2 (9%) were adults, and 2 (9%) were children. All had cough: 61 percent had paroxysms, 26 percent had post-tussive vomiting, and 9 percent had whoop. *B. holmesii* also has been isolated from a 10-month-old boy with bacteremia and from patients with septicemia, endocarditis, and respiratory failure.[283,380]

BORDETELLA TREMATUM

B. trematum has been isolated from wounds and ear infections.[395]

CHAPTER 141

CALYMMATOBACTERIUM GRANULOMATIS

Mariam R. Chacko

Granuloma inguinale is caused by *Calymmatobacterium granulomatis*. It was described first by McLeod in 1882, and *C. granulomatis* was isolated by Donovan in 1905. This disease has been known through the years by many different names, the most common being granuloma inguinale, donovanosis, and granuloma venereum.[30]

THE ORGANISM

C. granulomatis is an encapsulated gram-negative rod measuring 1.5×0.7 mm. Although some of its characteristics resemble those of *Klebsiella* and *Enterobacter*, *C. granulomatis* is considered a unique species distinct from other related organisms belonging to the subclass Proteobacteria.[21,30,31] However, the biochemical and bacteriologic characteristics of the organism have not been identified.[30,31]

Study of the organism reveals a complex cell envelope. In addition to having regular bacterial structures such as a mesosome, ribosomes, and nuclear material, the cytoplasm contains electron-dense granules; transmission electron microscopy shows an outer membrane, middle electron-opaque layer, and an inner plasma membrane. The organisms are enclosed mainly in large histiocytic cells and occasionally in polymorphonuclear cells and plasma cells. They multiply intracellularly to approximately 30 in number and eventually cause cell rupture.[7,30]

EPIDEMIOLOGY

Granuloma inguinale occurs predominantly in young and older adults and is a cause of genital ulcerative disease in tropical and subtropical regions of the world. As with all genital ulcerative diseases, granuloma inguinale has been given greater attention as a risk factor for development of human immunodeficiency virus (HIV) infection.[37] In South Africa, the prevalence of granuloma inguinale in patients with genital ulcer disease is reported to be approximately 10 percent.[34]

Granuloma inguinale is a rare occurrence in children. In the early 1950s, 4 percent of 1- to 4-year-old children in a Papua New Guinea population were found to have granuloma inguinale. Although the mode of transmission in adolescents and adults is considered to be sexual, the mode of transmission of the disease in these children was thought to be by skin-to-skin contact from sitting on the laps of infected adults.[30] More recent case reports show that otitis media, mastoiditis, neck mass, and cervical lymphadenopathy have been described as the initial manifestations of donovanosis in infants and children.[3,14,15] The modes of transmission in these cases are thought to be perinatal and by skin-to-skin contact.[3,14,15]

Granuloma inguinale has been reported since the early 1990s as endemic in South Africa, Papua New Guinea, India, and the Aboriginal community of Australia.[29] A resurgence of the disease was reported in the late 1980s in Durban, South Africa. After a rapid test for donovanosis was introduced in the early 1990s, the number of cases reported by the Durban Health Department in South Africa increased substantially.[27] As a result of the availability of the rapid test and implementation of an HIV/STI (sexually transmitted infections) initiative, the number of new cases of donovanosis in Australia decreased dramatically; five cases were reported in 2005.[2] In 1994, after 4 decades, a case of granuloma inguinale was reported in China.[13]

Granuloma inguinale is not a common occurrence in Europe or the United States today. However, the prevalence increased in developed countries in the 1990s, especially among migrant and poor people living in metropolitan areas. For example, three cases of granuloma inguinale were reported in Rome between 1993 and 2001, with most of them diagnosed in 2000 and 2001.[26] Until 1952, more than a thousand cases a year were reported to the Center for Disease Control (now the Centers for Disease Control and Prevention [CDC]). Since 1952, the prevalence of this disease declined rapidly; between 1971 and 1981, 50 to 90 cases a year were reported. Except for an isolated surge of 97 cases in 1990, fewer than 50 cases a year have been reported since 1982, and in 1993, 19 cases (15 male and 4 female) were reported. In 2000, no cases were reported in the United States.[5] Granuloma inguinale was detected in a white adolescent girl in California in 1985.[16] In 1991, nongenital granuloma inguinale was diagnosed in a man with testicular carcinoma in Texas.[25] In 1992, three unrelated cases of granuloma inguinale, seen within a period of a few weeks, were reported in Toronto; two occurred in immigrants, and one occurred in a native-born Canadian. The first patient was a recent immigrant from El Salvador, and the second patient had immigrated several years previously and had a history of sexual activity with a Jamaican who had immigrated recently. The sexual partner of the third case had come from Turkey.[18] Although the prevalence of the disease is low, this disease needs to be suspected in North America and Europe because of international travel and immigration. Granuloma inguinale usually occurs more commonly in male than in female patients. However, in adolescents, the disease can develop more commonly in girls than in boys. This ratio probably is a reflection of sexual activity between adolescent girls and adult men.[28]

The risk factors and mode of transmission of granuloma inguinale are not clear. The disease generally is considered sexually transmitted. However, in many cases, granuloma inguinale cannot be detected in the sexual partners of infected persons. Nonetheless, numerous studies have reported the disease in 12 to 50 percent of marital or steady sexual partners.[30] Anal intercourse also has been associated with rectal and penile lesions of granuloma inguinale.[22] O'Farrell and associates[35] studied the patterns of sexual behavior in men and women with genital ulcer disease and found that patients with granuloma inguinale and secondary syphilis were more likely than were patients with other

genital ulcer diseases to have had sexual intercourse despite the presence of ulcers. Studies reported from India and South Africa have noted a preponderance of granuloma inguinale cases in uncircumcised male patients with poor genital hygiene.[28]

Coexistence of granuloma inguinale with other sexually transmitted diseases occurs commonly. Syphilis has been described in as many as 23 percent of patients with granuloma inguinale. In one report, HIV-1 antibodies were found in as many as 8 percent of male patients with granuloma inguinale.[25,37]

PATHOGENESIS AND PATHOLOGY

The primary lesion in granuloma inguinale is an indurated nodule that erodes through the skin and becomes a granulomatous heaped ulcer. Adjacent lesions form and eventually coalesce, especially in the perineal area. Secondary infection of lesions may occur and may aggravate the tissue destruction and cause scarring. *C. granulomatis* organisms invade mononuclear endothelial cells. Extensive acanthosis and dense dermal infiltrates of mainly plasma cells and histiocytes have been observed in the indurated nodules. Polymorphonuclear cell infiltration also occurs, but lymphocytes are rare findings when secondary infection develops. The pathognomonic feature of granuloma inguinale is a large, infected mononuclear cell, 25 to 90 μm in diameter, that contains many intracytoplasmic cysts filled with deep-staining Donovan bodies. Metastatic spread to the bones, joints, liver, and lymphatics occasionally occurs.[30]

A possible link between human leukocyte antigen (HLA)-B57 and granuloma inguinale infection may exist; class I, class II, and DQ antigens have been detected in the genital ulcers of individuals with granuloma inguinale.[32] Circulating lymphocytes and tissue-level lymphocyte subpopulations in granuloma inguinale have been studied.[40,41] T-lymphocyte and B-lymphocyte infiltration in tissues is almost identical, without any significant difference in ulcerogranulomatous and hypertrophic variants. Both total leukocyte and absolute lymphocyte counts are increased in the ulcerogranulomatous variant of granuloma inguinale. Total T lymphocytes, CD4, CD8, and CD22 levels, and the CD4/CD8 ratio all are increased significantly in the ulcerogranulomatous variant. In contrast, the hypertrophic variant causes a significant elevation only in the CD4/CD8 ratio. This finding suggests a greater cell-mediated immune response in the ulcerogranulomatous variant of granuloma inguinale and is consistent with the paucity of Donovan bodies in smears obtained from patients with this variant.[40,41]

CLINICAL MANIFESTATIONS

The incubation period of granuloma inguinale usually is less than 2 weeks but may be as long as 3 months. The disease begins as one or more subcutaneous nodules that erode through the skin to produce clean, large, beefy-red, granulomatous ulcers that bleed easily. The lesions are sharply defined and painless, and the ulcers feel hard when palpated. The disease usually is limited to local tissue; therefore, constitutional symptoms are unlikely to be present. Autoinoculation is a common manifestation that produces "kissing" lesions. When left untreated at this early stage, the disease progresses and causes extensive mutilating lesions (see Chapter 48).[30]

The morphology of the cutaneous lesions of granuloma inguinale can vary, depending on the stage of the disease. The exuberant or hypertrophic stage appears before secondary infection develops. It consists of large, vegetating masses with overgrowth of granulation tissue, usually in the perianal region. The ulcerative stage is accompanied by secondary infection. In this stage, large, spreading, shallow necrotic ulcers with a foul odor may be noted. The cicatricial stage results after prolonged healing and is characterized by fibrosis, scarring, depigmentation, keloid formation, elephantiasis, and stenosis of the vagina, urethra, and anus. In patients in Durban, ulcerogranulomatous lesions occurred far more commonly than did hypertrophic and necrotic lesions. Although lymphadenopathy is an unusual occurrence in granuloma inguinale, pseudobuboes and pseudoelephantiasis of the genitals (massive edema) may be seen. Pseudobuboes are the result of deep, inguinal granulomata; pseudoelephantiasis is caused by cutaneous extension of lesions and inflammation.[10,25,30]

The genitalia are involved in 90 percent of cases, the inguinal region in 10 percent, the anal region in 5 to 10 percent, and extragenital sites in 1 to 5 percent. In male patients, lesions usually occur on the prepuce and also can occur on the coronal sulcus and frenulum of the penis.[30,31]

As ulcers enlarge, they can be mutilating and can lead to urethral stenosis. The most common clinical manifestation in pregnant and nonpregnant women is vulvar ulceration. Genital tract bleeding is the next most common finding in nonpregnant women. Multiple sites of genital ulceration (vulva, vagina, and cervix) have been noted only in nonpregnant women.[10,28,30] Extragenital sites, through hematogenous spread, have been reported in the mouth, chin, axillae, abdomen including the pelvic cavity, and foot.[9,11,23,30,38,39,42] These distant sites usually are associated with a primary lesion in the genital area.[30] Lesions in the oral cavity have been described after apparently successful treatment of genital lesions.[9] Donovanosis ulcers may take longer to heal in HIV-positive individuals, and greater destruction of tissue may be noted as well.[30,31]

In endemic areas, unusual manifestations of granuloma inguinale may cause confusion with a wide variety of diseases and can result in misdiagnosis. The differential diagnosis includes carcinoma, secondary syphilis, necrotic ulcerations of amebiasis, tuberculosis, and filariasis. In addition, secondary infection can confuse the diagnosis.[17,30]

DIAGNOSIS

Generally, granuloma inguinale is diagnosed on clinical grounds. The accuracy of a clinical diagnosis of granuloma inguinale can be as high as 63 percent in male patients and 83 percent in female patients. When compared with other genital ulcers, the ulcers are larger in granuloma inguinale, are painless, bleed easily to touch, and usually are not associated with inguinal lymphadenopathy.[36]

The diagnosis of granuloma inguinale can be confirmed by identification of Donovan bodies on a stained crush specimen from the lesion (see Fig. 48–22). Examination of appropriately stained specimens from active lesions remains the most reliable diagnostic test. Light-microscopic examination of biopsy specimens that have been fixed in formalin and embedded in wax is less reliable. Donovan bodies rarely are seen by this method.[30,36]

The common stain used to identify Donovan bodies is Wright-Giemsa blue-black stain. Sections that are formalin-fixed or stained with hematoxylin and eosin are less useful for detecting Donovan bodies. If donovanosis is suspected, a swab for this condition should be taken first, before swabs for other organisms, so that an adequate amount of cellular material can be obtained.[20,30,33] When *C. granulomatis* organisms are likely to be scarce or when smear or crush specimens are likely to be nondiagnostic, one should consider obtaining a biopsy of the lesion. Accordingly, a biopsy specimen preferably stained with Giemsa or silver is recommended in very early, very sclerotic, or heavily superinfected specimens.[20,30,33]

Successful isolation of *C. granulomatis* by culture on human epithelial cell lines with a modified *Chlamydia* culture technique

has been reported from South Africa and Australia.[4] Polymerase chain reaction (PCR) techniques for *C. granulomatis* also have been developed and further refined into a colorimetric detection system for use in diagnostic laboratories.

Donovan bodies have been identified on Papanicolaou smears from the cervix.[8] Serologic and skin tests for granuloma inguinale are highly sensitive but not specific. A serologic test using the indirect immunofluorescence technique has been evaluated and found to have a sensitivity of 100 percent, a specificity of 98 percent, a positive predictive value of 89 percent, and a negative predictive value of 100 percent in diagnosing granuloma inguinale. In the absence of culture methods for *C. granulomatis*, this test may prove helpful in the diagnosis of established lesions and not early ulcers.[12]

TREATMENT

Antibiotics with strong activity against *C. granulomatis* are those effective in the treatment of gram-negative bacilli or those whose lipid solubility ensures good intracellular penetration. The CDC recommends treatment of adolescents and adults with doxycycline, 100 mg orally twice a day for a minimum of 3 weeks, until lesions are healed.[5] Alternative regimens include the following: azithromycin, 1 g orally weekly for at least 3 weeks; or ciprofloxacin, 750 mg orally twice a day for at least 3 weeks; or erythromycin, 500 mg orally four times a day for at least 3 weeks; or trimethoprim-sulfamethoxazole, one double-strength tablet (160 mg/800 U) orally, twice a day for at least 3 weeks.[5] Children younger than 9 years of age can be treated with oral azithromycin suspension (10 mg/kg daily) trimethoprim-sulfamethoxazole (10 mg/kg/day trimethoprim), or erythromycin (30 to 50 mg/kg/day).[6]

Clinical response to antibiotics should be noted within a week of treatment; the lesions should become paler and less friable. After a week of treatment, the lesions become smaller, and total healing of the area takes 3 to 5 weeks. Relapse occurs in approximately 10 percent of cases, especially if use of the antibiotic is discontinued before the primary lesion has healed completely. Donovan bodies may reappear within 7 to 10 days.[30] Treatment can fail in patients with coexisting HIV infection, and more intensive and prolonged antibiotic therapy may be needed. As compared with HIV-negative patients, the mean duration to complete ulcer healing in these patients is significantly longer: 25.7 days versus 16.8 days.[19]

Merianos and associates[24] reported the possible effectiveness of ceftriaxone for chronic, recurrent granuloma inguinale. Patients in this study had been suffering from the disease for 1 to 5 years and had received 4 to 19 courses of antibiotics. A single daily intramuscular injection of 1 g of ceftriaxone diluted in 2 mL of 1 percent lidocaine was administered for 7 to 26 days. Clinical improvement was dramatic in most lesions; one third of patients recovered completely without a recurrence after receiving daily doses of ceftriaxone for 7 to 10 days. Patients with mild recurrences responded to additional ceftriaxone or short courses of oral antibiotics.[24] Vulvectomy is reserved for infections that have not responded to antibiotic treatment or for patients with severe vulvar elephantiasis.[10]

PROGNOSIS

Healing is complete in patients who seek treatment early in the course of the disease and who comply with their medication and follow-up regimens. O'Farrell[28] noted complete healing of lesions in 24 percent of patients who complied with follow-up. Complications of granuloma inguinale include pseudoelephantiasis, urethral stricture, and pelvic abscess, which may require surgery. Another complication is the acquisition of HIV infection and granuloma inguinale, especially when patients with ulcerations that are left untreated for a prolonged period have sexual contact with an HIV-positive partner.[28,30]

The severe, mutilating complications of granuloma inguinale are primarily a result of delayed treatment or poor compliance with medication. In Durban, South Africa, almost half of the male patients had ulcerations for 1 to 6 months before they sought medical care, and 16 percent had ulcerations for 1 to 3 weeks. In contrast, approximately 25 percent of female patients had ulcerations for 1 to 6 months, and 50 percent had ulcerations for 1 to 3 weeks.[28] Delayed medical attention may be related to limited education, ignorance of sexually transmitted diseases, absence of suitable medical facilities, or embarrassment in seeking treatment because of extensive genital lesions.

PREVENTION

Sexual partners of persons with the disease should be traced, examined, and treated. Treatment of granuloma inguinale when the nodule first appears is associated with a benign course. Thus, community-based eradication that targets men with granuloma inguinale in endemic areas should be implemented. Programs should be aimed at identification of lesions, provision of early treatment, and prevention of severe complications. Teaching the importance of personal genital hygiene, such as instruction on simple retraction of the foreskin in men and cleansing the penis with soap and water, also is effective.[28,30]

CHAPTER 142

CAMPYLOBACTER JEJUNI

Norma Pérez ✪ Gloria P. Heresi ✪ James R. Murphy

Campylobacter jejuni is a frequent cause of enteritis and less often of extraintestinal infection in humans. Since it first was recognized as a common human pathogen in the 1970s, appreciation of this agent's importance as a cause of disease has been increasing steadily. *C. jejuni* is one of the most frequent bacterial causes of human enteritis in the United States and is a leading cause of bacterial foodborne diarrheal disease throughout the world.[4,10,200] Immunoreactive complications may develop after infection.[157,169]

HISTORY

The pathologic consequences of infection with members of the group of bacteria that includes *C. jejuni* were recognized first in 1909 from studies of abortions in sheep.[130] In 1947, the sheep abortion–associated organism *Vibrio fetus* was isolated from a blood culture from a pregnant woman who had an influenza-like illness and delivered a stillborn infant with a necrotic, infarcted placenta.[219] In 1957, King[112,113] hypothesized that *V. fetus*–related organisms could be associated with human enteric disease. Butzler and colleagues[31] showed that bacteria similar to *V. fetus* were present in the stools of children with diarrhea. This observation was confirmed rapidly and repeatedly.[21,33,67,189,202] Major differences in biochemical activities, growth characteristics, and DNA base nucleotide content between true vibrios and *V. fetus* led to the establishment of the new genus *Campylobacter*.[217] The genome of a representative *C. jejuni* was published in 2000.[154] Information gleaned from this and comparative analyses of additional isolates have markedly advanced knowledge of these agents.[63,85]

THE ORGANISM

C. jejuni is a gram-negative rod that may vary in width from 0.2 to 0.9 μm and in length from 0.5 to 5.0 μm.[214] The rods may be short and S-shaped or longer spirals (Fig. 142–1). The organism grows best in cultures maintained at 42° C under microaerophilic conditions (5%-10% oxygen). *C. jejuni* belongs to rRNA superfamily VI, a specialized subgroup of gram-negative bacteria that

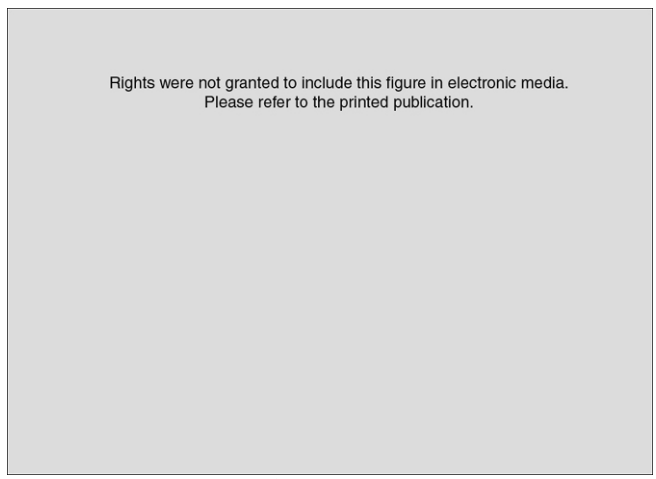

Figure 142–1 Scanning electron microscopy of *Campylobacter jejuni* strain 20-01. *(From Baqar, S., and Rice, B.: Campylobacter jejuni enteritis. Clin. Infect. Dis. 33:901-905, 2001.)*

also includes *Arcobacter* and *Helicobacter*. *C. jejuni* usually is motile, with either a single polar flagellum or two flagella, one at each end of the rod; nonmotile variants exist, and spores are not formed. Organisms obtained from stressed cultures may be coccoid or spherical. The species *C. jejuni* has two subspecies: *C. jejuni jejuni* and *C. jejuni doylei*. *C. jejuni doylei* can be differentiated from *C. jejuni jejuni* by the failure of *C. jejuni doylei* to grow at 42° C, lack of nitrate reduction, and sensitivity to cephalothin. For brevity, we refer to *C. jejuni jejuni* as *C. jejuni*. The spectrum of disease recognized as caused by *C. jejuni* is expanding.[5]

C. jejuni has a circular chromosome of 1.64 million base pairs (30.6% guanosine and cytosine).[154] Marked differences in pathogenic surrogates (motility, colonization of chicks, invasion, and translocation of cultured cells) are associated with variable chromosomal sequences within different passage sequences for a single isolate, and unique chromosomal sequences are associated with known pathogenic isolates of *C. jejuni*. Genomic analyses demonstrate that substantial differences exist among organisms classified by conventional means as *C. jejuni* and that some of these differences are associated with the capacity to cause disease in humans.[63,85,153] Genomic sequence analyses have yielded a catalogue of phase-variable surface structures (including lipo-oligosaccharide and capsule) that appear to relate to pathogenesis and immunity,[58,154] a lack of classical operon structure, repetitive DNA, and an unexpected capacity to produce polysaccharide.[154] Populations of *C. jejuni* are nonclonal, and interstrain exchange of genetic material occurs.[41]

EPIDEMIOLOGY

Human infection with *C. jejuni* occurs worldwide.[19] *C. jejuni* persists in zoonotic niches (Table 142–1), and most human infections are thought to arise from these reservoirs. Chickens and contaminated water are the main sources of campylobacteriosis in developed countries. The organism is a common commensal of the gastrointestinal tract of cattle, pigs, dogs, cats, and most birds used as human food,[25,185] and transmission from these sources occurs. In the United States, *C. jejuni* infection peaks in late summer and early fall (Fig. 142–2). Fresh-water bathing sites may yield *Campylobacter* organisms that are epidemiologically linked to human infections.[145,181,182] Dairy cows in the United Kingdom have higher concentrations of *Campylobacter* organisms in spring and autumn, but the concentration of *Campylobacter* organisms in beef cattle at slaughter does not change with season; as many as 90 percent of beef cattle may be stool-positive for *Campylobacter*.[196] In subtropical areas, the peak incidence of isolation of *C. jejuni* often is associated with the rainy season. In most tropical climates, rates of isolation are similar year-round. Studies in volunteers show an incubation period of 2 to 4 days after challenges ranging from 800 to 100 million colony-forming units.[18] Fecal shedding of *C. jejuni* by humans may last a median of 2 to 3 weeks, with a range of 3 days to several months.[33,109,149]

The distribution of *C. jejuni* infections within populations is linked to the level of industrialization. In industrialized countries, *C. jejuni* infection is found often in children and adults with enteritis and seldom in healthy individuals.[200] In less industrial-

ized areas, *C. jejuni* is isolated frequently from children, even in the absence of enteritis (Tables 142–2 and 142–3).

In industrialized countries, *C. jejuni* has been isolated from between 1 and 13 percent of children with diarrhea, and the prevalence of infection in healthy individuals has been reported to be between 0 and 1.5 percent.[21,31,170,189,200] A 5-year, laboratory-based national surveillance of *Campylobacter* spp. showed an isolation rate of 5.5 per 100,000 person-years (with *C. jejuni* accounting for 99% of the *Campylobacter* isolates; Fig. 142–3).[202] Population-based isolation rates of *Campylobacter* in the United States range from 28 to 1560 per 100,000 per year.[201,202] The rate of death attributable to *Campylobacter* is estimated between 100 and 124 per year in the United States.[8,9] The case mortality rate is between 0.10[131] and 0.23 percent.[81] It is possible that the mortality rate is higher. A registry-based study demonstrated about fivefold and twofold increases in mortality rates for the first 30 days or first year, respectively, after developing *Campylobacter* infection.[81] Population-based studies in England, the United States, and Sweden showed a bimodal age distribution, with a peak of illness occurring in children younger than 5 years of age and a second peak at 15 to 29 years of age.[172,202] The highest isolation rate occurs in the first year of life (see Fig. 142–3).

In less industrialized regions, *Campylobacter* is found in association with childhood diarrhea in 8 to 45 percent of cases, but it is isolated at similar rates from healthy children.[33,39,64] The highest rates of *Campylobacter* isolation are in children younger than 5 years of age.[33] As many as 75 percent of *Campylobacter* infections occurring during the first year of life are asymptomatic.[39]

In industrialized regions, most sporadic cases occur because of handling, preparation, and consumption of contaminated raw or undercooked poultry.[21,32,44,87,184,192,202] Raw milk and contaminated water less frequently are sources (see Table 142–1).[90,96,133,204,222] Poor kitchen hygiene plays a role in transmission; the risk of acquiring infection is inversely related to the frequency of using soap to clean cutting boards.[202] Barbecues represent a special hazard because they permit easy transfer of bacteria from raw meat to hands and other food and from there to the mouth.[33] Sporadic cases of *C. jejuni* infection occur much more frequently than do outbreaks.

Campylobacter is transmitted usually by a contaminated food or water vehicle. However, direct transmission of the agent may occur, usually to individuals with direct exposure to reservoir animals or to those who process contaminated animal products.[30] Person-to-person spread may occur in areas of high contamination, such as where diapered children are present.[155] In addition, intrapartum transmission is documented.[30,218] Asymptomatic mothers may transmit the infection to their newborns.[30]

In developing countries, transmission is multifactorial. Free-roaming poultry, toddlers, unsafe water supply, and lack of adequate disposal of excreta are documented sources.[69] However, proving that *Campylobacter* cause disease in regions where the

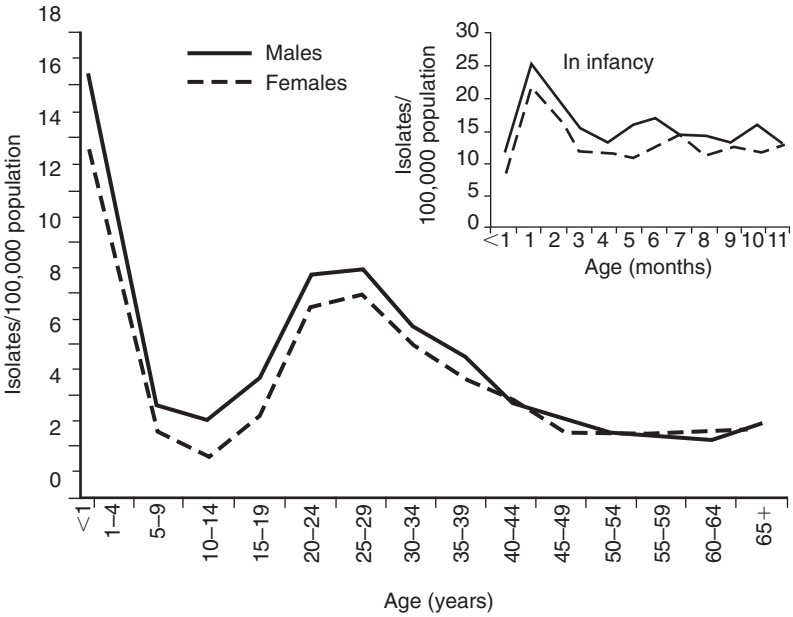

Figure 142–3 Annual isolation rates of *Campylobacter* by age and sex, United States, 1982 to 1986. *(From Tauxe, R. V., Hargrett-Bean, N., Patton, C. M., et al.: Campylobacter isolates in the United States, 1982-1986. Morb. Mortal. Wkly. Rep. CDC Surveill. Summ. 37:1-13, 1988.)*

agent is environmentally pervasive is difficult. Confounders include statistically indistinguishable rates of isolation from diarrhea cases and matched controls (see Table 142–2) and direct evidence that the presence in a household of a *Campylobacter* shared between humans and chickens is associated with protection from diarrhea.[144] Improved knowledge of the immune responses that protect from *Campylobacter* infection and disease and knowledge of the components of *Campylobacter* required to cause disease are needed to understand the agent's epidemiology better.

Because of the biochemical inactivity of *Campylobacter* organisms, discriminating species and subspecies by conventional chemotaxonomic methods is problematic. The consequences of this difficulty include ambiguities in epidemiologic investigations and low resolution in studies of mechanisms of virulence and immunity. Effort is being invested in devising genotyping schemes.[47,146,223]

PATHOLOGY

Most *C. jejuni* infections are not associated with illness or notable pathologic features. When illness does occur, watery diarrhea, invasive enteritis, or systemic infection may result. The spectrum of pathology reflects this range of manifestations. Acute watery diarrhea may occur in the absence of grossly visible pathologic features. Acute inflammation of the colon and rectum is the hallmark of *C. jejuni* invasive enteritis,[125] although hemorrhagic jejunitis and ileitis may also occur.[54,109,113,189] In patients who have undergone proctoscopy, normal mucosa is found in approximately 50 percent; in the remainder, mucosal edema, congestion, friability, and granularity are seen. The spectrum of histologic changes ranges from minimal edema with acute and chronic inflammatory cells and no vascular congestion to moderate inflammation and cryptitis to crypt abscess formation.[12] Acute appendicitis, mesenteric lymphadenitis, and ileocolitis have been reported in patients who have undergone appendectomies while they were infected with *C. jejuni*.[23] *C. jejuni* infection is at low frequency a precursor to immunoreactive complications wherein disease results from immunologic effectors generated in response to infection that damage neurons. The demonstration that, after adjustments for co-morbidities, *Campylobacter* infection is associated with increased mortality over the course of a 1-year period after infection suggests that as yet unidentified severe late disease occurs.[81] *C. jejuni* is one of a few microbes that have been hypothesized as triggering a common mechanism leading to lymphomas.[75]

PATHOGENESIS

The mechanisms by which *C. jejuni* causes diarrhea, dysentery, and, less frequently, systemic disease are not understood well. Evidence consistent with the production of a heat-labile enterotoxin has been presented.[73,100,123,174] However, this toxic activity is not universally associated with isolates from individuals who have *C. jejuni* illness. Some strains produce a cytotoxin,[101,124] but its relevance to disease has not been established. Some *C. jejuni* can invade various cultured cell lines.[32,55] Motility, surface structures, and molecular adaptations have been associated with capacity to cause disease,[13,14,60,61,74,82,107,136] but the pattern of their expression in disease-associated isolates is not uniform. Dogs,[166] rhesus,[57] rabbits,[195] mice,[57] and hamsters[92] have been evaluated as models of *Campylobacter* enteritis, but none faithfully reproduces the disease seen in humans. A mouse intranasal challenge model[16] has been developed for use in studies of *C. jejuni* invasiveness, and a ferret model[17] has been developed for studies of *C. jejuni*-induced diarrhea.

In vitro studies demonstrate a capacity to disrupt tight junctions of intestinal epithelial cell monolayers and preferentially induce proinflammatory cytokine responses. These capacities and the demonstrated microtubule-dependent eucaryotic cell evasion mechanism[114] may contribute to establishment and maintenance of *C. jejuni* in the gut.[36]

IMMUNITY

The preponderance of evidence of protective acquired immune responses to *C. jejuni* comes from studies of children in developing countries. Such children have more frequent symptomatic infections at younger ages; with increasing age, the rate of symptomatic infection decreases.* The number of *C. jejuni* organisms

*See references 20, 22, 24, 102, 103, 105, 127, 198, 203, 205.

excreted per gram of stool of infected individuals also declines with increasing age,[205] as does the duration of excretion of the organism.[203] These phenomena parallel increasing titers of *Campylobacter*-specific antibodies.[22,24,102,127,198,205,210] Additional inferential evidence includes that breast-feeding is associated with reduced frequency of *C. jejuni* diarrhea.[173,213] Adult volunteers who became ill after a first challenge were protected from illness after repeat challenge with a homologous strain,[18] and resistance related to the presence of anti *Campylobacter* antibodies. Prolonged, severe, and sometimes recurrent infections occur in immunodeficient patients.[128,132,161] Hypogammaglobulinemic patients have difficulty clearing *Campylobacter* organisms. Patients with late-stage acquired immunodeficiency syndrome (AIDS) are at increased risk of acquiring severe relapsing *Campylobacter* infection; patients with early stages of human immunodeficiency virus (HIV) infection and high CD4 counts are not at risk. Immunity to disease may not protect against asymptomatic colonization. The bacterial components against which the protective immune responses are directed are not known. The sum of this evidence forms the basis for attempts to develop *C. jejuni* vaccines.

Very little information is available on cellular immune responses to *C. jejuni*. Cellular responses may play an important role in facilitating the formation of antibody and in clearing intracellular *C. jejuni* from eukaryotic cells.

Despite the mass of evidence indicating protective roles for immune responses, the *Campylobacter* components against which protective immune responses are targeted are not known. Similarly, attempts to relate classic serotyping schemes, flagellar types, or presence or absence of virulence factors with disease-causing capacity have yielded associations of poor strength. The completion of the genome sequence of *C. jejuni*, NCTC 11168, in 2000[154] enabled studies to be pursued that are beginning to explain the relationships between bacterial components and immune responses. The *Campylobacter* glycome is remarkably plastic,[108] and *Campylobacter* spp. produce a surprising variety of carbohydrates (≈8% of the genome is dedicated to the biosynthesis of surface carbohydrates). Furthermore, multiple mechanisms exist for sequence variation for genes encoding the glycome. In a clinical trial, researchers demonstrated that passage of *C. jejuni* in volunteers can be associated with phase variation in lipo-oligosaccharide.[165]

CLINICAL MANIFESTATIONS

C. jejuni produces a spectrum of manifestations, the most common of which is enteritis. Bacteremia, other systemic manifestations, and perinatal infections occur infrequently.

ENTERITIS

Children with *Campylobacter* enteritis may have unformed stools, watery diarrhea, inflammatory diarrhea, or a combination of these symptoms.[5,21,23,33,109,149,189] Inflammatory diarrhea can be so severe that it is misdiagnosed as inflammatory bowel disease.[189] Inflammatory diarrhea is a more common occurrence in industrialized countries, and secretory watery diarrhea more typically occurs in developing areas. Patients with ciprofloxacin-resistant strains have longer duration of diarrhea than do patients infected with sensitive strains.[143]

Most cases of enteric illness subside within 7 days, although 20 to 30 percent last for 2 weeks and a few (5-10%) may persist longer, with a relapsing course lasting for weeks.[109,149] In one third to one half of patients, the initial symptoms are periumbilical cramping, intense abdominal pain, malaise, myalgia, and headache. An acute abdomen or appendicitis may be suspected at first[34] because acute abdominal pain occasionally may be the only initial symptom; pseudoappendicitis or mesenteric adenitis and terminal ileitis can be found.[158] The pain may be mild and intermittent for several weeks, and vomiting is a common occurrence. Secretory diarrhea with 10 or more profuse, watery stools per day may be present. Because this course occurs commonly in younger children, dehydration frequently (10%) is an outcome. Relapse of symptoms may occur.

The symptoms of inflammatory diarrhea are similar to those caused by *Shigella*, invasive *Escherichia coli*, and *Salmonella* and consist of generalized malaise, fever, abdominal cramps, tenesmus, bloody stools, and the presence of fecal leukocytes on light microscopy.[125] Fever without other symptoms may develop and can be associated with febrile seizures.[225] Toxic megacolon with massive bleeding may occur.[71,106,179] In neonates, blood-streaked formed stools or hematochezia may be associated with the isolation of *C. jejuni*.[71,106] The abdomen is tender, especially in the right lower quadrant. Splenomegaly occurs rarely.

EXTRAINTESTINAL INFECTIONS

Bacteremia with *C. jejuni* occurs much less commonly than does enteritis. Bacteremia was recognized first in malnourished children, patients with chronic illness or immunodeficiency, and patients at the extremes of age.[2,72,132,168] Cirrhosis, cancer, immunosuppressive therapy, and HIV infection commonly are underlying conditions in patients with bacteremia.[162] These findings led to the view that *C. jejuni* bacteremia was a disease of the relatively immunoincompetent patient. However, most *C. jejuni* blood isolates are from healthy individuals who often have histories of recent gastrointestinal disease.[190] The average incidence of *Campylobacter* bacteremia in England and Wales is 1.5 per 1000 intestinal *Campylobacter* infections. The Centers for Disease Control and Prevention (CDC) reports that only 0.4 percent of *C. jejuni* isolates in the United States are from blood cultures.[202] Most *C. jejuni* strains are susceptible to killing by serum, a finding that perhaps explains the transient nature of the bacteremia and its tendency to resolve without specific therapy. In HIV-infected patients, *Campylobacter* bacteremia occurs more frequently and with increased morbidity and higher mortality rates.[126,162,206] Fatal cases have been reported in the absence of enteric disease.[126]

The main reason for the increased recognition of extraintestinal *Campylobacter* infections appears to be the growing application of appropriate microbiologic culture methods. The incidence of *C. jejuni* bacteremia probably remains underestimated. Typically, blood cultures are not performed in individuals with the primary complaint of diarrhea. Rarely,[164] cholecystitis, urinary tract infection,[40] pancreatitis,[62] hepatitis,[115] and meningitis[49,210] can result from *Campylobacter* infection.

PERINATAL INFECTIONS

Occasionally, abortion or stillbirth, premature labor, neonatal sepsis, and meningitis caused by *C. jejuni* have been described.[156] *Campylobacter*-associated second trimester abortion generally is preceded by mild gastroenteritis.[138,187] The placenta may have areas of necrosis, infarction, microabscesses, and inflammation. The most likely route of placental/fetal infection is through the bloodstream, although a case with possible ascending spread has been reported.[45] Infected infants often are premature. Illness in neonates generally is mild or asymptomatic, but symptomatic gastroenteritis and asymptomatic bloody diarrhea caused by *C. jejuni* have been reported in newborn infants.[28,149] Bacteremia and meningitis also may occur.[68,210] The source of the organism in these cases usually has been the mother, who may be symptomatic or asymptomatic at the time of delivery.[28,186]

IMMUNOREACTIVE COMPLICATIONS

An episode of *C. jejuni* infection may be followed by immunoreactive complications such as Guillain-Barré syndrome (GBS),[79,80,104,134,171] Reiter syndrome,[99,160,163] reactive arthritis,[51,164,177] and erythema nodosum.[11,59,194] A preceding *C. jejuni* infection has been documented by serologic methods or stool culture in 12 to 60 percent of patients with GBS.[3,79,80,91,110,134] *C. jejuni* infection is the most common identified causal factor for GBS.[140,169] However, the risk of development of this syndrome after having a *C. jejuni* infection is less than 1 percent.[4] *Campylobacter*-associated GBS is associated with axonal degeneration and poorer outcome than in GBS associated with other causes.[169] During the 2 months after a symptomatic episode of *C. jejuni* infection, the likelihood of GBS is approximately 100 times (30.4 per 100,000) higher than the risk in the general population (0.3 per 100,000).[129] In a nested case-control study from 1991 to 2001 using data from the United Kingdom General Practice Research Database, 20 percent of GBS cases were attributable to *Campylobacter*.[199] GBS syndrome appears to be an age-related risk; one study found no cases in patients less than 20 years of age, 14 per 100,000 in patients aged 20 to 59 years, and 248 per 100,000 infections in those older than 60 years of age.[129] Certain serotypes of *C. jejuni* are associated more frequently with the subsequent development of GBS.[6,117]

Molecular mimicry between G_{M1} ganglioside and *C. jejuni* lipo-oligosaccharide is established as one of the causes of GBS.[227] A positive correlation of serologic evidence of *C. jejuni* and the presence of antibody to G_{M1} has been described.[70,98] Lipopolysaccharide extracted from *C. jejuni* was found to have core oligosaccharide resembling human ganglioside G_{M1}. Pure motor neuropathy with a tendency for more distal weakness and sparing of the cranial nerves has been associated with *C. jejuni* infection in patients with anti-G_{M1} antibody.[4,209] *Campylobacter* carrying the cst-II sialy transferase gene is associated with the development of GBS and Fisher syndrome and gene polymorphisms may determine which syndrome develops after having a case of *C. jejuni* enteritis.[227] Cases of Miller-Fisher syndrome, a polyneuritis variant characterized by ophthalmoplegia, areflexia, and cerebellar ataxia, also have been reported in association with *C. jejuni* infection.[97,228] Patients with Miller-Fisher syndrome often have antibodies to ganglioside G_{Q1b}. Reactive arthritis may be associated with *Campylobacter* enteritis, especially in adults with human leukocyte antigen (HLA)-B27.[51,177]

Campylobacter reactive arthritis may occur in 1 to 5 percent of patients infected.[164] The arthritis starts a few days to several weeks after the episode of diarrhea. Involvement of joints can be monarticular or multiple, as well as migratory, and both large and small joints can be affected. Synovial fluid is sterile, and fever and leukocytosis are absent; the duration ranges from 1 week to several months. The course is self-limited, and the prognosis is good.[77]

Severe, persistent, and relapsing *C. jejuni* infections have been reported in patients with immune deficiencies, including congenital and acquired hypogammaglobulinemia and malnutrition.[2,89,132] In patients with AIDS, increased frequency and severity of *C. jejuni* infection have been reported; the severity correlates inversely with the CD4 count.[120,159,161]

DIAGNOSIS

The initial characteristics of *C. jejuni* enteritis are not sufficiently unique to permit the diagnosis to be established on clinical grounds. The differential diagnosis should include *Shigella*, *Salmonella*, invasive *E. coli*, *E. coli* O157:H7, *Yersinia enterocolitica*, *Aeromonas*, and *Vibrio parahaemolyticus* infections, and amebiasis. Consideration should be given to pseudomembranous colitis caused by *Clostridium difficile* if the patient has been receiving antibiotic therapy. Fecal leukocytes are found in as many as 75 percent of cases of *Campylobacter* enteritis; gross or occult fecal blood is present in 50 percent.[18,21,125] White blood cell counts usually are normal, although a shift to the left may occur. Mild elevations in alanine aminotransferase, alkaline phosphatase, and the sedimentation rate are observed in as many as 25 percent of patients.

Methods for demonstrating *C. jejuni* include direct microscopy,[150,152] bacteriologic culture, antigen detection by electroimmunoassay (EIA) or enzyme-linked immunosorbent assay (ELISA),[84,178,212] DNA probes,[207] polymerase chain reaction (PCR),[98,118,147,216] and serology.[5] Detection of antigen by EIA is nearly as sensitive and specific as is culture. ELISA using recombinant P18 and P39 as antigens has demonstrated 91.9 percent sensitivity and 99 percent specificity.[178] PCR enables some culture-negative *Campylobacter* infections to be diagnosed.[118,119] Serologic tests appear useful for epidemiologic investigations but are not recommended for routine diagnosis.

C. jejuni can be detected by darkfield and phase-contrast examination of fresh suspensions of stool. The distinguishing characteristic of *Campylobacter* is darting motility. Gram stain of stool showing *Vibrio* forms is said to be useful in making a presumptive diagnosis.[176] Using the direct carbol-fuchsin Gram-stain method, Wang and Murdoch[221] reported 89 percent sensitivity and 99.7 percent specificity when examining stool samples of *Campylobacter*-infected patients. The indirect fluorescent antibody test can be used for identification of *Campylobacter* on smears; however, standardized reagents for this procedure are not available from commercial sources.

Establishing a definitive diagnosis of *C. jejuni* infection requires the demonstration of *C. jejuni* in stool or in a tissue sample. Unfortunately, not all laboratories culture for *C. jejuni*, despite its frequency. Culture of *C. jejuni* from stool requires special methods and special media. It can be accomplished with media that contain antibiotics[52] to which *Campylobacter* organisms are resistant. If culturing is to be done on medium free of antibiotics, diluted stool samples should be passed through a cellulose acetate membrane filter to reduce the number of other enteric microorganisms.[68] Inoculated plates should be incubated in 5 percent oxygen and 10 percent carbon dioxide at 42° C. Colony formation may not be grossly visible until 72 hours after plating. Identification of colonies as *C. jejuni/coli* is based on a Gram stain showing characteristic morphology and positive catalase and oxidase reactions. Hydrolysis of hippurate establishes an isolate as meeting the conventional inclusion criteria for *C. jejuni*. Routine media usually are adequate for isolation of *Campylobacter* from normally sterile body fluids and tissues. PCR analysis performed on fixed, routinely processed colon biopsies is an excellent diagnostic method for detecting *C. jejuni* from focal active colitis cases. An advantage of the PCR on tissue is that it can be done retrospectively from the paraffin block.[180]

TREATMENT

Most *C. jejuni* organisms are susceptible to macrolides, aminoglycosides, chloramphenicol, imipenem, and clindamycin and are resistant to cephalosporins, tetracyclines, rifampin, penicillins, trimethoprim, and vancomycin.[188,215] However, the development of resistance to macrolides is starting to emerge, with case reports worldwide.[65] Patterns of antibiotic resistance in *C. jejuni* show regional differences. In the past, quinolones were used as empiric therapy for adult traveler's diarrhea because of their good microbiologic activity against *Campylobacter*, *Shigella*, and *Salmonella* strains.[4,50,175]

However, since the late 1980s, *Campylobacter* strains have become increasingly resistant to fluoroquinolones worldwide,

TABLE 142–4 Antibiotic Resistance Pattern of *Campylobacter jejuni* Isolates

Location	Study Years	No. Tested	Percentage of Isolates Resistant to			
			Erythromycin	Fluoroquinolones	Tetracycline	Gentamicin
Netherlands[177]	1994-1997	1315	2	11-29	7-15	ND
Minnesota[172]	1994-1998	4953	ND	1.3-10.2	ND	ND
Spain, Barcelona[149]	1995-1998	909	5	81	72	1
Canada[53]	1995-1997	158	0	12.7	56	ND
Spain[158]	1997-1998	537	3.2	75	ND	0.4
Taiwan[106]	1994-1996	93	10	52	95	1
Thailand[73]	1995	57	ND	84	ND	ND

ND, no data.

except in Australia (Table 142–4). The emergence of resistance has been associated with the use of quinolones such as sarafloxacin, difloxacin, and enrofloxacin in veterinary medicine in Europe and the United States.[52,53,95,191] The association of human infection with fluoroquinolone-resistant *Campylobacter* spp. and consumption of poultry prompted the U.S. Food and Drug Administration (FDA) to withdraw enrofloxacin for use in poultry, effective September 2005.[142] Despite this measure, it will take time for fluoroquinolone-sensitive *Campylobacter* spp. to be reestablished in the environment.

In general, patients with quinolone-resistant isolates have a longer duration of diarrhea than do patients with fluoroquinolone-sensitive isolates.[191] Fluoroquinolone resistance in *C. jejuni* appears to be related to mutations in the genes encoding subunits of DNA gyrase.[88] The frequency of erythromycin-resistant *Campylobacter* isolates is low[175] (see Table 142–4); therefore, it remains the drug of choice in adults, as in children. Most patients with *C. jejuni* enteritis have mild symptoms and do not require antibiotic therapy. For these patients, oral rehydration and replacement of electrolytes are sufficient. Patients who may benefit from antibiotic therapy are those with fever, bloody stool, and symptoms lasting longer than a week.[5] Patients with HIV infection or other immunodeficiency syndromes should be treated.

Data on antibiotic treatment are controversial. A recent meta-analysis on the effects of antibiotic treatment on duration of symptoms caused by *Campylobacter* spp. looked at 11 randomized control trials. It concluded that antibiotic therapy (with erythromycin, ciprofloxacin, or norfloxacin) shortened the duration of intestinal symptoms by less than 2 days, especially if these drugs were given early in the course of disease.[208] In addition, antibiotic therapy shortened the excretion of *Campylobacter* spp. from feces.[208] All immunocompromised and bacteremic patients with *C. jejuni* infections should be treated with an appropriate antibiotic such as gentamicin, imipenem, or both drugs.[5]

PREVENTION

Tactics for prevention of *Campylobacter*iosis include breast-feeding and avoidance of raw food and food that has been cooked under conditions that permit the survival of bacteria or that has been handled in such a way that bacterial contamination may occur. Risks of foodborne illnesses including campylobacteriosis transmitted by restaurant-prepared meals may be reduced by mandating that food-service employees obtain training in food safety (e.g., thorough handwashing with soap and water after handling raw poultry or meat, cooking poultry to 180° F or until meat is no longer pink and juices run clear, separating raw poultry from other foods during preparation).[7]

A 24-month (2002 to 2004), population-based surveillance case-control study by FoodNet in the United States evaluated infants with laboratory confirmed *Campylobacter* infection and identified risk factors associated with their infection. Identified risk factors include drinking well water, eating fruits and vegetables prepared at home, having a pet with diarrhea in the home, visiting or living on a farm, riding in a shopping cart next to meat or poultry, and traveling outside the United States.[61] Prevention measures should then be targeted at the potential source. An interesting finding is that attendance at a daycare center did not pose an increased risk in this study.

Selected microorganisms may displace *Campylobacter* from its ecologic niches. This finding may prove useful in reducing *Campylobacter* contamination of food animals.[35,122,135,139] Attempts to develop vaccines against *Campylobacter*iosis continue, but no product is in advanced development.

CHAPTER 143

Other *Campylobacter* Species

Robert J. Leggiadro

Although they are not isolated as frequently as are *Campylobacter jejuni* and *Campylobacter coli*, the "other" *Campylobacter* spp. are gaining recognition as human pathogens. *Campylobacter fetus*, a classic cause of perinatal infection, also is an infrequent cause of bacteremia in immunocompromised hosts. *Campylobacter upsaliensis*, *Campylobacter lari*, and *Campylobacter hyointestinalis* are associated primarily with diarrheal disease. Populations affected by these three species include normal as well as immunosuppressed hosts, especially persons infected with human immunodeficiency virus (HIV), with or without a history of animal exposure. The clinical spectrum of these organisms should expand as the special diagnostic tests needed to identify them become more widely available.

HISTORY

McFadyean and Stockman[59] first described the organisms now known as campylobacters in 1913. These *Vibrio*-like organisms were implicated as a cause of epizootic abortion in sheep, and a few years later, Smith[82] reported their association with bovine abortion as well and gave them the name *Vibrio fetus*. Although never confirmed microbiologically, these organisms are thought to have been *C. fetus* according to current nomenclature.[49] Vinzent and associates[94] first reported *Campylobacter* infection in humans in 1947. These investigators described a pregnant woman with *V. fetus* bacteremia who subsequently aborted at 6 months' gestation. In addition to pregnancy, gastrectomy, tooth extraction, heart disease, diabetes, and cirrhosis were predisposing conditions in King's 1957 review of 15 patients with *V. fetus* bacteremia.[51]

Many reports describing "new" *Campylobacter* spp. were published in the 1980s and early 1990s. *C. upsaliensis* was reported to be a pathogen in dogs and humans.[69,77] *C. lari*, a common isolate from healthy seagulls, was found to be a cause of gastrointestinal and extraintestinal disease in humans.[4,87] Originally identified in the intestines of swine with proliferative ileitis, *C. hyointestinalis* was reported first as a human pathogen in a homosexual man with proctitis.[26] The hydrogen-requiring campylobacters, *Campylobacter concisus*,[93] *Campylobacter rectus*,[72] and *Campylobacter curvus*, have been associated with periodontal disease. *Campylobacter sputorum* has been identified in abscesses,[64] as well as in bacteremia,[41,88] and *Campylobacter mucosalis* was reported in two children with diarrhea.[27]

Once called *Campylobacter*-like organisms, *Helicobacter cinaedi* and *Helicobacter fennelliae* now are classified in the *Helicobacter* genus.[66] These pathogens cause enteritis and proctocolitis in homosexual men and, on occasion, bacteremia.[68,90] Two former *Campylobacter* spp., *Arcobacter butzleri* and *Arcobacter cryaerophilus*, are associated with abortion and enteritis in cattle and pigs, in addition to bacteremia and diarrhea in humans.[50]

MICROBIOLOGY

Campylobacter is a Greek word meaning "curved rod." Members of this genus are gram-negative, curved, S-shaped or spiral, non–spore-forming rods that are 0.2 to 0.9 μm wide and 0.5 to 5 μm long.[64] Organisms are motile by means of a single polar flagellum, but some have a flagellum at each pole.[37] They are microaerophilic and have a respiratory type of metabolism.[64] Campylobacters are oxidase-positive and reduce nitrates but do not ferment or oxidize carbohydrates.[70] Although most grow at 37° C, *C. jejuni*, the *Campylobacter* sp. most commonly identified in humans, grows optimally at 42° C.[2]

Most *Campylobacter* spp. require a microaerobic atmosphere containing approximately 5 percent oxygen, 10 percent carbon dioxide, and 85 percent nitrogen for optimal recovery.[64] Some species such as *C. sputorum*, *C. concisus*, *C. mucosalis*, *C. curvus*, *C. rectus*, and *C. hyointestinalis* may require hydrogen for primary isolation and growth. Many different selective media for isolation of *Campylobacter* spp. have been developed, but because of species differences in antibiotic resistance patterns, no single formulation isolates all species of clinical importance.[37] For example, *C. jejuni* and *C. coli* are resistant to cephalothin, whereas *C. fetus* is susceptible. A filtration method with nonselective media may be used to complement direct culture on selective media for the detection of antibiotic-susceptible *Campylobacter* spp. Because of their small

size and motility, campylobacters may pass through filters with pores of 0.45 to 0.65 μm, whereas other enteric flora are retained.[2,64]

Although colonies may appear on plates within 24 to 48 hours, growth of campylobacters from stool may take as long as 72 to 96 hours. Primary isolation from blood may require 2 weeks.[2] Gram stain of young cultures reveals vibrioid forms, and longer incubation may yield spherical or coccoid bodies. *Campylobacter* spp. usually can be distinguished from one another on the basis of biochemical tests and growth characteristics (Table 143–1). Although the significant pathogens *C. jejuni*, *C. coli*, and *C. lari* cannot be discriminated reliably by the use of 16s rDNA data, these sequences provide a substantially improved basis for the identification and differentiation of *Campylobacter* spp.[36] Many investigators have applied molecular techniques to identify enteric campylobacters directly from stool.[9]

EPIDEMIOLOGY

Much needs to be learned about the epidemiology of *Campylobacter* spp. other than *C. jejuni* and *C. coli*, a group of organisms that made up only about 1 percent of *Campylobacter* spp. reported to the Centers for Disease Control and Prevention (CDC) from 1982 to 1986.[12] However, this study found that age-specific isolation rates of *C. fetus* parallel those of *C. jejuni* and *C. coli*; rates peak in infancy and increase in young adulthood, and *C. fetus* increases substantially in elderly persons. Seasonal distribution patterns of *C. jejuni*, *C. coli*, and *C. fetus* also were similar, with peaks occurring in warm months. In this surveillance study, *C. jejuni* and *C. coli* isolates were predominantly from stool, whereas 54 percent of *C. fetus* isolates with a known source were from blood.[12] The epidemiology and antimicrobial susceptibilities of 111 *C. fetus* strains isolated from 103 patients from 1983 to 2000 in Quebec, Canada, were determined.[91] The isolation site was blood in 69 percent of the patients, stools in 20 percent, and other body fluids, including aorta, bile, synovial fluid, cerebrospinal fluid, tubo-ovarian abscess, ascites, and pleural fluid, in 11 percent of these patients.[91]

C. fetus, an important cause of sporadic abortion in cattle and sheep, may be isolated from the intestines and genital tracts of these animals.[70] Contaminated food and water are the suspected sources of infection for sheep, cattle, and other animals, including goats, pigs, cats, dogs, hamsters, guinea pigs, antelopes, chickens, and turkeys.[30] A *C. fetus* strain with markers of reptile origin was isolated from the blood of a febrile patient with precursor T-cell acute lymphoblastic leukemia.[92] Although the source of *C. fetus* infection in humans generally is not apparent,[38] a 1970 review of *Vibrio fetus* infection in humans found that one third of patients had recent contact with animals or animal products and one third denied such contact; no information was available on the remaining third.[8]

C. fetus bacteremia generally occurs in immunosuppressed hosts (especially elderly men), pregnant women, and neonates.[73,89] Predisposing conditions include alcoholism or cirrhosis, diabetes mellitus, heart disease, malignancy, splenectomy, and corticosteroid or other immunosuppressive therapy.[21,45,73] *C. fetus* is not considered a major cause of gastroenteritis, perhaps because of the failure of this organism to grow in stool specimens evaluated by routine laboratory methods for *C. jejuni* and *C. coli*.[12,70]

The epidemiology of human *C. fetus* infection as a foodborne, perinatal infection was reflected in the original report by Vinzent and colleagues[94] that described a 39-year-old pregnant woman who had a history of drinking raw milk from a cow that recently had aborted a pregnancy; this woman contracted a flulike syndrome in the sixth month of pregnancy. Two blood cultures grew *C. fetus*, and after 5 weeks of illness, a stillborn infant was delivered. In addition to raw milk,[96] raw beef liver[84] and "nutritional therapy" (raw fruit, vegetable juice, and calves' liver, along with coffee enemas) have been associated with *C. fetus* infection.[13] The last report described nine patients with malignant disease and one with systemic lupus erythematosus in whom *C. fetus* sepsis was associated with such therapy. Nine patients received their "nutritional therapy" in Mexico, and one died.[13]

First associated with human disease in a homosexual man with proctitis, *C. hyointestinalis* (*hyos*, "hog"; *intestinalis*, "pertaining to the intestines") originally was isolated from the intestines of swine with proliferative ileitis.[26,70] *C. hyointestinalis* also has been isolated from the stool of persons with nonbloody, watery diarrhea.[23] Two of these patients were homosexual men, the third was an elderly woman who had been traveling in Egypt, and the fourth was an infant from a large farm family that drank raw milk. These organisms are closer to *C. fetus* by DNA hybridization than are any other catalase-positive *Campylobacter* spp. and are resistant to nalidixic acid but susceptible to cephalothin.[76]

C. lari, frequently isolated from apparently healthy seagulls, is nalidixic acid resistant and thermophilic.[81] The name is derived from *laridis*, "of a sea bird," although seagulls do not play a direct role in its epidemiology.[87] Epidemiologically and microbiologically similar to *C. jejuni*, *C. lari* has been reported to cause enteritis in patients with and without a history of animal exposure and bacteremia in two elderly patients with multiple myeloma and permanent pacemakers.[62,65,79,87] A waterborne outbreak of *C. lari*–associated gastroenteritis also has been reported.[10]

Catalase-negative or weak *Campylobacter* spp. that are hippurate-negative and thermotolerant were isolated first from dogs in 1983.[77] This *C. upsaliensis* group is associated with gastroenteritis, breast abscess, spontaneous abortion, and bacteremia in normal

TABLE 143–2 Clinical Features Associated with Infection by "Atypical" *Campylobacter* and Related Species Implicated as Causes of Human Illness

Species	Common Clinical Features	Less Common Clinical Features	Additional Information
C. fetus	Bacteremia, sepsis, meningitis, vascular infections	Diarrhea, relapsing fevers	Not usually isolated from media containing cephalothin
C. upsaliensis	Watery diarrhea, low-grade fever, abdominal pain	Bacteremia, abscesses, abortion, hemolytic-uremic syndrome	Difficult to isolate because of cephalothin susceptibility
C. lari	Abdominal pain, diarrhea	Colitis, appendicitis, bacteremia	Seagulls frequently colonized; organism often transmitted to humans by contaminated water
C. hyointestinalis	Watery or bloody diarrhea, vomiting, abdominal pain	Bacteremia	Causes proliferative enteritis in swine
C. sputorum	Pulmonary, perianal, groin, knee, and axillary abscesses	Bacteremia	Three clinically relevant biovars: *C. sputorum* subspecies *sputorum*, *C. sputorum* subspecies *bubulus*, and *C. mucosalis*
H_2-requiring *Campylobacter**	Periodontitis	Diarrhea, osteomyelitis, bacteremia	Uncertain role as human pathogen

**Includes C. rectus, C. curvus, and C. concisus.*

hosts, as well as opportunistic infections in immunocompromised persons.[39,42,69] Conditions predisposing to *C. upsaliensis* bacteremia include gallbladder surgery, ectopic pregnancy, kwashiorkor, and acquired immunodeficiency syndrome (AIDS).[69] Young puppies and kittens are potential transmitters of *C. upsaliensis*,[40] and an outbreak in a childcare center suggesting direct transmission between humans also has been described.[33,48] In a sample of *Campylobacter* recovered from patients with campylobacteriosis in Los Angeles County, California, in 1998, the second most frequently isolated species was *C. upsaliensis* (6 [4%] of 155 isolates).[55] Of the six patients with *C. upsaliensis* isolates, five had pets, including three dogs, a cat, and a turtle, at home.[55] Routine selective media for *Campylobacter* spp. may fail to detect this organism, which is slow growing and susceptible to cephalothin.[34,56,95] Filtration methods may improve the yield from stool cultures.[9,34,35,47,48,58,83]

PATHOGENESIS AND IMMUNITY

Information on the pathogenic and immune mechanisms involved in *Campylobacter* infections other than those caused by *C. jejuni* and *C. coli* is scarce. Much of what is known has been learned from animal, clinical, and epidemiologic data. The association of *Campylobacter* bacteremia with hypogammaglobulinemia, HIV infection, kwashiorkor, pregnancy, and malignancy indicates the importance of both humoral and cell-mediated immunity in host defense against this genus.[2,17,56,65,80,98] The predilection of *C. fetus* for endovascular surfaces in adults and the central nervous system in neonates also is well documented.[22,78]

In pregnant animals, *C. fetus* bacteremia occurs after ingestion of the organism, with subsequent development of infection of the placenta and fetus.[60,67] Examination of infected animal placentas has revealed necrosis, infarction, and microabscesses, along with disruption of the placental circulation.[18] Placental changes similar to these have been described in humans after preterm maternal bacteremia, consistent with infection as a result of hematogenous rather than ascending spread.[80] Ascending infection with premature rupture of membranes and amnionitis in the absence of maternal bacteremia has resulted in stillbirth or early-onset disease.[28,44] Contamination of the baby at the time of vaginal delivery is important in the pathogenesis of neonatal sepsis and meningitis with *C. fetus* in live-born infants.[57,97]

Bacteremia may occur more commonly with *C. fetus* than with *C. jejuni* because the former is resistant to the bactericidal effects of human serum, whereas the latter is susceptible.[6] A surface-layer protein that covers *C. fetus* functions as a capsule and appears to be an important virulence property of the organism.[5] It inhibits C3b binding, and this action explains both the serum resistance and the phagocytic resistance of *C. fetus*.[7]

CLINICAL MANIFESTATIONS

The clinical spectrum of non-*jejuni* or non-*coli Campylobacter* infections varies with the age of the patient and the individual species (Table 143–2). *C. fetus* is responsible for most reported

disease patterns, including prenatal, neonatal, bacteremic, and focal infections, caused by this "other *Campylobacter*" group of organisms.[89] Pregnancies complicated by maternal infection with *C. fetus* may result in abortion, stillbirth, and prematurity.[22,71,80] Live-born infants may suffer from sepsis and meningitis with a high case-fatality rate.

Mothers may have fever and chills with bacteremia alone or with diarrhea. Maternal blood, placenta, cervix, vaginal, and stool cultures have yielded *C. fetus* in reported perinatal cases.[22,57,80,97] Maternal outcome is excellent.

Torphy and Bond[89] reviewed eight infants 12 hours to 22 days old with reported *C. fetus* disease. The initial symptoms, including fever, cough, respiratory distress, vomiting, diarrhea, cyanosis, convulsions, and jaundice, were consistent with neonatal sepsis. Meningitis developed in all eight infants, and six died. Four were premature, and three of them had an onset of illness at 2 days of age or younger and died during the first week of life. However, a subsequent review reported three additional neonatal patients who survived *C. fetus* meningitis after contracting the disease at 1 to 3 days of age.[97] Hemorrhagic infarction and necrosis, as well as cystic degeneration of the cerebral cortex, are the cerebral lesions most commonly reported in *Campylobacter* meningitis.[97]

Descriptions of *C. fetus* infection in children outside the neonatal age group are rare.[52,96,98] One was a 2½-year-old child with *V. fetus* bacteremia who had low-grade fever for 3 weeks and a cervical mass on the day of admission and was treated successfully with penicillin.[96] Her past history included drinking raw cow's milk and untested well water. A 16-month-old girl from India whose father operated a dairy business was admitted for evaluation of fever lasting 10 days and seizures for 5 days before admission.[52] Her provisional diagnosis was encephalitis, and a blood culture grew *V. fetus*. No antibiotics were administered, and the patient recovered uneventfully. The authors of the report emphasized the undulant nature of *C. fetus* infection, similar to that of brucellosis. *C. fetus* bacteremia also was detected in a nearly 5-year-old boy with agammaglobulinemia who had a 3-week history of anorexia, lethargy, fever, and, more recently, hepatitis.[98] Blood culture grew *C. fetus*, and liver biopsy demonstrated hepatitis with multiple areas of severe focal necrosis, bridging necrosis, and Kupffer cell hyperplasia. He responded rapidly to ampicillin therapy.

Most reported patients with *C. fetus* infection are men older than 45 years of age who have bacteremia with or without focal infection.[21,73,89] Most of them have underlying conditions such as diabetes, malignant disease, and hepatorenal or cardiovascular disease.[38,45] Typically, illness begins with fever, malaise, and headache. Chills and night sweats are prominent, as is weight loss in prolonged illness. Diarrhea, nausea, vomiting, and abdominal pain occur in as many as 38 percent of cases, and hepatosplenomegaly or jaundice develops in two thirds.[38,98] Pulmonary involvement is a rare finding.[8,38]

Three patterns of invasive *C. fetus* disease have been described.[74] Clinical manifestations of the first localized infection accompanied by septicemia include meningitis,[11,57] endocarditis,[25] pericarditis,[63] thrombophlebitis,[14] mycotic aneurysm,[74] cellulitis,[29,45] gluteal abscess,[20] septic arthritis,[54] salpingitis,[11] and peritonitis.[86] The second form is transient asymptomatic bacteremia, which may be self-limited.[38,73,75] Prolonged and recurrent bacteremia, with waxing and waning symptoms as spontaneous relapses and remissions occur, is the third pattern of invasive *C. fetus* infection.[8,19,46,75,98]

The vascular tropism of *C. fetus*, especially in the presence of preexisting vessel damage, is well recognized.[14,63,98] Possible explanations for this predilection include a surface receptor on the organism with an affinity for vascular endothelium that results in endothelial damage and subsequent thrombus formation. In addition, the organism's microaerophilic growth requirements may be favored by venous oxygen tensions.[63] Previous valvular heart disease is a common finding in endocarditis.[25] *Campylobacter* infection of prosthetic devices is rare, with only four cases of *C. fetus* and one infection each of *C. lari* and *C. upsaliensis* described in the literature.[16]

A report from the CDC reviewed clinical and epidemiologic information on 12 patients with *C. upsaliensis* isolates from 1980 to 1986.[69] Eight isolates were from blood, and three were from stool. Ages of the 12 patients ranged from 6 months to 83 years. Two infants with *C. upsaliensis* bacteremia that responded to amoxicillin therapy were included. One was a 10-month-old child who had fever, leukocytosis, and a history of culture-negative diarrhea, bronchiolitis, and *Klebsiella* bacteremia 3 months previously. The second was a 6½-month-old infant with fever, respiratory distress, and erythematous tympanic membranes. A 14-month-old child who lived on a farm with a private well and several household dogs and cats had a history of pica, including dirt from ground where chickens roamed. Stool culture obtained for evaluation of febrile, watery diarrhea yielded *C. upsaliensis*, and he recovered after receiving erythromycin therapy.[69]

Underlying medical problems in adults with *C. upsaliensis* bacteremia included peptic ulcer disease and partial large-bowel resection for a benign tumor, perforated gallbladder with peritonitis, AIDS, corticosteroid therapy, ruptured ectopic pregnancy, and cirrhosis with pancreatic insufficiency and partial gastrectomy.[69] One adult with a *C. upsaliensis* stool isolate was a 35-year-old woman with relapsing acute myelogenous leukemia. She was ill with fever and blood-tinged, watery diarrhea while thrombocytopenic and neutropenic. A healthy, 20-year-old student with a history of drinking raw milk and swimming in fresh-water lakes and rivers was the second adult reported with a *C. upsaliensis* stool isolate. He had fever, severe cramping abdominal pain, and nonbloody, watery diarrhea of 3 weeks' duration that responded to oral erythromycin.[69]

Kwashiorkor and gastroenteritis were the predominant clinical features in a retrospective series of 16 pediatric patients with *C. upsaliensis* bacteremia from South Africa.[56] The age range was 2 to 36 months, with a mean age of 15.5 months. The authors suggested that *C. upsaliensis* bacteremia was secondary to intestinal infection with the same organism, but no confirmatory stool culture data were available.[56] A gastrointestinal source also was postulated for the *C. upsaliensis* isolated from a breast abscess in a previously healthy, 46-year-old woman.[31] Hemolytic-uremic syndrome was reported in a 14-year-old girl with *C. upsaliensis* gastroenteritis.[15]

C. upsaliensis was the only organism isolated from 83 patients in a large stool culture survey using a filtration system for *Campylobacter* in Belgium.[35] Ninety-two percent of patients had diarrhea, which was of acute onset in most cases. Vomiting (14%) and fever (7%) were uncommon occurrences, and symptoms generally abated in less than a week. Gross or occult blood was identified in 25 percent of cases, and neutrophils were seen on fecal smear in approximately 20 percent. Erythromycin (11 patients) or amoxicillin (2 patients) eradicated the organism, with resolution of symptoms in all 13 patients treated with antibiotics.[35] Australian workers identified *C. upsaliensis* in 19 (0.1%) of 18,516 stool specimens from August 1992 to March 1999 at the Royal Children's Hospital in Melbourne.[48] Infection with *C. upsaliensis* was associated with milder disease than was infection with *C. jejuni*; patients with *C. upsaliensis* infection had significantly less fever, diarrhea, and rectal bleeding.

Six clinical *C. lari* isolates were referred to the national *Campylobacter* reference laboratory at the CDC in 1982 and 1983.[87] Clinical illness associated with these isolates included enteritis in four patients, severe crampy abdominal pain in a 7-year-old girl, and terminal bacteremia in a 71-year-old man with multiple myeloma and chronic renal failure. The ages of the four patients

with enteritis were 8 months, 3 years, 22 years, and 39 years. Diarrhea was watery or mucoid, and fever was an unusual occurrence. Potential exposure included consuming chicken, having contact with house pets, drinking untreated surface water, and eating raw oysters. *C. lari* colitis also developed in an HIV-infected woman.[24]

C. hyointestinalis has been isolated from the stool specimens of adult and pediatric patients experiencing nonbloody, watery diarrhea[23] and from a rectal culture of a homosexual man with proctitis.[26] Over a 4-year period, 20 strains of *C. curvus* were isolated from two separate and distinct clinical settings: a hospital survey of infectious causes of bloody diarrhea and an outbreak of Brainerd (chronic) diarrhea in northern California.[1] *C. curvus* also was reported to cause polymicrobial liver and lung abscesses in two patients with cancer, respectively. *C. rectus* was reported in a polymicrobial breast abscess in a patient with lymphoma.[1] The clinical features of other *Campylobacter* spp. are presented in Table 143–2.

DIAGNOSIS

Confirmation of infection with *C. fetus* and *Campylobacter* spp. other than *C. jejuni* and *C. coli* is based on positive culture results from clinical specimens.[2] *C. fetus* has been isolated from blood, cerebrospinal fluid, joint effusions, bile, urine, and pleural and pericardial fluid in standard culture media.[38] Blood cultures generally are positive within 4 to 14 days. Isolation of *C. fetus* and "other" *Campylobacter* spp. from stool requires incubation at 37° C and media without cephalosporins. Filtration techniques also may be warranted to detect these strains in stool cultures.

TREATMENT

Gentamicin, erythromycin, and imipenem are bactericidal for *C. fetus*, as is ampicillin to a lesser extent.[25,32,43,61,91] Cefotaxime, ticarcillin, amikacin, chloramphenicol, clindamycin, tetracycline, and ciprofloxacin have variable activity against different *C. fetus* strains.[25,91] Reported synergistic antimicrobial combinations in vitro include ampicillin and gentamicin or cefazolin and imipenem with gentamicin.[25,85]

Erythromycin continues to be the drug of choice for most patients with *Campylobacter* diarrhea.[2] The newer macrolide azithromycin, which has a broader spectrum of activity than does erythromycin, is effective therapy for *Campylobacter* enteritis, as well as for diarrhea caused by *Salmonella*, *Shigella*, *Vibrio cholerae*, and *Escherichia coli*, thus rendering it a useful drug in the treatment of traveler's diarrhea.[53] Increasing *Campylobacter* resistance to quinolones related to expanded use in humans and in animals used for food, especially chickens, diminished the usefulness of quinolones such as ciprofloxacin in the treatment of *Campylobacter* gastroenteritis in adults.[2,24,53]

Gentamicin, imipenem, ampicillin, and cefotaxime are therapeutic options in treating *Campylobacter* bacteremia and other extraintestinal infections.[2,3,25,43,91,97] Synergistic combination therapy is indicated for patients with meningitis and endocarditis, in which bactericidal activity is critical.[2,61] Patients with *Campylobacter* in their stool who are being treated for an extraintestinal *Campylobacter* infection with gentamicin should be prescribed supplemental oral therapy because gentamicin is ineffective against *Campylobacter* in the gut.[2]

Prolonged antimicrobial therapy and follow-up blood cultures are warranted for patients with *C. fetus* bacteremia because of the relapsing nature of the illness.[63,75] Chloramphenicol should be used with caution in treating *C. fetus* meningitis because clinical outcome and in vitro susceptibility results for this drug have been disappointing.[57,61]

CHAPTER 144

TULAREMIA

Ralph D. Feigin ❂ Pratip K. Nag

Tularemia is an acute febrile illness caused by *Francisella tularensis*. Although it is primarily a disease of animals, humans also are highly susceptible hosts.

HISTORY

McCoy[103] published the first documented evidence of tularemia in 1911 when he described a plague-like disease in ground squirrels (*Citellus beecheyi*) that occurred in Tulare County, California. Within 2 years, McCoy and Chapin[104] isolated and characterized the organism *Bacterium tularense* from naturally infected ground squirrels. They also detailed the pathologic process produced in ground squirrels, defined the susceptibility of other animal species to *B. tularense*, and identified fleas as vectors for the plague-like disease in 1912.

The first description of tularemia in humans may be that by Homma Soken, a court physician in eastern Japan.[130] In 1837, he described an illness as "hare meat poisoning." Nearly a century later, Vail[162] and Wherry and Lamb[171] independently reported the first etiologically proven case of tularemia in humans in 1914. Thereafter, knowledge of the organism, susceptible hosts, modes of transmission, and clinical manifestations of disease was acquired rapidly, and retrospective information was assessed in light of this new information. Much of the current understanding of the disease in humans originated from the work of Edward Francis,[50,51] a U. S. Public Health Service surgeon. Intrigued by the new diseases, which were called "deer fly fever" by Pearse[119] in 1911 and "plaguelike disease" by McCoy, Francis relocated to Utah in 1919 and established his laboratory in an unused coal shed.[51,52,53] Soon thereafter, he recognized the singular cause of these two diseases and renamed them "tularemia" because of isolation of *B. tularense* from blood.[130] He isolated the organism from humans and jackrabbits[50] and demonstrated transmission of the organism by the deer fly.[52]

For a more complete historical review, the reader is referred to the classic paper by Dr. Edward Francis,[51] "A Summary of the Present Knowledge of Tularemia." Almost 8 decades later, this article is accurate and contains most of the knowledge essential for understanding tularemia.

ETIOLOGY

The causative agent of tularemia, after having been placed in the genera *Bacterium*, *Bacillus*, *Brucella*, and *Pasteurella*, is now named *Francisella tularensis* in honor of Dr. Edward Francis. *F. tularensis* is a small (0.2 to 1.0 μm × 1 to 3 μm), nonmotile, non–spore-forming, highly pleomorphic gram-negative coccobacillus. It is a strict aerobe that infects as a facultative intracellular bacterium.[74]

Hesselbrock and Foshay[69] described the morphology as resembling that of the pleuropneumonia group of organisms; the usual coccoid form is a spheroidal cystic structure with a delicate, transparent cell wall. The morphology and mode of reproduction (chiefly budding) suggested relationships with fungi and the pleuropneumonia group and none with the genera *Pasteurella* and *Brucella*. Subsequent electron-microscopic studies confirmed the presence of a delicate, almost transparent cell wall, which Eigelsbach and associates[32] suggested could explain the instability of lyophilized cultures.

The outstanding growth characteristic of these fastidious organisms is their requirement for cysteine or sulfhydryl compounds in amounts exceeding those usually present in nutrient media.[42] Although *F. tularensis* grows best on cysteine-glucose-blood agar and on coagulated egg yolk medium and less well in thioglycolate broth, it can be isolated in routine cultures and on enriched chocolate agar.[91,106] Hornick[72] suggested that the addition of cycloheximide and penicillin facilitates isolation of the organism from the respiratory tract or skin ulcers. In one study by Johansson and colleagues,[80] an Amies agar medium with charcoal and a Thayer-Martin medium with antibiotics were equal in preserving bacterial viability for 1 week when compared with saline or Stuart medium.

F. tularensis is killed readily by heat. Exposure to a temperature of 56° C for 10 minutes is sufficient for killing. The organisms are not destroyed by freezing and may remain viable in frozen animal carcasses for as long as 3 years. However, adequate cooking renders the meat of game birds and animals harmless. Treatment with tricresol solution (1%) for 2 minutes also kills organisms in tissue; organisms from cultures are killed in 24 hours by 0.1 percent formalin.

All strains of *F. tularensis* seem serologically identical, but individual strains may possess varying degrees of virulence. Ormsbee and associates[115] reported that the immunizing antigens seem to be concentrated in the cell wall. The purest cell wall preparations contain at least four and possibly six different antigens, but the soluble fractions did not seem to provide protection against any of these antigens when mice were immunized with these preparations.

Despite serologic homogeneity, four distinct subspecies of tularemia have been identified thus far. *F. tularensis* subspecies *tularensis* (Jellison type A) accounts for approximately 90 percent of organisms isolated in North America and has been seen in Europe as well.[65] The less virulent strain *F. tularensis* subspecies *holarctica* (Jellison type B) is found primarily in Europe and Asia. These two strains have been found to coexist in the same ecosystem.[101] *F. tularensis* subspecies *mediasiatica* has been isolated primarily in central Asian republics of the former Soviet Union,[114] whereas the subspecies *novicida*, which is isolated rarely, appears primarily to be restricted to North America. However, in 2003, *F. tularensis* subspecies *novicida* was isolated in Australia.[172] Chromosomal DNA analysis of *F. tularensis* show greater than 95 percent genetic identity among the four subspecies[11,56,83,158] Broekhuijsen and associates[11] showed that microarray analysis of chromosomal DNA supports the typical taxonomic clustering of *F. tularensis* into four separate subspecies. Worldwide analysis of chromosomal DNA reveals a highly diverse *F. tularensis* subspecies *tularensis* with a genetic affinity to the moderately virulent *F. tularensis* subspecies *mediasiatica*. Johansson and associates[82] identified two genetically distinct clades within the subspecies *tularensis*: A.I., which is genetically more diverse, and A.II.[44] In contrast, *F. tularensis* subspecies *holartica* strains have less genetic diversity within the subspecies. Increasing evidence indicates that *F. tularensis* subspecies *holartica* strains found in Japan may represent a fifth subspecies based on their genetic diversity and unique biochemical differences from strains found in Europe and Asia.[11,83,114,132,158]

The complete genome sequences of *F. tularensis* subspecies *tularensis* strain SCHU S4 and subspecies *holartica* strain OSU 18 reveal a circular chromosome of approximately 1.89 Mb with a G+C content of 32 percent and approximately 1800 to 1900 predicted coding sequences.[92,123] Of the 1804 predicted coding sequences in the SCHU S4 genome, 302 are unique to *Francisella* and 5 are unique to the SCHU S4 and are of unknown function. Much work needs to be done in identifying genes that endow the species their pathogenicity. One unique region that codes for 25 genes that have no known bacterial homologs is a 33.9-kb duplicated region known as the *Francisella* pathogenicity island (FPI).[92,123] Deletions of genes in this region have generated mutants that have difficulty with survival in macrophages.[61,63,90,107] The fastidious growth requirements of *Francisella* can be accounted for by the large number of inactivated genes. This situation results in the disruption of more than half of the predicted metabolic pathways in the SCHU S4 genome, which accounts for the requirement of 14 essential compounds for *Francisella* growth and survival. *Francisella* lacks receptors for classic iron-binding proteins but produces a ferric uptake protein, Fur. Iron is an essential nutrient in *Francisella* because genes regulated by Fur have been identified in the SCHU S4 genome.[92]

F. tularensis does not produce any exotoxin, but pharmacologic tests indicate that the organism contains a lipopolysaccharide (LPS) similar to that of gram-negative bacilli.[24] Unlike LPS of other gram-negative enteric organisms, the LPS of *F. tularensis* is 1000-fold less potent and does not activate macrophages or endothelial cells to release proinflammatory cytokines through toll-like receptors.[3,133,154] Characterization of the structure and function of LPS in different species of *F. tularensis* is in progress.[124,167] The O-antigens of the major subspecies *F. tularensis* that are pathogenic to humans are identical in their carbohydrate content and structure, a finding implying that the differences in virulence among subspecies probably is not the result of the O-antigen.[128,157,166,168]

F. tularensis also possesses a capsule composed of carbohydrates, mannose, rhamnose, and two dideoxy sugars yet to be described, along with proteins and alpha-hydroxylated 14:0 and 16:0 lipids.[70] The capsule provides protection from serum complement mediated lysis and may be differentially regulated intracelluluarly.[60,131,142]

The presence of type IV pili has been demonstrated using electron microscopy in the *F. tularensis* live vaccine strain (LVS). The expression of a type IV pili is independent of the presence of a capsule.[58] Genes for type IV pili are present in the genome of the pathogenic *F. tularensis* subspecies *tularensis* SCHU 4 strain are related closely to those found in *Neisseria* and *Pseudomonas aeruginosa* species.[92] Although the functions of type IV pili in other bacteria involve attachment to host cells, twitching motility, biofilm formation, and DNA uptake, many of these functions remain to be identified in *F. tularensis*. Forslund and associates reported that the absence of the pilin results in the decreased ability of the bacteria to spread effectively when introduced by peripheral routes.[48]

EPIDEMIOLOGY

Tularemia is ubiquitous in the Northern Hemisphere between 30 and 71 degrees of north latitude.[71] The disease has been reported throughout the United States, in East Asia, and in Europe.[54,110-112,149] *F. tularensis* has been found in Canada and Mexico but has not been reported in South America or Africa. Within the United States, the disease most commonly occurs in the south central region. From 1990 to 2000, three states (Arkansas, Missouri, and Oklahoma) accounted for approximately half of all reported cases.[16]

In the United States, the incidence of tularemia has been recorded since 1927. From 1990 to 2004, the incidence of tularemia was 0 to 0.06 per 100,000 persons.[16,17] The number of human cases declined steadily from 1939 (2291 cases[77]) until 1975 (129 cases). Since then, the number of reported cases of tularemia has increased, with a range between 90 and 310 cases annually.[17] This range probably is a gross underestimate of the actual incidence. In 1968, in a serologic survey of 1936 subjects in California, approximately 1 percent of this population had antibody against *F. tularensis*.[40] Using skin test antigens, Casper and Phillip[15] showed that 6.6 percent of 365 persons in eastern Montana had evidence of previous infection with *F. tularensis*. Of the persons in whom skin test results were positive, 80 percent had no previous history of the disease, a finding thus indicating a high number of subclinical or self-limited infections. The mortality rate for tularemia is zero to four cases per year.[17]

Persons especially at risk are hunters, trappers, meat processors, muskrat farmers,[174] cooks, lawn mowers and brush cutters,[45] sheep herders and shearers,[78] and laboratory workers.[138,163] The incidence of tularemia among American Indians/Native Alaskans (0.5 per 100,000) is significantly higher when compared with whites (0.04) and African Americans (<0.01). In all age groups, boys and men have a higher incidence of tularemia than do girls and women.[16] During 1990 to 2000, the average annual incidence of tularemia ranged from 0.06 to 0.1 per 100,000 in boys (0.03 to 0.06 in girls) 0 to 14 years of age, and the highest incidence occurred in boys aged 5 to 9 years (0.1 to 0.06 for girls). In comparison, adults more than 75 years of age have an incidence of tularemia higher than that of children.[16] Children acquire tularemia by the same routes as adults: vector bites, animal bites, and ingestion of infected, inadequately cooked meat.

Tularemia occurs year-round. However, peaks occur in the summer and winter months, depending on the region. May through August accounted for 70 percent of all cases of tularemia onset during 1990 to 2000.[16] Tularemia occurs more commonly in the central and southern states during the summer months, when ticks are more prevalent. The incidence in the northern and eastern states peaks in the winter months during the hunting season.

The most common sources of human infection are contact with infected animals or their carcasses and bites by ticks or tabanid flies (deer flies). Less commonly, people acquire the disease from the bite of a diseased animal or one in which the mouth has been contaminated by the ingestion of a diseased animal. Numerous outbreaks of human tularemia have occurred by water transmission,[8,53,79,86] in water contaminated by voles, beavers, lemmings, and muskrats. Infection also may occur by aerosolization of the organisms, especially in laboratory workers,[87,163] lawn mowers and brush cutters,[45] and occasionally farm workers (inhalation of dust and threshing material contaminated by voles and other rodents).[28,71] Person-to-person transmission has not been documented.

Hopla,[71] in describing the ecology of tularemia, states that "rarely does one encounter a zoonotic disease of such complexity." Indeed, to understand the development of epizootics and transmission to humans, one must consider the role of numerous vertebrates (humans and other animals, both wild and domestic) and many invertebrates.

Approximately 100 species of wild mammals, 9 species of domestic animals, 25 species of birds, and several species of fish and amphibians have been found to be infected naturally,[113] but probably fewer than a dozen species of mammals are important in the transmission of *F. tularensis*.[71] Lagomorphs (rabbits and hares) and some rodents (muskrats, voles) are highly susceptible to *F. tularensis*; sheep and domestic rabbits are susceptible but have low sensitivity to the organism; and cats, cattle, dogs, and horses are virtually insusceptible to infection. Vertebrate animals are called reservoirs, but they rarely are true reservoirs because

most of them become sick and either die or recover, with elimination of the organism. The varying hare (snowshoe rabbit) is less susceptible to *F. tularensis* and may serve as a reservoir because of its high natural resistance and carrier state.[49] Protozoa, which serve as reservoirs for many other intracellular pathogens, may do the same for *F. tularensis*.[1]

Many invertebrates can be infected experimentally by *F. tularensis*, but relatively few are infected naturally. In 1924, Parker and Spencer[117] first described ticks as vectors for *F. tularensis* infection in guinea pigs. However, the role of ticks in the spread of the human disease was not recognized until 1949, when Washburn and Tuohy[170] reported that 56 percent (391 of 704) of tularemia cases in Arkansas were associated with exposure to ticks. To date, ticks remain the most common vectors for *F. tularensis* in the United States and can serve as reservoirs because the organism can be transmitted from generation to generation by transovarian passage.[71]

At least 13 species of ticks have been found to be infected naturally by *F. tularensis*.[71] The species involved in transmission to humans are *Dermacentor andersoni* (wood tick), *Dermacentor variabilis* (dog tick), and *Amblyomma americanum* (Lone Star tick). A fourth tick, *Haemaphysalis leporispalustris* (rabbit tick), is important in the epidemiology of tularemia. Although this tick does not transmit tularemia directly to humans, it perpetuates the cycle of infection by acting as the sylvatic vector between rabbits.[68]

When the tick feeds on an infected animal, the organisms penetrate the gut into the hemolymph and are disseminated throughout the body, including the salivary glands. The tick then transmits the organisms by injecting them, along with saliva, when it feeds on another animal. In addition, transmission by tick fecal contamination also is likely. Ticks, biting flies (i.e., deer flies), and fleas probably are responsible for the continuing endemic disease in susceptible animals and for epizootic disease. Infrequently, mosquitoes and mites may transport *F. tularensis* mechanically from animal to animal or from animal to human.[71] Humans act as terminal hosts of *F. tularensis* because they do not transmit it to other humans or to other mammals.

A few cases of tularemia acquired by cat bite have been reported.[5,14,170] Because cats rarely are infected by *F. tularensis*, such transmission probably is the result of mechanical transmission from the contaminated teeth or claws of a cat that has come into contact with or has fed on an infected animal. Cat bites may be an important source of disease in children.

Ecogenetic analysis of *F. tularensis* in North America shows that the subspecies have specific geographic distributions across the continent.[44,144] *F. tularensis* subspecies *holartica* was found along the northwestern coast and along the tributaries of the Mississippi River. In contrast, the subspecies *tularensis* spanned the region from the east coast to Arkansas, Oklahoma, Texas, and Louisiana in the south; South Dakota in the north; and the Sierra Nevada in the west. Genetic analysis of the subspecies *tularensis* in this vast region revealed that type A.I. clusters east of the 100th meridian, whereas most type A.II. clusters to the west of this line.[144] This spatial separation of subspecies *tularensis* clades A.I. and A.II. coincides with the distribution of vectors *A. americanum* and *D. variabilis* in the east and *D. andersoni* and *Chrysops discalis* (deer fly) in the west. The spatial clustering of A.I. and A.II. also coincides with the distribution of an important host, cottontail rabbits, *Sylvilagus floridanus* and *Sylvilagus nuttallii*, respectively.[44]

PATHOGENESIS

BACTERIAL AND HOST INTERACTIONS

Much of the knowledge regarding interactions between *F. tularensis* and the host was derived from experimental studies using live attenuated strains. During World War II, live attenuated strains of *F. tularensis* were developed in the Soviet Union in an effort to produce a vaccine.[126,160] In 1956, a mixture of attenuated strains of *F. tularensis* was transferred from the Soviet Union to the United States. From this mixture, a strain of suitable virulence was selected, tested for safety and efficacy, and designated *F. tularensis* LVS.[33,35,76] This strain has been used extensively in experimental studies on the development of immunity in humans.

Capsulated *F. tularensis* organisms are thought to be opsonized by human macrophages and dendritic cells through the activation of complement, especially C3, and binding to the complement receptor 3 (CD11b/CD18).[7] The interaction of complement-coated *Francisella* with the macrophage membrane initiates an actin-dependent process then engulfs the bacteria into a unique asymmetric spacious pseudopod loop that forms the phagosome.[20,159] The bacteria resides in a moderately acidified phagosome (pH = 6.7) and accumulates the late endosomal markers (lamp-1, lamp-2, CD63). However, through as yet undefined process, phagolysosome maturation is not allowed to progress, and this prevents bacterial degradation by lysosomal hydrolases. The phagosomes are surrounded by a dense fibrillar coating that begins to disintegrate approximately 3 to 4 hours after infection, a process that allows the bacteria free access to the cytoplasm.[19] Virulence factors that facilitate this process remain to be identified. Mutation of genes in the FPI, especially *iglB* and *iglC*, have been shown to interfere with phagosome escape, macrophage growth, and virulence.[139] Approximately 24 hours after infection, replication of cytosolic *Francisella* induces apoptosis that leads to cell death and release of bacteria. Tularemia is followed by effective immunospecific protection of the host; reinfection has been documented in only nine persons.[13] Studies in which the infecting bacteria were suppressed by the use of a bacteriostatic agent such as tetracycline showed that protective immunity seems to be activated approximately 2 weeks after onset of the disease. When tetracycline treatment was initiated on the day of onset of tularemia and was given for 10 days, early relapses were common occurrences. When tetracycline treatment was administered for 14 days, relapses occurred less frequently, thus indicating that protective immunity had begun to arise.[135] Innate immunity involving interferon-γ (IFN-γ), tumor necrosis factor (TNF), and interleukin-12 (IL-12) and the cells that produce these cytokines (natural killer cells, neutrophils, macrophages) are thought to help control the initial phase of a primary infection by curtailing the replication of *F. tularensis*.[21] Approximately 2 to 3 weeks after infection, *F. tularensis* elicits both humoral and cell-mediated immune responses. Both responses reach maximal levels during the second week after infection.[18] Because *F. tularensis* is described as a facultative intracellular parasite, the general consensus is that long-term control and clearance ultimately depend on cell-mediated immunity, just as in infections with *Listeria monocytogenes* and *Mycobacterium tuberculosis*.[147,175] This finding was confirmed by several trials showing that vaccination with killed tularemia preparations, despite inducing agglutinating serum antibodies, provided poor protection.[13,76,134] Numerous studies showed that passive transfer of mononuclear leukocytes from infected animals to noninfected animals conferred resistance when the nonimmunized animals were challenged with a virulent strain.[140] Ultimately, the presence of tularemia-specific $CD4^+$ and $CD8^+$ T lymphocytes is responsible for clearance of the bacteria.[24,25,38,173] Infection with LVS disrupts the production of proinflammatory cytokines from human macrophages and endothelial cells.[47,155] This event is consistent with the lack of increase in proinflammatory cytokines, with the exception of a slight increase in IFN-γ during the early phase of the infection, in humans with ulceroglandular tularemia.[4]

The importance of the humoral immune response in tularemia is not very clear, although it is thought to be of minor significance.[37] Although the presence of immunoglobulin A (IgA) antibodies in nasal secretions correlates with resistance to infection by aerosolized organisms, earlier work by Bellanti and associates[6] showed that humoral immunity plays a minor role in resistance to tularemia. However, more recent animal studies showed that protection against tularemia LVS can be transferred by immune mouse serum and depends on host INF-γ, IL-2, and $CD4^+$ T cells.[74,129] Specific antibodies probably are involved initially in delaying the infection, thereby allowing time for the induction of cytokine production and specific T-cell–mediated immunity. This suggestion is consistent with the observation that although neutrophils have only a minor role in resistance to infection, mice depleted of $CD4^+$ T cells or $CD8^+$ T cells, or both, remained capable of controlling and partly resolving a primary sublethal *F. tularensis* infection.[24] Antibodies may function as opsonins for macrophages and neutrophils, but the level of anti-tularemia antibody does not correlate with protection.[153] Elkins and associates[36] showed that mice deficient in B cells do not succumb to sublethal doses of tularemia during a primary infection. However, in secondary infection, the presence of cytokines from B cells modulates the response of neutrophils against tularemia-infected hepatocytes and prevents the uncontrolled degranulation of neutrophils that may lead to severe tissue damage and poor clinical outcome.[10,23,27]

The role of neutrophils in the control of *Francisella* infection is thought to be minor but necessary. McCaffrey and Allen[102] recently showed that neutrophils, like macrophages and dendritic cells, rapidly opsonize *Francisella* but are prevented from mounting the respiratory burst to kill the organism. The organisms then escape to the cytosol of the neutrophils and replicate. However, studies in which neutrophils were depleted from mice showed that mice given a sublethal dose of the LVS or mice chronically infected with LVS became susceptible to infection and died.[140] Although the mechanism of action of neutrophils in these cases is unclear, it may involve direct lysis of LVS-infected hepatocytes.[23]

Persistence of immunity to *F. tularensis* depends on the T-cell response to a variety of antigens; this response may not be noted for as long as 2 weeks after exposure. Poquet and associates[127] showed that virulent strains of *F. tularensis* produce high levels of phosphoantigens that cause a proliferation in gamma-delta T cells to a greater extent than does exposure to the LVS. The reduced number of this T-cell subtype in vaccinated individuals could explain the lack of complete protection seen in vaccinated laboratory workers. As with membrane proteins stimulating an alpha-beta T-cell response, heat shock protein chaperones such as DnaK and Cpn60 also create a non-immunodominant proliferation of T cells in immunized individuals.[41] Denaturation of the protein or carbohydrate of a macromolecular antigen of *F. tularensis* has shown that T-cell reactivity is associated with only protein determinants, whereas human immune serum reacts mostly with carbohydrate determinants of the organism.[2,34,157]

INVASION AND DISEASE PRODUCTION

A single *F. tularensis* organism of a virulent strain can produce fatal infection in susceptible animals such as mice, guinea pigs, and hamsters.[176] As few as 10 organisms of a virulent strain injected intradermally or 25 organisms given by aerosol may produce systemic disease in human volunteers.[76] The organism may gain access to the human body through the skin, conjunctiva, oropharynx, respiratory tract, or gastrointestinal tract. It spreads by the lymphatics or hematogenously, and bacteremia usually develops during the first week of infection (3 to 12 days).[87] Infection commonly involves the skin, regional lymph nodes, liver, spleen, and lungs. Rarely, the gastrointestinal tract and the central nervous system also are involved.

Histopathologic examination of mammals experimentally infected with *F. tularensis* indicates that the organism disseminates and causes cellular changes in a manner typical of intracellular parasites. After the organism is introduced into a susceptible host, multiplication occurs locally, with early spread to regional lymph nodes occurring within 48 to 96 hours.[35,46] The developing cutaneous ulcer or soft tissue focus goes through a series of changes, in which polymorphonuclear leukocytes are replaced by macrophages. In time, necrosis, epithelioid cell infiltrates, giant-cell formation, and true granulomata may develop.[66,105,137] Organisms are difficult to demonstrate in tissue but occasionally are found at the periphery of lesions. In addition to the development of classic necrotic and granulomatous lesions, degeneration of the parenchyma in the liver and spleen may occur, as may marked hyperplasia of the reticuloendothelial system. These granulomata can organize to form microabscesses and abscesses. The pace of the illness depends on the virulence of the strain, as well as the inoculum size, portal of entry, and immune status of the host. When organisms enter the blood circulation, typical endotoxemia may ensue, sometimes in association with acute rhabdomyolysis.[85]

Autopsies of fatal cases of tularemia in humans have confirmed the findings in experimental animals.[62,97,121] Lymph nodes from patients with nonfatal disease have shown follicular hyperplasia with conglomerates of macrophages and caseating granulomata.[88,97,99,148] These findings are similar to those seen in miliary tuberculosis. In fact, tularemia and tuberculosis may be histopathologically distinguishable only because of the difference in timing of the development of tissue changes,[88] a difference related to the rapid replication of *F. tularensis*.

CLINICAL MANIFESTATIONS

Regardless of the portal of entry, the mode of onset of tularemia and the general features of the disease are the same. The usual incubation period of tularemia is 3 to 4 days, with a range of 1 to 21 days. The onset of symptoms is abrupt. Symptoms include fever, with a temperature usually higher than 39.4° C (103° F), chills, headache, myalgia, anorexia, vomiting, and occasionally photophobia. Fever may be continuous or biphasic, with an intermittent period of defervescence. In untreated patients, fever may persist for longer than 3 weeks. Physical findings usually include lymphadenopathy, hepatosplenomegaly, pharyngitis, and skin lesions. Temperature-pulse dissociation has been described in as many as 42 percent of cases.[43,55,118] A variety of skin rashes (e.g., maculopapular, vesicular, and pustular rashes, erythema nodosum,[122] erythema multiforme) may appear during the second week of illness and can last for a few days to several weeks.[87,151]

Laboratory studies, including a complete blood count, erythrocyte sedimentation rate, urinalysis, and *Proteus* OX2/OX19 titers, usually are not helpful in diagnosing tularemia. Sterile pyuria has been reported in patients with tularemia, 22 percent in one study[43] and 32 percent in another.[120] Sterile pyuria combined with a history of fever, dysuria, or low back pain had led to an erroneous diagnosis of urinary tract infection in 11 percent of the patients reported by Evans and associates.[43] Increased liver function test values with jaundice and atypical lymphocytosis also have been reported.[57,64] The six clinical syndromes of tularemia can be classified by the portal of entry: ulceroglandular, glandular, oculoglandular, typhoidal, oropharyngeal, and pneumonic.

ULCEROGLANDULAR TULAREMIA

Ulceroglandular tularemia, the most common form of the disease, accounts for more than 75 percent of all cases (adults and chil-

dren).[96] The organism gains access through the skin. Approximately 2 days after the onset of general symptoms, the patient complains of tender, swollen lymph nodes, most commonly in the axillary or inguinal areas. Within 24 hours, the portal of entry may become evident when a painful swollen papule develops distal to the regional node. This papule ruptures and leaves a punched-out ulcer with raised edges. The ulcer is indolent and, in untreated cases, may persist for longer than a month. The skin over the involved nodes may be inflamed. In untreated cases, approximately 50 percent of the lymph nodes suppurate and drain. In other cases, the nodes remain firm, enlarged, and tender for several months. Mild, generalized lymphadenopathy and enlargement of the liver and spleen may be present.

GLANDULAR TULAREMIA

The glandular form of tularemia is the second most common form of tularemia, and it accounts for 15 percent of all cases.[96] Glandular tularemia is almost identical to the ulceroglandular form, except the portal of entry cannot be identified.[22] The consensus is that the portal is an insignificant break in the skin. Isolated cases of cervical lymphadenopathy have been related causally to *F. tularensis* infection.

OROPHARYNGEAL TULAREMIA

The oropharyngeal form, which accounts for fewer than 5 percent of all tularemia cases,[96] resembles the ulceroglandular form. The infection is introduced into the oropharyngeal mucosa through infected, inadequately cooked meat. The organisms enter through abrasions, or aerosolization may occur during chewing. Local involvement consists of acute tonsillitis with cervical adenitis.[9] The tonsils may be covered by an exudate or membrane that extends in all directions and may resemble a diphtheritic membrane. Complaints of sore throat usually are out of proportion to the visible pathologic features, but ulcers sometimes are present. The cervical lymph nodes may suppurate. Infrequently, *F. tularensis* invades the lower portions of the gastrointestinal tract, in which case vomiting, diarrhea, and abdominal pain are prominent symptoms. Awareness of the ability of *F. tularensis* to cause oropharyngeal involvement is important for physicians caring for children.[73,95]

OCULOGLANDULAR TULAREMIA

In oculoglandular tularemia, which accounts for approximately 1 percent of all cases,[96] the portal of entry is the conjunctival sac, which may become inoculated by rubbing with contaminated fingers, having contact with infected water, splashing of infected liquids, or inhaling infected aerosols. The eyelids may become edematous and the conjunctivae inflamed and painful. Numerous small, sharply defined, yellowish nodules and ulcers may be present on the palpebral conjunctivae.[143] In some cases, corneal ulceration occurs. As seen in cat-scratch disease, the Parinaud complex of unilateral preauricular lymph node involvement and conjunctivitis can result.[143,145] The regional lymph nodes, the preauricular nodes, and the submaxillary and cervical nodes are swollen, tender, and painful.[122] In severe cases, the axillary nodes may be involved.[51]

TYPHOIDAL TULAREMIA

Typhoidal tularemia is manifested as fever of unknown cause. The symptoms are those of acute septicemia, with no localized skin lesions and often without lymphadenopathy. Patients are seriously ill, and shock may develop. The symptoms and signs of typhoidal tularemia are toxemia, continuous fever, myalgia, and severe headache. Patients may be delirious and may exhibit meningismus. Patients often complain of having severe pharyngeal pain, but pharyngeal lesions may not be evident. Diarrhea occurs in this form of tularemia in both adults and children. Sometimes, a dry cough and retrosternal pain are present. Pleuropulmonary involvement is a common finding in adults with typhoidal tularemia.[31] In children, typhoidal tularemia can be the result of ingestion of the causative agent, and necrotic lesions may be present throughout the bowel.[31] Inhalation of aerosolized organisms is a more common mode of acquisition in adults (laboratory workers, farmers).

PNEUMONIC TULAREMIA

The pneumonic form of the disease occurs most commonly in laboratory workers and is the most severe and lethal form.[76] Pneumonic tularemia may be acquired by the aerogenic route,[28,45,156] or pulmonary disease may be associated with other forms of tularemia, particularly the typhoidal type. Dienst[31] and Miller and Bates[106] published outstanding descriptions of pleuropulmonary tularemia. Miller and Bates stressed that the symptoms and signs of pleuropulmonary tularemia are nonspecific and vary with the location and degree of pulmonary involvement. The variable radiographic features may be confused with those of tuberculosis, mycotic infection, common bacterial pneumonia, lymphoma, or carcinoma of the lung. In the series of Miller and Bates[106] of 29 patients, pleural effusion developed in 6 patients. Pleural effusions have been found to contain more than 3 g of protein/100 mL and more than 1000 white blood cells/mm^3 with a lymphocytic predominance.[59] Because of the necrotizing nature of the pathologic process, the lung may heal with residual fibrosis or calcification. In other instances, the disease is so fulminant that death occurs before the pathologic features can progress fully.

ADDITIONAL CLINICAL MANIFESTATIONS

All large series of reported cases have included patients with subcutaneous nodules resembling those seen in sporotrichosis. The nodules usually are distributed on the anterior or posterior surface of the arm and may extend from the primary lesion to the regional lymph nodes. Initially, these nodules are firm and movable, but later they become fixed to the skin and may suppurate. They vary in size from less than a centimeter to more than several centimeters, if they become confluent. As many as 30 single nodules may be present. Other unusual manifestations of tularemia include pericarditis, appendicitis, peritonitis, liver abscess, cerebellitis with ataxia, meningitis, encephalitis, osteomyelitis, rhabdomyolysis, and venous thrombosis.

The incidence of these forms in children is somewhat different from that in adults. Although the pneumonic form previously was thought to be relatively rare in children,[95] more recent studies on the changing epidemiology and clinical manifestations of this disease showed that the occurrence of pneumonic tularemia is not uncommon.[75] In a 1985 study by Jacobs and associates,[75] 14 percent of tularemia cases in children were the pneumonic form. This percentage contrasts with the absence of pulmonary involvement in a series of 48 cases of tularemia in children reported by Levy and associates[95] in 1950. The distribution of these forms of tularemia also varies with the geographic location. In a report of 67 children with tularemia in Finland, 79 percent of the cases were of the ulceroglandular form, and 8 percent were glandular.[161] This distribution is significantly different from that in the United States. In the study by Jacobs and associates,[75] who

reported on 28 cases of tularemia in children, 45 percent were ulceroglandular, and 25 percent were glandular. The authors of the Finnish study attributed the higher proportion of the ulceroglandular form in their study to heightened awareness of the disease and early diagnosis. In addition, the differences also could be explained by the different strains of *F. tularensis* and different vectors in the two regions.

F. tularensis also can occur in the setting of an immunocompromised host. The pneumonic form of tularemia was reported in a patient with chronic granulomatous disease requiring lobectomy.[100] Pneumonic tularemia also was seen in a patient who previously had undergone peripheral blood stem cell transplantation for acute myelogenous leukemia (it resulted in a solitary pulmonary nodule) and in a patient infected with human immunodeficiency virus (HIV).[64,108] In addition, pneumonic tularemia was noted in a patient with a ventriculoperitoneal shunt.[125] Impairment of normal immunity could prevent adequate protection from *F. tularensis* and could necessitate more prolonged therapy.

DIAGNOSIS

The diagnosis of tularemia is established by a thorough history of possible exposure, clinical manifestations, and serial serologic tests. Obtaining a careful family history often is rewarding because several family members commonly are infected simultaneously. In some instances, however, a positive history never is elicited. Tularemia has no absolute pathognomonic features. In diagnosing tularemia, the physician must account for the endemic rate of the disease in the area, the season of the year, the clinical manifestations of the disease, the precise epidemiologic setting,[146] and the unresponsiveness of the disease to antibiotics that are not effective against tularemia.

The diagnosis is confirmed by the standard agglutination test, which is available commercially and is reliable. Unfortunately, it does not provide an early diagnosis because agglutinating antibodies usually are not detectable until the second week of illness. Occasionally, seroconversion is not confirmed until the patient has experienced 4 to 6 weeks of illness. In rare cases, agglutinating antibody may never be detected. A fourfold increase in convalescent titer confirms the diagnosis, but a presumptive diagnosis should be considered in patients with acute titers of 1:160 or greater. This titer may indicate current or past infection, but in a clinically suspicious case, it should be considered an indication for presumptive therapy. Titers of 1:1280 or greater often develop in patients with active disease as the initial manifestation of seroconversion.

The agglutination test is specific, but cross-reaction with *Brucella* and occasionally with cholera vaccine (in recent recipients) has been reported. It can easily be clarified by simultaneous testing with the individual antigens (tularemia and brucellosis). Antibiotic therapy does not prevent the development of agglutinating antibodies.

An enzyme-linked immunosorbent assay with bacterial sonicate antigen (ELISA-S) determines the presence of IgM, IgG, and IgA antibodies to *F. tularensis*.[165] This test has the advantage of confirming the diagnosis of tularemia earlier in the illness than does the agglutinating test. However, the ELISA test is not able to indicate when the onset of the disease occurred because the anti-tularemia antibody titers decrease slowly. Like other ELISA-based methods that have been developed recently, however, the ELISA-S test is not available commercially. *F. tularensis* also may be identified by direct fluorescent antibody or immunohistochemical stains of human specimens such as secretions or biopsies.[29,30]

Another method used for making the early diagnosis of tularemia is the whole-blood lymphocyte stimulation test.[89,150] During an epidemic in Finland in 1983, this technique was compared with the bacterial agglutination test in the diagnosis of 200 cases. The lymphocyte stimulation test yielded positive results in 21 percent of cases during the first week of illness and in 97 percent during the second week. In contrast, the bacterial agglutination test detected only 2 percent of the cases in the first week and 53 percent in the second week.[150] The skin test (Foshay) is an accurate method of diagnosis.[12] The skin test is positive earlier in the illness than is the agglutination test, but the skin test antigen is not available commercially.

Of the other diagnostic modalities recently evaluated, a polymerase chain reaction (PCR)–based assay holds promise for early detection of *F. tularensis* infection.[98] The PCR test has been shown to be effective in establishing the diagnosis of tularemia even when samples of a tularemic ulcer were obtained 1 to 14 days after infection.[141] When PCR and culture of the wound and blood were compared with agglutination tests, the sensitivity of PCR was 75 percent, and the sensitivity of culture was 62 percent.[80] In addition to increasing the safety for laboratory personnel, the PCR method was more sensitive and could detect infection at earlier stages. Compared with conventional PCR-based assays, real-time PCR (RT-PCR) has been shown to be more specific and 10 times more sensitive.[164] These assays are not available commercially at this time.

Based on PCR techniques, several assays have been developed to allow for the correct identification of *F. tularensis*. One such example is species level differentiation, which can be done by targeting the 16S rDNA and the *lpnA* gene of *F. tularensis*.[141] Real-time PCR analysis for a 30-bp sequence upstream of the gene for RNA helicase can differentiate between *F. tularensis* subspecies *tularensis* and subspecies *holartica*. In addition, several other high-resolution DNA analysis techniques exist mostly for the experimental purpose of species differentiation.[84]

In a Norwegian field study, a rapid immunochromatography assay proved inexpensive, time efficient, and portable when compared with PCR and ELISA, but this method was less sensitive than PCR.[8] This assay could accelerate identification and treatment decisions in clinical practice.

Gram-stained smears of patient specimens such as exudate and sputum usually do not reveal the organism. However, collecting the specimens poses no danger, and examination of direct smears helps to rule out other causative agents. Specimens should not be cultured for *F. tularensis* in the usual hospital or diagnostic laboratory because isolation of these organisms in facilities other than a level P-3 laboratory is hazardous to laboratory personnel. If confirmation by culture is indicated, physicians should notify the laboratory of the potential for the specimen to contain *F. tularensis*, so that appropriate laboratory precautions can be taken.

The differential diagnosis of tularemia depends on the clinical form of the disease. Ulceroglandular and glandular tularemia must be differentiated from disease caused by ordinary bacterial pathogens such as *Streptococcus* and *Staphylococcus*, from disease caused by *M. tuberculosis* and atypical mycobacteria such as *Mycobacterium marinum*, and from anthrax, HIV infection, and cat-scratch disease. In older patients with inguinal lymphadenopathy, lymphogranuloma venereum, granuloma inguinale, and other sexually transmitted diseases should be considered. Occasionally, sporotrichosis and infectious mononucleosis are diagnosed in these patients. Oculoglandular fever is somewhat more distinctive, but one must not rule out the possibility of disease caused by common bacterial pathogens, *L. monocytogenes* infection, herpes zoster, inclusion conjunctivitis, and keratoconjunctivitis. Oropharyngeal tularemia must be differentiated from streptococcal tonsillopharyngitis and corynebacterial disease. Typhoidal tularemia can be confused with ordinary bacteremia and must be differentiated from the more common bacterial and enteric disease, as well as from malaria, miliary tuberculosis, brucellosis,

and typhoid fever. Tularemic pneumonia must be differentiated from other bacterial as well as nonbacterial pneumonia, including tuberculosis, *Mycoplasma* infection, legionnaires' disease, psittacosis, viral pneumonia, Q fever, fungal infection, and chemical pneumonitis.

TREATMENT

Streptomycin traditionally is the drug of choice for the treatment of tularemia. The recommended dose is 30 to 40 mg/kg/day administered intramuscularly in two divided doses for 7 days. If a patient has mild symptoms initially or responds dramatically to therapy, an alternative streptomycin regimen of 30 to 40 mg/kg/day for 3 days followed by 15 to 20 mg/kg/day for 4 days may be given intramuscularly. In severe cases or if a child does not become afebrile and asymptomatic within a few days of therapy, extension of treatment beyond 7 days is indicated. Streptomycin-resistant strains of tularemia are reported, but they are rare.[116] Defervescence and alleviation of other signs and symptoms occur promptly, usually within several days. Response may be delayed if the lymph nodes have progressed to suppuration.

Because of the recent shortage of streptomycin in the United States,* alternative antibiotic regimens must be considered. Unfortunately, because of the lack of controlled clinical trials of the newer antibiotics for the treatment of tularemia, experience with alternative antibiotic regimens is limited. In a review of the various treatments of tularemia reported in the literature, Enderlin and associates[39] concluded that streptomycin remains the drug of choice, with a cure rate of 97 percent and no relapse. Gentamicin is an acceptable alternative to streptomycin, with a cure rate of 86 percent and a relapse incidence of 6 percent. These authors attributed some of the treatment failure with gentamicin to a delay in initiation of therapy and the short duration of therapy in some severe cases, as well as to other underlying medical problems.[39] The recommended dosage of gentamicin for tularemia is 5 mg/kg/day divided into two intramuscular doses.

Bacteriostatic agents such as tetracycline and chloramphenicol also have been used to treat tularemia, with cure rates of 88 percent and 77 percent, respectively. However, these agents are considered suboptimal for the treatment of tularemia because of a high incidence of relapse after therapy is stopped (12% for tetracycline and 22% for chloramphenicol).[39]

Although in vitro susceptibility testing indicates that the third-generation cephalosporins may be effective against *F. tularensis*, one report showed treatment failure in eight children given ceftriaxone.[26] Treatment with other antibiotics reported sporadically in the literature includes one successful case with imipenem and cilastatin,[94] seven successful cases with ciprofloxacin or norfloxacin in adults,[108,136,152] and four isolated cases with erythromycin.[67] An efficacy trial in Sweden of ciprofloxacin demonstrated successful outpatient management of *F. tularensis* in 10 of 12 patients 1 to 10 years of age.[81] The dosage used was 15 to 20 mg/kg/day in two divided doses for a 10- to 14-day course of therapy. Defervescence occurred in the fourth day of treatment. Despite the lack of clear data on safety in children, this treatment was reported as efficacious in a 17-year-old patient in the United States who developed tularemia after being bitten by a cat.[5]

Children receiving streptomycin should be monitored for ototoxicity. Hearing screening should be considered before initiation of streptomycin or gentamicin therapy. If the child has preexisting hearing loss, the alternative streptomycin regimen or gentamicin therapy can be considered, with close monitoring of serum levels in severe cases. In these cases, audiologic evaluation is indicated after therapy is initiated.

*As of November 1995, streptomycin is available from Pfizer Streptomycin Program, Pfizer Pharmaceuticals, New York, NY (800-254-4445).

Bed rest and supportive therapy are, of course, indicated. In a severely ill patient who shows signs of endotoxic shock, appropriate monitoring and admission to an intensive care unit are indicated, and corticosteroid therapy should be considered. Suppurative lymph nodes may require surgical drainage.

Before the advent of effective antimicrobial therapy, tularemia often was a protracted illness that lasted weeks or months. Subsequently, a long period of convalescence was necessitated by debility. Antibiotics have interrupted the natural history of the disease. When the disease is diagnosed promptly, the course generally is less than a month. As a result of administering appropriate antibiotic therapy, the mortality rate has declined from 5 to 30 percent to less than 1 percent, except in cases of fulminant pneumonic and typhoidal disease.

PREVENTION

Prevention of human tularemia depends on prevention of exposure to either the vectors or contaminated animal tissue. Children living in areas of tick endemicity should have their skin and hair checked frequently for ticks. Ticks should be removed carefully with tweezers (not with fingernails) by pulling perpendicular to the skin where the ticks have attached.[109] Care should be taken not to squeeze the ticks between the fingers. Persons living in tick-infested areas should wear clothing with tightly fitting cuffs at the wrists and ankles when staying outdoors. Tick repellents should be used with caution on children.

Children should be warned against handling sick or dead rodents or rabbits. Incineration or burial should be used to dispose of rabbits caught by household pets. Rubber gloves should be worn for preparing game animals, and the meat should be cooked thoroughly before eating. Hunters, especially rabbit hunters, should take precautions against contracting tularemia.

The only tularemia vaccine available in the United States is the *F. tularensis* LVS developed in 1960. It is unlicensed and is classified as an investigational product, but it is available to laboratory personnel. This vaccine appears to have reduced significantly the incidence of typhoidal tularemia and the severity of ulceroglandular disease in laboratory personnel. One lot of vaccine was found to induce an 80 percent response, with IgG to the ether-extracted antigen of the LPS membrane protein by day 14 and a 100 percent response by 21 days.[169] In vitro, lymphocyte responses to several antigens were noted by 14 days, in contrast to controls, in whom the ether-extracted antigen response appeared first.[169] The efficacy of this vaccine for prevention of naturally occurring disease in the United States is unknown. Vaccine strategies using bacterial proteins, such as heat shock proteins and other components, have not been successful. Further work in designing mutants that have specific gene changes to create attenuated strains may serve as a new avenue in the future.[93]

CHAPTER 145

HAEMOPHILUS INFLUENZAE

Stephen J. Barenkamp

Relatively few species of the genus *Haemophilus* are pathogenic to humans, and nearly all that cause human disease are either encapsulated or unencapsulated strains of *Haemophilus influenzae*. These strains of *H. influenzae* are small, gram-negative pleomorphic coccobacilli that generally are considered to be normal constituents of the microbial flora of the upper respiratory tract of humans.[192,233] Strains without polysaccharide capsules often cause infections of mucosal surfaces, such as otitis media, bronchitis, conjunctivitis, sinusitis, and types of pneumonia.[256] Encapsulated strains, especially *H. influenzae* type b (Hib), cause invasive diseases such as septicemia, meningitis, septic arthritis, cellulitis, epiglottitis, pneumonia, and empyema. Before Hib vaccines became widely available, *H. influenzae* was the leading cause of bacterial meningitis in the United States and most other countries, and it also was an important cause of other bacteremic illnesses, primarily in young children.[49,418]

The organism now known as *H. influenzae* was described first in 1892 by Robert Pfeiffer,[295] who isolated it from the lungs and sputum of patients during the 1889 to 1892 pandemic of influenza. He proposed that the organism was the cause of influenza, and it initially was known as the Pfeiffer influenza bacillus. The bacteria were difficult to culture on routine media until investigators appreciated that supplementation with X (hemin) and V (nicotinamide adenine dinucleotide [NAD]) factors was required for its growth. By the early 20th century, the organism had been recovered from the blood and cerebrospinal fluid (CSF) of young children with meningitis. Although doubts remained about the etiologic role of the Pfeiffer bacillus as the cause of influenza, not until the influenza pandemic of 1918 was its etiologic role questioned seriously. In 1920, the organism was renamed *Haemophilus influenzae* to acknowledge its inappropriate historic association with influenza and to emphasize its requirement of blood factors for growth (from the Greek *haemophilus*, or "blood-loving").[420] In 1933, the viral cause of influenza was discovered, and this discovery refuted any remaining confusion about the erroneous association between *H. influenzae* and influenza virus.

Key concepts relevant to the development of treatment and prevention modalities derive from the pioneering work of Margaret Pittman[298,299] in the early 1930s. Paralleling earlier research on the pneumococcus, she defined two major categories of *H. influenzae*: encapsulated strains and unencapsulated strains. Among the encapsulated strains, Pittman characterized six distinct serotypes (designated a through f), which now are known to differ biochemically in the composition of their polysaccharide capsules (Table 145–1). She observed that Hib strains were recovered primarily from the blood and CSF of young patients with meningitis and that unencapsulated strains and other *H. influenzae* serotypes were recovered primarily from respiratory tract secretions. Furthermore, Pittman demonstrated that antibody to Hib capsule conferred type-specific protection against lethal infection in rabbits. This observation led to the use of antiserum prepared by immunization with formalin-killed Hib, initially in horses and later in rabbits, as the first treatment of disease. Before this development, Hib meningitis and other forms of invasive Hib disease almost always were fatal.[380] However, not until the late 1930s did treatment of children with meningitis with both Hib antiserum and sulfonamides substantially reduce the case-fatality rate.[7,8]

In 1933, Fothergill and Wright[125] described the age-related risk of acquiring *H. influenzae* meningitis, which affected mostly children younger than 5 years of age. Importantly, these investigators noted the correlation between the age-related risk of disease and the absence of bactericidal antibodies. Later, researchers identified antibody to Hib capsule as the major antibody contributing to the protective activity of bactericidal serum.[181,341] These observations suggested that naturally acquired type b anticapsular antibody is protective and that early stimulation of protective immunity with vaccines could be possible. Unfortunately, the advent of effective antimicrobial agents focused attention away from the need for primary prevention. Even with effective antimicrobial therapies and excellent hospital care, significant mortality rates (≈5%) and neurologic morbidity (≈20%) remained.[93,94] Ultimately, appreciation that the morbidity and mortality of the disease could not be eliminated completely by treatment gave impetus to the development of vaccines for prevention.

TABLE 145–1 Structures of *Haemophilus influenzae* Capsular Polysaccharides

Type	Structure
a	4)-β-D-Glc-(1 → 4)-D-ribitol-5-(PO4 →
b	3)-β-D-Rib*f*-(1 → 1)-D-ribitol-5-(PO4 →
c	4)-β-D-GlcNAc-(1→ 3)-α-D-Gal-1-(PO4 → 3 ↑ R = OAc | H R
d	4)-β-D-GlcNAc-(1→ 3)-β-D-ManANAc-(1 → 6 ↑ | R = L-serine | L-threonine R L-alanine
e	3)-β-D-GlcNAc-(1→ 4)-β-D-ManANAc-(1 →
e′	3)-β-D-GlcNAc-(1→ 4)-β-D-ManANAc-(1 → 3 ↑ 2 β-D-fructose
f	3)-β-D-GalNAc-(1→ 4)-α-D-GalNAc-1-(PO4 → 3 ↑ OAc

In the early 1970s, investigators purified and characterized the type b capsular polysaccharide (polyribosylribitol phosphate [PRP]) and proposed it as a potential vaccine candidate. Subsequently, the protective efficacy of a PRP vaccine against invasive Hib disease was demonstrated in older children in a 1974 field trial conducted in Finland.[288] This and other studies culminated in the licensure of PRP vaccine in the United States in 1985, thus rendering it the first vaccine available for the prevention of Hib disease.[63] Unfortunately, this vaccine induced equivocal immune responses and incomplete protection in older children and provided no protection for young infants, those at greatest risk of acquiring Hib disease.[408] Improved vaccines used polysaccharide-protein conjugate techniques, and four such vaccines were licensed for use in children. Three of these vaccines were shown to protect young infants against Hib disease,[38,330,391] and with the universal immunization of young infants, invasive Hib disease nearly has been eliminated in many populations.[4,37,289] Unfortunately, Hib disease continues to be a significant cause of morbidity and mortality among children in numerous resource-poor countries around the world where access to Hib vaccines is still limited.[9,285,362,404]

MICROBIOLOGY

MORPHOLOGIC AND CULTURAL CHARACTERISTICS

H. influenzae is a small, gram-negative coccobacillus that in clinical specimens can appear filamentous or pleomorphic, especially when specimens are obtained from patients who previously have received antibiotics. The organism is nonmotile, non–spore forming, and facultatively anaerobic, and it requires two supplemental factors for in vitro growth.[192] The X factor (hemin) is a heat-stable, iron-containing protoporphyrin essential for activity of the electron transport chain, which is important for aerobic growth. The heat-labile V factor is a coenzyme, NAD. Both factors are present within erythrocytes and are released by appropriate heating or enzyme lysis of the red blood cells that permits growth on chocolate agar. The requirement for these factors for growth remains the primary basis for the laboratory differentiation of *H. influenzae* from other *Haemophilus* spp.[22,192]

The growth of *H. influenzae* is fastidious, and clinical specimens need to be inoculated promptly onto appropriate media, such as chocolate agar.[192] The organism can be grown in most enriched liquid or solid media supplemented with X and V factors. Although not mandatory for growth, 5 to 10 percent carbon dioxide makes some strains grow better. In blood or liquid media, *H. influenzae* may not grow to sufficient quantity to result in visual turbidity; therefore, to detect positive cultures, blood and CSF cultures should be assayed for release of carbon dioxide or routinely subcultured at 24 to 48 hours. After being incubated overnight on solid media, colonies appear that are 0.5 to 1.5 mm in diameter and usually are rough or granular in appearance. Encapsulated strains generally produce slightly larger colonies that are mucoid or glistening. Fermentation reactions and other metabolic activities are variable and, therefore, not particularly useful for identification. However, a biotyping scheme based on the metabolism of indole, urea, and ornithine decarboxylase activity has been used to subtype strains.[192]

CAPSULAR POLYSACCHARIDES

Several surface structures of *H. influenzae* contribute to the organism's pathogenicity, but one of the most important is the capsular polysaccharide. Strains can express one of six unique polysaccharide capsules (a, b, c, d, e, or f; see Table 145–1) or lack capsule expression completely (nontypeable strains). The

Hib capsule is of particular clinical, pathogenic, and immunologic importance because Hib accounts for 95 percent of all strains that cause invasive disease.[49,231] The Hib polysaccharide consists of a repeating polymer of ribosyl and ribitol phosphate (PRP) that has a 1-1 linkage.[98] The genes involved in production of the Hib capsule have been cloned and consist of two repeating 17-kb DNA fragments separated by a 1-kb bridge region (*bex A*)[172,200]; 98 percent of Hib organisms tested contain this duplication.[200] Encapsulation often is unstable, with loss of capsule production associated with loss of one 17-kb repeat.[199] These strains produce type b capsule but in barely detectable amounts. Of importance is that the release of Hib capsular antigen in the body fluids of infected individuals can be detected by specific immunologic techniques (i.e., latex agglutination) that are useful for rapid diagnosis.[184,410] The other capsular serotypes are composed of hexose rather than pentose sugars,[98,99,383,384] and they also occasionally result in invasive disease.[58,66,164,278]

NONCAPSULAR CELL WALL ANTIGENS: PROTEINS

The cell envelope of *H. influenzae* is typical of other gram-negative bacteria, consisting of a cytoplasmic membrane, a peptidoglycan layer, and an outer membrane that represents the outermost layer of the envelope. The outer membrane contains an array of proteins, lipopolysaccharides (LPSs), and phospholipids, many of which serve important functional roles for the organisms. Since the late 1990s, our understanding of many of the outer-membrane components and of their contributions to the pathogenesis of disease has advanced significantly.[101,126,167,256]

Early laboratory investigations of *H. influenzae* identified and characterized numerous major and minor outer-membrane proteins (OMPs) of the organism.[31,253,255,260,272,356] However, an understanding of the functional roles of most of these proteins was lacking.[356] More recent studies have helped to clarify the roles in disease pathogenesis of an expanding number of these OMPs. Several proteins have been shown to be important for attachment of *H. influenzae* to host respiratory mucosal tissues.[53,82,251,320,427] Other surface proteins have been shown to play a central role in bacterial acquisition of iron, a phenotypic trait critical for survival of the organism in the human host.[6,179,193,343,354,424] Other studies have identified bacterial surface proteins important in resistance of *H. influenzae* to components of the host innate immune system, the first line of defense in the nonimmune host.[88,163,232] The availability for study of the completed genomes of several representative *H. influenzae* strains[121,168,254,352] is certain to increase the rate of discovery of other proteins important in disease pathogenesis during the next several years.

NONCAPSULAR CELL WALL ANTIGENS: LIPOPOLYSACCHARIDE

Early studies of *H. influenzae* LPS demonstrated that, although they differed chemically and structurally from the LPS of Enterobacteriaceae, both types of LPS shared numerous biologic properties. LPS purified from Hib produced a dermal Schwartzman reaction, was lethal to mice, caused a febrile response in rabbits, evoked polyclonal B-cell activation, and had limulus lysate activity.[123] In addition, human leukocytes incubated with *H. influenzae* LPS generated potent procoagulant activity,[247] a property that may be relevant to understanding the mechanisms responsible for intravascular coagulation in severe infection.

During the past several years, knowledge concerning the genetics, structure, biosynthesis, and role in pathogenesis of the *H. influenzae* LPS has increased greatly. The structure of *H. influenzae* LPS consists of a conserved triheptose inner core linked by a single 2-keto-3-deoxy-octulosonic acid molecule to lipid A, from which extend oligosaccharide extensions (outer core), mainly hexose sugars, that vary from one strain to another.[161,227,228] *H. influenzae* LPS lacks the repetitive side chains typical of gram-negative enteric bacteria but displays great complexity in its outer core sugars and other substituents such as phosphorylcholine[411,412] and sialic acid.[10,47] Several of these sugars and nonsugar substituents of *H. influenzae* LPS are phase variable.[159,160,412] Phase variation of many of these substituents is mediated by translational switching of genes that contain tetranucleotide repeats within the 5′ ends of the respective reading frames.[161,176,412] Phase-variable expression of several of these LPS components has been shown to contribute to the pathogenesis of disease, as further explained later.

IMMUNOGLOBULIN A PROTEASES

Immunoglobulin A (IgA) proteases are bacterial enzymes, the only known substrate of which is human IgA1. These secreted enzymes cleave the IgA heavy chain at specific sites.[196] IgA proteases are regarded as potentially important virulence factors because mucosal defense is in part IgA mediated. *H. influenzae* produces at least two distinct types of IgA protease that cleave different peptide bonds within the IgA1 hinge region.[252,300] Other work demonstrated that strains of *H. influenzae* isolated from patients with disease express higher levels of IgA protease than do strains isolated from asymptomatic carriers,[395] a finding again suggesting that IgA protease is an important virulence factor for *H. influenzae*. In more recent work, investigators identified and characterized another IgA protease gene that is present in approximately one third of *H. influenzae* strains.[115] This latter gene, designated *igaB*, is distinct from the previously characterized IgA protease gene, and its presence appears to be associated with higher levels of IgA protease expression and with a greater likelihood of causing disease.[115]

POPULATION STRUCTURE

Numerous powerful typing techniques have been developed for identifying individual *H. influenzae* strains and for defining the relationships among strains.[242,268,294] These techniques have provided valuable information for a variety of epidemiologic studies and have served to define the population structure for *H. influenzae* organisms as a whole. Encapsulated *H. influenzae* can be grouped into two distinct primary phylogenetic divisions.[268] Furthermore, the population structure of encapsulated *H. influenzae* is clonal. Most of the invasive disease worldwide is caused by serotype b strains of a limited number of clones.[200] Strains producing serotype c, e, and f capsules belong to single divisions and have no close genetic relationships with strains of other serotypes.[268] Serotype a and b strains occur in both primary phylogenetic divisions, probably as a result of transfer and recombination of serotype-specific sequences of the cap region between clonal lineages.[201,268] In contrast to the encapsulated strains, the unencapsulated or nontypeable *H. influenzae* strains demonstrate substantial genetic diversity.[267,294] Contributing to the genetic diversity of the nontypeable *H. influenzae* are apparently rather high rates of recombination among individual bacterial strains.[79,242]

ANTIBIOTIC RESISTANCE

Another important microbiologic feature of *H. influenzae* has been the development of antibiotic resistance. Resistance to a wide variety of antibiotics (sulfonamides, trimethoprim-sulfamethoxazole, erythromycin, tetracycline, penicillin) has been described, but these antibiotics are not essential for therapy.

Of greater importance is resistance to ampicillin, first noted in the mid-1970s,[13] because this drug was the primary antibiotic used for the treatment of disease. Since then, ampicillin resistance has become widespread, with between 5 and 40 percent of all isolates in various parts of the world now resistant.[57,95,183] The mechanism of resistance usually involves the production of plasmid-mediated β-lactamase enzyme, and resistant strains often are characterized by their plasmid or β-lactamase enzyme content.[183] Resistance to chloramphenicol usually is mediated by the enzyme chloramphenicol acetyltransferase.[318,400] Although chloramphenicol-resistant strains are rare findings in the United States, they are more prevalent in some areas of the world, and strains resistant to both ampicillin and chloramphenicol have been reported.[62,281,386] Currently, third-generation cephalosporins are the mainstays of therapy for invasive disease; concern, however, about the potential for increasing resistance to these highly effective agents further emphasizes the need for means to prevent disease.

PATHOGENESIS

ACQUISITION AND CARRIAGE OF ORGANISMS

Illness caused by *H. influenzae* infection results from a series of pathogenic events beginning with exposure to the organism, followed by colonization of respiratory mucosal membranes.[126] Under natural conditions, *H. influenzae* is exclusively a pathogen of humans, and it usually is transmitted asymptomatically from person to person by transfer of respiratory secretions.[279,284] The incubation period is unknown because many transmission cycles may occur before a susceptible person becomes ill. Furthermore, in some individuals, the organism can be carried in the upper respiratory tract for many months before it causes disease.[84,261,309,357]

Both typeable and nontypeable organisms may be present as part of the normal flora of the upper respiratory tract. Nearly all individuals (as many as 80%) are colonized at some point with nontypeable strains.[284,309] In the pre-vaccine era, Hib carriage rates were lowest in adults and young infants and highest in preschool-aged children.[385] In a prospective longitudinal study conducted at a daycare center in Dallas, Texas, where no invasive infections occurred, the average rate of colonization with Hib was 10 percent.[261] During the 18 months of the study, 71 percent of the children 18 to 35 months of age and 48 percent of the children 36 to 71 months of age were colonized at some time. Carriage rates were substantially higher in households or daycare centers in which a case occurred. For example, colonization prevalence rates among children in daycare centers where a case of invasive disease had occurred were as high as 58 to 91 percent.[151,407] Similarly, within families in which a case of invasive disease occurred, rates of colonization of 60 to 70 percent in siblings and 20 percent in parents were observed.[55,407] Whether the high carriage rates in these exposed semiclosed populations were the cause or the result of disease was not clear.[233,245] Close contact among exposed susceptible individuals, as occurs within families and daycare centers, facilitated the risk of transmission and acquisition of disease.

Despite a low point prevalence of Hib pharyngeal carriage (1-5%) in the pre-vaccine era, most young children became colonized with Hib during the first 2 to 5 years of life.[233,385] Consequently, specific Hib immunity developed in these colonized children.[157,341] Hib strains were demonstrated to persist in the nasopharynx for months,[245,261] and they often were not eliminated by treatment with antimicrobial agents that did not penetrate into respiratory secretions.[350,351] The relationship between carriage of Hib and the subsequent development of disease and immunity is not well understood. Factors that influence the efficiency of transmission and the ability of the organism to establish colonization also are understood poorly. Two factors that probably potentiate the risk for acquiring infection and invasive disease are the size of the bacterial inoculum[368] and the presence of a concomitant viral infection.[198]

Data derived from animal models of infection may be of some benefit in understanding the dynamic nature of the colonization process. Inoculation of Hib organisms into the nose of infant animals resulted in local infection.[249,322] In this model system, rhinorrhea was not noted, but nasopharyngeal washings revealed numerous polymorphonuclear leukocytes and organisms that reached maximal density in approximately 24 hours. Shortly thereafter, bacteremia could be detected in the animals. With colonization of humans, Hib is found on the surface of the respiratory mucosa. Rarely, by electron microscopy, an organism can be observed penetrating a nasal mucosal epithelial cell.[368] An acute inflammatory response to the submucosal bacteria occurs, but it is not marked. The exact mode of entrance of the organisms into the vascular compartment is unknown, but the assumption is that they enter through the lymphatics, probably carried by phagocytic cells, which are found in the submucosa. In support of this hypothesis, Rubin and Moxon[322] detected early transient bacteremia in rats after nasal inoculation.

PATHOGENESIS OF MUCOSAL INFECTIONS

Mucosal colonization and mucosal infections occur much more frequently than do invasive bacteremic infections, particularly in those populations in which Hib vaccine is in widespread use. These latter infections, most of which are caused by nontypeable *H. influenzae*, still cause considerable morbidity and are associated with substantial health care costs.[331,369] Mucosal infections generally involve direct movement of organisms through the nasal ostia to the sinuses, up the eustachian tubes, where they cause otitis media, and down the bronchi, where they cause bronchitis and pneumonia. Bacteremia rarely is involved, and such infections generally are not life-threatening. These infections appear to be enhanced by antecedent viral infection,[72] eustachian tube malfunction,[371] foreign bodies, or mucosal damage from smoking or other irritants.[326]

A considerable amount of recent research has focused on gaining a better understanding of the pathogenesis of mucosal surface infections caused by nontypeable *H. influenzae*. The same principles almost certainly apply to the early steps in mucosal colonization by encapsulated *H. influenzae*. The following model has been proposed to explain the early events in the colonization process.[167] Following transmission from an *H. influenzae* carrier to a new host,[84] bacteria first come in contact with the upper respiratory tract. Here they must overcome the nonspecific mucociliary defenses if colonization is to persist.[346] The major OMPs of *H. influenzae*, P2 and P5, and probably other factors, promote bacterial binding to mucus and help to establish an early foothold for the bacteria in the upper respiratory tract.[310,368] Local elaboration of LPS and other bacterial products then causes damage to ciliated cells and further impairs mucociliary function.[403] Subsequently, several adhesins, including HMW1 and HMW2, pili, Hia, Hap, and others, help to mediate direct adherence to nonciliated epithelial cells.[24,30,120,139,140,365] Cleavage of IgA1,[115,395] invasion into cells and the subepithelial space,[124,368,372] and phase and antigenic variation of surface antigens facilitate evasion of local immune mechanisms.[176,412] Binding and uptake of iron and heme allow organisms to persist on the respiratory mucosa despite the relative scarcity of these nutrients.[345,417] In the setting of a viral infection, allergic disease, or exposure to cigarette smoke, bacteria spread from the nasopharynx to other sites within the respiratory tract and produce symptomatic disease.[72,283,371]

PATHOGENESIS OF INVASIVE DISEASE

Once mucosal colonization with Hib and other potentially invasive strains has been established, dissemination may occur from the upper respiratory tract mucosa to the bloodstream and then elsewhere in the body.[322] The incidence of invasive disease is a small fraction of the carrier rate for Hib.[261] When dissemination does occur, the organism appears to invade the mucosa by separating the apical tight junctions of the columnar epithelium and moving intercellularly.[368] The resulting bacteremia initially is low in concentration but steadily increases over the course of hours.[280] The dynamics between bacterial proliferation and clearance is influenced by antibody, complement, and phagocytes, all of which have an effect on the magnitude of the bacteremia.[414] The polysaccharide capsule of Hib is antiphagocytic and a major virulence factor. In the absence of anticapsular antibody, bacteremia increases steadily over a course of hours.[158] When the bacterial concentration exceeds 10^4 organisms per milliliter, metastatic seeding occurs, especially to the meninges through the choroid plexus. Although meningitis is the most frequently recognized manifestation of invasive Hib disease, other potential metastatic sites include the lungs, joint synovium, pleura, peritoneum, and pericardium.[49,380]

The pathogenic events that lead to pneumonia, cellulitis, and epiglottitis are less well understood, even though these invasive infections are associated with bacteremia. Presumably, pneumonia occurs after the aspiration of a critical number of virulent organisms, epiglottitis involves focal infection of the epiglottis, and cellulitis occurs by secondary seeding of deep subcutaneous tissues through the bloodstream.[141] With all forms of invasive Hib disease, invasion of the bloodstream occurs as either a primary or a secondary event.

Viral interactions enhance the pathogenesis of Hib.[271,374] Influenza virus infection has been shown to reduce neutrophil chemotaxis, bacterial killing, systemic macrophage function, the number of circulating T cells, T-cell blastogenesis, and expression of delayed cutaneous hypersensitivity.[1,2,80] Reduced bacterial killing may result from a defect in phagosome-lysosome fusion, a defect that is maximal 5 to 7 days after viral infection and inoculation of Hib.

BACTEREMIA IN ANIMAL MODELS

During bacteremia, organisms are cleared continually from the vascular compartment by antibody, complement, and the reticuloendothelial system.[250,322] The balance of these processes determines the magnitude and duration of the bacteremia. If bacterial clearance is stopped by reticuloendothelial blockade, bacterial densities increase to a maximum, and death quickly ensues, presumably because of the effects of endotoxin.

Initially, bacterial concentrations are very low (≈100 organisms/mL blood). They then steadily increase in density over the course of the next 24 hours and reach a plateau value.[322,323] In young animals, this plateau level is 10^7 organisms per milliliter of blood and usually is associated with the features of human sepsis. In older animals, the plateau value is lower, approximately 10^4 organisms per milliliter of blood. These animals have low-grade fever but a relative paucity of symptoms. This primary bacteremia leads to seeding of serous surfaces, such as the peritoneum, diarthrodial joints, pleura, pericardium, and meninges. Early in the infectious process, organisms can be obtained from all these surfaces but without an observable inflammatory response; later in the process, an inflammatory response ensues. In experimental animals, the first evidence of an immune response is antibody directed against somatic antigens.

Strains of Hib vary in virulence potential. Furthermore, the other five capsular types or nonencapsulated strains result in only transient, low-level, or undetectable bacteremia, even with large inocula (>10^7 colony-forming units).[428] Complement and the spleen are critical factors for host defense in the rat. Rats depleted of C3 and splenectomized (or with iatrogenic splenic congestion caused by hemolytic anemia) have an increased incidence and magnitude of bacteremia.[69,428] These studies suggest the importance of the alternative pathway of complement (opsonic antibody) and reticuloendothelial phagocytes as determinants of intravascular clearance.

MENINGITIS

Bacteremia precedes the development of meningitis, except for rare situations in which direct extension of infection from adjacent sinuses or an ear infection occurs. Data from experimental studies in infant rats and infant monkeys support this hypothesis.[249] Both the magnitude and duration of bacteremia are probably the primary determinants of invasion of the central nervous system (CNS). After a critical bacterial concentration is exceeded in blood, Hib appears to enter the CNS through the choroid plexus.[360] This theory is supported by the following: (1) the earliest histopathologic lesion seen in the CNS is choroid plexitis, (2) the choroid plexus is one of the foci seeded from the bloodstream, and (3) bacterial density early in infection is greater in the lateral cerebral ventricles than in other CSF compartments.[360] Furthermore, pulse-chase experiments using tracer strains show that organisms enter the CSF through the choroid plexus and that inflammation of the choroid plexus is a uniform feature of meningitis. Subsequently, organisms infect the CSF and the arachnoid villi of the leptomeninges and cause blockage of CSF return, thereby increasing bacterial density and CSF pressure.[360] Generally, the magnitude of CSF bacterial density correlates with the severity of clinical illness.[114,336] Egress of CSF from the subarachnoid space is by flow through the subarachnoid villi, and bacterial density in CSF can be increased or decreased by manipulating CSF egress, which occurs in meningitis through inflammatory responses. The inflammatory response of the choroid plexus is followed by pachymeningitis, which also inhibits CSF reabsorption and increases pressure. Phlebitis of the cerebral blood vessels and thrombosis can occur. All these events contribute to decreased blood flow to the cortex. The resulting increased bacterial density, inflammation, edema, cranial nerve damage, and overall increased CSF pressure are responsible for the morbidity and mortality associated with meningitis.[93,111,360] Parenchymal invasion of the brain rarely occurs.

IMMUNOLOGY

Resistance to *H. influenzae* infection depends on successful integration of a wide variety of host defenses, including the following: (1) mucosal factors that prevent the organism from attaching and penetrating the respiratory epithelium[206,361,366]; (2) activation of the alternative and classical complement pathways that leads to killing of the organism and initiation of other inflammatory responses[367,419]; (3) induction of antibody formation[148,150]; (4) phagocytosis and killing by macrophages and polymorphonuclear cells in tissues, the circulation, and the reticuloendothelial system[34,266,421]; and (5) cell-mediated immunity.[96] Assessing the role of each of these immunologic mechanisms independently or determining which mechanisms are most important in host defense is difficult. Although antibodies are not the sole defense against bacteremia, they have been the research emphasis of vaccine development.[148] The goal has been to induce antibodies that are bactericidal, opsonophagocytic, and ultimately protective. Although usually only antibody is measured in these studies,

other immune factors are induced and probably play important roles in protection.

ANTICAPSULAR ANTIBODY

Initially, antibody activity was assessed by measuring agglutinin and bactericidal titers of serum. In 1933, Fothergill and Wright[125] suggested that bactericidal activity was responsible for immunity to Hib meningitis and that acquisition of this immunity correlated with the age of the individual. Although antibodies to several surface antigens of *H. influenzae* play roles in conferring immunity to Hib,[353] antibody to Hib capsular polysaccharide appears to be of primary importance.[317] Newborns and young infants are at low risk for the development of infection, presumably because they have maternally acquired antibody. Young children at highest risk of acquiring disease have low or undetectable levels of antibody, whereas older children at lower risk have higher antibody levels. By the time they reach 5 years of age, most children have naturally acquired anticapsular antibody that appears to provide protection,[157,341] although natural exposure also induces antibodies to OMPs, LPS, and other surface antigens of the bacteria that contribute to natural immunity. The evidence that anticapsular antibodies protect humans from the acquisition of invasive Hib disease is considerable: they activate complement,[367,419] are opsonophagocytic[273] and bactericidal,[125,273] and protect animals from lethal Hib challenge.[370] Moreover, passive prophylaxis with serum preparations containing anticapsular antibody protects agammaglobulinemic patients[317] and high-risk children from the acquisition of invasive Hib disease.[328] Furthermore, in the pre-antibiotic era, immune serum was an effective therapy for Hib disease,[7,299] However, the most compelling evidence for the protective efficacy of PRP antibody is the clinical protection achieved in older children vaccinated with purified PRP vaccine[288] and in younger infants immunized with Hib conjugate vaccines.[289] Induction of antibody to Hib polysaccharide is the immunologic basis of all Hib vaccines.

A precise minimal level of anti-PRP antibody that is protective has not been established.[148] Data from passive protection of agammaglobulinemic children, challenge experiments in infant rats, and studies of naturally acquired antibody levels in healthy individuals of various ages suggest that the minimal serum concentration of anti-PRP antibody that provides protection ranges from 0.05 μg/mL in animals[342] to 0.15 to 1.00 μg/mL in humans.[189,288] Such estimates are crude and do not take into account the different functional properties of different immunoglobulins[150,219] or the contribution of antibodies to other Hib antigens. In addition, antibody levels decline over the course of time, and a given peak level may not reflect levels at the time of exposure, which would predict long-term protection better.[17,288] In a Finnish PRP vaccine trial, an antibody level greater than 1.0 μg/mL 1 month after immunization correlated with clinical protection for a minimum of 1 year.[288] However, this antibody level may not be extrapolated readily to the immunogenicity data evaluated in different studies or with different Hib conjugate vaccines.

CLASS- AND SUBCLASS-SPECIFIC ANTIBODY

Several studies have shown variable immunoglobulin class, isotype, idiotype, and IgG subclass responses to PRP polysaccharide after natural Hib exposure, disease, and immunization.[190,342] Most individuals respond with IgG antibodies after receiving PRP immunization, although some children have predominantly IgA or IgM responses.[190] Schreiber and associates[342] showed that IgG antibody is bactericidal, opsonic for polymorphonuclear leukocytes in the presence of complement, and protective for animals. IgM antibody is equally protective and more bactericidal than is IgG in the presence of complement, but it opsonizes poorly. IgA antibody is not bactericidal, opsonic, or protective for animals. Some researchers have hypothesized that IgA-specific antibody blocks the activity of other more functional antibodies and thereby may depress immunity.[264]

Data from experiments in mice and humans suggest that polysaccharide antigens induce restricted IgG subclass responses.[315] The findings of increased susceptibility to Hib disease in IgG subclass–deficient patients (predominantly IgG2 and IgG4 deficiencies),[282,344] and the low levels of IgG2 in children younger than 2 years of age[349] suggest that differences exist in the role of subclass-specific anticapsular antibodies. In adults, natural exposure or immunization with PRP vaccine results in a predominantly IgG2 subclass response.[307] In children, IgG1 and IgG2 antibodies develop after they receive PRP immunization, but IgG1 antibodies predominate after immunization with Hib conjugate vaccines.[12,173,187] Human anti-PRP antibodies express predominantly kappa light chains,[376] and these antibodies may be grouped into a few restricted clonotypes. These clonotypes and antibody specificities have been characterized by idiotype analysis[218,221] and by amino acid sequencing of the immunoglobulin light chain.[376] Individuals of different ages produce different proportions or repertoires of antibody.[220] Some differences in binding specificity and affinity have been described with the different anti-PRP antibodies,[219,338] but whether the antibodies have different degrees of protective potency or are substantially different in proportion in individuals given different vaccines is not clear.

The role of mucosal immunity in killing Hib or inhibiting adherence or penetration of the mucosa is understood poorly, although studies of secretory IgA antibody to the Hib capsule have been conducted.[296,297] Moreover, Hib strains produce IgA proteases that can inactivate mucosal antibody.[115,252] The observation of reduced carriage of Hib in children given Hib conjugate vaccines[263,373] suggests that mucosal immunity may be important in reducing transmission of the disease.

CELLULAR IMMUNE RESPONSES

Most of our understanding of the interactions of B cells, T cells, and antigen-presenting cells (macrophages) is derived from extensive research in mice.[87] Based on T-cell involvement in antibody synthesis, antigens can be classified as T-dependent (thymus-dependent) or T-independent immunogens. Because most protein antigens induce helper T-cell regulation of antibody synthesis, they are considered T-dependent. These antigens first are recognized and processed by macrophages and then are presented to both T and B cells. The activated T cells induce proliferation and differentiation of specific antigen-reactive B-cell subpopulations. They also retain the memory necessary for subsequent booster responses.[32] Through the release of cytokines, helper T cells appear to regulate the following: (1) the magnitude of the immune response, especially in young infants; (2) the switch in immunoglobulin classes (IgM to IgG); (3) the functional activity of antibody; and (4) the capacity to elicit immunologic memory.

Polysaccharides consist of repeating oligosaccharide units and elicit weak immune responses involving minimal T-cell influences.[32] These T-independent antigens elicit antibody responses primarily by direct stimulation of B cells. In general, polysaccharide vaccines have the following T-independent immunologic characteristics: (1) delayed ontogeny of immune responsiveness in the young, (2) limited and variable quantitative immune responses, (3) restricted isotype (predominantly IgM) and IgG subclass responses, and (4) lack of a booster or anamnestic response with secondary antigenic challenge. The quest for an Hib vaccine that is immunogenic and protective in young infants has involved attempts to convert the PRP antigen from a T-

independent to a T-dependent antigen by using the carrier-hapten principles first defined by Landsteiner in the first half of the 20th century.[204] PRP can be considered a hapten that is linked covalently to a T-dependent immunogen, a carrier, to form a conjugate vaccine. The Hib conjugate vaccines, which demonstrate markedly enhanced immunogenicity, are described in a subsequent section.

GENETIC FACTORS

When compared with protein vaccines, the immune responses to most polysaccharide antigens are variable and may be influenced by genetic factors. Several studies have shown associations between the immune responses to PRP vaccine and genetically determined factors such as red blood cell antigens, human leukocyte antigen, or immunoglobulin allotypes.[11,154,348,416] However, because many factors influence immunogenicity, whether these associations have relevance is not known, and establishing controls for them is difficult. In addition, whether the antibody differences are important clinically also is not known. No single genetic relationship regulating susceptibility or the immune responses to polysaccharide antigens has been demonstrated convincingly.

COMPLEMENT

The importance of complement components in host defense against Hib is substantiated by elimination of the bactericidal activity of serum by heat, by the susceptibility of complement-depleted animals to Hib disease, and by the increased susceptibility of patients with specific congenital complement deficiencies.[83,367,419] Hib is capable of activating both the classical and the alternative complement pathways,[83,367] thereby initiating opsonophagocytosis and cell killing and eliciting other inflammatory responses. Whereas the alternative pathway probably is most important early in the course of infection in a nonimmune host, the antibody-dependent classical complement pathway is more likely to predominate as a defense mechanism at a later stage of infection.[419] Both encapsulated and unencapsulated organisms activate complement, thus underscoring the importance of noncapsular antigens in host defense.[265,266] Although the Hib capsule is a poor activator of the alternative complement pathway, antibody to the capsule activates both the classical and the alternative pathways.[367] Other cell wall antigens activate the alternative pathway, and antibody to these antigens activates the classical pathway.[83,367,419] Thus, antibodies to both capsular and noncapsular antigens activate the complement system, primarily through the classical pathway. Activation of the terminal complement components mediates the bactericidal activity of serum.

Studies have explored the contribution of LPS structure to the susceptibility of *H. influenzae* to complement-dependent serum bactericidal activity.[117,161,223,411] Phase-variable structural modifications to the core LPS structure, including additions of phosphorylcholine,[412] sialic acid,[347] and other carbohydrate moieties,[102] all have been shown to influence the susceptibility of these organisms to complement-mediated killing. Related studies in animal models of infection also have demonstrated the importance of these phase-variable LPS modifications to disease pathogenesis in vivo.[47,117,381,411]

PHAGOCYTOSIS

Opsonization leading to phagocytosis and killing of *H. influenzae* also is an important determinant of host defense.[265,266,370,421] Impairment of phagocytic function or a reduction in the number of phagocytes results in increased susceptibility to disease, as does loss of the spleen or impairment of its function (e.g., hemoglobinopathies).[70,302] The opsonic activity of serum is influenced greatly by the roles of complement and antibody. Opsonization and phagocytosis of Hib appear to be dependent on (1) IgG binding, (2) antibody activation of the classical complement pathway with deposition of C3b on the bacterial surface, and (3) direct bacterial activation of the alternative complement pathway.[275] Relatively little is known about direct cell-mediated killing of *H. influenzae*.[96]

EPIDEMIOLOGY

HAEMOPHILUS INFLUENZAE TYPE b

Humans are the only natural host for *H. influenzae*, and asymptomatic nasopharyngeal carriage, usually by unencapsulated strains, is a common finding.[108,233] In the era before widespread use of Hib conjugate vaccines, nasopharyngeal acquisition of Hib strains also was quite common and was shown to increase after infancy and to persist for weeks to months. Most children were colonized at some time during the first 5 years of life.[233] Colonization rates greater than 70 percent occurred after recent exposure in closed populations, such as among family members or daycare center contacts of a patient with disease.[261] Person-to-person transmission occurred through respiratory droplets, and fomites also were thought to play a role. As Hib conjugate vaccine administration became part of the routine infant immunization schedule in many countries, an associated and pronounced drop in the rate of nasopharyngeal carriage of Hib strains occurred.[262,373]

Before immunization was developed, invasive Hib disease was a leading infectious disease problem worldwide that affected primarily young children (Table 145–2).[401,415,418] Hib strains are responsible for more than 95 percent of invasive infections in children. According to population-based studies, an estimated 20,000 to 25,000 persons acquired invasive Hib disease annually in the United States, 85 percent of which occurred in children younger than 5 years of age.[49] The incidence of Hib meningitis and all invasive Hib disease was 40 to 69 and 67 to 130 cases per

TABLE 145–2 Worldwide Incidence of Invasive *Haemophilus influenzae* Type b Disease before the Use of Hib Vaccines in Children Younger than 5 Years

Region	Years	Hib Meningitis*	All Hib Disease*
Australia/New Zealand	1985-1987	25-53	39-92

100,000 children younger than 5 years, respectively. Invasive Hib disease developed in an estimated 1 in every 200 children in the United States during the first 5 years of life.[77] Hib pneumonia was estimated to cause as many as 15 percent of cases of ambulatory pneumonia in children younger than 6 years old, but the true incidence was unknown because microbiologic diagnosis is difficult to establish. Overall, the incidence of Hib disease in the pre-vaccine era was similar to that of paralytic poliomyelitis during its peak epidemic years before immunization. A bimodal seasonal pattern had been observed in several studies, with one peak occurring between September and December and a second peak between March and May.[311,415] The attack rate of Hib was slightly higher in boys.[225]

The widespread use of Hib conjugate vaccines altered the epidemiology of invasive Hib disease dramatically (Fig. 145–1). The first Hib conjugate vaccine was licensed in the United States in 1987 for use in children aged 18 months or older.[64] Subsequently, decreases in the incidence of Hib disease were seen in older children and, unexpectedly, in unimmunized infants and children as well. This finding was attributed to a direct effect of vaccination on nasopharyngeal carriage, thus decreasing the environmental burden of Hib infection and, ultimately, the transmission of disease. In late 1990, Hib conjugate vaccines were approved for use in infants as young as 2 months of age, and this advance heralded a dramatic decline in the incidence of invasive Hib disease in all children.[65] In populations in which immunization rates are high, the development of invasive Hib disease has been eliminated almost completely.

Some population-based studies of the incidence of *H. influenzae* disease were conducted outside the United States, primarily in Western Europe, and they showed an incidence approximately one third to two thirds of that in the United States.[286,327,363] The incidence of Hib disease is especially high in certain ethnic groups, including the following: Aboriginal children in central Australia[166]; Navajo Native Americans; Native Alaskans; and Apache, Yakima, Athabaskan, and Canadian Native Americans.[217,246,409,426] *H. influenzae* appears to rank as a leading cause of bacterial meningitis in some developing countries as well.[9,54,362,404,425] As was seen in the United States, a substantial reduction in Hib disease occurred with the implementation of widespread vaccination programs. Studies in Asia showed a disease incidence one tenth to one thirtieth of that in the United States before the introduction of vaccine, but methodologic questions exist regarding the accuracy of these disease assessments, particularly related to antibiotic use and the validity of culture results.[425]

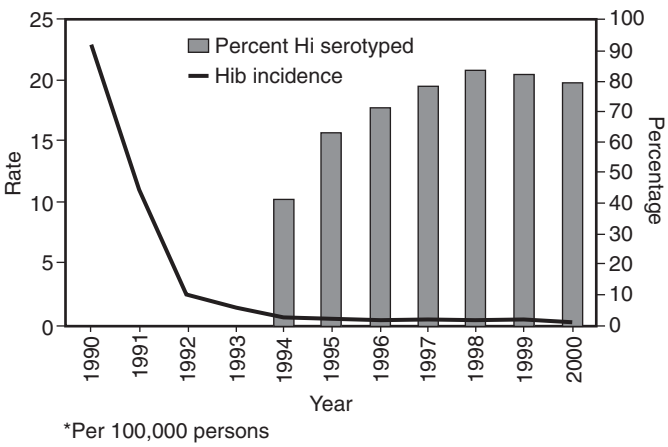

Figure 145–1 Incidence rate of *Haemophilus influenzae* type b (Hib) invasive disease per 100,000 persons and the percentage of *Haemophilus influenzae* (Hi) isolates serotyped in children younger than 5 years—United States, 1990-2000. *(From Centers for Disease Control and Prevention: Progress towards elimination of Haemophilus influenzae type b invasive disease among infants and children—United States, 1998-2000. M.M.W.R. Morb. Mortal. Wkly. Rep. 51[11]:234-237, 2002.)*

Children between the ages of 6 and 18 months are at highest risk for acquiring invasive Hib disease[225]; however, the age distribution of specific clinical syndromes of the disease varies. The peak incidence of Hib meningitis occurs in children 6 to 9 months of age and declines markedly after 2 years of age.[129,375] Hib cellulitis tended to occur during the first year of life, whereas epiglottitis generally occurred in unimmunized children older than 2 years of age. Invasive *H. influenzae* disease was seen much less frequently in adults because of the development of protective antibodies over the course of time, but it occurred more frequently in immunocompromised patients. Nonetheless, Hib caused pneumonia and meningitis in adults,[109,292] and diseases caused by other serotypes and nontypeable strains, especially pneumonia, otitis media, bronchitis, and sinusitis, are common findings in all age groups.[256] Most adults in whom invasive *H. influenzae* disease develops were not immunized as children and have an underlying condition such as chronic obstructive pulmonary disease, human immunodeficiency virus (HIV) infection, alcoholism, pregnancy, or malignancy.[50,109,292]

The development of invasive Hib disease in a given individual is the consequence of a complex interaction of a variety of factors, including the risk of exposure, the characteristics of the organism, and the host.[127] In populations that experienced a high incidence of disease, such as Native Americans or Alaskans, the age-specific incidence peaked in a younger age group (<6 months), presumably because of early or intense exposure to Hib at home or in the community.[222] Several factors that may reflect environmental exposure to the organism, such as household size,[149] crowding,[388] attendance at a daycare center,[78,177] low family income,[27,128,129] and low parental education level,[128,129] have been shown to be risk factors for the acquisition of disease, whereas breast-feeding appears to be protective.[293] Several underlying medical conditions, including HIV infection,[60,337] sickle-cell anemia,[302] asplenia or splenectomy,[70] antibody[110] and complement deficiency syndromes,[118] and malignancy,[413] are associated with an increased risk for the acquisition of Hib disease.

Although the direct contagiousness of invasive Hib disease is limited, small outbreaks and direct secondary transmission of disease can occur.[55,406,407] Numerous studies estimated the risk of developing secondary disease in household contacts in the 30 days after the onset of disease in an index case. Overall, the attack rate for contacts of all ages in the pre-vaccine era was 0.3 percent, which represents a risk approximately 600-fold higher than the age-adjusted risk in the general population.[55,406] However, attack rates varied inversely with age, with children younger than 4 years old being at greatest risk. Among household contacts, nearly two thirds of secondary cases occurred within the first week after the onset of disease in the index patient.[375] Controversy continues about the degree of risk for the development of secondary Hib disease in daycare center contacts exposed to a child with invasive Hib disease. Such risk in unimmunized children younger than 2 years of age ranged from 0 to 3.2 percent,[27,279] whereas the risk for those older than 2 years was less than 1 percent.

A cause for concern in recent years has been the reappearance or persistence of Hib disease in highly immunized populations.[23,238-240,358] The factors underlying these problems are still the subject of debate, but with the reemergence of Hib disease in the United Kingdom in the late 1990s, attention focused on the lack of a booster dosing of infants as part of the regular immunization series and the decreased immunogenicity of combination vaccines in which the Hib conjugate vaccine was com-

bined with acellular pertussis vaccine components.[238,239] The Alaskan experience uncovered other problems.[358] In this population, high Hib nasopharyngeal carriage rates in the rural population and the poor antibody response of young infants to certain Hib vaccines appeared to be responsible for the reappearance of Hib disease in Native Alaskans.[357,358]

NON–TYPE b ENCAPSULATED *HAEMOPHILUS INFLUENZAE*

H. influenzae organisms expressing one of the five non–type b capsular types are also carried in the nasopharynx of a small percentage of the population.[84,233] With the success of the Hib conjugate vaccine in preventing invasive disease caused by type b organisms, concern has been expressed that disease caused by other encapsulated strains could become more prevalent.[65] Indeed, several clusters of invasive disease caused by *H. influenzae* type a have been reported during the past few years,[5,185,292,313] as have occasional cases of disease caused by other serotypes.[278,387] However, surveillance studies for the most part have failed to document a sustained increase in the incidence of disease caused by non–type b serotypes after introduction of the Hib conjugate vaccines.[65] These data suggest that the concern about serotype replacement may be more theoretical than actual.

NONTYPEABLE *HAEMOPHILUS INFLUENZAE*

Asymptomatic colonization of the mucous membranes of the upper respiratory tract by nontypeable *H. influenzae* strains is very common, occurring in 60 to 90 percent of young children.[202] Infants often become colonized with nontypeable *H. influenzae* early during the first year of life.[106] Nasopharyngeal colonization is a dynamic process characterized by relatively rapid turnover of individual strains and, not infrequently, simultaneous carriage of several distinct clones.[84,108] With increasing age, nasopharyngeal carriage of nontypeable *H. influenzae* occurs less frequently, but it is still present in a significant percentage of the population.[202] Nontypeable *H. influenzae* organisms are associated only rarely with invasive disease,[103,276] but they are a common cause of mucosal surface infections such as otitis media, sinusitis, bronchitis, and occasionally pneumonia.[207,208,256,396]

CLINICAL MANIFESTATIONS

BACTEREMIA

Occult bacteremia (i.e., not associated with a primary focus of infection) is not a common occurrence with Hib, but bacteremia does precede essentially all invasive Hib infections. In the prevaccine era, Hib was the second leading cause, after *Streptococcus pneumoniae*, of occult bacteremia primarily affecting children 6 to 36 months of age.[16] Most children initially have fever and peripheral leukocytosis. Unlike *S. pneumoniae* bacteremia, the condition is not benign. In approximately 30 to 50 percent of children with occult Hib bacteremia, a focal infection such as meningitis, pneumonia, or cellulitis develops.[81,197]

MENINGITIS

Meningitis is the most serious manifestation of invasive Hib disease; however, no clinical feature differentiates Hib meningitis from other causes of bacterial meningitis in children.[111] The onset of disease can be fulminant,[178] but more commonly the signs and symptoms are nonspecific (particularly in young infants) and may include irritability, fever, lethargy, poor feeding, or vomiting. Children younger than 18 months old often do not have nuchal rigidity. Older children are more likely to have headache, photophobia, and meningismus. With fulminant Hib meningitis, very rapid neurologic deterioration may occur with increased intracranial pressure, seizures, coma, and respiratory arrest.[111] Ten to 20 percent of children with meningitis will have other foci of infection such as cellulitis, arthritis, or pneumonia,[26,119] and essentially all have concomitant bacteremia.

CSF examination typically reveals pleocytosis (mean, 4000 to 5000 white blood cells/μL) with a predominance of polymorphonuclear leukocytes.[93] Approximately 75 percent of patients have hypoglycorrhachia, and approximately 90 percent have an elevated CSF protein concentration. Eighty percent of meningitis cases caused by Hib will have a positive CSF Gram stain. As with other types of bacterial meningitis, however, previous antimicrobial therapy significantly decreases the concentration of Hib organisms in the CSF and diminishes the sensitivity of Gram staining.[39] Previous treatment does not affect the total blood cell count and differential, glucose, or protein substantially, thus permitting a diagnosis of meningitis to be made. In more than 90 percent of cases, capsular antigen can be detected in CSF or serum.[410] Anemia, leukocytosis, thrombocytosis, and thrombocytopenia also are observed frequently.[111]

Complications of Hib meningitis include seizures, cerebral edema, subdural effusions or empyema, inappropriate secretion of antidiuretic hormone, cortical infarction (often manifested by focal neurologic abnormalities), cerebritis, intracerebral abscess, hydrocephalus, and, rarely, cerebral herniation.[44,93,111,301] Computed tomography (CT) and magnetic resonance imaging (MRI) of the head should not be performed routinely for Hib meningitis, but these studies may be helpful if focal neurologic findings are present or if the clinical course becomes complicated. Small subdural effusions are common findings but usually do not have clinical significance.[111]

Even with prompt intensive care, the mortality rate from Hib meningitis is approximately 5 percent, and significant long-term morbidity, including sensorineural hearing loss, delay in language acquisition, developmental delay, gross motor abnormalities, vision impairment, and behavior abnormalities, may occur in 15 to 30 percent of survivors.[93,94,111,301,377] A substantial proportion of such abnormalities may resolve over time, thus emphasizing the need for long-term monitoring of these patients.[111]

PNEUMONIA

Hib pneumonia is clinically indistinguishable from other bacterial pneumonias.[142,397] Most patients have a preceding upper respiratory tract infection, fever, and cough accompanied by peripheral leukocytosis with a predominance of polymorphonuclear leukocytes. Radiologically, Hib pneumonia may be segmental, lobar, interstitial, or diffuse, and many patients have evidence of pleural or pericardial involvement on radiographic examination. Cavitation and pneumatoceles are rare occurrences but have been reported.[15,71] CT or MRI can be useful adjuncts to the evaluation of complicated disease caused by Hib.[76] Blood, pleural fluid, tracheal aspirate, and lung aspirate cultures are positive in 75 to 90 percent of cases. Detection of capsular polysaccharide in pleural fluid, serum, or urine can establish the diagnosis, particularly if antimicrobial therapy had been instituted previously. Although fever may persist for several days while the patient is receiving adequate therapy, uncomplicated Hib pneumonia rarely is associated with long-term pulmonary dysfunction. In the developing world, in addition to disease caused by Hib, pneumonia caused by nontypeable *H. influenzae* is a continuing problem[135,207] that also is associated with significant morbidity and mortality rates.

EPIGLOTTITIS

Acute upper airway obstruction caused by Hib infection of the epiglottis and supraglottic tissues occurred in the pre-vaccine era, primarily in children 2 to 7 years of age.[33,241] Its onset usually is abrupt, with high fever, sore throat, dysphagia, and sepsis. Antecedent upper respiratory tract infection with cough occurs in approximately 50 percent of patients.[48,216] The child may drool because of an inability to swallow oropharyngeal secretions, and progressive respiratory distress with tachypnea, stridor, cyanosis, and retractions may develop over a period of hours. The child usually is agitated and may sit forward with the chin extended to maintain an open airway. In children younger than 2 years old, Hib epiglottitis may be manifested in an atypical fashion, with low-grade fever and a cough suggestive of croup.[216]

The most important aspect of the management of a child with epiglottitis is maintenance of a patent airway. Nasotracheal intubation is preferable to tracheostomy because it is equally effective, is not permanent or disfiguring, and has fewer inherent risks.[33] Seventy to 90 percent of patients with epiglottitis will have positive blood cultures; tissue for culture of the inflamed epiglottis should be obtained only after the airway has been secured. A lateral neck radiograph revealing dilatation of the hypopharynx and the "thumbprint" sign (swollen epiglottis)[46] can be helpful if the clinical findings are subtle, but in most cases, diagnostic studies should not delay intubation and direct inspection of the epiglottis in controlled surroundings. The mortality rate is 5 to 10 percent, almost always related to abrupt airway obstruction.

JOINT INFECTION

Before the use of Hib conjugate vaccines became routine, Hib was the leading cause of septic arthritis in children younger than 2 years of age.[119] This condition affects a single large joint at the knee, ankle, elbow, or hip in more than 90 percent of cases. Contiguous osteomyelitis occurs in 10 to 20 percent.[119,205] No feature clearly distinguishes septic arthritis caused by Hib from that of other bacterial causes. Patients initially are febrile, and more than two thirds have decreased range of motion, local warmth, and swelling.[85,119,205] Usually, pain, swelling, and erythema of the involved joint are preceded by a nonspecific upper respiratory illness. The clinical features may be subtle, with only decreased range of motion of the joint or abnormal gait as the initial finding. Hib capsular antigen concentrations are very high in the infected joint fluid of children with septic arthritis, and rapid detection of antigen is useful diagnostically. Septic arthritis of the hip requires surgical drainage, and resolution generally is rapid, but long-term cartilage damage may result from Hib arthritis despite adequate therapy.[377]

CELLULITIS

Cellulitis is a relatively uncommon form of Hib disease and was seen in the pre-vaccine era almost exclusively in children younger than 2 years of age. Most cellulitis (74%) is located in the cheek (buccal cellulitis), the periorbital region, and the neck[85] and rarely on the extremities. Facial cellulitis occurs most commonly in infants and is manifested as acute fever and a unilateral, raised, warm, tender and indurated area that may progress to a violaceous hue, although this finding is not unique to Hib disease.[379] Aspirate cultures of the point of maximal swelling usually yield the organism, and bacteremia is a typical finding.[122,175] A secondary focus (including meningitis) may be present in 10 to 15 percent of patients.[26] Orbital cellulitis generally is a complication of ethmoid sinusitis and, consequently, can be caused by non-Hib strains. An etiologic diagnosis can be established by blood culture or aspiration of subcutaneous tissues. Antibiotics always are indicated, but the need for surgical drainage depends on the degree of involvement of the tissues within the orbit.

PERICARDITIS

Hib pericarditis usually is a complication of adjacent pneumonia and is characterized by fever, an ill appearance, respiratory distress, and tachycardia.[68,97,314] The radiographic or clinical diagnosis can be confirmed by two-dimensional echocardiography,[423] and it may be suggested by finding capsular polysaccharide in serum or pericardial fluid or in Gram-stained pericardial fluid. Cultures of pericardial fluid are positive in more than 70 percent of cases.[85] Early drainage is an important part of the management of this illness, and early pericardectomy or pericardiostomy is preferred over repeated pericardiocentesis.[248,314]

NEONATAL DISEASE

H. influenzae causes 2 to 8 percent of neonatal early-onset sepsis.[56,171,402] Most of these cases are caused by nontypeable strains, most of which are concordant with those isolated from the maternal genital tract.[402] The precise pathogenesis is unknown, but neonatal disease often is associated with prematurity, low birth weight, premature rupture of membranes, and maternal chorioamnionitis; several cases have occurred after cesarean delivery, thus suggesting in utero transmission.[324] Clinical manifestations include pneumonia, bacteremia, and conjunctivitis. More than two thirds of neonatal *H. influenzae* disease occurs on the first day of life, with an overall mortality rate of 55 percent.[132]

OTHER INVASIVE INFECTIONS

Other invasive Hib infections include endophthalmitis,[378] CSF shunt infections,[210,312] necrotizing fasciitis, pyomyositis,[270] peritonitis,[74,131] scrotal abscess,[215] brain abscess,[113] polyserositis,[243] tenosynovitis,[269] epididymitis,[156] lung abscess,[214] periappendiceal abscess,[235] and bacterial tracheitis.[59] Invasive disease also may be characterized by fever alone, fever with petechiae, or fever of unknown origin.[51,393]

DISEASES CAUSED BY NON–TYPE b *HAEMOPHILUS INFLUENZAE*

Respiratory tract infections associated with nontypeable *H. influenzae* are a major cause of morbidity and mortality today in both developed and nonindustrialized nations.[207,401] Previously, invasive disease caused by nontypeable *H. influenzae* was a rare occurrence and generally was associated with underlying medical conditions such as prematurity, malignancy, cystic fibrosis, asthma, leakage of CSF, CNS shunts, congenital heart disease, lymphoproliferative disorders, and immunoglobulin deficiency.[107,137,274] More recently, with a decline in the rate of infections caused by Hib, other *H. influenzae* serotypes such as types a, e, and f, and nontypeable strains have become relatively more common causes of both mucosal surface infection and invasive disease.[170,185,382,387]

Invasive disease caused by non–type b *H. influenzae* has been reported more frequently in recent years, although it is unclear that the absolute incidence of disease has increased.[65] Several clusters of cases of invasive disease caused by *H. influenzae* type a have been reported.[5,164,165,185,278] One such report suggested that

an IS1016-bexA deletion present in the chromosome of the recovered type a strains, a deletion similar to that present in many Hib strains,[200] could be a marker for more virulent type a clones.[5] Other serotypes also have been reported as causing cases of non–type b disease.[278] Urwin and associates[387] identified 91 cases of invasive *H. influenzae* type f disease in a multistate area over the course of a 6-year period. The incidence of invasive type f disease was 0.5 cases per 1 million population in 1989 and 1.9 cases per 1 million population in 1994. In children, pneumonia and meningitis each accounted for 40 percent of the total cases. Overall, the mortality rate from type f *H. influenzae* disease was 21 percent in children. Serotype f also has been reported as a cause of endocarditis[130] and septic arthritis[143] in healthy, normal children.

Invasive disease in normal children caused by nontypeable *H. influenzae* also has been reported occasionally.[103,274] Heath and associates[170] conducted an active prospective surveillance study of *H. influenzae* infections in the United Kingdom and Republic of Ireland. During the study period (October 1992 to December 1998), 102 cases of invasive disease caused by nontypeable *H. influenzae* were reported. Children with nontypeable *H. influenzae* infection were compared with those who had Hib disease. The former were more likely to be younger (16 vs. 22 months) and more likely to have pneumonia and bacteremia ($p < .001$) than were those with Hib disease. In 1998, the incidence of non–type b *H. influenzae* disease in all children younger than 5 years of age in the United Kingdom was 1.3 per 100,000, versus 0.6 per 100,000 population for Hib disease. Most non–type b strains isolated were nontypeable.

Mucosal Infections

Unencapsulated or non-Hib strains cause a variety of mucosal infections, including otitis media, sinusitis, conjunctivitis, and bronchitis.[195,208] *H. influenzae* is the second leading cause of acute otitis media in adults and children,[195] and it has features similar to those of other causes of otitis, namely, fever and symptoms referable to the upper respiratory tract in addition to nonspecific symptoms such as irritability, vomiting, and diarrhea.[209] Data published in 2004 suggest that nontypeable *H. influenzae* is the most common cause of persistent and recurrent middle ear disease, particularly in populations that have received the pneumococcal conjugate vaccine.[40,61,290] Sinusitis caused by nontypeable *H. influenzae* may be manifested as common cold symptoms that are persistent or more severe than usual.[396,398,399] Older children and adults are more likely to complain of headache and paranasal, dental, or facial pain. Other common symptoms are a daytime cough that may worsen at night or reactive airway disease unresponsive to therapy. Rarely, chronic otitis or sinusitis may result in the development of mastoiditis or a parameningeal abscess.[186] Conjunctivitis usually is bilateral and purulent and may occur in outbreaks.[41-43] Though common, these infections rarely are life-threatening and are not associated with bacteremia.

DIAGNOSIS

A high index of suspicion for the possibility of Hib disease must be maintained when evaluating children with appropriate clinical manifestations and findings. The primary criterion for the diagnosis of *H. influenzae* infection is Gram stain or isolation of the organism from an infected focus (e.g., CSF, pleural fluid, sputum, or blood). Because most invasive Hib disease is associated with bacteremia, blood cultures should be performed for any febrile child with potential Hib disease.[197] The specimens need to be processed immediately because the organism is fastidious. Although most commercial blood culture media support the growth of *H. influenzae*, the inoculum should be applied, when possible, directly to chocolate agar or a semi-synthetic medium containing heme and NAD.[22,134,192,291] In liquid medium, growth may not be sufficient to result in turbidity; therefore, for blood cultures, advanced detection systems or subcultures should be performed.[192] In addition, selective media that suppress the growth of gram-positive organisms may increase the recovery of *H. influenzae* from upper respiratory tract specimens.[67] Identification of an isolate as *H. influenzae* relies on its dependence on heme and NAD.[192]

Other techniques that may assist in microbiologic diagnosis include rapid antigen detection, staining techniques, and immunofluorescence.[184,230,410] Such techniques are useful in the context of a patient whose cultures are sterile because of previous antibiotic therapy, or they can confirm the clinical diagnosis before bacterial growth occurs. The three techniques most commonly used for antigen detection are latex particle agglutination (LPA), countercurrent immunoelectrophoresis (CIE), and coagglutination (CoA). False-positive results on CSF are rare by all three tests; however, false-positive reactions have occurred when testing serum and urine. False-positive reactions occur as a result of nonspecific agglutination (i.e., rheumatoid factors) and because of antigenic cross-reactivity with *Escherichia coli*, *S. pneumoniae*, staphylococci, or meningococcus. Overall, LPA appears to be more sensitive than is CoA, and LPA and CoA are more sensitive than is CIE in CSF, serum, urine, joint fluid, and pleural fluid.[184,230,237] False-positive results can occur in the urine of children with nasopharyngeal carriage of the organism or, more commonly, for several days after immunization with Hib conjugate vaccine.[364] Acridine orange is a fluorescent stain that binds to cellular nucleic acids and may be useful in situations in which smaller bacterial concentrations are present.[194] Immunofluorescent staining of purulent specimens from patients with partially treated disease also has been useful.[75]

TREATMENT

INVASIVE DISEASE

Bacteremia plays a central role in the pathogenesis of invasive Hib disease; therefore, occult invasion of the CNS always must be considered in the context of any manifestation of Hib infection.[141,197] In addition, severe Hib disease often is fatal if it is not treated adequately. Therefore, elimination of Hib bacteremia and its complications requires antimicrobial therapy that will (1) penetrate the blood-brain barrier to achieve bactericidal concentrations and (2) be of adequate duration to sterilize the primary and potential secondary foci. The choice of specific antibiotic therapy must take into account the local antibiotic susceptibility patterns of invasive isolates (Table 145–3). *H. influenzae* resistance to several antimicrobials, including ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, rifampin, and certain second-generation cephalosporins, has been increasing in several areas of the world.[95,169,183]

For proven or suspected Hib meningitis, cefotaxime or ceftriaxone is recommended until the antibiotic susceptibility of the organism is known or an alternative diagnosis is established.[111] Both antibiotics have bactericidal activity against Hib strains, including those that produce β-lactamase, and they penetrate effectively into infected CSF and are well-tolerated. Cefuroxime should not be used for the treatment of *H. influenzae* meningitis because delayed sterilization of CSF may be at least twofold more common than with ampicillin plus chloramphenicol or with the third-generation cephalosporins.[20,359] Moreover, ampicillin, formerly a mainstay of therapy for this infection, should not be used empirically to treat infections caused by Hib because as many as 50 percent of Hib isolates in the United States are resistant,

TABLE 145–3 Selected Antimicrobial Agents for Treatment of *Haemophilus influenzae* Infections

Antimicrobial Agent	Total Daily Dose (mg/kg)	Dose Frequency
Parenteral Antibiotics*		
Ampicillin†	200-400	q4-6h
Cefuroxime‡	75-150	q8h
Cefotaxime	150-200	q6-8h
Ceftriaxone	50-100	q12-24h
Oral		
Amoxicillin§	40-90	tid/bid
Amoxicillin-clavulanate	40-90	tid/bid
Erythromycin-sulfisoxazole§	40 (erythromycin)	qid
Trimethoprim-sulfamethoxazole§	8 (trimethoprim)	bid
Clarithromycin§	15	bid
Azithromycin§	10	qd
Cefuroxime axetil	30	bid
Cefprozil	30	bid
Cefpodoxime	10	bid
Cefixime	8	qd

**Other parenteral agents may be used in special circumstances, but they should not be considered first line. Such agents include ureidopenicillins, carbapenems, and fluoroquinolones.*

†*Not to be used presumptively because of the prevalence of resistant strains.*

§*Do not use these oral agents if resistance is suspected or prevalent in your area.*

usually through plasmid-mediated β-lactamase production.[183] Chloramphenicol, another medication that frequently was used to treat Hib disease,[244,325] now rarely is used because safer antibiotics with greater activity are available. Although adequate bactericidal blood and CNS levels of chloramphenicol can be achieved, even with oral administration,[112,332] the use of this agent requires monitoring of drug levels. Dose-dependent, yet reversible, bone marrow toxicity may occur, particularly in neonates, in patients with liver disease, or in those who require prolonged treatment.[244] Idiosyncratic aplastic anemia, a dose-independent complication of chloramphenicol use, is an extremely rare occurrence.

Cefuroxime has good activity against *H. influenzae* and is useful for empiric treatment of nonmeningitic infections such as pneumonia, periorbital cellulitis, and septic arthritis.[392] Other parenteral agents that have activity against *H. influenzae* include meropenem, ampicillin-sulbactam, aztreonam, and other third-generation cephalosporins such as ceftazidime.[234] In general, the spectrum of activity of these agents is too broad for routine use in pediatric infections in which Hib is an important pathogen.

Children with occult Hib bacteremia need to be reevaluated carefully because focal disease may develop in 30 to 50 percent of such patients who are clinically well.[81,197] The duration of therapy is determined by the site of infection and the clinical response. Children with uncomplicated Hib meningitis can be treated for 10 days.[14,111] Children with Hib cellulitis can be switched to oral therapy after several days of parenteral therapy, provided these patients have had a satisfactory clinical response and do not have meningitis. Patients with septic arthritis should receive at least 10 to 14 days of therapy,[119] whereas children with pericarditis, empyema, or osteomyelitis may require longer courses of antibiotic treatment (3 to 6 weeks).[68,119] These patients often can be switched to oral antibiotics after susceptibility, a good therapeutic response, and adequate antimicrobial blood levels have been documented and compliance has been ensured.

Equally important in the overall management of a child with invasive Hib disease is supportive care. For Hib meningitis, several studies showed that adjunctive therapy with dexamethasone moderates the inflammatory cascade and may decrease the likelihood of hearing loss.[277] The recommended dose is 0.6 mg/kg/day given every 6 hours for 4 days, with the first dose administered just before or concurrently with the first antibiotic dose.[14,277,303] Management of a child with meningitis requires continuing careful evaluation for complications such as the development of shock, inappropriate secretion of antidiuretic hormone, seizures, subdural empyema, and secondary foci of infection.[93,94,301] Prolonged fever is a common occurrence, with approximately 10 percent of children febrile for at least 10 days.[111] Repeat lumbar puncture to document sterility of the CSF is not necessary in uncomplicated cases.

In children with epiglottitis, protection of the airway is the most important component of therapy and should be initiated even before the administration of antimicrobials.[46] Endotracheal intubation or tracheostomy is performed optimally in the operating room by personnel experienced with these procedures in children. Before establishing the airway, one should take care not to precipitate laryngospasm by attempting to examine the epiglottis or by performing procedures such as venipuncture.[33,46] Blood should be obtained for culture, and intravenous antibiotics should be initiated as soon as possible after the airway has been secured.

Patients with subdural empyema, pericarditis, or pleural empyema usually require percutaneous or surgical drainage.[68,93] Infected joint fluid should be aspirated from children with septic arthritis to confirm the diagnosis and reduce pressure.[119] Repeated aspirations or placement of a surgical drain also may be needed. Infection of the hip requires surgical incision and drainage to decompress the joint; failure to do so may result in avascular necrosis of the femoral head.[119]

NONINVASIVE DISEASE

Noninvasive *H. influenzae* infections, usually caused by nontypeable strains, include otitis media, sinusitis, conjunctivitis, bronchitis, and pneumonia. Numerous orally administered antimicrobials are available to treat these infections (see Table 145–3). Despite the increasing prevalence of β-lactamase–producing organisms, amoxicillin remains the drug of choice for empiric treatment of otitis media in most areas because of its low cost and proven safety.[14,213] Several other antimicrobials with activity against *H. influenzae* are available and include the following: amoxicillin-clavulanate; trimethoprim-sulfamethoxazole; erythromycin-sulfisoxazole; newer macrolides such as clarithromycin and azithromycin; and second- and third-generation cephalosporins such as cefuroxime axetil, cefixime, cefpodoxime, cefdinir, and cefprozil.[95] Cefaclor was used widely but has poor activity against β-lactamase–producing organisms,[229] and it causes a serum sickness–like illness in approximately 2 percent of recipients.[191,394] The quinolone antibiotics, such as ciprofloxacin, also are active but are not licensed for use in children younger than 18 years old because of quinolone-induced arthropathy seen in juvenile animals. In the context of poor clinical response or isolation of β-lactamase–producing organisms, amoxicillin-clavulanate (Augmentin), cefixime, and cefpodoxime appear to be the most useful.[14,213]

Most mucosal infections are treated presumptively without obtaining definitive cultures, and, consequently, the duration of therapy and the need for alternative antibiotics are based on assessment of the clinical response. Otitis media usually is treated for 7 to 10 days, and sinusitis should be treated for at least 1 week beyond the resolution of symptoms.[14,213,396] If resistance is suspected and leads to failure of treatment, an empiric change in antibiotics is indicated.[213]

PREVENTION

The near elimination of invasive Hib disease in the United States and other countries is a direct result of the routine use of Hib conjugate vaccines and represents a remarkable success story.[65] Prevention with hyperimmunoglobulin also has been shown to be effective in high-risk populations, but it is costly, of short-lived benefit, and not licensed for general use.[328] Antimicrobial prophylaxis is effective for the prevention of secondary Hib disease, but it represents only a minor proportion of the overall disease burden.[14,27]

ACTIVE IMMUNIZATION

The first Hib vaccine was the PRP polysaccharide vaccine, which is composed of purified Hib capsular polysaccharide PRP.[21,319] In 1985, in children older than 18 months of age, it became the first vaccine to be licensed for the prevention of Hib disease. Children younger than 18 months of age had inadequate immune responses with PRP vaccination.[18,188] PRP vaccine has immunologic properties similar to those of some other polysaccharide vaccines, which generally are considered to be T-independent immunogens.[3] As a result, antibody responses are limited and are of short duration, particularly in young children, and no booster response occurs with repeated administration of the vaccine. Furthermore, the induced antibody may have reduced functional qualities (i.e., primarily IgM, low avidity).[316,349]

Licensure of PRP vaccine was based on the findings of a large randomized clinical trial conducted in Finland in 1974[287,288] that suggested a protective efficacy of 90 percent for children who were immunized between 18 and 71 months of age. Subsequent to licensure of this vaccine in the United States, it became apparent that routine use of the vaccine resulted in efficacy less than that determined in the Finnish vaccine trial, between 0 and 88 percent.[408] This vaccine is mainly of historical significance because its role has been supplanted by development and licensure of the PRP-protein conjugate vaccines.

Hib conjugate vaccines were developed in an effort to enhance immune responses to the PRP antigen. Basic to all conjugate vaccines is the use of a covalently linked (conjugated) immunogenic protein carrier that confers on the PRP polysaccharide hapten recognition by T cells and macrophages and stimulation of T-dependent immunity.[204,408] Four Hib conjugate vaccines have been developed and evaluated in infants, and all use PRP polysaccharide or oligosaccharides derived from it as the primary immunogen (Table 145–4): PRP-D (diphtheria toxoid), HbOC (mutant diphtheria toxin), PRP-OMP (major OMP of *Neisseria meningitidis* serogroup B), and PRP-T (tetanus toxoid). The immune response after receipt of Hib conjugate vaccination has the following general characteristics: (1) it is quantitatively enhanced, particularly in younger infants; (2) repeat administration of vaccine elicits booster responses; and (3) maturation of class-specific immunity with a predominance of IgG antibody and probably enhanced functional properties occurs.

The first Hib conjugate vaccine licensed was PRP-D, but it was less immunogenic than are the conjugate vaccines developed subsequently and rarely is used in the United States. In children 15 months of age or older who received PRP-D, high antibody concentrations were achieved with a single dose.[35,173] In infants, however, antibody levels greater than 1 μg/mL developed in fewer than half, even after they received three doses.[89,187] Numerous case-control studies demonstrated that a single dose of vaccine was at least 80 percent efficacious in preventing disease in children 18 months or older. In infants in Finland who received vaccine at 3, 4, 6, and 14 to 18 months of age, the protective efficacy after three doses was 94 percent.[104] In contrast, a trial conducted in Native Alaskan infants found no evidence of protection in that high-risk population.[405]

A single dose of HbOC is highly immunogenic in children older than 18 months of age,[173,224] and after the administration of three doses in infancy, high antibody levels are achieved.[89,321] Two prospective clinical studies showed that two or three doses of HbOC administered in the first 6 months of life provide a high degree of protective efficacy. In the Kaiser Permanente northern California region population, HbOC was 100 percent efficacious after two doses administered in infancy.[38] The vaccine also was evaluated in Finland in infants who received vaccine at 4, 6, and 14 to 18 months of age, and efficacy was 95 percent after two doses.[105] Data from a third post-licensure study in infants in Los Angeles County also suggested a protective efficacy of 89 percent after two doses and 94 percent after three doses.[390]

PRP-OMP induces an immune response that is less age-dependent than is the response to the other Hib conjugate vaccines. Adults and children respond to a single vaccine dose with high antibody levels.[321] In infants as young as 6 to 8 weeks, a single dose of PRP-OMP induces a good antibody response.[52] In addition, the antibody levels achieved after two doses are higher than those achieved after two doses of any of the other conjugate vaccines,[52,89] and a third dose does not enhance the response. PRP-OMP was evaluated in a randomized, double-blind, placebo-controlled trial involving high-risk Navajo Native American infants[330] who received vaccine at 2 and 4 months of age; an overall efficacy of 95 percent was reported. Additional data from a population-based case-control study in Los Angeles County suggested a level of effectiveness similar to that seen for HbOC.[389]

PRP-T is highly immunogenic in adults and older children,[73,340] and high concentrations of antibody are achieved in infants with a three-dose immunization series at 2, 4, and 6 months of age.[89] The protective efficacy of PRP-T was evaluated in two large prospective randomized trials that were terminated prematurely because of the licensure of other Hib conjugate vaccines for infants. More than 12,000 infants were enrolled in studies in southern California and North Carolina, and no cases of invasive Hib disease occurred in the vaccinated children versus 5 cases in the control groups.[133,391] Efficacy subsequently was

TABLE 145–4 Characteristics of *Haemophilus influenzae* Type b Conjugate Vaccines

Vaccine	Polysaccharide Size	Protein Carrier	Linkage	Trade Name*
PRP-D	Medium	Diphtheria toxoid	Protein with 6-carbon spacer	ProHIBiT
HbOC	Small	CRM_{197} (mutant diphtheria toxin)	PS, no spacer	HibTITER
PRP-OMP	Medium	*Neisseria meningitidis* outer-membrane protein complex	Protein and PS with bigeneric spacer	PedvaxHIB
PRP-T	Large	Tetanus toxoid	PS with 6-carbon spacer	ActHIB

HbOC, mutant diphtheria toxin; PRP-D, diphtheria toxoid; PRP-OMP, major outer-membrane protein of N. meningitidis *serogroup B; PRP-T, tetanus toxoid; PS, polysaccharide.*
**HbOC, PRP-OMP, and PRP-T also are available in combination with diphtheria-tetanus-pertussis, diphtheria-tetanus–acellular pertussis, and hepatitis B vaccines.*

shown in a study in England; after three doses in infancy, the efficacy of PRP-T was estimated to be 100 percent.[45] In Finland, during the first 2 years of its general use, more than 100,000 infants were immunized, and only 2 cases of invasive Hib disease occurred in vaccinees, both after a single dose. In no infant who has received two or more doses of vaccine in any study has Hib disease developed.[289]

HbOC, PRP-OMP, and PRP-T are licensed for use in infants at 2, 4, 6, and 12 to 15 months of age. Any Hib conjugate vaccine can be used as the booster dose or in different sequences.[14] Several issues, however, remain to be determined regarding the use of Hib conjugate vaccines in infants. Direct comparisons of Hib conjugate vaccines need to be considered in the context of varying study designs, differences in vaccine lots, and different laboratory and statistical methodologies. Despite these difficulties, certain concepts are apparent: (1) all Hib conjugate vaccines are safe in infants; (2) PRP-D is the least immunogenic conjugate vaccine; (3) only PRP-OMP induces a good immune response after one dose in young infants, but antibody levels are lower than those induced by multiple doses of HbOC and PRP-T vaccine; and (4) PRP-OMP, HbOC, and PRP-T appear to be efficacious, but no direct comparison of the protective efficacy of these vaccines has been completed.

In addition, certain mixed sequences of Hib vaccines given to infants (i.e., PRP-OMP followed by HbOC or PRP-T) may enhance the antibody response.[146,155] Furthermore, simultaneous receipt of other non-Hib vaccines and the impact of concurrent or previous receipt of the carrier protein (carrier priming)[152,153,212] are issues that need to be explored. Combination vaccines that include Hib (Hib plus diphtheria-tetanus-pertussis [Hib-DTP], Hib plus diphtheria and tetanus toxoids and acellular pertussis [Hib-DTaP], and Hib-hepatitis B) currently are licensed, and other combinations (Hib plus inactivated poliovirus vaccine [Hib-IPV] and Hib-DTaP/IPV) are being evaluated in infants and children.[36,305,335]

Schmitt and associates[339] surveyed the impact and effectiveness of DTaP (IPV)-Hib combination vaccines in Germany. Although combination DTaP-Hib vaccines have been documented to elicit lower anti-Hib titers than separate vaccines do, the impact of this finding is unclear. Schmitt and colleagues[339] showed that combination vaccines were effective in reducing the incidence of Hib disease in Germany.[339] The study of Schmitt and associates is encouraging. More recent data from Canada also suggest that a multiple-component, Hib-containing combination vaccine is safe and effective in preventing invasive Hib disease in young children.[333,335]

The phenomenal success of the Hib vaccination strategy has been related to the effectiveness of Hib conjugate vaccines in preventing colonization. Fernandez and associates[116] reported that the anti-Hib capsular polysaccharide antibody concentration required to prevent colonization was greater than that needed for protection against invasive disease. Whether concentrations in the range that Fernandez and associates suggested was important (>5 μg/mL) can be achieved and sustained by using conjugate vaccines in all population groups remains a subject of investigation. Studies in some high-risk population groups (Native Alaskans) documented that invasive disease is prevented best by the use of PRP-OMP Hib vaccine,[357,358] at least for the first dose of vaccine, and that even the use of PRP-OMP Hib vaccine in these individuals may not eliminate carriage of the organism in the population.[91,136] Thus, the use of combination vaccines in this population group is unlikely to be as effective as is the use of PRP-OMP Hib conjugate vaccine.[358]

To date, essentially all *H. influenzae* vaccines are based on immunity to the Hib capsule. Antibodies to other components of the bacterium also have been shown to be bactericidal, opsonophagocytic, and protective in animal studies.[25,29,90,100,162,203,255,258,259,421] Vaccines containing alternative antigens in theory could provide supplemental protection against Hib, although this protection does not appear to be necessary in most individuals based on the efficacy of the available Hib conjugate vaccines. However, more importantly, such alternative vaccines could provide immunity to non-Hib strains that are ubiquitous colonizers of the upper respiratory tract of humans.[108,202] One of the basic microbiologic problems that must be overcome before such vaccines are developed is the known diversity of many of the candidate vaccine antigens of interest.[29,138] Because of the known strain-to-strain variability in many of these antigens,[92] finding an antigen relevant to all or most strains has been a challenging task.[29,257] Even so, recent human trials have reported success in preventing some cases of *H. influenzae* otitis media with a novel pneumococcal polysaccharide–*H. influenzae* protein D conjugate vaccine,[304] and many other candidate vaccine antigens remain the subject of active pre-clinical research.[28,90,203,422]

PASSIVE IMMUNIZATION

Although active immunization clearly is preferred for the control of Hib disease, passive immunization has potential utility in the following settings: (1) in selected high-risk groups with a risk of acquiring disease soon after birth and too young to respond to vaccination (i.e., Eskimos or Native Americans); (2) in functionally asplenic patients; (3) in immunocompromised patients; and (4) for prevention of secondary disease in households, daycare centers, or institutions. A human hyperimmunoglobulin from adult Hib-immunized donors called *bacterial polysaccharide immunoglobulin* has been prepared,[355] but it is not commercially available. Pharmacologic studies showed that high levels of antibody can be achieved after intramuscular injection, and significant protective efficacy against invasive Hib disease was demonstrated in Apache children who were given three doses during the first year of life.[328] The use of concurrent active immunization with bacterial polysaccharide immunoglobulin also may be an effective strategy.[211] Another possible approach in such groups would be maternal Hib immunization,[144] to induce transplacental antibody, but questions remain regarding the safety and acceptability of vaccinating pregnant women and the inability to immunize women who do not receive prenatal care.

IMPACT OF *HAEMOPHILUS INFLUENZAE* TYPE b VACCINATION

The impact of widespread vaccination with Hib conjugate vaccine has been dramatic and reproduced in several areas of the United States[4,65,263] and in many countries throughout the world.[182,289,306,334] Exclusively using HbOC vaccine,[37] the Kaiser Permanente northern California region eliminated Hib disease except for a rare case in an unimmunized child and a few cases in children with incomplete immunizations. In the Kaiser Permanente southern California region,[389] PRP-D and subsequently PRP-OMP vaccines were used in older children between 1987 and 1990. Since 1990, PRP-OMP vaccine has been administered almost exclusively. A few cases of PRP-D failure and only two cases of PRP-OMP failure occurred; disease essentially has been eliminated. Similar control of disease has been achieved with the use of PRP-OMP vaccine in Alaskan and Navajo Native American populations,[329] in Los Angeles County,[389] Minnesota, and Dallas.[263] In U.S. sites under surveillance by the Centers for Disease Control and Prevention, similar eradication of disease has been achieved, although some localized populations with increased rates of disease still remain.[65,358]

In general, the decrease in the incidence of disease has exceeded expectations, given the estimated proportion of the population completely immunized. In addition, in essentially all these populations, a significant decrease in the incidence of disease was

observed in infants before the licensure and recommended use of vaccines in that age group. These findings probably are explained by a reduction in Hib carriage as a result of vaccination[263,373] and, consequently, decreased transmission from immunized children to unimmunized young children and infants.

The immunization schedules vary in different countries to parallel immunization practices for other vaccine-preventable diseases. Moreover, the age-specific incidence of disease varies in different countries. Initially, in the United Kingdom, the occurrence of disease was such that physicians felt justified to use only a three-dose schedule at 2, 3, and 4 months of age and not to provide a booster dose in the second year of life. As alluded to earlier, this schedule, which was introduced in the United Kingdom in 1993, appeared to be related to the reappearance of Hib disease in older children observed in the late 1990s.[19,180,238,308] This experience underlies the importance of giving a fourth dose when children are between 12 and 18 months of age.

CHEMOPROPHYLAXIS

Secondary disease accounts for less than 2 percent of all cases of invasive Hib disease. Chemoprophylaxis, however, can protect susceptible persons from acquiring Hib by eliminating Hib colonization in close contacts. Children younger than 4 years old have a 600-fold increased risk of acquiring Hib disease after household contact with a case.[406] Risk also appears to be increased in daycare center settings, but this risk is defined less well.[147,279] In addition, adults and older children who are colonized can transmit Hib to susceptible children, even though they have little risk for acquiring invasive disease themselves.

Antimicrobial agents effective for chemoprophylaxis must achieve bactericidal levels intracellularly and in mucosal secretions. Rifampin, which achieves high concentrations in respiratory secretions,[236] is the most effective antimicrobial agent for eradicating Hib from the nasopharynx. Rifampin, in a dosage of 20 mg/kg once daily (maximal daily dose, 600 mg) for 4 days eradicates Hib carriage in 95 percent or more of household [27,145] or daycare center[151] contacts of a case. Cohort studies showed the effectiveness of rifampin prophylaxis in preventing secondary Hib disease in household and daycare center attendees.[145,151,226] Antimicrobials effective in the treatment of Hib disease, such as ampicillin, trimethoprim-sulfamethoxazole, erythromycin-sulfisoxazole, and cefaclor, were shown to be ineffective for antimicrobial prophylaxis.[174] They eliminated Hib carriage in fewer than 70 percent of culture-positive contacts and, therefore, are not recommended for chemoprophylaxis.

Both the U.S. Public Health Service Advisory Committee on Immunization Practices[64] and the American Academy of Pediatrics Committee on Infectious Diseases[14] recommend rifampin prophylaxis for all household contacts, including adults, and for the index patient (therapeutic antibiotics do not eradicate Hib from the nasopharynx consistently) if the household has a contact younger than 4 years old who is not fully immunized. Prophylaxis should be instituted as soon as possible because the risk of acquiring secondary disease is greatest during the few days after the onset of disease in the index patient and within 2 weeks of the onset of disease. With regard to the daycare center setting, no consensus exists concerning the need for chemoprophylaxis because of uncertainty about the magnitude of the risk of acquiring secondary Hib disease in this setting. Some authors recommend chemoprophylaxis if classroom contacts include those younger than 2 years of age, whereas others think that recommendations should be individualized.[86,279] However, virtually all experts recommend prophylaxis if two or more cases of Hib disease have occurred among attendees within 60 days.[14,64]

In all situations in which the potential for secondary disease exists, this risk should be explained to families, with an emphasis placed on the importance of seeking prompt medical attention for febrile illnesses. Clinicians should not obtain pharyngeal cultures to determine whether prophylaxis should be administered because doing so only delays the prompt administration of chemoprophylaxis.

CONCLUSION

The perspective on *Haemophilus* disease has changed dramatically in recent years. Before the availability of Hib conjugate vaccines, invasive Hib was one of the most important bacterial pathogens of children. It was the leading cause of bacterial meningitis and an important cause of other bacteremic illnesses. The spectrum of illness is broad, morbidity and mortality rates are significant, and subtleties in making an early diagnosis and instituting appropriate management exist. Currently, when one considers that most antibiotic use worldwide is for upper respiratory tract infections, including otitis media, and that *H. influenzae* causes a significant proportion of these illnesses, it still must be considered an important pediatric pathogen.

Although various aspects of disease caused by *H. influenzae* are reviewed in this chapter, what is clear is that the most important aspect has been disease prevention by routine immunization of infants with polysaccharide-protein conjugate vaccines. This achievement is the culmination of more than 100 years of research on *H. influenzae*. Although historically many technologic problems and misunderstandings about the organism and its pathogenesis have occurred, much has been accomplished in recent years. The impact of routine infant immunizations with Hib conjugate vaccines is relatively recent and very dramatic. The public health benefits parallel the eradication of poliomyelitis and the control of other vaccine-preventable childhood diseases. Widespread Hib immunization virtually has eliminated Hib disease in the United States and in many developed countries where it is used routinely. The degree of disease control exceeds all expectations and is in excess of what the known levels of immunization would have predicted. Unfortunately, Hib conjugate vaccines currently are used routinely in relatively few developing countries and only electively in some additional countries, thus leaving most of the world without the benefit of immunization. The World Health Organization has taken up the challenge to expand Hib immunization worldwide.

Progress also has been achieved at the pre-clinical level in the development of vaccines against other *H. influenzae* serotypes and nontypeable strains. Control of infection caused by these organisms will have an important public health impact, and the use of such vaccines may have a role in adolescents and adults. The technologies that led to the development of Hib conjugate vaccines served as a prototype for vaccines to prevent disease caused by other encapsulated bacteria including pneumococci, meningococci, and group B streptococci. As such, the lessons learned in the quest to eliminate Hib disease have had important implications in the control of many other bacterial diseases.

CHAPTER 146

Other *Haemophilus* Species (*aphrophilus, ducreyi, haemolyticus, influenzae* Biogroup Aegyptius, *parahaemolyticus,* and *parainfluenzae*)

Stephen J. Barenkamp

Most serious pediatric infections caused by organisms of the *Haemophilus* genus are caused by *Haemophilus influenzae*. However, other *Haemophilus* spp. also can cause disease occasionally. Other *Haemophilus* spp. that have been well documented as causes of illness in pediatric and adolescent patients include *Haemophilus aegyptius*, *Haemophilus aphrophilus*, *Haemophilus ducreyi*, and *Haemophilus parainfluenzae*. As discussed later, *H. aegyptius* has been classified as a member of the species *Haemophilus influenzae* (*H. influenzae* biogroup aegyptius), but given the unique characteristics of this organism and the distinctive illnesses with which it is associated, it is described in this chapter. Other *Haemophilus* spp., such as *Haemophilus haemolyticus* and *Haemophilus parahaemolyticus*, rarely, if ever, cause illness in the pediatric population and are not discussed here.

Members of the *Haemophilus* genus are gram-negative coccobacillary bacteria that are facultatively anaerobic. They demon-

strate optimal growth when they are incubated in a humid atmosphere containing 5 to 10 percent carbon dioxide.[99,100,130] Most species have fastidious nutritional requirements and require special media, supplements, or both for optimal growth.[99,100] X factor (hemin), V factor (nicotinamide adenine dinucleotide), or both are required for in vitro growth.[140] Organisms with the "para-" prefix require V factor only. The specific nutritional requirements of *Haemophilus* isolates are sole characteristics used to subclassify these organisms into the different species (Table 146-1).

HAEMOPHILUS APHROPHILUS

BACTERIOLOGY

H. aphrophilus was described first by Khairat[98] in 1940 in association with a fatal case of endocarditis. He suggested the species name *aphrophilus* because the organism required relatively high concentrations of carbon dioxide for isolation on the usual media. In earlier times, a well-known manifestation of carbon dioxide was the formation of bubbles of gas in fermenting wine (i.e., froth, or *aphros*).[24,98] Although the organism originally was classified as a *Haemophilus* sp. because of the growth requirement for X factor, more recent studies suggest that it can grow independent of this factor.[99,135,177] Some authors have suggested that given this X factor independence, the organism should be placed in another genus,[99,133,177] but at present it remains in the *Haemophilus* genus.

EPIDEMIOLOGY AND PATHOGENESIS

H. aphrophilus is a component of the normal oral flora. Using a selective medium, Kraut and coworkers[103] isolated the organism from gingival scrapings and interdental material of one third of the healthy adults they examined. With respect to disease pathogenesis, dental disease or manipulation has been suggested to predispose the individual to transient bacteremia, which results in seeding of distant tissue sites where localized infection subsequently develops.[24,75,132,135,156] In addition, several case reports of patients with *H. aphrophilus* disease reported an association between human infection and contact with or bites from dogs and cats.[64,90,132,135,188] However, a causal relationship has been difficult to confirm, and the human mouth and respiratory tract probably are the portals of entry for most infections.

CLINICAL MANIFESTATIONS

H. aphrophilus is a rare cause of infection and disease in pediatric patients, with fewer than 50 cases reported in the literature.* Brain abscesses and endocarditis are the pediatric infections reported most commonly with this organism.[20,24,58,64,90,127,135] Other sites of infection in children documented in the literature include the oropharynx,[24] the abdominal cavity,[24,96] and various superficial soft tissue sites.[135,195,196] Infections with *H. aphrophilus* do not appear to be associated with any distinctive clinical features compared with infection caused by other organisms at the same sites. However, infections caused by *H. aphrophilus* frequently are associated with underlying conditions, such as congenital heart disease, trauma, and immunosuppression, thus predisposing the host to infection.[24,60,64,86,127,135,143,195]

TREATMENT

Antimicrobial susceptibility testing has not been well standardized for this organism, and disk-diffusion testing, in particular, has been found to be unreliable.[24,85,135,177] Tube or agar dilution testing generally is considered to be the preferred testing method. Older reports found that *H. aphrophilus* was susceptible uniformly to certain antibiotics, including chloramphenicol and the aminoglycosides.[24,135,177] Susceptibility to penicillins has been variable. Even so, penicillin has been used successfully for treatment of susceptible organisms,[24,75,135,188] at times in combination with aminoglycosides and other antimicrobials. Some reports document the usefulness of ampicillin or ceftriaxone for treatment of infection.[20,124,132] Numerous different antibiotics probably can be used to treat *H. aphrophilus* infections successfully. The choice for treatment should be guided by appropriate in vitro susceptibility testing.

HAEMOPHILUS DUCREYI

BACTERIOLOGY

In 1889, Ducrey[51] first identified *H. ducreyi* in purulent material recovered from genital ulcers of patients with soft chancre or

*See references 12, 20, 24, 58, 64, 89, 90, 96, 127, 195, 196.

chancroid. Although unable to culture the organism in vitro, Ducrey[51] was able to establish the specificity of the infectious agent by serial cutaneous inoculations.[128] *H. ducreyi* originally was assigned to the *Haemophilus* genus because of its requirement for hemin (X factor) and a guanosine plus cytosine content within the expected range for *Haemophilus* spp.[8,184] However, more recent studies, including genetic transformation and DNA hybridization analyses, suggest that *H. ducreyi* is not related to the true haemophili, such as *H. influenzae*, and potentially should be placed in a separate genus.[8,184]

The last few years have seen significant advances in the characterization of bacterial components that may contribute to disease pathogenesis. Two cytotoxins, a hemolysin, a diffusable cytolethal distending toxin, and two classes of serum resistance proteins have been identified, their respective genes have been cloned, and their potential contributions to disease pathogenesis have been investigated.[1,10,42,44,136,139,187] The lipo-oligosaccharide of *H. ducreyi* has been characterized in much greater detail, and relevant biosynthetic genes have been cloned and studied.[3,15,62,123,176,185,201] Genes encoding the major outer membrane proteins of the organism have been cloned and the corresponding proteins characterized,[101] and a novel class of pili expressed by *H. ducreyi* has been identified.[34] *H. ducreyi* requires heme for growth, and several of the critical molecules required for heme acquisition and utilization have been identified.[54,55,174,179] The knowledge gained from molecular characterization of these important bacterial components should enhance efforts to understand the pathogenesis of disease better.

EPIDEMIOLOGY

Chancroid is a genital ulcerative disease that is found throughout the world. It is seen frequently in Africa, Asia, and Latin America, where it may be a more common cause of genital ulcer disease than is syphilis.[8,21-23,128,181,184] Although generally considered a relatively uncommon cause of illness in the United States, chancroid continues to be diagnosed, particularly among patients, including adolescents, who present with genital ulcer disease in large urban areas.[26,80,84,125,126,163] Furthermore, data suggest that chancroid may be more common in the United States than suspected because it can be difficult to diagnose correctly using traditional clinical and laboratory means.[50,129,184] Symptomatic disease among patients in the United States has been reported most commonly among nonwhite heterosexual men.[26,65,80,128] However, symptomatic disease is not restricted to men, and female prostitutes have been implicated as important sources of infection in several of the outbreaks reported in the United States.[26,80,128]

H. ducreyi has been the subject of renewed medical and scientific interest since the early 1980s. This interest followed from epidemiologic studies, primarily from Africa, demonstrating that the presence of genital ulcer disease (much of which was chancroid) was strongly associated with an increased risk of heterosexual transmission of human immunodeficiency virus (HIV) infection.[23,92,104,105,129,144,191] Mechanisms proposed to explain this enhanced transmission have included increased shedding of HIV through the ulcers,[104,184] increased numbers of HIV-susceptible cells (e.g., CD4 T lymphocytes) in genital ulcers of a person exposed to HIV,[170,184] or increased viral load in the blood and semen of individuals co-infected with HIV and *H. ducrei*.[53]

PATHOGENESIS

Relatively little is known about the pathogenesis of *H. ducreyi* infection, although significant progress has been made coincident with renewed interest in the organism.[4,167,184] Several useful in vivo models of *H. ducreyi* infection have been developed. They include a temperature-dependent rabbit model of dermal infection,[145] a primate model of genital chancroid infection in adult pigtailed macaques,[182] a swine model of dermal infection,[87] and an experimental model of human infection.[6,7,17,18,138,167,171] Numerous putative virulence factors have been identified, and their contributions to the pathogenesis of disease are being investigated using several in vitro and in vivo model systems. Some of the molecules and characteristics studied include bacterial lipooligosaccharide,[16,36,203] pili,[3,4,19,63,74,161,168,175,185] the cytolethal distending toxin,* a hemolysin,[10,52,137,139,183,198,202] serum resistance proteins,[1,42] lectin-binding proteins,[1,91,187,190] and the ability to adhere specifically to epithelial cells of genital origin.[9,109] The contribution of these proposed virulence factors to the pathogenesis of natural infection in humans is still being defined. However, it is known that strains deficient in expression of several of these factors are attenuated in their ability to cause disease in the experimental model of human infection.[5,30,67,70,91,169] Ongoing investigations of *H. ducreyi* undoubtedly will define the virulence mechanisms of the organism more clearly and should enhance efforts to develop protective vaccines.[2,6,43,48,82]

CLINICAL MANIFESTATIONS

The incubation period of chancroid usually is between 4 and 7 days. It rarely is less than 3 days or more than 10 days.[11,128,154,155] Typically, the first lesion noted is a small inflammatory papule surrounded by a zone of erythema. Within 2 or 3 days, a pustule forms that soon ruptures, leaving a sharply circumscribed ulcer with ragged undermined edges *without* induration.[111,128,154] The base of the ulcer usually has a granular appearance and always is painful. In male patients, the most common sites of appearance of the ulcers are on the distal prepuce, on the mucosal surface of the prepuce on the frenulum, and in the coronal sulcus. In female patients, most lesions are at the entrance to the vagina.[111,128,154] Painful, tender, inguinal adenopathy is present in as many as 50 percent of patients and usually is unilateral. The involved lymph nodes rapidly may become fluctuant and rupture, with the formation of inguinal ulcers.[128,154]

The combination of a painful ulcer with tender inguinal adenopathy is suggestive of chancroid and, when accompanied by suppurative inguinal adenopathy, is almost pathognomonic.[38] However, a significant percentage of patients with *H. ducreyi* infection may have ulcers that can be confused with other genital ulcer diseases, such as herpes or syphilis.[71,111,128,154] Furthermore, as many as 10 percent of patients with chancroid may be co-infected with *Treponema pallidum* or herpes simplex virus (HSV).[38] Thus, it becomes mandatory to establish a definitive diagnosis by laboratory means if one is to be confident about the diagnosis.

DIAGNOSIS

As noted earlier, diagnosing chancroid on clinical grounds alone is difficult because the clinical presentation often is not classic, and many clinicians do not have a great deal of experience with the disease.[38,184] Definitive diagnosis of chancroid requires isolation of the organism from a genital ulcer or from involved lymph nodes. However, the organism is fastidious and is difficult to isolate, even under the best of circumstances.[128] To obtain specimens for culture, a swab should be used to obtain material from the purulent base of an ulcer, or a fluctuant inguinal lymph node should be aspirated directly. Gram stain of purulent material may reveal gram-negative rods in the characteristic "school-of-fish" pattern, but this appearance probably is more characteristic of in

*See references 45, 46, 69, 72, 76, 108, 112, 146, 147, 173, 200.

vitro propagated organisms.[127] However, even with use of the selective media now recommended for isolation of *H. ducreyi*, the sensitivity of culture has been estimated to be no higher than 80 percent.[38,111]

Given the low sensitivity of culture, alternative diagnostic tests that are not based on culture have been evaluated. Early studies examined the utility of diagnosing chancroid serologically with an enzyme-linked immunosorbent assay (ELISA) using either an outer-membrane protein preparation or a lipo-oligosaccharide preparation of *H. ducreyi*.[11] More recent studies employed slightly altered antigen preparations and serum preparation techniques meant to improve the sensitivity and specificity of the assay.[39] Although these modifications did lead to improvement in the performance characteristics of the assay, the ability of the modified assay to aid in establishing the diagnosis of acute infection remains limited because many patients do not develop a serum antibody response until several weeks after onset of infection.[39,181] More recent work has focused on the use of recombinant proteins as test antigens for a serologic test.[56] This newer assay does appear to show promise for seroprevalence studies, but its utility in the diagnosis of acute infection has yet to be demonstrated. Another newer diagnostic test relies on detection of *H. ducreyi* with monoclonal antibodies directed against the hemoglobin receptor,[141] but it has yet to undergo extensive field testing.

Nucleotide-based diagnostic methods also have been described.[93,157,184] Perhaps most promising are the polymerase chain reaction–based techniques. These assays demonstrate high sensitivity and appear to identify certain patients with chancroid from whom bacterial cultures for *H. ducreyi* are negative.[181,184] Multiplex polymerase chain reaction assays that can amplify and detect DNA from *H. ducreyi*, *T. pallidum*, and HSV from genital ulcer specimens simultaneously are undergoing field trials and have shown early promise.[117,134,184]

Even if chancroid is diagnosed definitively, patients should also be tested for HIV at the time of diagnosis. In addition, as many as 10 percent of patients with chancroid may be co-infected with *T. pallidum* or HSV.[38] Appropriate testing for these other pathogens should be considered strongly when a patient presents with any form of genital ulcer disease.

TREATMENT AND PREVENTION

Successful antimicrobial treatment of genital ulcers caused by *H. ducreyi* cures infection, resolves clinical symptoms, and prevents transmission to others. However, in cases of extensive ulcerative disease, scarring may result, despite successful antimicrobial therapy.[38] The Centers for Disease Control and Prevention (CDC) currently recommends one of four antibiotic regimens for treatment of chancroid in adolescents and adults.[38,111,162] These regimens are as follows: (1) azithromycin, 1 g orally in a single dose; (2) ceftriaxone, 250 mg intramuscularly in a single dose; (3) ciprofloxacin, 500 mg orally twice a day for 3 days; or (4) erythromycin base, 500 mg orally four times a day for 7 days.[38,162] All four regimens generally are effective for treatment of chancroid among patients without HIV infection.[162] A successful response to therapy usually is apparent within 48 to 72 hours, as shown by decreased ulcer tenderness and pain.[38,154,162] Complete healing of ulcers may take up to 28 days but often is achieved in 7 to 14 days.[154] Healing of fluctuant adenopathy is slower than that of the ulcers and may require needle aspiration through adjacent intact skin or incision and drainage to achieve a successful response to therapy.[59,162]

Patients with HIV infection must be monitored closely because they may require longer courses of antimicrobial agents than the standard regimens just outlined.[38,162] Treatment failures have been noted with several of these regimens,[29,162,186] and some suggestion exists that persons who are most immunosuppressed are at the greatest risk for failure of standard regimens.[186] Some experts recommend using the erythromycin 7-day regimen for treating all HIV-infected patients because of good experience with this regimen in the HIV-infected population and limited successful experience with the alternative regimens.[162]

It is critical to identify all sexual contacts of infected persons to prevent further spread of *H. ducreyi* disease. The CDC recommends that all persons who have had sexual contact with a patient with proven *H. ducreyi* infection within the 10 days before onset of the patient's symptoms be examined and treated.[38] Contacts should be examined and treated even in the absence of symptoms.

In the longer term, alternative strategies for control of chancroid should be examined. If feasible, vaccination for prevention of *H. ducreyi* infection would be a worthy goal. Data generated in animal models of infection are somewhat encouraging.[2,48,82] Protective immunity to both homologous and heterologous challenge has been reported after immunization of rabbits with cell-surface extracts of *H. ducreyi*.[82] In other work, a purified pilus preparation also was reported to induce immunity in that same model.[48] More recently, immunization with the hemoglobin receptor protein was reported to protect against infection in the swine model of chancroid.[2] These data suggest that prevention of chancroid by vaccination may be an achievable goal. However, data from the experimental human model of infection suggest that development of a protective vaccine for human use may not be a straightforward process.[6]

HAEMOPHILUS INFLUENZAE BIOGROUP AEGYPTIUS (*HAEMOPHILUS AEGYPTIUS*)

BACTERIOLOGY

H. influenzae biogroup aegyptius (*H. aegyptius*) was described originally by Koch[102] in 1883 in Egyptian patients with conjunctivitis. A more detailed description of the organism and the clinical characteristics of disease followed 3 years later in the work of Weeks.[193] The Koch-Weeks bacillus has continued to be an important cause of conjunctivitis since these initial reports. Because of several reportedly unique characteristics,[120] the Koch-Weeks bacillus originally was designated a unique species of the *Haemophilus* genus (*H. aegyptius*) distinct from *H. influenzae*. However, more recent phenotypic and phylogenetic studies, including DNA relatedness analyses, have raised questions about the validity of this separation.[33,178] The organism is designated currently as *H. influenzae* biogroup aegyptius, although debate continues in the literature as to the appropriateness of this designation.[114]

This organism has been the subject of intense scientific study since the 1980s as a result of its association with a newly described fulminant and often fatal disease called *Brazilian purpuric fever*.[31,32] *H. influenzae* biogroup aegyptius was isolated from 9 blood cultures and from a single hemorrhagic cerebrospinal fluid culture collected from 10 clinically ill children in Serrana, Sao Paulo State, Brazil.[32] The *H. influenzae* biogroup aegyptius strains causing Brazilian purpuric fever initially were thought to be members of a single virulent clone.[33,178] This clone was characterized by the presence of several unique features, including a 24-Md plasmid with a characteristic restriction endonuclease pattern,[33] a unique multilocus electrophoretic enzyme typing pattern,[131] one of two rRNA gene restriction fragment length polymorphisms,[33,49] a single sodium dodecyl sulfate–polyacrylamide gel electrophoresis profile for whole-cell lysates,[33] specific reactivity with monoclonal antibodies recognizing epitopes unique to Brazilian purpuric fever strains,[110,178] agglutination with antisera specific for the Brazilian purpuric fever clone,[33] and conservation of certain major outer-membrane proteins.[151] Although

most Brazilian purpuric fever-associated strains of *H. influenzae* biogroup aegyptius appear to be members of a unique clone, a few Brazilian purpuric fever-associated strains have been identified that lack some of the defining characteristics.[178,180] Furthermore, two cases of Brazilian purpuric fever reported from Australia were associated with strains clearly distinct from the Brazilian purpuric fever clone.[114,178]

EPIDEMIOLOGY

In the United States, *H. influenzae* biogroup aegyptius has remained an important cause of conjunctivitis, with disease most commonly reported from the southern states.[83] The United States has experienced only one reported case of possible Brazilian purpuric fever.[189] In Brazil, the epidemiology of Brazilian purpuric fever has been defined more clearly during the last several years.[83] The median age of patients with Brazilian purpuric fever is 2 to 3 years, with an overall range of ages of 3 months to 10 years.[31,32] Brazilian purpuric fever appears to occur with the onset of warmer temperatures and is less likely to occur during the Brazilian winter.[83] Furthermore, it appears to occur more commonly in small agricultural towns than in larger cities.[31,32,83] Case-control studies attempting to identify risk factors for development of disease identified a history of preceding conjunctivitis as associated strongly with the development of Brazilian purpuric fever[31,32,82] (although many of the controls also gave a history of conjunctivitis) and suggested that attendance at a daycare center was an additional risk factor.[32]

PATHOGENESIS

Efforts to identify virulence factors of *H. influenzae* biogroup aegyptius responsible for the fulminant nature of Brazilian purpuric fever have been ongoing since the initial descriptions of the illness. Progress to date has been limited,[37] but some genome-based studies have demonstrated clear differences between *H. influenzae* biogroup aegyptius prototype strains and other *H. influenzae*.[113,122,166] Brazilian purpuric fever clone strains express numerous novel or unique surface molecules or secreted proteins that theoretically could result in enhanced virulence.[33,37,110,114,158,197] Distinctive lipo-oligosaccharide phenotypes,[37,158] immunoglobulin A (IgA) proteases,[37,114,121] pili,[15,149,150,197] and secreted proteins[197] for Brazilian purpuric fever strains have been reported. However, none has been shown to have a specific role in bacterial virulence. One study suggested that the risk of developing Brazilian purpuric fever correlated with the lack of serum bactericidal activity against the Brazilian purpuric fever clone, but this observation needs further confirmation.[159]

Both in vitro and in vivo models have been developed for further investigating the pathogenesis of Brazilian purpuric fever.[149,158,194] In these model systems, the strains associated with Brazilian purpuric fever demonstrated increased virulence compared with control strains not associated with Brazilian purpuric fever, but, again, the specific molecular correlates of this increased pathogenicity have yet to be identified clearly.[149,158] It seems likely that during the next few years, the in vitro and in vivo models will prove useful in further defining specific virulence factors of the Brazilian purpuric fever strain.

CLINICAL MANIFESTATIONS

The clinical presentation of Brazilian purpuric fever is distinctive and dramatic.[31,32,83] The syndrome initially manifests as a purulent conjunctivitis without distinguishing characteristics. Symptoms of Brazilian purpuric fever typically appear 3 to 15 days later, after the conjunctivitis has resolved. The affected children experience the acute onset of fever, which may be associated with vomiting and abdominal pain. Death frequently ensues within 48 hours after the development of disseminated purpura, vascular collapse, and hypotensive shock. The precise pathophysiologic mechanisms responsible for progression from conjunctivitis caused by the Brazilian purpuric fever clone to full-blown Brazilian purpuric fever are unknown. The overall case-fatality rate since Brazilian purpuric fever first was recognized is estimated to be 70 percent.[83] Children may develop conjunctivitis with the Brazilian purpuric fever clone and, after recovery from the conjunctivitis, have no further problems.[83] The risk factors that predispose only some children to develop Brazilian purpuric fever are not well understood.

TREATMENT

Data from the limited number of Brazilian purpuric fever cases studied suggest that early antimicrobial therapy may improve survival.[32] One suggested regimen is high-dose ampicillin with chloramphenicol. The small number of patients treated to date does not permit a comparison of the efficacy of different antibiotic regimens.[32]

Most of the patients who developed Brazilian purpuric fever in the Brazilian studies were treated with topical antimicrobials for conjunctivitis, yet they still developed systemic disease,[32] a finding suggesting that local topical therapy is ineffective in eradicating the organism from the host. One study examined the relative efficacy of oral rifampin and topical chloramphenicol in eradicating conjunctival carriage of the Brazilian purpuric fever clone.[142] Although the number of patients who actually carried the Brazilian purpuric fever clone was small, rifampin was shown to be significantly better in eradicating carriage of the Brazilian purpuric fever clone than was topical chloramphenicol.

HAEMOPHILUS PARAINFLUENZAE

BACTERIOLOGY

H. parainfluenzae was identified as a species distinct from *H. influenzae* first by Rivers in 1922.[153] Both organisms are fastidious, gram-negative coccobacilli, but with in vitro culture, *H. parainfluenzae* can be propagated on nutrient agar plates with supplemental factor V alone (thus the "para" designation), rather than with both factor X and factor V, which are required by *H. influenzae* isolates (see Table 146-1). Testing for hemolysis on blood-containing media differentiates *H. parainfluenzae* from hemolysis-producing species, such as *H. haemolyticus* and *H. parahaemolyticus*.[99,100] Recovery of *H. parainfluenzae* organisms from blood cultures is enhanced by routine subculturing of all specimens. The organisms tend to grow as small colonies along the side walls of the blood bottles or in the red cell mass, thus leaving the broth clear.[81] Routine subculturing to supplemented chocolate agar and incubation with supplemental carbon dioxide should allow recovery of any *H. parainfluenzae* organisms that are present.[41,79,81]

EPIDEMIOLOGY AND PATHOGENESIS

H. parainfluenzae is found commonly in the oropharyngeal flora of normal children.[78,107,116] The organism can be recovered from oropharyngeal cultures of one fourth or more of healthy children. Of children who develop serious invasive disease caused by *H. parainfluenzae*, more than half give histories of identifiable preceding illnesses, such as upper respiratory tract infection, otitis

media, and dental infections.[13,25,78,88] These historical findings suggest that local inflammation in the upper respiratory tract may predispose to transient bacteremias with this organism, which allows for seeding of other sites, such as the meninges and the heart valves. No specific virulence factors of the organism have been identified to date.

CLINICAL MANIFESTATIONS

As noted previously with *H. aphrophilus*, *H. parainfluenzae* remains an uncommon cause of infection in pediatric patients. However, increasing numbers of cases have been reported since the 1970s.[25] The most commonly reported infection is meningitis.* The clinical courses of the patients described with *H. parainfluenzae* meningitis are not remarkably different from those typical of acute bacterial meningitis caused by other organisms. However, the average age of affected children is 2.2 years,[25] an age significantly greater than that of the typical pediatric patient with bacterial meningitis.

The infection next most commonly reported is endocarditis.† *H. parainfluenzae* endocarditis has numerous unique features. The reported cases of pediatric endocarditis usually occur in adolescents and involve female patients more commonly than male patients.[25] The clinical presentation often is subacute and frequently is not associated with localizing signs on physical examination (i.e., pathologic murmurs), at least initially.[41,115,116] Another unique feature of *H. parainfluenzae* endocarditis is the high incidence of major arterial occlusion secondary to release of large emboli from the heart.[25,41,73,115,172] This high incidence of embolization is thought to result from the particularly friable nature of the vegetations.[25,73] Another characteristic feature noted by several authors is the relatively slow and variable response of endocarditis caused by this organism to antimicrobial therapy.[25,41,115,116] Other *H. parainfluenzae* infections reported in pediatric patients include brain abscesses,[78,118] septic arthritis,[25] urinary tract infection,[25] peritonitis,[119] and sepsis in neonates.[40,152]

TREATMENT

H. parainfluenzae usually is susceptible in vitro to multiple antibiotics, including chloramphenicol, aminoglycosides, trimethoprim-sulfamethoxazole, and third-generation cephalosporins.[25,41,94,116] Although most isolates in the past were susceptible to penicillins, more recent studies documented an increasing incidence of β-lactamase–producing strains resistant to penicillin and ampicillin.[25,160] For β-lactamase–negative, penicillin-susceptible organisms, administration of ampicillin with an aminoglycoside has been recommended for serious *H. parainfluenzae* infections.[41,81] Individual case reports document successful treatment with a variety of other antimicrobials, including ampicillin alone, cephalosporins, chloramphenicol, and trimethoprim-sulfamethoxazole.[35,41,95,116] At present, pending results of susceptibility testing, it would be reasonable to initiate therapy for serious *H. parainfluenzae* infections with a third-generation cephalosporin, perhaps in combination with an aminoglycoside.

CHAPTER 147

HELICOBACTER PYLORI

Samson Cantu ❂ Mark A. Gilger

The discovery of *Helicobacter pylori* in 1983 as the bacterial cause of peptic ulcer disease[161] has revolutionized the understanding, diagnosis, and treatment of acid peptic disease. *H. pylori* appears to infect approximately 50 percent of the world's population, thus rendering it one of the most common bacterial infections in humans.[87,101] An understanding of *H. pylori* is important to pediatricians because this infection usually is acquired in childhood.[87] This chapter details current consensus and understanding of this important pathogen.[39,61,87]

BACKGROUND

The presence of bacteria in the gastric mucosa has been known for more than 100 years.[146] In 1874, Böttcher[13] observed bacteria in the human stomach. Bizzozero[7] described spirochetes in the stomach of dogs in 1893, and his observations were confirmed by Solomon[150] and by Kasai and Kobayashi[88] in the dog, cat, rat, and monkey. Muhlens[121] and later Luger and Neuberger[103] reported finding spiral organisms in ulcerating carcinomas of the stomach in humans. In 1938, Doenges[33] explored the issue of gastric spirochetes and their clinical relevance. He reported a 43 percent prevalence of spiral organisms in the human stomach in an autopsy review of 242 patients without known gastrointestinal disease. Specimen autolysis, however, rendered interpretation of the pathologic significance of the gastric spirochetes impossible. Freedburg and Barron[55] verified the findings of Doenges in 1940 when they identified spirochetes in the stomachs of 37 percent of patients who had undergone partial gastric resection for carcinoma or ulcer disease. Work on the clinical significance of gastric spiral bacteria continued until a report by Palmer was published in 1954.[128] In an attempt to confirm the findings of spirochetes in the gastric mucosa, Palmer performed an exhaustive review of gastric fundus biopsies from 1000 adult patients, 80 percent of whom were being evaluated for upper gastrointestinal complaints and 20 percent were healthy control volunteers. Palmer noted, "None of the 1180 specimens was found to contain spirochetes or any structure which could reasonably be considered to be of spirochetal nature." He concluded that spirochetes are not part of the human gastric mucosa in health or illness. Palmer, a prominent researcher in gastritis, inadvertently may have curtailed further research into the role of gastric spiral bacteria.

In 1975, Steer,[151] using electron microscopy, noted curved bacteria in stomach biopsy specimens from patients with gastric ulcers. A few years later, Warren, an Australian pathologist, noted the appearance of spiral bacteria overlaying inflamed gastric mucosa. Warren noted that this organism looked like a *Campylobacter*. He and Marshall began a series of culture experiments using *Campylobacter*-specific methods. The story culminates in 1983 and 1984, respectively, with their reports of successful culture of the curved bacillus.[114,161] In an attempt to fulfill the remainder of Koch's postulates, Marshall and associates[112] and Morris and Nicholson[120] independently ingested pure cultures of *H. pylori*, and symptomatic acute gastritis developed in both. The organism subsequently was recovered from the gastric mucosa by endoscopy and successfully cultured, thus completing Koch's postulates.

MICROBIOLOGY AND PATHOPHYSIOLOGY

H. pylori initially was named *Campylobacter pyloridis* because of its resemblance to *Campylobacter* spp.[161] Later changed to *C. pylori*, it became clear that the bacterium did not belong to any known genus. An entirely new genus, *Helicobacter*, was created, with "helico" describing the spiral shape and "pylori" denoting its typical location. *H. pylori* is a spiral-shaped, gram-negative bacteria with four to seven unipolar sheathed flagella (Fig. 147–1).[9,126] It is 0.5 μm wide and 3 to 5 μm long and has a smooth surface.[1,117] It generally is S-shaped in vivo but can take on many forms, from U-shaped to cocci to rodlike.[117]

H. pylori inhabits a unique ecologic niche: the submucosa of gastric epithelium. Several attributes, including adherence, shape, microaerophilism, urease production, and motility, allow adaptation to the acidic gastric environment. *H. pylori* overlays the intercellular tight junctions of epithelial cells, beneath the mucous layer. Specific adhesion molecules appear to be tropic to gastric mucus-producing cells.[96] This adherence allows the organism to maintain colonization despite the rapid gastric cell turnover.[98] The spiral shape may allow the organism to corkscrew through the gastric mucus (see Fig. 147–1). This spiral movement has been demonstrated in vitro with methylcellulose solutions.[98] *H. pylori* is microaerophilic and grows slowly in culture media.[9,126] One-millimeter translucent colonies grow after 5 to 7 days on blood- or serum-supplemented media with a low concentration of oxygen and carbon dioxide at a temperature of 37° C, which promotes optimal growth. This microaerophilism is well suited to the low oxygen levels of the gastric submucosa.[96] *H. pylori* is the most potent urease producer of any known microbe; researchers have estimated that as much as 10 percent of its total protein production is urease, and the organism appears to surround itself in a cloud of ammonia.[1,4,9,128] The urea is converted to ammonium and bicarbonate.[8,63] Little evidence supports that the notion that the ammonium produced is cytotoxic to gastric epithelium.[79] The bicarbonate creates an alkaline environment in the gastric submucosa. *H. pylori* produces several other enzymes, including mucinase,[148] lipase,[145] catalase,[102] hemolysin, and cytopathic

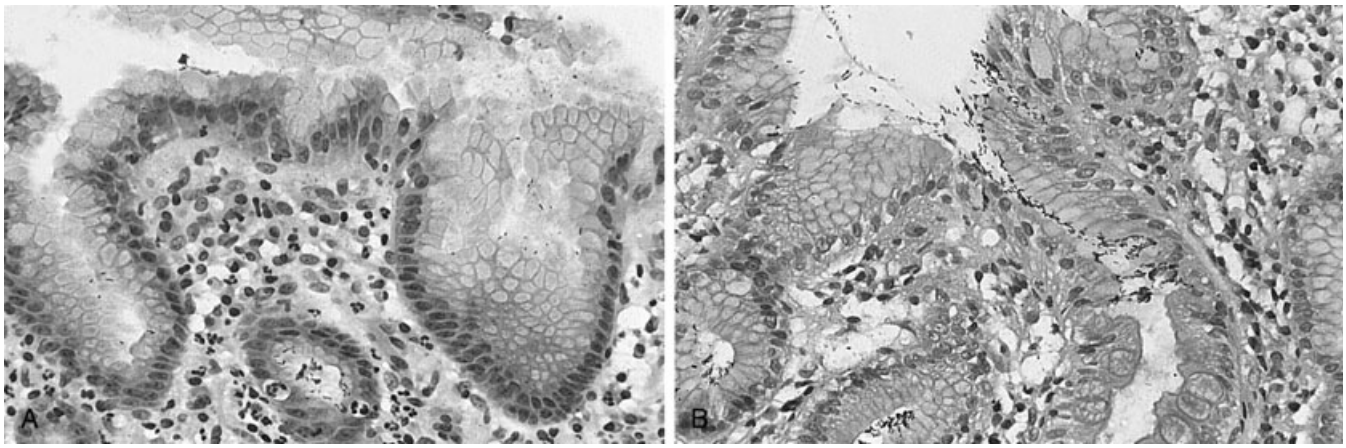

Figure 147–2 **A,** High-power light microscopy of *Helicobacter pylori* demonstrating chronic active gastritis with small numbers of *H. pylori* seen on the epithelial surface and mucus. An aggregate of *H. pylori* organisms is visible within the gastric pit (Genta stain). **B,** More *H. pylori* organisms and mild intestinal metaplasia. *(Courtesy of Dr. Robert Genta, Baylor College of Medicine.)*

toxin.[100] The multiple, unipolar flagella (see Fig. 147–1) provide motility that may enable the organism to escape the acid lumen of the stomach[98] and evade host immune responses.[96]

H. pylori may be more akin to normal gastrointestinal flora because the bacterium and the host can coexist for decades without apparent problems.[69] *H. pylori* infection produces inflammation, although in most cases the host is asymptomatic.[11] The inflammatory response is characterized by infiltration of polymorphonuclear leukocytes, monocytes, lymphocytes, and plasma cells into the lamina propria (Fig. 147–2).[102] A significant immune response, including the production of antibodies, is produced by the host, but it does not clear the organism in most cases.[100] *H. pylori* produces a chronic infection that persists for decades, possibly for life.[102] This lifelong colonization is accomplished by the same features that allow survival in the gastric mucosa, namely, high urease production, flagellar motility, spiral shape, microaerophilism, and adherence.[102]

Numerous potential virulence factors, such as urease, catalase, cytotoxin, and lipopolysaccharide, have been identified, although whether any of these substances actually contribute to symptomatic disease is unknown. The urease of *H. pylori* is a potent antigen that induces elevations in antiurease immunoglobulin G (IgG) and IgA.[102] Interestingly, the ammonia produced by the urease does not appear to have a significant role in pathogenesis.[70] Catalase, another *H. pylori* enzyme, prevents the formation of oxygen metabolites from hydrogen peroxide in neutrophils,[43] which may provide an ability to evade host destruction. A vacuolating cytotoxin has been identified in many *H. pylori* strains,[43] although whether it is more common in patients with symptomatic disease is unclear. *H. pylori* has a peculiar lipopolysaccharide outer membrane. Unlike most gram-negative bacteria, its lipopolysaccharide coat is a significantly less potent inducer of the host complement cascade, some 1000-fold less potent than that of the Enterobacteriaceae.[102] This low biologic activity of the outer membrane of *H. pylori* may be another adaptive mechanism allowing gastric colonization.[10]

EPIDEMIOLOGY

H. pylori is one of the most common bacterial infection in humans, with an estimated 1 billion people in the world being infected.[87,101] It is estimated that in developing countries more than 80 percent of the population is infected with *H. pylori*, whereas in industrialized countries the infection rate remains under 40 percent (Fig. 147–3).[68,131,136] Transmission appears to be from person to person.[97,116,154] Transmission via the fecal-oral route is the primary mode of infection.[14,45,49,110,122,153] The presence of pets may be a risk factor for *H. pylori* infection, given that the bacterium has been isolated from domestic animals.[15,16,36,80] Interestingly, breastfeeding appears to increase the risk of acquiring *H. pylori* infection, possibly secondary to close contact with infected mothers, and breast milk does not protect against infection.[35,142,163] *H. pylori* usually is acquired in childhood,[27,101] and humans appear to be a natural reservoir for infection.[72] Environmental sources of *H. pylori* infection, such as municipal water sources, have been confirmed in Peru and Mexico.[104,118]

Children are important factors in the transmission of *H. pylori* infection, which clusters within families with children.[41,109,116,125,162] Family clustering emphasizes the role of crowding and personal hygiene in the person-to-person spread of infection. The prevalence of infection increases with age. In the United States, for example, only about 20 percent of individuals younger than 30 years old are infected, as compared with 50 percent of those older than 60 years.[111] Infection in young children is a rare event in the United States and developed nations.[102] The phenomenon of increasing prevalence with age most likely reflects a cohort effect; that is, the high prevalence in older persons simply reflects a higher childhood infection rate.[102] This cohort effect may be explained best by a lower standard of living of older persons during childhood. Socioeconomic status varies inversely with the prevalence of infection, with low-income individuals having the highest rates of infection.[52] Conversely, Ozen and associates[127] found that low household population and a history of antibiotic use during the previous 6 months served as protective factors against infection. A higher prevalence of infection exists in developing countries than in developed countries (see Fig. 147–3),[116] and the prevalence of infection varies greatly around the world. In Nigeria, for example, 58 percent of children younger than 1 year old and 91 percent of children older than 10 years were infected.[82] Such differences have been attributed to socioeconomic factors, hygiene, and the number of household occupants.[78] *H. pylori* is more prevalent in blacks and Hispanics than in whites in the United States.[149]

The rate of *H. pylori* reinfection in the pediatric population ranges from 2.4 percent per year to about 20 percent per year.[89,124,139,143] Magista and colleagues[108] demonstrated that the difference in re-infection rate is dependent primarily on the socioeconomic status of the family and the local prevalence of *H. pylori*. They and others[50,51] also noted that living in an area with a high prevalence of *H. pylori* resulted in a fourfold higher risk of re-infection.

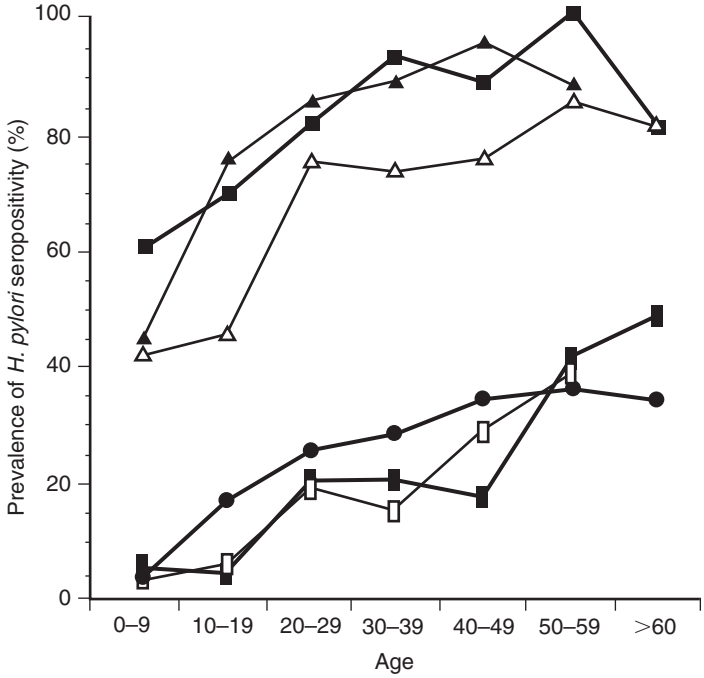

Figure 147–3 Seroepidemiology of *Helicobacter pylori* infection demonstrating the difference in disease prevalence between developing and developed countries. *(Data from Graham, D. Y., Adam, E., Reddy, G. T., et al.: Seroepidemiology of Helicobacter pylori infection in India: Comparison of developing and developed countries. Dig. Dis. Sci. 36:1084-1088, 1991.)*

Although *H. pylori* infection remains common worldwide, the seroprevalence of *H. pylori* infection in U.S. children has dropped significantly in all ethnic groups.[62]

CLINICAL MANIFESTATIONS

Gastritis develops in most *H. pylori*–infected patients, but complications associated with infection develop in only a few.[87] For example, the lifetime risk of peptic ulcer disease developing is estimated to be 10 to 15 percent, whereas gastric cancer will develop in less than 1 percent of *H. pylori*–infected persons.[87] This finding is especially true in children, in whom peptic ulcer is considerably less common than in adults. To confound matters, children have no specific symptoms of *H. pylori* infection.[60,64,65,76,106,137,140] Symptoms such as epigastric pain, nighttime awakening with abdominal pain, hematemesis, and recurrent vomiting are suggestive but in no way predictive of infection.[40,91,123] Because these clinical symptoms are typical of peptic ulcer disease, testing for *H. pylori* infection alone has no relevance but rather should be done to determine the presence of an underlying condition.[95] Such symptoms possibly are present only if *H. pylori* infection is found with a duodenal ulcer. Furthermore, the presence of *H. pylori* infection alone in both adults and children usually is asymptomatic.[31,34,38,55,66,73,134]

The association of *H. pylori* infection with recurrent abdominal pain of childhood remains a topic of ongoing debate. The critical issue is whether *H. pylori* antral gastritis is a source of abdominal pain. The issue remains unresolved.[59,105,106,124,141,154,157] A logical conclusion for the pediatrician would be that a child with active upper gastrointestinal tract complaints in whom *H. pylori* infection is suspected deserves either treatment of the infection or diagnostic upper endoscopy to determine the presence of ulcer disease. *H. pylori* infection also has been associated with protein-losing enteropathy, as well as iron deficiency anemia.[20,21,23,26,81,168]

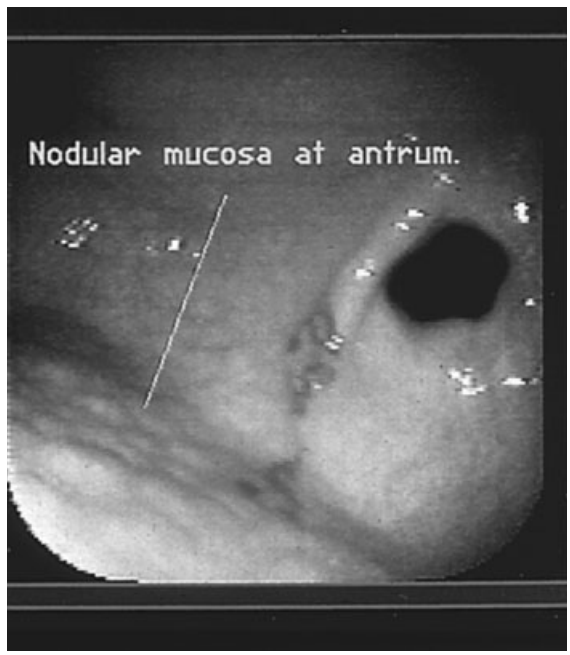

Figure 147–4 Endoscopic view of the gastric antrum demonstrating marked nodularity of the gastric surface.

DIAGNOSIS

The "gold standard" for diagnosis of *H. pylori* infection is culture of the organism from gastric biopsy samples or histologic review.[161] Upper endoscopy or other invasive means are necessary to obtain such biopsy specimens. In children, upper endoscopy can be quite helpful in that it often reveals a distinct nodularity at the antrum (Fig. 147–4), but it also may appear normal. This

nodularity is found in two thirds of infected children but only rarely in adults.[17,77,78] Histologically, prominent lymphoid follicles are seen. Routine staining with hematoxylin and eosin may be adequate but must be performed properly to see the bacteria clearly. Alternative staining techniques, such as acridine orange, silver stains, and the "triple" stain, improve visualization.[56,94,107] The triple, or Genta, stain (Steiner + hematoxylin-eosin + alcian blue) may offer some distinct advantages because it is significantly more sensitive than is hematoxylin-eosin staining and is particularly useful for the detection of small numbers of bacteria, which often is the case in children (see Fig. 147–2). Although culture and histology require the need for endoscopy, culture may be important. In cases of recurrent *H. pylori* infection in which antibiotic resistance is suspected, culture allows in vitro antibiotic sensitivities to be determined.

Noninvasive methods for detection of *H. pylori* infection are detailed in Table 147–1 and include serology, varying methods for detection of urease production, detection of salivary antibody, stool culture, stool antigen, polymerase chain reaction (PCR), and urine ammonia production.[135] The ^{13}C-urea breath test is considered the best available noninvasive diagnostic test in children.[87] Serology, on the other hand, is not useful. Measurement of *H. pylori* stool antigen can be performed by either a polyclonal or monoclonal antibody technique.[44,90] This test detects the presence of antigen, thus providing evidence of active infection for both primary diagnosis or proof of cure. It appears to be of equal accuracy to the urea breath test.

H. pylori infection induces a vigorous neutrophilic and lymphocytic (T-cell and B-cell) response that fails to clear the infection. The humoral immune response produces antibodies that can be detected in gastric secretions, as well as systemically. A number of *H. pylori* antigens have been determined with the use of bacterial cell wall sonicates, urease, or membrane extracts as the capture antigen.[24,28,30,47,147,156] Some commercial assays have been found to have inappropriate positive and negative cutoff values for use in children.[25,28] Care must be taken to ensure that the serologic tests performed have been verified for use in children. Although detection of IgA, polymeric IgA, and IgM antibodies against haptoglobin can be performed, such detection is not reproducible and thus not of any useful clinical value. Serologic diagnosis, though simple and widely available, does not indicate symptomatic disease.

H. pylori is a vigorous producer of urease. This characteristic has been used to create a variety of tests to detect the presence of urease. The urea breath test uses a labeled carbon of urea, either radioactive carbon 14 (^{14}C)[6] or a nonradioactive, stable isotope, carbon 13 (^{13}C).[71] Patients fast 4 to 8 hours and then drink the labeled carbon accompanied by a meal to delay gastric emptying; then, the amount of labeled carbon dioxide in the breath is measured. Only those with gastric *H. pylori* present (and thus gastric urease activity to degrade the labeled urea) will be identified. Urea breath testing is useful for both initial diagnosis and determination of successful treatment because the results return rapidly to normal after eradication. The radioactive ^{14}C

TABLE 147–1 Summary of Methods for Detecting *Helicobacter pylori*

Method	Sensitivity (%)	Specificity (%)	Advantages	Disadvantages
Invasive				
Histology	93-99	95-99	Widely available; detection best with special stains; can evaluate underlying mucosal damage; gold standard	Expensive; at least two biopsies required; observer error; recent antibiotics or proton pump inhibitor use can lead to false-negative results
Culture of biopsy specimens	77-92	100	In vitro antibiotic susceptibility can be determined	Expensive; organism requires special transfer and culture technique; requires up to 1 wk for results; recent antibiotics or proton pump inhibitor use can lead to false-negative results
Rapid urease test CLO test hpFast PyloriTek	89-98	93-98	Rapid results; easy to perform; less expensive than other invasive techniques	Formalin, simethicone, local anesthetic spray, recent antibiotics, bismuth, or proton pump inhibitor use can lead to false-negative results; poor technique or handling will affect results
Noninvasive				
Urea breath test ^{13}C ^{14}C	90-100	89-100	Inexpensive, represents entire mucosa (not subject to biopsy sampling bias)	Antibiotics or proton pump inhibitor use can lead to false-negative results; presence of ulcer disease not determined; can be difficult to collect in children younger than 2 yr
Serology (ELISA) HM-CAP Pylori.STAT	44-99	89-95		
Rapid serology FlexSure QuickVue				
Stool antigen testing (HpSA)	85-94	97.7	Inexpensive, more accurate than serology; may become the test of choice in children	Stool must be collected
Saliva	71-93	82-92	Easy to collect; inexpensive	Low sensitivity, especially in children younger than 2 yr

ELISA, enzyme-linked immunosorbent assay.

Data from Graham, D. Y.: Helicobacter *Today. Altrincham, Cheshire, United Kingdom, Norris Communications, 1995, p. 5, 67; Yen-Hsuan, N., Jaw-Town, L., Shui-Feng, H., et al.: Accurate diagnosis of Helicobacter pylori infection by stool antigen test and 6 other currently available tests in children. J. Pediatr.* 136:*823-827, 2000; Rothenbacher, D., Inceoglu, J., and Brenner, H.: Acquisition of Helicobacter pylori infection in a high risk population occurs within the first 2 years of life. J. Pediatr.* 136:*744-748, 2000; Gilger, M. A., Tolia, V., Johnson, A., et al.: The use of an oral fluid immunoglobulin G ELISA for the detection of Helicobacter pylori infection in children. Helicobacter* 7:*105, 2003; and Luzza, F., Oderda, G., Maletta, M., et al.: Salivary immunoglobulin G assay to diagnose Helicobacter pylori infection in children. J. Clin. Microbiol.* 35:*3358-3360, 1997.*

method does not deserve consideration for use in children. The stable isotope ^{13}C methodology currently is the simplest and most accurate noninvasive test available method for detection of *H. pylori* infection. Its usefulness remains limited, however, because of the need for specialized equipment for analysis.

The urease production of *H. pylori* can be measured directly in gastric biopsy specimens with a variety of commercial assays.[115,120] A portion of the gastric biopsy specimen is placed into a urea medium, and hydrolysis of urea leads to a color change in the medium from tan to pink. False-negative results have been noted in children because of the low numbers of organisms.[42] Such testing is useful for establishing a rapid diagnosis during endoscopy but requires gastric biopsy. Urease activity also can be detected by measurement of another nonradioactive, stable isotope, ammonium, in the urine after oral ingestion.[86] This noninvasive test has not proved to be accurate.

H. pylori has been identified in saliva and dental plaque by culture[93] and PCR.[22] Others have identified salivary antibody to *H. pylori* with an indirect immunofluorescence assay.[83] The saliva test is not accurate in young children and cannot be recommended.[58] Viable *H. pylori* organisms have been cultured from feces in Gambian children.

TREATMENT

Cure of *H. pylori* infection associated with peptic ulcer disease in both children and adults significantly reduces the likelihood of recurrence of peptic ulceration.[85,113,138,167] First-line therapy for *H. pylori* infection in children is a twice-daily, three-drug regimen that includes amoxicillin, clarithromycin, and a proton pump inhibitor given for 14 days.[19,57,87,158,165] Table 147–2 presents a variety of suggested regimens for the treatment of *H. pylori* infection in children. *H. pylori* infection is difficult to cure. Confirmation of successful treatment has been defined as absence of detectable organisms by tissue biopsy or the urea breath test at least 1 month after completion of treatment.[5] Because tissue biopsy is invasive, urea breath testing or stool antigen detection is helpful for determination of successful treatment. Serologic tests are not useful for detection of cure because of the prolonged elevation of titers, which remain elevated for 6 months to 1 year or longer after treatment.

A growing body of evidence indicates that acquisition of *H. pylori* infection in childhood is a significant risk factor for the development of gastric cancer such as adenocarcinoma (Fig. 147–5).[84,129,155] An estimated twofold to sixfold increased risk for

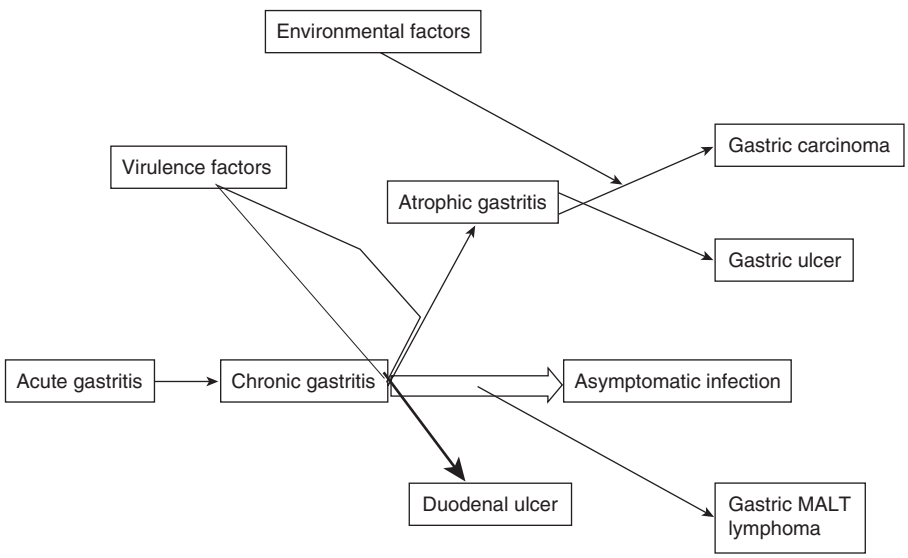

Figure 147–5 Timeline of possible outcomes of *Helicobacter pylori* infection starting from the acute acquisition of infection and possible sequelae. MALT, mucosa-associated lymphoid tissue. *(D, Graham, personal data.)*

the development of gastric cancer exists among *H. pylori*–infected patients.[32,53,159,160] A current concern is whether *H. pylori* treatment decreases the risk for development of gastric cancer.[152] Multiple studies have demonstrated that no significant difference exists between treated groups and placebo groups. Patients in whom gastric cancer develops appear to already have atrophic gastritis or metaplasia at baseline.[99,119,164] This finding argues for treatment of *H. pylori* infection in childhood, before the onset of atrophic gastritis. The location of the infection within the stomach may influence the outcome. For example, antral-predominant infection more commonly leads to increased acid secretion, which results in duodenal peptic ulcers and a low risk for gastric cancer. In contrast, fundus-predominant infection leads to decreased acid secretion, which results in atrophic gastritis and a higher risk for gastric cancer.[99] Treatment of gastric lymphoma with antibiotics directed at *H. pylori* has resulted in regression of the tumor.[2,165] Some researchers argue that the risk of developing either lymphoma or adenocarcinoma provides cause for the treatment of all children infected with *H. pylori*. Because the risk for development of cancer cannot be predicted accurately and because most children with *H. pylori* infection have no clinical symptoms, no current rationale exists for treating all children infected with *H. pylori*.

In children, the most effective anti-*Helicobacter* treatment currently available is "triple therapy" that includes amoxicillin, clarithromycin, and a proton pump inhibitor (Table 147–2).[74,87,111] Efficacy rates of 85 to 95 percent have been reported for this combination. In patients allergic to penicillin, amoxicillin may be replaced with metronidazole. Metronidazole, to which the *H. pylori* organism is highly sensitive, has a high rate of resistance because of its overuse for other infections.[46] A multicenter study in Europe found the overall resistance to be 25 percent for metronidazole, 24 percent for clarithromycin, but only 0.6 percent for amoxicillin.[92] In cases of antimicrobial resistance, the use of rifabutin, furazolidone,[29,48,75,132,133,166] and fluoroquinolones such as ciprofloxacin, along with rifampin and streptomycin, has been reported as options in treating resistant *H. pylori* infection.[37,45,54,144] These second-line regimens have no particular advantage over the first-line antibiotics and should be considered only when resistance is suspected. No single antibiotic agent given alone is effective therapy against *H. pylori*.[113,130,138] Extensive study continues to determine the optimal treatment of *H. pylori*, but to date, triple therapy remains the accepted standard.

When cure of infection has been obtained, the long-term rates of reinfection are as low as 1 percent per year in developed countries but much higher in developing nations.[12,130] However, reinfection may be more likely to occur in families, especially when small children are the first infected.[3] No conclusive evidence currently exists, however, to recommend routine treatment of the entire family.[124]

Vaccination against *H. pylori* infection appears possible. Work in a mouse model has shown that oral immunization with a sonicate of *Helicobacter fetus* plus the adjuvant cholera toxin results in protection against an oral challenge.[18] Continued animal model investigation may yield promising direction for future vaccines.

FUTURE DIRECTIONS

H. pylori is a major cause of peptic ulcer disease in children and adults, which has caused a dramatic reappraisal of many previous notions about ulcer disease. Although the dictum "No acid, no ulcer" still holds, many other previous considerations, such as genetic predisposition, must be re-examined. Figure 147-5 demonstrates a proposed *H. pylori* timeline. It emphasizes the acquisition of an acute infection in childhood, persistent chronic gastritis, and the possible progression to ulcer, atrophic gastritis, and potentially gastric carcinoma and lymphoma.

CHAPTER 148

KINGELLA SPECIES

Thomas L. Kuhls

The genus *Kingella* consists of four species: *Kingella kingae*, *Kingella denitrificans*, *Kingella oralis*, and *Kingella potus*. *K. kingae* is being recognized increasingly as an important cause of invasive infections in children. With improved methods of recovering this fastidious member of the family Neisseriaceae and increasing awareness that the microorganism is not a culture contaminant, *K. kingae* infections are being encountered almost annually by many pediatric infectious disease specialists.[13] The assumption, however, is that most *K. kingae* infections continue to be treated empirically because the organism is difficult to isolate from clinical specimens. *K. denitrificans* rarely causes endocarditis,[4,10,26] empyema,[44] and chorioamnionitis[42] in adults; it has been isolated from a single child with endocarditis.[61] *K. potus* has been isolated from a wound caused by a bite from an arboreal mammal found normally in the rainforests of Central and South America.[38] To date, *K. oralis* has not been found to cause human infections.[17]

HISTORY

During the 1950s and early 1960s, Elizabeth O. King isolated gram-negative bacilli from clinical specimens that had phenotypic and growth characteristics identical to those of *Moraxella* spp., except that the organisms were beta-hemolytic and did not contain catalase.[28] In honor of King, the organism initially was named *Moraxella kingii* in 1968,[28] later renamed *Moraxella kingae* in 1974,[8] and finally reclassified as *Kingella kingae* in 1976.[29] The Centers for Disease Control and Prevention received 78 *K. kingae* isolates from 1953 to 1980, 75 percent of which were recovered from blood, bone, or joint specimens.[25] Most of the isolates were obtained from children younger than 6 years old. During the 1980s, increasing numbers of children with *K. kingae* infection were reported because of better awareness of the microorganism and better culturing techniques for fastidious agents. Not until the 1990s did the importance of *K. kingae* in causing invasive infections in children become apparent.

MICROBIOLOGY

Kingella spp. are small (0.6 to 1 μm × 1 to 3 μm), gram-negative rods that may resist Gram decolorization.[51] The organisms can appear coccoid and exist in pairs or short chains. The nonencapsulated bacilli are fastidious aerobes that grow best at 33° C to 37° C in both nutrient and blood agar. At least 4 days of incubation usually is required before *Kingella* spp. can be detected in clinical specimens grown on agar plates, but growth can be detected earlier with newer automated detection culturing systems.[40,80,81,88] Two types of bacterial colonies are found on agar plates: small, smooth, and nearly translucent colonies and larger spreading colonies that appear pitted because of corrosion of the agar surface. The larger colony type, however, generally is not present after the initial colonies have been subcultured, unless the organism is cultured under anaerobic conditions. Biochemical characteristics of the genus *Kingella* include negative reactions for motility, catalase, indole, and urease and a positive reaction for oxidase. All members of the genus, except *K. potus*, are able to produce trace acid from glucose.

K. kingae and *K. denitrificans* are the only members of the genus reported to cause invasive infections in children. *K. kingae* can be differentiated from *K. denitrificans*, *K. oralis*, *K. potus*, and *Neisseria* spp. by a distinct narrow zone of beta-hemolysis surrounding the colonies. Unlike *K. denitrificans*, *K. kingae* does not reduce nitrates or nitrites and produces acid from maltose. *K. kingae* can be confused easily with isolates of *Eikenella corrodens* and *Cardiobacterium hominis*, both of which can cause suppurative infections in humans. In addition, *K. kingae* can be misidentified as beta-hemolytic streptococci in Gram-stained specimens when decolorization is incomplete.

EPIDEMIOLOGY

Kingella spp. are a part of the normal oropharyngeal flora of children. In 1969, *K. kingae* was isolated from 1.1 percent of nose and throat swabs obtained from children and adults.[27] In this study, however, the cultures were incubated for only 24 hours and selective media were not used; thus, the prevalence rate of carriage most likely was much higher. More recently, throat and nasopharyngeal specimens from infants and children attending two daycare centers in Israel were cultured on selective media.[82,86] Specimens were collected every 2 weeks for a duration of 11 months. Monthly prevalence rates of *K. kingae* carriage ranged from 6 to 35 percent, with the highest rates found in the months December through April. Overall, at least one positive *K. kingae* culture was obtained in 73 percent of the children. The rate of *K. kingae* carriage in this study was similar to the previously reported carriage rates of *Streptococcus pneumoniae* in children of the same age group and much higher than the rates of *Haemophilus influenzae* type b (Hib) carriage seen in young children during the pre-vaccine era. Unlike these respiratory tract pathogens, *K.*

kingae was isolated only from the tonsillar areas of the children and not from the nasopharynx. The investigators did not isolate *K. kingae* from 2- to 4-month-old infants attending a well-care clinic but did isolate the organism from 8 percent of healthy children older than 8 years of age who were scheduled for elective surgical procedures.[82] The same investigators also evaluated more than 2000 oropharyngeal specimens in 2001 and determined that carriage was highest in children younger than 3 years of age and lowest in adults, 3.2 and 0.8 percent, respectively, and that carriage rates did not differ between sexes or during different seasons of the year.[87] High rates of oropharyngeal carriage in children attending daycare centers also have been observed in the United States and again in Israel.[22,34,83]

K. kingae isolates from the tonsils of daycare attendees have been shown by immunoblotting, pulsed-field electrophoresis, and ribotyping techniques to be more commonly type-specific than are isolates from unrelated individuals, thus suggesting that the organism is transmitted from person to person in the daycare setting.[22,34,66,83] Two outbreaks of *K. kingae* skeletal infections in daycare centers have been reported.[22,34,83] In both instances, isolates from children with invasive disease were identical to strains found in other pharyngeal-colonized children at the daycare centers.

Osteoarticular *K. kingae* infections occur most commonly in children 6 months to 4 years of age,[24,36,81,87] but *K. kingae* endocarditis occurs in all age groups, including adults.[15,24,72,77] In southern Israel, the annual incidence of *K. kingae* invasive infection has been estimated to be 22 cases per 100,000 children aged 2 years or younger.[79,87] The rate of invasive infection was a quarter that found for invasive Hib infection during a period when children were not receiving conjugated Hib vaccine in a previous study.[81] In children with suppurative arthritis, *K. kingae* has been isolated more commonly than has Hib from joint aspirates that were cultured directly in BACTEC bottles.[80] In more recent series of patients in whom suppurative arthritis developed after the advent of the routine use of conjugated Hib vaccine, *K. kingae* was the most common cause of infection in children younger than 36 months old.[41,47]

Invasive *K. kingae* infections occur more frequently in males than in females in most studies[24,36,41,79,87] and tend to occur between the months of July and December.[12,15,81,87] Upper respiratory tract symptoms, dental abnormalities, or evidence of stomatitis usually precedes the signs of invasive illness.[24,36,81,89] Infections have occurred in several children after or while experiencing a primary varicella infection or an episode of herpetic gingivostomatitis.[1,37,40,74] In Israel, 61 percent of children with an invasive infection had evidence of a respiratory tract infection or stomatitis at the time of *K. kingae* infection.[79,87]

PATHOGENESIS AND IMMUNITY

No studies have defined the mechanisms of pathogenesis of *Kingella* infection. *Kingella* spp. have type 4 pili, which may allow the organisms to adhere to oropharyngeal epithelium.[75] Because *K. kingae* normally colonizes the oropharyngeal mucosa of young children and infection frequently is associated with upper respiratory tract infections, dental abnormalities, and evidence of stomatitis, damage to the oropharyngeal mucosa by viruses or trauma probably allows *K. kingae* access to the bloodstream. After a period of transient bacteremia, *K. kingae* can seed other tissues and cause focal infection in joints, bones, disk spaces, and heart valves.

The outer-membrane proteins of *K. kingae* have been characterized, and many have been found to be immunogenic.[90] Although children convalescing from invasive infection experience increases in the amount of specific immunoglobulin G (IgG) antibodies, the responses are mild and extremely variable.[65]

CLINICAL MANIFESTATIONS

K. kingae causes various infections in children (Table 148–1), with the most common invasive infection being suppurative arthritis.[39,46,81,87] Infants and young children usually have acute monarticular joint swelling and tenderness. To date, no cases of polyarticular infection in children have been reported. No features of the illness distinguish it from other bacterial causes of suppurative arthritis. Patients often have symptoms of an upper respiratory tract illness or stomatitis shortly before or at the time of illness.[1,39,40,46,55,79,89] Eighty-six percent of children in one series had temperatures higher than 38° C at initial evaluation.[36] The knee is the joint affected most commonly.[6,16,19,21,48] However, *K. kingae* has been reported to cause infection in the hip,[7,37,48] ankle,[6,48] elbow,[6,19] wrist,[58,81] sternoclavicular joint,[15,16,73] and shoulder.[21,81] Most children do not have an underlying illness that increases their susceptibility to infection, although *K. kingae* suppurative arthritis has developed in a child undergoing therapy for acute lymphocytic leukemia.[55]

K. kingae osteomyelitis has a more insidious onset than suppurative arthritis does, with most patients having symptoms for at least 1 week before a bone infection is diagnosed. Fever is present in only half the children with *K. kingae* osteomyelitis.[36] The proximal and distal ends of the femur are the most common sites of infection,[15,18,24,64] which often occurs in an epiphysis.[7,19,36,63,81] *K. kingae* osteomyelitis of the talus[3,15,72] and calcaneus[24,37,81,84] also develops in young children, although unlike individuals with the more frequently encountered osteomyelitis associated with puncture wounds, these children have relatively mild symptoms and no history of trauma or penetrating injury. In fact, in a young child with osteomyelitis of the talus or calcaneus and no history of penetrating trauma, *K. kingae* infection should be suspected highly. Less commonly, *K. kingae* causes infection in the tibia,[24,63] clavicle,[59] ulna,[50] radius,[12] humerus,[6,81] and sternum.[18,54] In one child with *K. kingae* osteomyelitis of the neck of the femur, the histopathologic findings of the infected bone resembled those of eosinophilic granuloma.[64]

Numerous cases of *K. kingae* spondylodiskitis in children have been reported.[12,24,36,37,52,54] These children usually are younger than 5 years old and have an insidious onset of back stiffness and tenderness, eventually leading to their refusal to walk. Fever was present in two thirds of patients, but temperatures were never higher than 39° C.[41] Various disks from T11-T12 to L5-S1 have been involved, and one patient with cervical involvement has been reported.[52]

Fewer than half of the reported cases of *K. kingae* endocarditis have occurred in children,[6,22,31,74,76] and nearly three quarters of the patients have had preexisting structural cardiac defects.[24,77] The history and physical findings of *K. kingae* endocarditis do not differ from those seen in children with subacute endocarditis of other bacterial causes. At least a third of patients with *K. kingae*

TABLE 148–1 Infections in Children Caused by *Kingella kingae*

Dactylitis
Endocarditis
Endophthalmitis
Meningitis
Orbital cellulitis
Osteomyelitis
Pulmonary infection
Soft tissue abscess
Spondylodiskitis
Subglottic and epiglottic infections
Suppurative arthritis
Transient bacteremia

endocarditis have oral or pharyngeal mucosal alterations before systemic symptoms develop.[24,77] Children usually are febrile, and they often have a new or changing heart murmur, splenomegaly, and petechial rash.[9] Patients also can exhibit more acute symptoms, including evidence of septic shock and cardiac failure.[5,15,72] *K. kingae* endocarditis occasionally has occurred in immunosuppressed individuals,[15,30,77] including patients with acquired immunodeficiency syndrome (AIDS).[33,70]

Isolation of *K. kingae* from the blood of a febrile infant should not suggest necessarily that the child has endocarditis or an unidentified focal infection. Numerous children with transient *K. kingae* bacteremia during infancy in whom a focal infection did not develop have been identified.[35,48,78,79] A rash mimicking gonococcemia[58,62] or meningococcemia rarely develops in bacteremic children.[69] Rarer *K. kingae* infections include meningitis,[49,56,69,71] endophthalmitis,[11,24] pulmonary infections,[45] dactylitis,[14,81] subglottic[81] and epiglottic[32] infections, orbital cellulitis,[17] and soft tissue abscesses.[27,57] Recently, a child with *K. kingae* bacteremia and simultaneous manifestations of Henoch-Schönlein purpura was described.[23]

A 3-year-old child with vaginitis from which *K. denitrificans* was isolated and a 22-month-old with *K. denitrificans* endocarditis are the only reported examples of other members of the *Kingella* genus causing infection during childhood.[60,61]

LABORATORY FINDINGS AND DIAGNOSIS

No characteristic laboratory findings suggest the presence of an invasive *K. kingae* infection. Leukocytosis (>10,000 white blood cells/mm^3) is present in only 60 percent of children with an invasive infection. However, the erythrocyte sedimentation rate frequently is elevated (>20 mm/hr) in children with bone and joint infections.[36] Interestingly, the C-reactive protein level in *K. kingae* osteoarticular infections usually is normal, thus suggesting that this test may be less helpful than the erythrocyte sedimentation rate in diagnosing this infection.[16,41] In children with culture-proven suppurative arthritis, the leukocyte count in synovial fluid is variable (10,000 to 161,000 white blood cells/mm^3), but neutrophils usually predominate.[81] Organisms are identified by Gram stain in less than 15 percent of clinical specimens.[24,36] Plain radiographs demonstrate soft tissue swelling and joint effusions in half the cases of suppurative arthritis, but lytic lesions or disk space narrowing develops in 95 percent of cases of osteomyelitis or spondylodiskitis.[24] Technetium 99m bone scans may be of assistance in diagnosing *K. kingae* osteomyelitis during the early course of disease, when plain radiographs do not yet demonstrate abnormalities.[24] In children with *K. kingae* endocarditis, large vegetations often are demonstrated by echocardiography, especially in those who have had symptoms for a long time or when evidence of embolization is present.

K. kingae infection is diagnosed by isolating the organism from an appropriate clinical specimen. The organism is isolated from blood in only 5 percent of patients with osteoarticular *K. kingae* infections.[19] The fastidious nature of the organism, the low number of organisms found in clinical specimens, and its slow growth pattern hamper recovery of *K. kingae*. Conventional cultures should be examined at least once per week for 3 weeks to detect the organism. The recovery rate of *K. kingae* can be enhanced greatly if culture material, including purulent synovial fluid, is inoculated directly into BacT/Alert, Isolator, or BACTEC culture systems.[38,80,81,88] In one study, 91 percent of episodes of *K. kingae* suppurative arthritis would have been missed if the specimens had not been cultured in BACTEC bottles.[80] In addition, growth of the organism can be detected within 72 hours with these culturing systems; hence, prolonged incubation and extensive subculturing of blood with newer technologies is not necessary.[2,53] Once growth is detected, the clinical microbiology laboratory often has difficulty identifying it as *K. kingae*. Clinicians should suspect that a patient has a *K. kingae* infection when slow-growing, gram-negative rods that display beta-hemolysis are isolated from a normally sterile body site.

In the future, broad-spectrum polymerase chain reaction (PCR) amplification may be a routine technique used to diagnose *K. kingae* infections directly from clinical specimens.[46,68] In France, culture-negative osteoarticular specimens from children have been tested with 16S ribosomal DNA PCR, and 14 percent of samples were positive for *Kingella* DNA sequences, thus suggesting that this testing method most likely is more sensitive than are current culturing techniques.[73]

TREATMENT AND OUTCOME

K. kingae almost always is susceptible to β-lactam antibiotics.[15,31,85] However, three isolates obtained from children and an isolate from an adult patient with AIDS have contained β-lactamase.[6,67] Similarly, a *K. denitrificans* isolate obtained from the bone marrow of a 39-year-old patient with AIDS contained β-lactamase.[43] A few isolates have shown in vitro resistance to anti-staphylococcal β-lactams without the presence of β-lactamase.[6,16] Isolates of *K. kingae* universally have been susceptible to second- and third-generation cephalosporins and aminoglycosides.[15,31] Rarely, resistance to chloramphenicol and trimethoprim-sulfamethoxazole has been reported.[6,64,85] Many isolates, however, demonstrate at least partial resistance to erythromycin, clindamycin, and vancomycin.[6,15,31,85]

Children with invasive *K. kingae* infection have been treated with a variety of antibiotics, including penicillin G, ampicillin, cephalosporins, chloramphenicol, trimethoprim-sulfamethoxazole, and the anti-staphylococcal β-lactams. Occasionally, osteoarticular infections have resolved without administration of antimicrobial therapy.[39] Most infections should be treated initially with intravenous ampicillin because this antibiotic is tolerated relatively well and is inexpensive. All *K. kingae* isolates, however, should be checked for β-lactamase activity.

The duration of antibiotic treatment for *K. kingae* osteoarticular infection has ranged from 17 days to 6 months.[36] Oral therapy with an antibiotic such as amoxicillin can be considered when gastrointestinal absorption is demonstrated and compliance can be monitored. Many clinicians use normalization of the erythrocyte sedimentation rate as a guide to the duration of therapy. Surgical drainage of the bone, joint, or disk space usually is not required, except for infections in the hip and shoulder. The prognosis of patients with *K. kingae* osteoarticular infection is excellent; chronic mild complications from the initial infection have been reported only rarely. However, persistent narrowing of the intervertebral disk space commonly occurs in cases of *K. kingae* spondylodiskitis.[36]

Patients with *K. kingae* endocarditis usually respond rapidly to antibiotic therapy and become afebrile in a few days. High-dose intravenous therapy generally is continued for 4 to 6 weeks. In cases in which prosthetic valves are infected, surgical excision of the valve usually is not needed for cure unless an abscess forms. Unlike osteoarticular infections, the complication rate of *K. kingae* endocarditis is high; cerebral infarction and death have been reported after embolization of vegetations.[15,77]

CHAPTER 149

Legionnaires' Disease, Pontiac Fever, and Related Illnesses

Paul H. Edelstein

Legionnaires' disease is an acute pneumonic illness caused by gram-negative bacilli of the genus *Legionella*. Pontiac fever is a febrile, nonpneumonic, systemic illness closely associated with, if not caused by, infection with *Legionella* spp.

HISTORY

Legionnaires' disease was recognized first as a distinct clinical entity when it caused an epidemic of pneumonia at an American Legion convention in Philadelphia in 1976; 221 people were affected, and 34 died.[61] Investigators were unable to determine the exact cause of the outbreak immediately; this mystery provoked considerable fear and widespread speculation about the cause. Approximately 6 months later, two investigators at the Centers for Disease Control and Prevention, Joseph McDade and Charles Shepard, announced that they had discovered the etiologic agent, a fastidious gram-negative bacillus.[107] Researchers subsequently determined that both the organism and the disease had been studied previously as long ago as the 1940s but had been forgotten.[34,47,142] Because of the historical association with the American Legion convention, this disease now is called *legionnaires' disease*, and the etiologic agents belong to the family Legionellaceae.

ETIOLOGIC AGENT

Legionella is the only genus in the family Legionellaceae. Fifty species of *Legionella* and more than 70 different serogroups now are recognized (Table 149–1). *Legionella pneumophila* is the species responsible for the 1976 Philadelphia epidemic, and it causes most cases of legionnaires' disease.[34,38,47,93,99,142] Serogroup 1 of *L. pneumophila* is estimated to cause approximately 70 to 90 percent of all cases of legionnaires' disease in previously healthy people.[39,103] *Legionella* spp. other than *L. pneumophila* and serogroups other than *L. pneumophila* serogroup 1 cause 25 to 40 percent of nosocomial outbreaks of legionnaires' disease; of these, *L. pneumophila* serogroups 4 and 6, *Legionella micdadei*, and *Legionella dumoffii* are the most common.[76,153] *L. pneumophila* and *Legionella longbeachae* are the only two *Legionella* spp. that normally infect nonimmunocompromised patients.

The Legionellaceae are obligately aerobic, mesophilic, motile, gram-negative bacilli with variable oxidase and catalase reactions.[46] Amino acids rather than carbohydrates are used as an energy source. One unique bacterial characteristic is a nutritional requirement for L-cysteine, a characteristic shared among gram-negative rods with only *Francisella tularensis*. In addition, both the cellular fatty acid and ubiquinone content differ from those of other mesophilic gram-negative bacilli.

Sequencing of the genomes of three different *L. pneumophila* serogroup 1 strains revealed that these bacteria harbor a number of eukaryotic-like genes, a number of secretion systems, remarkable plasticity, and the presence of mobile elements. Approximately 10 percent of the approximately 3.5-Mb genome is devoted to strain-specific genes.[21,28,29]

The antigenic relationships among different *Legionella* spp. and among serotypes of the same species are complex.[142] The serologic typing scheme is based on surface antigens (O antigens), which primarily are lipopolysaccharides. These surface antigens are shared by different species and, in rare cases, by other gram-negative bacilli, such as *Pseudomonas* spp. Thus, identifying an unknown strain with the use of serologic methods alone occasionally leads to a false or misleading identification. Cross-reactions also may be observed when testing for human antibodies to *Legionella* spp. Patients with infections caused by some *Pseudomonas* strains, *Campylobacter jejuni*, and other gram-negative bacilli may form antibodies to *Legionella* spp.[45]

Because of these complexities, definite identification of *Legionella* spp. other than *L. pneumophila* often requires the capabilities of a research laboratory. However, isolation and presumptive identification of *L. pneumophila* should be within the capabilities of most clinical laboratories.[46]

Legionella is ubiquitous in the aqueous environment and can be found, often in high concentration, in lake water, ponds, bathing water, hot-water tanks, hot-water plumbing, and air-conditioning cooling towers.[142] Its optimal temperature for growth ranges from approximately 28° C to 40° C (82° F to 104° F). The natural hosts and probable reservoirs of environmental *Legionella* bacteria probably are fresh-water amebae such as *Acanthamoeba* and *Hartmannella*.[58] Factors that promote the environmental growth of *Legionella* include the presence of other microorganisms, use of plumbing materials that promote bacterial growth (certain types of rubber gaskets), stagnation, and warm temperatures.[142] In the home, older municipal water distribution systems, use of electric rather than gas water heaters, and use of well water all appear to promote the presence of *Legionella* in water.[58,138] Most newly discovered *Legionella* spp. have been environmental isolates not associated with clinical illness.[58]

A large number of bacterial virulence factors have been described, the most important of which is the Dot/Icm complex. This complex is composed of 26 genes that form a type IV secretion system, which is required for growth of *L. pneumophila* within macrophages. *L. pneumophila* is not killed actively by macrophages, which in fact provide sustenance for the bacterium. The Dot/Icm complex allows the bacterium to evade normal phagolysomal trafficking and bacterial destruction by injecting effectors into the host macrophage within minutes of initial bacterial-macrophage contact.[2] A few effectors have been described, although more probably will be found. The end result is that the normal host processes are hijacked into providing a intracellular compartment for the bacterium that associates with the endoplasmic reticulum.[30,114,131] Other bacterial virulence factors include a variety of enzymes, iron-binding proteins, and miscellaneous proteins enhancing intracellular growth and survival or invasion.[30]

The availability of intracellular iron appears to play a key role in the growth of intracellular *L. pneumophila*. Interferon-γ, the production of which is increased during *L. pneumophila* infection of macrophages, down-regulates the number of iron-binding receptors on macrophages, which has the effect of decreasing the availability of intracellular iron and, hence, limiting intracellular growth of the bacterium.[23]

L. pneumophila is serum-resistant.[142] High-titer antibody promotes phagocytosis but may not enhance killing. Macrophage activation factors possibly are more important than is antibody in promoting phagocytosis and bacterial killing.[80]

EPIDEMIOLOGY

INCIDENCE AND FREQUENCY

The incidence of pediatric legionnaires' disease has been studied only by use of serosurveys, which also have been used for most studies involving the adult population.* Because of the less than absolute specificity of serologic testing, frequent failure to obtain appropriately timed paired serum samples, and almost uniform lack of culture confirmation of disease, these serosurveys can be used only as crude measurements of the incidence of the disease.[34,127,142] Regardless, pediatric legionnaires' disease rarely appears to be the cause of pneumonia in otherwise healthy children.† Fewer than 10 culture-confirmed cases of legionnaires' disease have been reported in otherwise normally healthy children, and fewer than 30 culture-confirmed cases have been reported in immunosuppressed children.‡

A retrospective serosurvey of 500 patients with pneumonia, 83 percent of whom did not need hospitalization, found that only 5 of the 132 patients younger than 15 years old had significant antibody titers against *L. pneumophila* and none seroconverted.[60] The estimated incidence of legionnaires' disease in the overall population was approximately 12 per 100,000 per year. In a year-long prospective study of 191 children hospitalized with pneumonia, titers rose significantly in only 1 child (0.92% of cases with paired serum samples available).[118] In another prospective study of 52 children younger than 4 years old with lower respiratory tract infections, no cases of legionnaires' disease were

identified.[4] Four of 211 Iowa children (1 to 19 years of age) with atypical pneumonia demonstrated seroconversion to *L. pneumophila*.[129] In a retrospective Israeli serosurvey, titers rose in two of 37 children.[113] A 2-year prospective study in France found that only two of 278 children (0.7%) hospitalized for pneumonia had legionnaires' disease based on seroconversion.[32] One of these two children was immunosuppressed. With these data, one could estimate that the mean frequency of legionnaires' disease as a cause of pneumonia requiring hospitalization in the normal pediatric population is approximately 1 percent. This rate is about the same as the 0.5 to 4 percent frequency found in the adult population.[34,103,142] Legionnaires' disease is not a major cause of pneumonia in either children or adults.

The frequency of legionnaires' disease in the immunosuppressed pediatric population is unknown. Several case reports document this disease in children being treated for acute leukemia, in children with chronic granulomatous disease, and in children after bone marrow or solid organ transplantation or after being treated with steroids for other reasons.* No large studies of this disease in the immunosuppressed pediatric population have been performed, however. One retrospective study of 55 pediatric cancer patients with atypical pneumonia found 1 patient with a rise in antibody titer to *L. pneumophila*.[132] Nosocomial or community-acquired legionnaires' disease has been reported in several "immunologically normal" infants, who may have had some degree of immune system compromise that predisposed them to this disease.[33,57,62,78,79,87,95,116,126] Neonates appear to be at risk of acquiring nosocomial, water-birthing–related, and community-acquired legionnaires' disease.[69,98] Neonates in intensive care units may be at particularly high risk for the acquisition of nosocomial legionnaires' disease because of the immaturity of their immune system and because of the humid and warm conditions of neonatal incubators, which are ideal for growth of the bacterium.

Whether atypical, mild, or asymptomatic *Legionella* infection occurs in children is unknown. Several cases of Pontiac fever in children have been reported in outbreaks of this disease.[66,82,85,100] The risk of acquiring Pontiac fever was found to be greater for younger people in one outbreak,[82] just the opposite finding in another investigation of an outbreak.[85] The true frequency of Pontiac fever in children is difficult to determine because the diagnosis is impossible to make with certainty in the sporadic form. Several of the serosurveys already cited have found asymptomatic elevations of *L. pneumophila* antibody in widely varying frequency. Andersen and colleagues[4] found that an increase in antibody titer unrelated to acute illness developed in 27 of 52 children over a period of several years; some of these children had significantly high titers. Muldoon and coworkers[112] found that 15 percent of 126 children sampled had antibody titers to *L. pneumophila* of 256 or greater, which was not significantly different from those seen in an adult control population. The striking finding was that antibody titers rose with age, doubling each year until 3 years of age, at which time the values reached a plateau; this finding held even when patients with pneumonia were excluded. In contrast, using a different and perhaps more specific antigen preparation, Mundel and colleagues[113] in Israel found a much lower prevalence of elevated antibody titers. That these findings may be geographic rather than methodologic is exemplified by the study of Orenstein and associates,[118] who obtained results similar to the Israeli study despite using the same type of antigen used by Andersen and colleagues.[4] The significance of these elevated titers in children without documented pneumonia is unclear, and these findings can be interpreted as cross-reactions to other colonizing or infecting bacteria, asymptomatic infection, or atypical disease.

*See references 35, 51, 71, 84, 91, 92, 96, 121, 122, 132, 134, 139, 143.

Several investigators have examined the question of whether atypical disease caused by *Legionella* occurs in children. Unfortunately, all these studies are based exclusively on serologic testing, which may not be entirely specific. Italian physicians found that two children with acute, reversible cerebellar ataxia exhibited significant antibody titer changes to *L. pneumophila*.[117] Another Italian study found two children with pericarditis who had significant antibody changes.[137] None of 140 British infants with sudden death had measurable antibodies to *L. pneumophila* despite suggestions that they might be linked.[149] Three studies have shown that children with cystic fibrosis have higher antibody levels to *Legionella* than normal children do, although these data are suspect because of known cross-reactions between *Legionella* and *Pseudomonas aeruginosa*.[31,49,88] Thus, despite several epidemiologic surveys, the prevalence of atypical *Legionella* infections in children is unclear.

In adults, true incidence figures for legionnaires' disease are difficult to find. Estimates based on serologic surveys range from 2 to 20 cases per 100,000 population per year.[34,127,142] A prospective study in Ohio found that the incidence of legionnaires' disease requiring hospitalization was approximately 6 per 100,000 per year, in what is thought to be a geographic region with an above-average frequency of the disease.[104] Estimates of the proportion of cases of adult pneumonia caused by legionnaires' disease range from 1 to 25 percent, with a reasonable mean of 3 percent.[103] Mild or atypical *Legionella* infection certainly occurs in adults, although the exact incidence is unknown. This approximately 3 percent prevalence is based on several outbreaks of Pontiac fever and case reports from the original Philadelphia outbreak of people with relatively mild disease.[34,61,64,65,90,142] Asymptomatic infection may occur in adults, based on the same types of serosurveys discussed for children. Neither oropharyngeal colonization nor a carrier state has been documented. A study of a cross-section of adults showed that approximately 6 percent exhibited oropharyngeal colonization with *L. pneumophila* on the basis of immunofluorescent studies, although none of the positive results could be confirmed by culture and, therefore, are suspect.[20]

DISEASE OUTBREAKS

Many epidemics of legionnaires' disease and Pontiac fever have been recognized.[19,34,66,142] In the case of legionnaires' disease, most outbreaks have occurred in residents, employees, or visitors in large buildings, such as hotels, hospitals, factories, retail stores, and office buildings. Nosocomial legionnaires' disease has been reported in hospitals throughout North America and Europe. In most cases in which thorough investigations have been performed, the reservoir has been the potable water distribution system, air-conditioning cooling towers, or both.[34,142] Outbreaks have been ended by disinfecting water and cooling tower systems by hyperchlorination or pasteurization.[34,142] In some of these outbreaks, disease occurred for many years until effective disinfection procedures were implemented. Attack rates in legionnaires' disease epidemics consistently have been less than 5 percent overall. Incubation periods ranging from 2 to 19 days have been observed.

Pontiac fever outbreaks generally have been associated with exposure to an aerosol of warm water contaminated with *Legionella*.[65,90,142] Examples include whirlpool baths, an engine assembly plant using contaminated water to cool machine lathes, and a health department building in which condensate in the air-conditioning system was contaminated. Attack rates in Pontiac fever outbreaks have been high, in the range of 95 to 100 percent. The incubation period is short, approximately 12 to 36 hours.[65]

Sporadic culture-proven cases of legionnaires' disease have been well documented. In fact, 70 to 85 percent of cases of

legionnaires' disease in the United States and elsewhere are neither nosocomial nor associated with an epidemic.[86,87,103] Some of these community-acquired cases represent undetected small case clusters, as has been shown for community-acquired cases in Glasgow, Scotland.[11] In that city, living close to a cooling tower was a risk factor for the acquisition of legionnaires' disease. Though difficult to prove, sporadic Pontiac fever probably occurs.[34,142]

Risk factors for the acquisition of legionnaires' disease can be divided logically into two main categories: those that increase exposure to contaminated water and those that suppress pulmonary defense mechanisms.[34,142] Included in the former category are occupational or residential exposure to warm or stagnant water, traveling and residence in hotels, and stays in hospitals with contaminated water distribution systems; a risk factor for residential acquisition of disease is the use of well water.[138] Included in risk factors that suppress pulmonary defense mechanisms are surgical procedures requiring general anesthesia, administration of glucocorticosteroids, cigarette smoking, chronic lung disease, and diseases (including human immunodeficiency virus [HIV] infection) or therapy that compromises the innate or cellular immune systems. Males are more than twice as likely as are females to contract the disease, perhaps as a result of the greater male prevalence of cigarette smoking and chronic lung disease. Middle-aged and older people also are at higher risk than are younger people. Other than exposure to aerosols of contaminated water, no particular predisposing factors for the development of Pontiac fever have been identified. Legionnaires' disease is not contagious, and transmission from patients to staff or other patients has never been documented.

PATHOLOGY, PATHOGENESIS, AND IMMUNITY

The exact mode of disease production in legionnaires' disease is unknown. Very good, but indirect, epidemiologic and pathologic evidence suggests that the initial infection results from inhalation of an aerosol.[34,142] The bacterial form that causes infection is unknown, with possibilities including a sporelike form, intra-amebal bacteria, bacteria enmeshed in biofilm (sessile phase), and bacteria released from biofilm (planktonic phase).[58,63] Some patients have acquired the disease after aspiration of *Legionella*-contaminated tap water rather than via aerosol inhalation.[176,83,102,146]

In guinea pigs infected by the aerosol route, multiplication of *L. pneumophila* begins within 16 hours.[36] This multiplication most likely takes place within alveolar macrophages, although some extracellular growth may occur. Cell culture studies show that multiplication occurs only intracellularly and not in the extracellular tissue culture medium.[80] This intracellular location of bacteria protects them from serum factors such as antibody and complement, as well as from the effects of antimicrobials that are not concentrated in cells. Killing of *L. pneumophila* within macrophages in cell culture is limited by failure of phagolysosomal acidification and fusion.[80]

The mechanism by which *L. pneumophila* avoids killing by macrophages is mainly by injecting phagosomal maturation-altering compounds into its host cell within minutes of initial contact, although all of the details of this process remain to be elucidated.[3,30] An additional mechanism involves shedding of bacterial flagellin into the host cytosol, which acts via the innate immune system to alter killing of the bacteria by macrophages.[128] In the late phases of bacterial multiplication in macrophages, the bacteria change phenotype to enable infection of the next susceptible macrophage; they become highly motile, quite small, and more resistant to antimicrobial agents.[8,110] The *L. pneumophila*–containing vacuole becomes huge and occupies almost the entire volume of the macrophage over a period of a few days. The bacteria effect escape from the presumably nutrient-depleted macrophage by inducing cellular apoptosis and then can infect available uninfected macrophages.[2] Innate macrophage resistance to bacterial infection may be mediated by toll-like receptors (TLRs), in particular, TLR-2 and TLR-5 and perhaps TLR-4.[72-74] Acquired macrophage resistance to infection derives from activation by interferon-γ and the resultant down-regulation of available iron stores.[22]

Polymorphonuclear leukocytes do not ingest or kill the organism effectively in vitro, although Davis and colleagues[36] suggest that they may form the bulwark of initial host defenses based on in vivo studies. Clinical evidence suggests that leukopenic hosts without concomitant macrophage dysfunction are not high-risk candidates for legionnaires' disease, although they may be at higher risk than the normal population.[26,47]

The histopathologic correlate of bacterial lung invasion is intense intra-alveolar inflammation.[142] Large airways are not affected, nor are small ones to the level of the terminal bronchioles. Both the terminal bronchioles and alveolar ducts may be involved in the inflammatory process. The interstitial spaces generally are not involved, although necrosis of alveoli may bridge the interstitial spaces. The alveoli contain a variable mixture of polymorphonuclear leukocytes, alveolar macrophages, and necrotic debris. Hemorrhage is observed, as are microabscesses. Later, fibrin formation and a predominance of histiocytes occur.

Gross lung changes evolve in the classic pattern of lobar pneumonia, with first red and then gray hepatization.[142] Lymph nodes are involved occasionally. The lung segments involved often are subpleural, a finding that sometimes suggests septic or bland infarction to the clinician. The pleural space is involved variably and seemingly is more prone to infection in immunosuppressed patients. One of the most striking pulmonary findings is the usual absence of significant intrabronchial exudate. This absence of intrabronchial exudate and lack of bronchial inflammation may mislead a bronchoscopist to conclude that pneumonia is not present.

Despite frequent signs and symptoms of extrapulmonary disease in patients with legionnaires' disease, no specific extrapulmonary pathologic findings have been identified.[142] In fatal cases, organisms often can be recovered or detected in various reticuloendothelial organs, such as the liver or spleen; however, detection of associated significant inflammation seldom occurs. Occasionally, patients have nonbacterial endocardial vegetations. Some patients have nonmassive hilar and paratracheal adenopathy, the result of bacterial adenitis. Patients may have metastatic foci, with abscesses in almost any location, including the myocardium, pericardium, peritoneum, brain, kidney, bowel wall, perirectal region, prosthetic heart valves, and hemodialysis shunts[47,142] (Table 149–2). Bacteremia occurs in some patients; it has been documented by positive blood cultures and is substantiated indirectly by the extrapulmonary foci of infection found in some patients.[47,142] Whether bacteremia accounts for some of the systemic clinical findings in legionnaires' disease is unknown. Elaboration of toxins by *Legionella* has been postulated to account for some aspects of the systemic disease, but supporting evidence is not convincing.[142]

Host cytokine production in response to *L. pneumophila* infection most likely causes most of the acute toxicity of the disease. Cell culture and animal experiments show that tumor necrosis factor, interferon-γ, and other cytokines are produced during *L. pneumophila* infection.[12,152] Humans infected with *L. pneumophila* have been shown to produce a number of cytokines during infection, as well as inflammatory markers such as procalcitonin, neopterin, and C-reactive protein.[55,124,140]

Episodes of recurrent or relapsing legionnaires' disease in patients with elevated antibody titers support experimental evidence suggesting that the humoral immune system plays a minor

role in this disease.[47] Also supporting this evidence is the rarity of legionnaires' disease case reports in patients with hypogammaglobulinemia or other diseases in which the humoral immune system primarily is deficient. The rise in specific antibody levels does not seem to have any clinical correlates, nor does the absolute antibody level.[47] Patients may recover from legionnaires' disease without any significant increase in antibody levels, again providing indirect evidence of the limited role of the humoral immune system.

The roles of antibody and complement in host defenses against legionnaires' disease have been explored in experimental models of infection. Several studies have shown that passive or active immunization is protective against intraperitoneal and subcutaneous chamber infection in rats, mice, and guinea pigs.[5,50,75,130] Pre-opsonization of *L. pneumophila* before intratracheal inoculation of hamsters was found to be partially protective, but several investigators have shown that active immunization fails to protect against pneumonia after intratracheal, aerosol, or intranasal inoculation of large numbers of *L. pneumophila* bacteria.[9,40,50] Protective immunity to pulmonary challenge in the guinea pig can be achieved after sublethal infection or infection with an avirulent mutant strain and by vaccination with an *L. pneumophila*–derived metalloproteinase or outer-membrane protein.[13-16,150]

Evidence for the importance of the cellular immune system in preventing infection largely is indirect and based on the greater prevalence of legionnaires' disease in immunosuppressed patients with cellular immunodeficiencies.[47,142] Curiously, legionnaires' disease in patients with acquired immunodeficiency syndrome (AIDS) has been reported infrequently, although one epidemiologic survey showed that patients with AIDS had a disease attack rate approximately 40 times greater than that in the normal population.[15,16,103,150] Development of cellular immunity after infection or vaccination can be demonstrated in vitro for both humans and animals, the clinical importance of which is unclear.[142]

Vaccination for prevention of legionnaires' disease may be feasible because it has been demonstrated to be effective in an animal model.[14-16,150] Whether vaccination in susceptible host populations would be successful is unknown, even if justified economically or on epidemiologic grounds.

The pathogenesis of Pontiac fever has not been studied. No differences have been detected between an *L. pneumophila* strain isolated from an outbreak of Pontiac fever and strains isolated from outbreaks of legionnaires' disease; these studies have included examination of virulence in an animal model, toxin production, and biochemical characteristics.[142] Detailed clinical studies of patients with Pontiac fever have not been performed, which renders creation of an experimental model of this disease difficult. Because it has a short incubation time that can be as brief as 12 hours, this disease probably does not represent widespread bacterial multiplication within the body, and more likely it represents a toxin-induced or allergic disease. In fact, the link between *Legionella* and Pontiac fever is circumstantial; entirely possible is that other microbes, or their toxins, coexisting with *Legionella* may cause the disease.[65,90] The clinical syndromes most like Pontiac fever are bath-water fever, humidifier fever, and extrinsic allergic alveolitis; these syndromes are thought to be caused either by the direct toxic activity of inhaled endotoxin or by an allergic reaction to microorganisms, most particularly amebae such as *Naegleria* spp.[48,111,133] *L. pneumophila* makes a poorly active endotoxin, thus suggesting that if inhaled endotoxin is the cause of Pontiac fever, the endotoxin comes from non-*Legionella* bacteria. Support for inhaled endotoxin as the cause of Pontiac fever is found in two studies of endotoxin present at outbreaks of the disease.[27,59]

CLINICAL FINDINGS OF LEGIONNAIRES' DISEASE

SIGNS AND SYMPTOMS

Legionnaires' disease usually is manifested as pneumonia.[47] The pneumonia is atypical in that the usual pathogenic bacteria generally are not isolated from respiratory tract secretions or blood and patients do not respond, except fortuitously, to antimicrobial agents commonly used to treat pneumonia in adults (e.g., penicillins, cephalosporins, and aminoglycosides). Beyond these findings, considerable speculation and controversy continue over whether a distinct clinical syndrome exists. Several prospective studies of both community-acquired and nosocomial legionnaires' disease have failed to demonstrate any clinical, radiographic, or nonspecific laboratory features that distinguish legionnaires' disease from other common causes of pneumonia.[41,54,70] The classic clinical findings are reviewed because many physicians believe that they are distinctive for *Legionella* pneumonia. Whether legionnaires' disease in children mimics the clinical findings in adults is unknown because of the rare instances of well-documented pediatric cases and the possibility of spectrum bias.

The onset of pneumonia may be either insidious or abrupt. Recurrent chills, abdominal pains, myalgia, headache, malaise, anorexia, and severe fatigue are common manifestations. Diarrhea consisting of loose, nonbloody stools several times a day occurs in approximately 30 to 40 percent of cases. Fever may be low-grade or absent initially. Over the course of a day to several days, these nonspecific symptoms gradually worsen, often resulting in severe debilitation. Noteworthy is the frequent absence of symptoms referable to the respiratory system. Rash, splenomegaly, adenopathy, and rhinorrhea are exceptionally uncommon findings. Physical examination early in the illness generally is remarkable for a paucity of localizing findings and the frequent impression that the patient has an influenzal or typhoidal illness.

Within a day to several days after onset, a high fever usually, but not always, develops. Pulse-temperature dissociation occurs in approximately half of epidemic-associated cases. Respiratory complaints, especially dyspnea and pleuritic chest pains, may become prominent. Cough usually is not a major complaint,

although it is a common manifestation. The sputum almost never is frankly purulent; blood-streaked sputum or frank hemoptysis is observed in 20 to 30 percent of patients. Many patients experience confusion, cerebellar ataxia, lethargy, agitation, or some other neurologic disorder. Severe abdominal or back pain may occur, sometimes with localization. Physical examination at this time reveals a "toxic" febrile patient with apparent multisystem disease. Chest examination usually discloses findings of consolidating pneumonia, with bronchial breath sounds, increased vocal fremitus, and dullness to percussion. Depending on the stage of consolidation, rales may or may not be heard. Pleural friction rubs or signs of pleural effusion can be observed. Despite frequent symptoms of abdominal pain, signs of peritoneal irritation, such as decreased bowel sounds or rebound tenderness, seldom are detected. Signs of meningeal irritation rarely occur but have been reported.

Most normal healthy patients recover without specific therapy, usually by day 7 to 10 of illness. Those who do not recover generally die of progressive respiratory failure, along with failure of other organ systems. Empyema, pulmonary cavitation, renal failure, memory loss, fatigue, and neurologic disorders all are potential complications and may persist for weeks to months after onset of the disease. A variety of extrapulmonary diseases may occur very rarely as a result of legionnaires' disease, the most common of which are pancreatitis,[108] hepatitis, and myopericarditis.[6,105] Myositis, as measured by elevated serum creatine kinase levels, occurs commonly, with severe muscle disease such as rhabdomyolysis being a rare complication.[89,148] Most of these extrapulmonary diseases improve rapidly with resolution of the pneumonia.

Focal infection without pneumonia is a very rare manifestation of *Legionella* infection, with only a handful of cases reported (see Table 149–2). Direct inoculation of bacteria into surgical or traumatic wounds is the usual mode of pathogenesis, although bacteremia and bacteremic metastatic infection have been reported.[106,125]

RADIOGRAPHIC FINDINGS

The roentgenographic hallmark of legionnaires' disease is an acinar filling pattern with consolidation.[34,47,142] There is no distinctive predilection for any lung region; pleural-based consolidation and bilateral infiltrates may occur. Nodular infiltrates may be seen, as may cavitation in the areas of original consolidation. Purely interstitial infiltrates are distinctly uncommon findings in established disease but occur rarely very early in the disease process; these interstitial infiltrates rapidly progress to consolidating ones within a day or so. Pleural effusion, with or without parenchymal infiltrates, can occur. Pleural effusion has been documented as the only chest finding in patients treated early with specific antibiotic therapy.

LABORATORY FINDINGS

General

Multiple nonspecific abnormal laboratory results can be detected in patients with legionnaires' disease.[34,47] Hematologic abnormalities may include leukocytosis or leukopenia, usually with a left shift; lymphopenia; thrombocytosis; and disseminated intravascular coagulation. Proteinuria and pyuria are common findings; myoglobinuria also may be present. Hyponatremia and hypophosphatemia occur commonly, as do elevations in aminotransferase enzymes, bilirubin, alkaline phosphatase, and creatine kinase. Severe azotemia occurs, though rarely. Elevation of cold agglutinin titers, cold agglutinin–induced hemolytic anemia, and elevation of complement fixation titers to *Mycoplasma pneumoniae* also may occur. Arterial oxygenation usually is depressed in relation to the extent of pneumonia. In patients with severe disease, severe oxygen desaturation related to either oxygen intoxication or respiratory distress syndrome also may develop. Taken together, these multiple laboratory abnormalities often suggest multisystem disease to the clinician.

Specific

Diagnosis of legionnaires' disease is accomplished best by recovery of *Legionella* from sputum or other lower respiratory tract secretions or tissues.[46] Urine antigen testing is the most useful single test but can have false-negative results. Other specific diagnostic methods are detection of *L. pneumophila* antigen by immunofluorescent microscopy and detection of *Legionella* DNA in respiratory tract specimens by polymerase chain reaction (PCR). Serologic diagnosis is of uncertain value in children but is useful in adults.

Selective media and techniques that facilitate isolation of *Legionella* from sputum are available.[46] Sputum is pretreated with an acid solution. This material, as well as a non-pretreated sample, is plated on buffered charcoal–yeast extract medium supplemented with α-ketoglutaric acid (BCYE-α) and on BCYE-α supplemented with antibiotics (BMPA or PAC and MWY or PAV media). *Legionella* organisms grow on these media 3 to 7 days after inoculation and incubation at 35° C in air. Culture diagnosis has a higher yield than does immunofluorescent microscopy or serology and does not produce any false-positive results. Sputum culture yield depends on the severity of the illness; it is close to 100 percent for legionnaires' disease in immunocompromised patients and for patients with ventilator-dependent pneumonia. However, sputum culture yield can be as low as 10 to 25 percent in mild legionnaires' disease. Blood and pleural fluid cultures have much lower yields than do respiratory tract cultures. Blood culture yield is so low that its utility is debatable; severely immunocompromised patients and those with very severe pneumonia are most likely to have positive blood cultures.

Immunofluorescent microscopy for *L. pneumophila* is a rapid and highly specific (99.9%) technique for establishing the diagnosis.[46] It can be performed in 1 to 2 hours after receipt of the specimen and, like culture, can be performed with sputum. It does have several disadvantages. The test requires considerable technical expertise in reading; if the test is performed by inexperienced technologists, its results often are erroneous. Moreover, one must take scrupulous care to avoid carryover from other samples and false-positive results caused by contaminated reagents. Cross-reacting organisms are rare findings in clinical samples; they frequently can be detected by experienced technologists on the basis of morphologic characteristics and staining pattern. Nonetheless, certain cross-reacting bacteria, such as some *Pseudomonas* strains, still cause rare false-positive results. Some strains of *Bacteroides fragilis*, *Streptococcus pneumoniae*, *Bacillus* spp., and *Candida* spp. also can cross-react with diagnostic reagents, although cross-reactions caused by these organisms rarely, if ever, result in a false-positive diagnosis of legionnaires' disease. Because of these difficulties, few laboratories perform this testing.

Serologic testing is of most value in epidemiologic studies and of least value in the acute diagnosis of sporadic cases.[45] As many as 25 percent of patients with culture-documented disease fail to undergo seroconversion against the homologous serotype; such failure is not related solely to early treatment or immunosuppression, although these factors may cause failure of antibody formation. As long as 3 months may be required for antibody levels to increase after the onset of illness; the median time is approximately 2 weeks. In addition, as with any other means of immunologic diagnosis of this disease, the multiplicity of antigenic

types renders serologic testing extremely cumbersome. Because 5 to more than 25 percent of the normal population have elevated antibody titers to *Legionella*, only a fourfold rise in titer is considered significant. Only paired samples, drawn 3 to 6 weeks apart, should be tested. Because of day-to-day variation in test results, these samples must be tested simultaneously for optimal results. For maximum yield, samples taken as long as 9 to 12 weeks after onset of the disease should be tested if earlier samples reveal no changes. As with immunofluorescent detection of bacterial antigen, a negative serologic result does not exclude disease.

The specificity of serologic diagnosis is fairly high in adults, in the range of 95 to 99 percent.[45] Cross-reactive antibodies may be found in the serum of patients with leptospirosis, melioidosis, *B. fragilis* infections, *P. aeruginosa* infections, and possibly *Haemophilus influenzae* or enteric bacterial infections. However, even 99 percent specificity is not sufficient for certainty of diagnosis of a sporadic case. If the estimated 1 percent prevalence of legionnaires' disease in children is correct, less than half of all seroconversions yield truly positive results (positive predictive accuracy of 45%). This observation, combined with the studies cited previously showing age-related elevations in anti-*Legionella* antibody in young asymptomatic children, renders serologic diagnosis of pediatric legionnaires' disease highly suspect.

Detection of soluble bacterial antigen in urine can be used to diagnose *L. pneumophila* serogroup 1 infections successfully and is the most sensitive and most rapid test for community-acquired legionnaires' disease.[44,46] An enzyme immunoassay and immunochromatographic card kit for this procedure are available commercially (Wampole, Cranbury, NJ, and Binax, South Portland, ME, respectively). The major drawback of this test is that it preferentially detects only *L. pneumophila* serogroup 1 infections. Otherwise, it has excellent sensitivity (90-99% versus culture and 60-70% in patients with community-acquired legionnaires' disease) and extraordinary specificity (>99.9%). In some cases, the urinary antigen test yields positive results when sputum culture for *L. pneumophila* serogroup 1 is negative, especially in previously treated patients and in epidemics of legionnaires' disease. The urine antigen test is less sensitive in nosocomial legionnaires' disease and in legionnaires' disease in immunocompromised patients because other serogroups and other *Legionella* spp. become likely in these groups. Thus, although the urine antigen test detects approximately 60 to 70 percent of those with community-acquired legionnaires' disease, fewer than 40 percent of nosocomial cases test positive with this test. A negative urine antigen test should not be used as the sole reason to stop therapy for legionnaires' disease because 30 to 100 percent of patients with legionnaires' disease can have a false-negative test, depending on the identity of the infecting strain.

PCR has been used to detect *L. pneumophila* in sputum, serum, and urine. Though both sensitive and specific, PCR tests have been done on a research basis and have not been validated in large well-controlled studies. A commercial PCR assay (BD ProbeTec; Becton Dickinson, NJ) has become available recently but lacks published evaluations.[115]

With the exception of the urine antigen test, none of the nonculture tests is as sensitive as is culture diagnosis under ideal circumstances. Thus, culture must be performed in every case; if desired, the other tests can be used to provide same-day answers. Because none of the *Legionella*-specific tests is 100 percent sensitive, the clinician sometimes must treat for legionnaires' disease in the absence of confirmatory laboratory tests. One or 2 days of therapy with erythromycin apparently does not affect the sensitivity of the diagnostic tests, although therapy with azithromycin or levofloxacin can affect culture yield. Regardless, therapy should not be withheld pending the results of laboratory tests.

TREATMENT OF LEGIONNAIRES' DISEASE

No adequately sized prospective clinical studies of antimicrobial therapy for legionnaires' disease have been performed. All recommendations regarding therapy are based on retrospective and small prospective clinical studies, as well as laboratory studies.

Because of the superiority of newer fluoroquinolone agents and azithromycin in experimental nonhuman studies and on the basis of uncontrolled trials of these agents in adults with legionnaires' disease, the current recommendation is that adults with severe legionnaires' disease and immunocompromised patients with the disease be given either azithromycin or fluoroquinolone therapy rather than erythromycin or clarithromycin therapy. Nonhospitalized patients with mild legionnaires' disease can be treated equally well with any of the specific therapies, including erythromycin, tetracycline, the newer fluoroquinolones, azithromycin, or clarithromycin.[42,43,101] No inherent reason other than age-specific drug toxicity precludes these guidelines for children.

Fluoroquinolone antimicrobial agents generally are contraindicated in children, although the evidence suggests that the risk for toxicity from short courses of therapy is low. The scope of this chapter does not allow discussion of the use of these drugs in children, but in some cases, the benefit of using these drugs in very severe legionnaires' disease may be greater than the potential risk for the development of drug side effects.

Erythromycin remains the drug of choice for treatment of mild legionnaires' disease in children. Generally, it is given intravenously in four daily divided doses of 15 mg/kg. Intravenous therapy can be changed to oral therapy (30 to 50 mg/kg/day in divided doses) once clinical improvement is evident. Therapy should be given for a minimum of 18 to 21 days. Relapses may occur when intravenous erythromycin therapy is changed to the oral route and after a course of therapy that is too short. Some patients with mild illness may be treated initially with oral therapy. Clarithromycin (7.5 mg/kg every 12 hours) may be used in place of erythromycin, although there is good laboratory and reasonable clinical data showing that this drug is no more effective for legionnaires' disease than erythromycin is.[18,120] Clarithromycin is not approved by the U.S. Food and Drug Administration (FDA) for the treatment of legionnaires' disease.

Azithromycin, which is approved for use in children in the United States, is as active against *Legionella* bacteria as are the newer fluoroquinolone agents, thus rendering it a candidate for the drug of choice for severe pediatric legionnaires' disease or for legionnaires' disease in immunocompromised children. The drug dose for children with this type of pneumonia has not been studied, but based on extrapolation from adults, a dose of 10 mg/kg (maximum, 500 mg) given once daily for 3 to 5 days should be sufficient in most cases, with extended duration of therapy (7 to 10 days) for severely immunocompromised patients. Azithromycin is available in both intravenous and oral forms and is approved by the FDA for use in adults with legionnaires' disease.

Newer fluoroquinolone agents, along with azithromycin, are considered the drugs of choice for the treatment of severe legionnaires' disease in adults. Levofloxacin in a dosage of 500 mg daily for 10 to 14 days is used commonly in the United States to treat this disease. No dosage guidelines exist for the treatment of pediatric legionnaires' disease because of the potential for drug toxicity in this population. Levofloxacin is the only available quinolone agent approved by the FDA for the treatment of legionnaires' disease in adults; note that neither ciprofloxacin nor moxifloxacin is approved for this indication. Ciprofloxacin appears to be effective for this indication on the basis of case reports, and moxifloxacin may be effective based on limited laboratory studies. Combining azithromycin with levofloxacin has been reported to be more effective than levofloxacin alone in a very small, inade-

quately controlled study; until this finding is confirmed in larger studies, such use probably should be avoided.[30]

Alternative drugs to erythromycin include tetracycline and possibly co-trimoxazole. Neither of these agents has been approved for this use by the FDA, although limited clinical and experimental data support their effectiveness, more so for tetracycline than for co-trimoxazole. Co-trimoxazole should be used only if there is no possibility of using a macrolide, tetracycline, or fluoroquinolone drug. Doxycycline, because of its high lipid solubility, may be more effective than is tetracycline, although whether it is remains conjecture. The dosage of doxycycline used in children is 2 to 4 mg/kg/day given in one or two doses. Use of tetracyclines is associated with a risk of dental staining in children younger than 8 years old. The daily co-trimoxazole dosage is 15 to 20 mg/kg of the trimethoprim component and 75 to 100 mg/kg of the sulfamethoxazole component in three divided doses. The duration of therapy for these drugs is the same as that for erythromycin.

Rifampin combined with erythromycin is a less favorable alternative to the use of azithromycin alone. However, if erythromycin is a preferred therapy for reasons of cost, toxicity, or availability, rifampin probably should be added in the case of severe disease or in immunocompromised patients. The dosage is 16 to 20 mg/kg/day given in two divided doses for the first 2 days of therapy. This drug rapidly diminishes bacterial counts in experimental disease and has been effective in combination with other drugs in patients in whom erythromycin therapy has failed. Use of this drug for the treatment of legionnaires' disease is not approved by the FDA. A recent small nonrandomized study has shown that adult patients treated with combination rifampin and clarithromycin had significantly longer hospital lengths of stay than did those treated with clarithromycin alone, along with a trend toward a worse outcome in other outcome measures in those given combined therapy. The best correlation with length of stay was the duration of rifampin therapy. Because the greatest effect of rifampin in experimental animals takes place in the first day or two of therapy, giving this drug for more than 2 days may do more harm than good. The best policy would be to use an alternative to erythromycin or clarithromycin in patients with severe illness and thereby avoid the question of combination therapy.[67] No good clinical or laboratory evidence indicates that combining rifampin with either azithromycin or a fluoroquinolone is of clinical benefit.

Treatment of extrapulmonary foci of infection does not appear to differ significantly from treatment of legionnaires' disease without extrapulmonary disease. The duration of therapy and indications for surgical drainage need to be assessed individually in these cases.

RESPONSE TO TREATMENT

Most patients improve dramatically within a few days after initiation of specific therapy.[34,41,47,142] Response may be as rapid as 6 hours after administration of the first dose of erythromycin therapy. Patients regain their appetite, lose symptoms of myalgia and fatigue, and feel better overall. As long as a week may be required for a patient to become completely afebrile, and rarely as long as a month is required for some severely immunosuppressed patients. The chest radiograph changes slowly and even may appear to worsen despite overall clinical improvement; progressive consolidation after 3 to 4 days of intravenous antimicrobial therapy is unusual.

The mortality rate in otherwise healthy adults who are treated promptly is approximately 5 percent, whereas in treated immunosuppressed patients, it is approximately 20 percent. Untreated fatality rates range from 15 to 20 percent in normally healthy patients and upward of 80 percent in immunosuppressed patients. Even in previously healthy patients, delayed therapy and the development of respiratory failure are exceptionally poor prognostic factors.[52,119,144]

DIFFERENTIAL DIAGNOSIS

Other causes of atypical or culture-negative pneumonia may resemble legionnaires' disease closely. *M. pneumoniae* pneumonia usually is a milder illness that does not require hospitalization. Cough is a prominent symptom in mycoplasmal pneumonia, whereas it is not in legionnaires' disease. Neither rash nor otitis is found in legionnaires' disease. Laboratory abnormalities also are seen more commonly in legionnaires' disease. Serologic testing may provide positive results for both diseases, a confusing finding that can be clarified by performing specific laboratory testing. Fortunately, treatment is the same for both diseases.

Psittacosis and Q fever also may resemble legionnaires' disease closely. A history of bird or cattle exposure may be helpful, but its absence does not exclude either of these zoonoses. An interstitial rather than an acinar-filling infiltrate on a chest radiograph would be a point against legionnaires' disease. Pathogen-specific laboratory tests help in this differential diagnosis. A tetracycline can be used successfully for all three of these diseases.

Early in their evolution some diseases, including typhoid fever, acute coccidioidomycosis, influenza, typhus or spotted fever, and leptospirosis, may resemble legionnaires' disease. Distinguishing these diseases on the basis of their clinical evolution, laboratory results, and exposure or travel history generally is easy.

Tularemia may pose a problem in the differential diagnosis because immunologic test results for legionnaires' disease can be falsely positive in patients with tularemia, and some of the growth characteristics of *Francisella tularensis* closely resemble those of *Legionella*. In regions endemic for tularemia, clinicians must work closely with the laboratory to facilitate this differential diagnosis. One case record of tularemia misdiagnosed as legionnaires' disease reported that the patient responded to erythromycin therapy.

Dual infection sometimes occurs in legionnaires' disease. Coexistence of legionnaires' disease with pneumonia caused by *Mycobacterium tuberculosis*, pneumococcus, *H. influenzae*, *Neisseria meningitidis*, *Pneumocystis carinii*, *Moraxella catarrhalis*, and various viral agents has been reported. Thus, dual infection should be suspected in patients not responding to therapy for pneumonia. Pathogen-specific laboratory tests often are useful in these cases.

CLINICAL SYNDROMES CAUSED BY OTHER *LEGIONELLA* SPECIES

Relatively few cases have been reported of disease caused by the non–*L. pneumophila Legionella* spp.[53] The ones described appear to have few differences in clinical findings, diagnostic methods, or treatment. One group contends that these infections are more difficult to treat than are *L. pneumophila* infections, but whether this difficulty represents differences in host factors or reduced susceptibility of the bacteria to antibiotic therapy is unclear.[53] Whether the lower frequency of these infections reflects decreased virulence, inadequate efforts to diagnose them, rare environmental presence, or all three is unknown. The mode of spread and the nosocomial reservoirs of these species are not defined as well as they are for *L. pneumophila*. These infections are less likely to be diagnosed by immunologic means because fewer laboratories routinely test for all possible species. As with *L. pneumophila* and even more so for the non–*L. pneumophila Legionella* spp., treat-

ment sometimes must be based solely on clinical suspicion without the benefit of confirmatory laboratory tests.

PONTIAC FEVER

CLINICAL SIGNS AND SYMPTOMS

Fever, myalgia, malaise, chills, and headache are the most common symptoms of Pontiac fever.[65] The symptoms may begin suddenly or have a more gradual onset lasting several hours. Many symptoms, such as dry nonproductive cough, chest pain, and pharyngitis, are referable to the respiratory tract. Nausea is a common manifestation, but diarrhea and vomiting occur less frequently. Neurologic symptoms, including dizziness, confusion, and poor coordination, also have been reported. Pontiac fever symptoms usually are at their worst within a day after onset of the illness and gradually resolve over a 2- to 7-day period. Physical examination shows only tachycardia and fever. Leukocytosis has been the sole laboratory abnormality reported. Chest radiographs show no abnormalities. Pulmonary function testing has not been performed in patients with Pontiac fever. Rechallenge by return to the contaminated building in the original Pontiac outbreak produced an illness that was mild in comparison to that after the first exposure; the length of time between the first and second exposure was not stated clearly.

SPECIFIC DIAGNOSIS

The diagnosis of Pontiac fever primarily is one of exclusion.[34,142] Significant rises in anti-*Legionella* antibody level, combined with characteristic symptoms, and isolation of *Legionella* from an aerosol source are the diagnostic criteria. Detailed epidemiologic and environmental studies must be performed to diagnose Pontiac fever specifically because of the nonspecificity of the symptoms and the ubiquitous presence of environmental *Legionella*. Establishing a definitive diagnosis in sporadic cases is difficult.

TREATMENT

Antimicrobial therapy does not appear to be effective for the treatment of Pontiac fever. Removal of the patient from the area of the contaminated water source appears to be the best means of management.

CHAPTER 150

STREPTOBACILLUS MONILIFORMIS (RAT-BITE FEVER)

Carrie L. Byington ❂ Robert D. Basow

Rat-bite fever is an acute febrile illness usually acquired by humans from the bite of a rat or other rodent. It is a zoonosis with worldwide distribution.[109] *Streptobacillus moniliformis* is the leading cause of rat-bite fever in the United States, but in Asia, the illness is caused most often by a spirochete, *Spirillum minus* (see Chapter 155).[46] Infection with *S. moniliformis* is characterized by a relapsing fever, rash, and prominent arthralgia and arthritis. Infection may be acquired after the bite of an animal, by contact of skin or mucous membranes with an infected animal or contaminated cage, or by ingestion of food or water contaminated by rats. When the organism is acquired by ingestion, the resulting illness is termed "Haverhill fever" after an outbreak that occurred in Haverhill, Massachusetts, in 1926.[62,66]

HISTORY

The first description of rat-bite fever is found in the 2500-year-old Indian *Compendium of Medicine*, the *Susruta Sambita*.[22] In this text, a description of the illness is given that remains valid today: "The blood of any part of the human body coming in contact with the semen of rats or scratched with their nails or teeth is vitiated and gives rise to the appearance of nodes, swellings, eruptions of circular erythematous patches on skin, pustules, violent and acute erysipelas, breaking pain in the joints, extreme pain in the body, fever, anemia, aversion to food, shivering, and horripilation." The disease also was known in ancient Japan, where treatment consisted of the local application of herbs and dynamite to cause an "explosion in the wound."[22]

The first modern accounts of the disease are found in a lecture by professor Eli Ives at Yale University in 1831.[35] The first case report was published in 1839.[107] In 1900, Miyake[59] gave a detailed description of the disease, which he named sodoku, from the Japanese *so* (rat) and *doku* (poison). Schottmüller,[88] Blake,[12] Levaditis and colleagues[52] were the first to isolate and describe the causative agent of streptobacillary rat-bite fever in 1914, 1916, and 1925, respectively. The organism has been known as *Streptothrix muris ratti* and *Streptobacillus muris minus* but currently is referred to as *S. moniliformis*.[43]

Haverhill fever was reported first in 1926 after an outbreak of epidemic illness that was traced to contaminated milk.[66] They called the illness *erythema arthriticum epidemicum*. Shortly thereafter, the causative organism was isolated and named *Haverhillia multiformis* and was shown to be identical to *S. moniliformis.*[62]

EPIDEMIOLOGY

Approximately 200 cases of rat-bite fever have been reported in the United States.* In addition, the disease has been reported worldwide.† *S. moniliformis* is responsible for most of the cases seen in North America, whereas the spirillary form is seen more commonly in Asia. Only one case of spirillary rat-bite fever has been reported in the American literature in the past 40 years.[23] Two outbreaks of Haverhill fever are reported in the literature.[56,62]

*See references 3, 4, 7, 15, 18-20, 23, 25, 30, 44, 68, 94.
†See references 6, 8, 9, 11, 16, 29, 41, 49, 50, 56, 84, 87, 89, 96.

Rat-bite fever currently is not a reportable illness in the United States, so its true incidence is unknown. Although it is considered to be a rare occurrence, the illness probably is underdiagnosed. More than 2 million animal bites are reported annually in the United States, and rat bites account for at least 1 percent of them.[31] A review of animal bites in Maryland during a 3-year period found that approximately 4.7 percent were caused by rats or lagomorphs.[26] Among bitten patients, the risk of rat-bite fever developing is significant, with reported rates being between 4 and 11 percent.[74,106] Half of all *S. moniliformis* isolates identified at the Microbial Diseases Laboratory in Berkley, California, between 1970 and 1998 involved children younger than 9 years old.[40] Not surprisingly, children living in crowded urban centers or rural impoverished areas seem to be at greatest risk.[26,44,71,104] Recently, however, reports of rat-bite fever are emerging among individuals who keep rats as pets.[4,8,25,102] Most of the other reported cases involve laboratory personnel who handle rats.[7]

Rat-bite fever usually is transmitted through the bite of a rat, but it also may be transmitted by rat scratches.[19,25] Rat-bite fever likewise has been reported after handling of pet rats and in individuals who dwell in rat-infested homes.[34,83] Rat-bite fever was reported after varicella in a child who handled pet rats frequently while she had open skin lesions,[68] and septic arthritis caused by *S. moniliformis* was reported in a child who kissed pet rats.[42]

Between 10 and 100 percent of rats, both wild and laboratory, carry *S. moniliformis* as normal nasopharyngeal flora and excrete it in their urine.[4,97] The disease also has been transmitted to humans from mice,[72] squirrels,[58] weasels,[27] gerbils,[108] and such rat-eating carnivores as cats,[37,60] dogs,[63,75] and pigs.[105] In addition, *S. moniliformis* can cause disease in turkeys,[61] guinea pigs,[48] koalas,[82] spinifex hopping mice,[45] and nonhuman primates.[101] These animals could pose a potential source of infection for humans.

Haverhill fever is transmitted by the ingestion of food or water contaminated by rats. Previous outbreaks have involved unpasteurized milk, ice cream made from raw milk, and water.[56,66]

BACTERIOLOGY

S. moniliformis is a pleomorphic, microaerophilic, nonmotile, nonencapsulated, non–acid-fast, gram-negative bacillus. It measures 1 to 5 μm in length.[43] The organism is oxidase- and catalase-negative and will ferment glucose, maltose, fructose, galactose, and salicin.[43]

The organism is fastidious and requires special handling for isolation. Optimal growth is achieved in trypticase soy agar or broth supplemented with 20 percent horse or rabbit serum.[62] Alternatively, brain-heart infusion broth supplemented with "Panmede" (a papain digest of ox liver) also has been shown to support the growth of *S. moniliformis*.[93] Sodium polyanethol sulfonate (SPS), which is added to most aerobic blood culture bottles at a concentration of 0.05 percent, will inhibit the growth of *S. moniliformis* at concentrations as low as 0.0125 percent.[92] Blood culture bottles without SPS added should be used for primary isolation of *S. moniliformis* when rat-bite fever is suspected. SPS is not added to anaerobic blood culture bottles, and *S. moniliformis* may be isolated in standard anaerobic culture media. Cultures

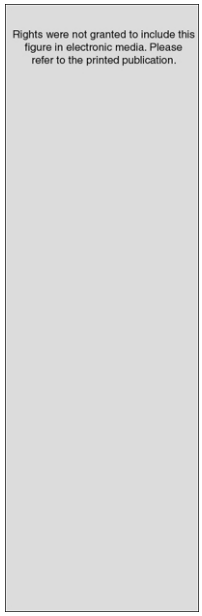

Figure 150–1 The colonies are white, soft "puffballs" 1 to 2 mm in diameter. (See companion Expert Consult web site for color version.) (*From Albedwawi, S., LeBlanc, C., Show, A., et al.: A teenager with fever, rash and arthritis. C. M. A. J. 175:354, 2006.)*

should be incubated at 35° C to 37° C in a humid environment with a partial pressure of carbon dioxide between 8 and 10 percent.

The morphologic characteristics of the bacterium are dependent on the environment.[62] In favorable media, the typical appearance is that of short rods that may grow in chains. In other conditions, the organism tends to grow in long, interwoven filaments that commonly contain beaded and fusiform swellings throughout their length. In broth culture, colonies usually appear in 2 to 10 days.[43] The colonies are white, soft "puffballs" measuring 1 to 2 mm in diameter (Fig. 150–1).[4] On blood agar plates, the colonies are round, gray, and glistening and measure 1 to 2 mm in diameter after 2 to 3 days of incubation.[43]

Stable L-forms of the organism develop spontaneously in vivo or in vitro. These cell wall–deficient forms have a "fried egg" appearance with dark centers and lacy edges when grown on solid media.[43,64] They are resistant to penicillin and other antibiotics active against the bacterial cell wall. L-phase variants may be deposited in tissues and prolong the symptoms of illness.[29]

CLINICAL MANIFESTATIONS

Streptobacillary rat-bite fever typically has an incubation period of less than 7 days, with a reported range of 1 to 22 days.[18] Young children have a predilection for shorter incubation times. The illness is characterized by the acute onset of shaking chills, fever, headache, and vomiting. There is a single case report of rat-bite fever without fever.[96]

At initial evaluation, the bite site usually is well healed, without evidence of inflammation or regional adenopathy. Within the first week of illness, arthralgia or arthritis with or without joint effusion develops in more than 50 percent of patients. The arthritis, usually involving large joints, tends to be migratory, nonsymmetric, and extremely painful.[6,34,44,89] Rat-bite fever has been mistaken for rheumatoid arthritis.[51]

Within 1 to 8 days after the onset of fever, a pink-red maculopapular rash develops in approximately 75 percent of patients and frequently involves the palms and soles (Fig. 150–2).[1,25,57,67] The rash, lasting as long as 3 weeks, may be generalized, petechial, purpuric, or pustular, and approximately 20 percent desquamate. With untreated infection, there may be persistent or recurrent episodes of fever and arthritis.[35,99] The rash generally does not recur. The untreated mortality rate of *S. moniliformis* infection is 10 percent.[18,71,77] The prognosis generally is excellent in patients treated with antibiotics, and the mortality rate is thought to be less than 1.5 percent. However, infection in infants younger than 3 months may be particularly severe or fatal, even with the administration of appropriate antibiotic therapy.[54,57,90]

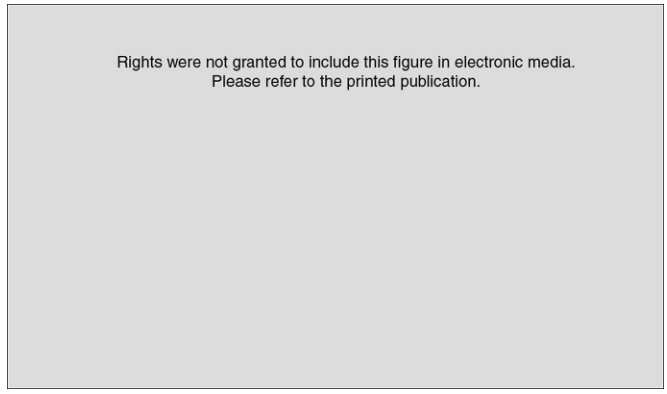

Figure 150–2 Within 1 to 8 days after the onset of fever, a pink-red maculopapular rash develops in approximately 75 percent of patients and frequently involves the palms and soles. (See companion Expert Consult web site for color version.) (*From Albedwawi, S., LeBlanc, C., Show, A., et al.: A teenager with fever, rash and arthritis. C. M. A. J. 175:354, 2006.)*

Haverhill fever is similar to streptobacillary rat-bite fever, with an abrupt onset of fever and chills (100%), rash (95%), and arthritis (97%).[2,57] Generally, the incubation period is 1 to 3 days. Upper respiratory and gastrointestinal complaints are common. Multiple recurrences of fever are found rarely, and the rash tends to be small and uniform in size.[56]

Complications of *S. moniliformis* infection include anemia,[77] cutaneous or subcutaneous abscess formation,[18,41,64,103] interstitial pneumonia,[57,90] mastoiditis,[65] meningitis,[8,90] pericardial effusion,[17] pancreatitis, prostatitis,[109] and septic arthritis.[42,53,80,84] Abscess formation in organs, including the brain,[28] the female genital tract,[64] and the spleen,[21] has been reported. Unusual and potentially devastating complications include chorioamnionitis[33] and periarteritis nodosa.[70] The most frequent serious complication is bacterial endocarditis, which was uniformly fatal in the pre-antibiotic era.[55,73,81,95] Six cases of endocarditis occurring in children younger than 18 years have been reported since 1934.[57,69,78,90,95,98] Five of the six patients died during the acute illness. Four received no antibiotic treatment. Endocarditis caused by *S. moniliformis* has been reported in an adult infected with human immunodeficiency virus.[76] The patient recovered with antibiotic therapy. Fatal endocarditis has been reported in a pet shop employee.[94]

Iron-deficiency anemia is the only complication that has been reported after Haverhill fever.[56] No fatalities caused by Haverhill fever have been reported, and the prognosis is excellent.[56]

PATHOPHYSIOLOGY AND PATHOLOGY

Factors influencing the virulence of *S. moniliformis* are not well described. The organism has an affinity for synovial tissue in both animals and humans, but the mechanisms by which *S. moniliformis* produces arthritis are unknown.[38,39,44,47,53,86,100] Studies performed in mice indicate that *S. moniliformis* is only slightly immunogenic and produces mild leukocytosis and minimal homologous antibody production.[85,86] In addition, the organism is resistant to phagocytic destruction.[85] These factors may allow chronic infection to development.

The pathologic features of streptobacillary rat-bite fever have been described in a limited number of autopsy reports. Common features include ulcerative endocarditis with secondary septic embolization in the liver and spleen, septic arthritis, and interstitial pneumonia.[12,90] Mononuclear meningitis and erythrophagocytosis also have been reported.[90] In most reports, the site of the bite reveals little histologic evidence of inflammation.[57]

DIAGNOSIS

Correct diagnosis of rat-bite fever requires a high index of suspicion on the part of the physician. The diagnosis is suggested in a febrile patient with a history of exposure to rats, but in most clinical settings, the exposure history is not elucidated until after the diagnosis is made.

Nonspecific signs include an elevation in the white blood cell count,[12] usually in the range of 10,000 to 30,000 cells/mm^3 with a left shift, mild anemia, and a false-positive serologic test for syphilis, which may occur in 25 percent of patients.[77] Direct visualization of the organism on Giemsa stain of blood or joint fluid may suggest the diagnosis. Serologic assays are not currently available for humans. An enzyme-linked immunosorbent assay has been developed to monitor infection in rodent colonies.[13] Polymerase chain reaction has been effective for detection of *S. moniliformis* from humans and animals and may offer an alternative to traditional culture methods.[5,10,14,36]

S. moniliformis has been cultured from blood, joint fluid, abscesses, pericardial fluid, meninges, and tissues obtained at autopsy.[17] The organism has strict growth requirements, and the choice of culture media and technique is of critical importance for optimal growth of the bacterium (see the section "Bacteriology"). In general, routine aerobic blood cultures are not satisfactory for isolation.

If the organism is isolated, it may be identified rapidly by gas-liquid chromatography. *S. moniliformis* has a characteristic fatty acid profile, with major peaks being palmitic, linoleic, oleic, and stearic acid.[64,79] Electrophoretic protein patterns also have been described that can distinguish Haverhill fever strains from rat-bite fever strains.[24]

The differential diagnosis for streptobacillary rat-bite fever includes illness caused by *S. minus*, which may be indistinguishable (see Chapter 155). It also includes all relapsing fevers, such as *Borrelia recurrentis*, malaria, and typhoid. Rocky Mountain spotted fever must be considered,[67] as well as other infectious entities, including leptospirosis, Lyme disease, disseminated gonococcal infection, meningococcemia, brucellosis, and syphilis. Viral infections also may be mistaken for rat-bite fever. Acute rheumatic fever should be considered as well. Noninfectious entities include drug reactions, collagen vascular disease, and Pel-Ebstein fever.

TREATMENT AND PREVENTION

In proven cases of streptobacillary rat-bite fever, the treatment of choice is penicillin G. In adults, the dosage of penicillin should be no less than 400,000 to 600,000 IU/day continued for at least 7 days.[77] If no response is seen within 2 days, the dosage should be increased to 1.2 million IU/day. Children have been treated successfully with 20,000 to 50,000 U/kg/day of intramuscular or intravenous penicillin, up to a maximum of 1.2 million IU/day.[91] In children who do not require hospitalization, oral penicillin V, 1 to 2 g/day in divided doses, may be given.[91] In penicillin-allergic adults, both streptomycin and tetracycline have been effective.[67,89] In children, streptomycin and erythromycin have been used, but treatment failures with erythromycin have been reported.[41] Clarithromycin has been used successfully to treat an adult with rat-bite fever.[102] Antibiotics, including cefuroxime, cefotaxime, gentamicin, and ciprofloxacin, have good activity against *S. moniliformis* in vitro.[32] Several reports document successful treatment with cephalosporins, including cefuroxime and ceftriaxone.[19,25,42,76]

Endocarditis secondary to *S. moniliformis* should be treated with high-dose penicillin G in combination with streptomycin or gentamicin. In children, the dosage is 160,000 to 240,000 IU/kg/day, up to the adult maximum of 20 million IU/day.[81,91] Treatment should be continued for at least 4 weeks. Antibiotic susceptibility testing of the organism should be performed, and minimum inhibitory and bactericidal concentrations for several antimicrobial agents should be determined. It is desirable to have a peak serum minimum bactericidal concentration of at least 1:8. Recently, successful treatment of endocarditis with ceftriaxone in combination with gentamicin was reported.[76]

Haverhill fever is treated in much the same way, with penicillin G being the current drug of choice. Most individuals can be treated as outpatients.

Rat-bite fever can be prevented by controlling rodents in urban areas, properly handling rodents, and avoiding unpasteurized milk products. Individuals who own rats and those who work with rodents should receive anticipatory guidance regarding the handling of these animals and the signs and symptoms of rat-bite fever. If a rat bites an individual, prophylactic antibiotics, such as amoxicillin or amoxicillin-clavulanic acid, may prevent rat-bite fever, but current data do not support the routine use of antibiotics after all rat bites. Some researchers would suggest that because of the serious nature of rat-bite fever in young infants, infants younger than 3 months who are bitten by a rat should receive antibiotic prophylaxis.[54]

CHAPTER 151

BARTONELLA (CAT-SCRATCH DISEASE)

Joseph J. Nania ✪ Kathryn M. Edwards

Cat-scratch disease (CSD) is an acute, self-limited infection that begins as a papule or nodule at the site of a scratch or bite by a cat, followed by regional lymphadenopathy. *Bartonella henselae* is the causative agent of CSD. In a small number of patients, more serious systemic complications, including involvement of the central nervous system, liver, spleen, bone, heart, eyes, or skin, may occur. Although CSD was recognized as a clinical entity in the 1930s, the first written report, by Debre from France, was not published until 1950.

ETIOLOGY

For more than 40 years, numerous attempts were made to isolate the responsible organism from infected nodes in patients with CSD with no success. The first clue to its etiology was recognized in 1983, when Wear and colleagues[35] used Warthin-Starry silver stain to demonstrate small, pleomorphic, gram-negative bacilli in lymph nodes and skin papules from patients with CSD. Initial attempts to culture the bacillus were unsuccessful, but in 1988, an organism was isolated by English and associates[10] from the lymph nodes of patients with CSD and subsequently termed *Afipia felis*. The discovery of bacillary angiomatosis and its association with *B.* (formerly *Rochalimaea*) *henselae* encouraged further investigation of the role of this newly recognized organism in CSD.[28] In 1992, Regnery and coworkers,[27] using indirect fluorescent antibody (IFA) assays, demonstrated elevated antibodies to *B. henselae* in serum samples from patients with suspected CSD. Other researchers used enzyme-linked immunosorbent assays (ELISAs) for each agent to demonstrate that patients with CSD had significant serologic responses to *B. henselae* and *Bartonella quintana* but not to *A. felis*. These data further supported the view that the causative agent of CSD was related antigenically to the *Bartonella* genus and not to *Afipia*.[33] In a physician survey to identify cases of CSD occurring during a 13-month period in cat owners in Connecticut, Zangwill and colleagues[37] demonstrated that of 45 patients with clinical CSD, 38 had antibody titers of 1:64 or higher for *B. henselae* as compared with only 4 of 112 samples from controls ($p < 0.001$). CSD was associated strongly with owning a kitten. Finally, the use of polymerase chain reaction (PCR) helped confirm the causative agent of CSD as *B. henselae*.[2] Eventually, PCR amplification was used to detect *B. henselae* not only in purulent material aspirated from involved nodes but also in CSD skin test material.[1,16,32] Subsequently, *B. henselae* has been cultured from lymph nodes obtained from patients with CSD.[13]

B. henselae is a fastidious gram-negative bacillus that requires an incubation period of up to 5 weeks to culture.[5] It belongs to the genus *Bartonella*, along with other species such as *Bartonella bacilliformis* (the agent of Carrión disease) and *B. quintana* (the agent of trench fever). Colony morphology varies from small, dry, gray-white colonies to smooth, creamy yellow colonies.

TRANSMISSION

Domesticated house cats are healthy carriers of *B. henselae*, and cat fleas (*Ctenocephalides felis*) play a major role in cat-to-cat transmission. Approximately 90 percent of patients with CSD have a history of exposure to cats, particularly a kitten with fleas or a scratch or bite from a kitten. Although they remain asymptomatic, domestic cats serve as persistent reservoirs for *B. henselae*. Reported rates of *B. henselae* seroprevalence in cats vary considerably, with the highest rates seen in cats living in warm, humid climates. In the United States, the southeastern region, Hawaii, and coastal California have the highest *B. henselae* seroprevalence in cats (40-54.7%), whereas rates are much lower (3.7% to 6.7%) in the Rocky Mountain and midwestern regions.[20] Blood samples obtained from pet and impounded cats in the San Francisco Bay region grew *B. henselae* 41 percent of the time. *B. henselae* also was detected in fleas from infected cats by both direct culture and PCR, although no data support cat-to-human transmission via fleas. Interestingly, Chang and colleagues[8] found that *Ixodes pacificus* and *Dermacentor* ticks from five of six California counties were PCR-positive for *B. henselae*. Co-infection with *B. henselae* and *Borrelia burgdorferi* was described in a report of three patients in New Jersey.[11] *Ixodes* ticks obtained from the patients' households were PCR-positive for *B. henselae* in two of the three

cases. These findings should alert clinicians to consider the possibility of *Bartonella* infection in humans after tick bites, although the frequency of transmission by this route is unknown.

EPIDEMIOLOGY

CSD generally affects children and young adults, and, although it occurs worldwide, regional differences in disease rates exist. The Centers for Disease Control and Prevention estimates that more than 24,000 cases of CSD occur annually in the United States. Using a national inpatient database, Reynolds and coworkers[30] estimated that 437 pediatric hospitalizations for CSD (0.60 per 100,000 population) occurred in 2000. Rates were higher in children younger than 5 years and markedly higher in southern states, thus underscoring the regional differences in prevalence of *B. henselae*. Higher rates of disease generally are reported in the autumn, with 60 percent of hospitalizations in Reynolds and associates' study occurring between July and October. Zangwill and colleagues[37] suggested that the seasonality of CSD could be explained by the breeding patterns of cats and fleas, as well as increased contact with kittens, which often are kept indoors during the winter months.

PATHOLOGY

Pathologic examination of the primary inoculation lesion demonstrates dermal necrosis, with variable numbers of histiocytes and occasional multinucleated giant cells accompanied by scattered microabscesses with neutrophils, eosinophils, lymphocytes, and plasma cells. The epidermal changes are nonspecific and consist of parakeratosis, hyperkeratosis, edema, and exocytosis of inflammatory cells. Characteristic findings in the lymph nodes, similar to the primary lesion, are follicular hyperplasia, focal cortical necrosis, and necrotizing granulomata with central microabscesses and palisading histiocytes. A perivascular neutrophilic infiltrate may be present. Subsequently, the lesions progress to small cortical granulomata and "stellate microabscesses" within the granulomata. Warthin-Starry or Steiner silver impregnation stains may reveal pleomorphic bacilli in clusters or short chains within the areas of central necrosis or around small vessels. Bacteria are visualized easily in early lesions. Granulomata with microabscess formation also can be found in other sites such as the liver, spleen, and bone. Because other infections such as tularemia and fungal and mycobacterial infection may have similar histopathologic characteristics, biopsy findings must be correlated with the clinical findings, serologic studies, cultures, and PCR.

In vitro observations have identified important new properties of *B. henselae*. By inducing activation of the nuclear factor NFκB and expression of adhesion molecules, *B. henselae* infects and activates endothelial cells, an important step in the pathogenesis of CSD and bacillary angiomatosis.[8,14] Animal studies have shown that interferon-γ–mediated activation of macrophages is involved in clearing *B. henselae* infection and that microbicidal activity is mediated to a large extent by nitric oxide.[25] The importance of cell-mediated immunity in CSD is suggested by the positive skin reaction to injected material aspirated from cat-scratch nodes and the granulomatous lesions noted in biopsy specimens.

CLINICAL MANIFESTATIONS AND COURSE

The most common clinical manifestation, often referred to as *typical CSD*, is a gradually enlarging regional lymph node occurring 1 to 3 weeks after a scratch or bite from a cat. An inoculation site, which often appears as a red papule 3 to 5 mm in diameter, can be detected in two thirds of patients. Constitutional symptoms of malaise, fatigue, anorexia, emesis, and headache are common but usually are mild. Fever occurs in fewer than half the patients with typical CSD, thus rendering the common name "cat scratch fever" inexact. Physical examination generally reveals a skin papule at the inoculation site and regional lymphadenopathy (Fig. 151–1). In approximately 50 percent of cases, lymphadenopathy is the only manifestation of the disease and occurs most commonly in the upper extremity (axillary or epitrochlear lymph nodes, 46.1%), the head and neck area (cervical or submandibular, 26.1%), and the lower extremities (femoral or inguinal, 17.5%).[7] Supraclavicular lymphadenopathy, which often raises concern for malignant neoplasm, accounts for only approximately 2 percent of typical CSD. Suppuration of the involved lymph nodes occurs in about 10 percent of patients (Fig. 151–2). More unusual manifestations of CSD include neuroretinitis, subacute iritis, optic neuritis, focal chorioretinitis, and the oculoglandular syndrome of Parinaud (Fig. 151–3). Patients with

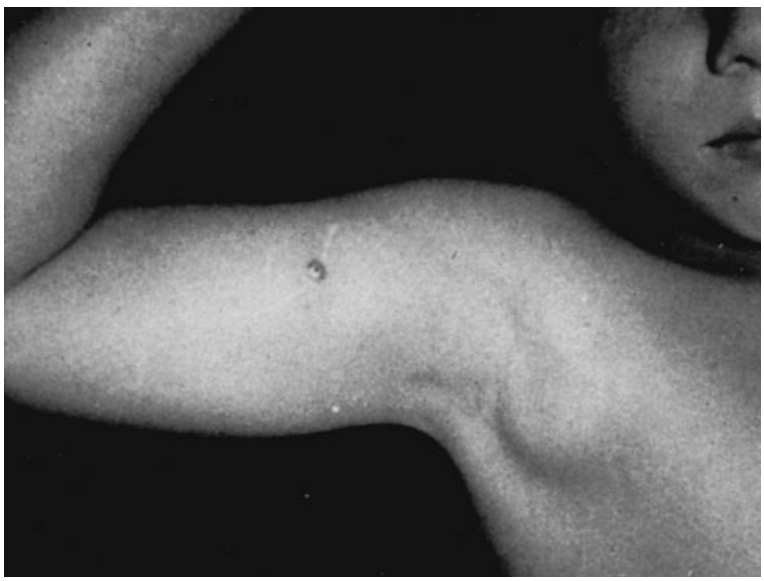

Figure 151–1 Cat-scratch disease involving an axillary lymph node with a primary granuloma of the upper part of the arm. Note that the primary lesion is within the line of a healed scratch. *(Courtesy of Hugh A. Carithers, M.D.)*

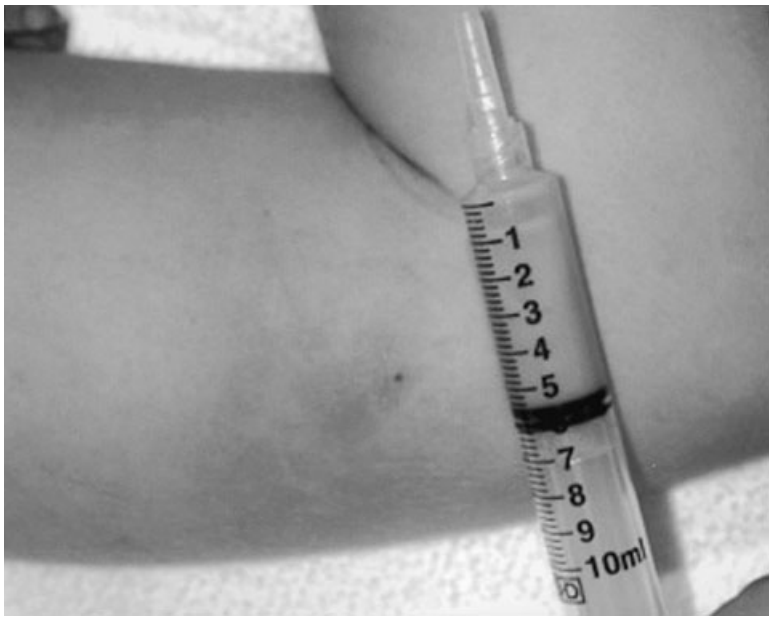

Figure 151–2 Purulent material aspirated from an epitrochlear lymph node of a child with cat-scratch disease. The primary lesion was on the index finger.

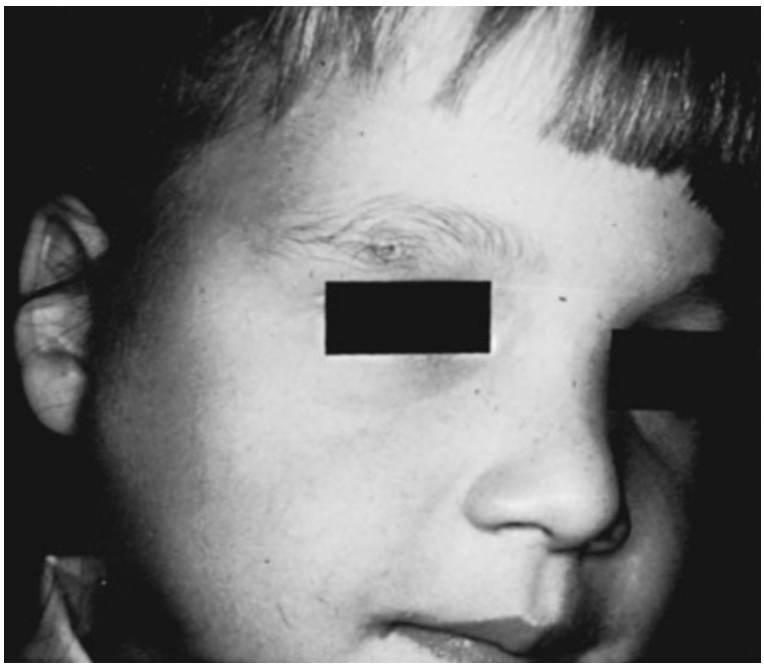

Figure 151–3 Child with the oculoglandular syndrome of Parinaud as a manifestation of cat-scratch disease. Note the parotid swelling and the primary site in the right eyebrow. *(Courtesy of James D. Cherry, M.D.)*

this syndrome have painful conjunctivitis without evidence of drainage and preauricular adenopathy. Most patients recover from Parinaud syndrome spontaneously without residua in 2 to 4 months.

Hepatosplenic CSD is an important cause of prolonged fever in children and should be included in the differential diagnosis of fever of unknown origin. Often these children will have fever for several weeks (mean, 3 weeks), abdominal pain (occurring in about two thirds of patients),[3,9] joint pain, headache, weight loss, and chills. Significant lymphadenopathy is lacking in more than 50 percent of cases, thus rendering the diagnosis more difficult to establish. Hepatic or splenic enlargement (or both) is found in half of these children, but hepatic transaminase levels usually are normal. Erythrocyte sedimentation rates invariably are elevated and frequently are greater than 100 mm/hr. Abdominal imaging usually demonstrates typical granulomatous lesions in the liver or spleen that often are diagnostic of this entity (Fig. 151–4). Although both ultrasound and computed tomography (CT) will show these lesions, a number of reports suggest that CT has lower sensitivity than ultrasound does.[9,21] As is the case with other infections causing hepatosplenic granulomata, late calcification of the lesions has been described.

Neurologic complications have been reported in approximately 2 percent of CSD cases and led to an estimated 51 pediatric hospitalizations in 2000.[30] Encephalopathy, the most common manifestation, typically occurs 1 to 6 weeks after the onset of lymphadenopathy. Fever and seizures develop abruptly, followed by confusion, disorientation, and, occasionally, combativeness. Status epilepticus is well described. Cerebrospinal fluid examination frequently is normal, but occasional mild pleocytosis

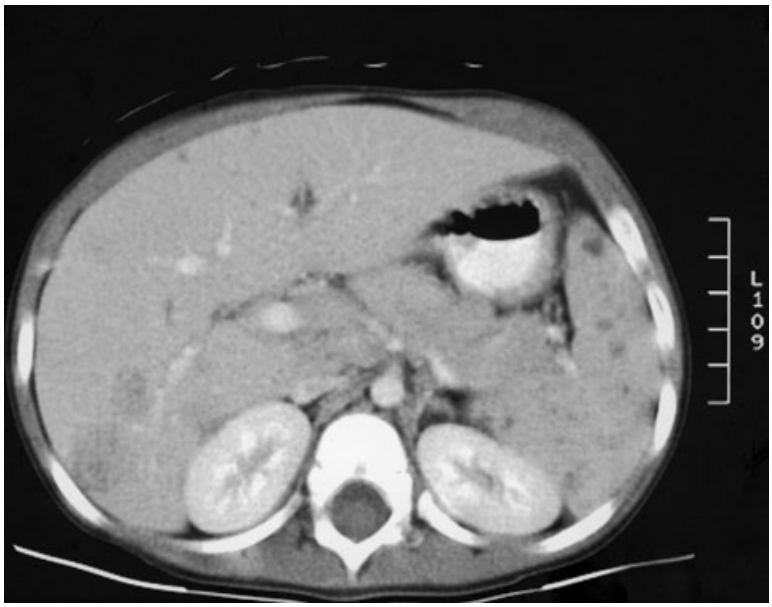

Figure 151–4 Multiple hypodense lesions in the liver and spleen on computed tomography seen in a child with prolonged fever, abdominal pain, and positive *Bartonella henselae* serology.

or elevated protein levels are seen. Electroencephalographic findings frequently are abnormal, with diffuse slowing or focal abnormalities found in most patients. CT of the head generally is normal. Resolution of seizures and normalization of mental status often occur as suddenly as does the onset. Neurologic recovery commonly occurs within weeks and almost always is complete within a year. Persistent deficits or a need for prolonged anticonvulsant therapy has been reported in only a few cases.[17,29]

Osteomyelitis caused by *B. henselae* is well described in the literature, and an early report found that it occurred in 2 of 1200 cases.[7] With improved imaging, serologic methods, and PCR for diagnosis, it is now clear that *B. henselae* osteomyelitis can occur as part of a disseminated infection that involves the liver and spleen, in the setting of otherwise typical CSD, or as a seemingly isolated manifestation in which a primary cutaneous inoculation site and regional lymphadenopathy have not been apparent.[18,34] The pathogenesis is not clear, but it probably represents hematogenous spread of the organism, although local spread from a lymph node or abscess has been reported. The clinical manifestation of osteomyelitis can be acute, but many patients have weeks or months of pain and intermittent fever before recognition of osteomyelitis. A high proportion of reported cases involve the axial skeleton, with the vertebrae and pelvis accounting for nearly 50 percent of cases. Involvement of the long bones of the limbs, the sternum, and the skull and multifocal bony lesions have been described. The most common finding on plain radiography or CT is osteolytic lesions, but bone marrow lesions without cortical destruction, seen as hyperintense foci on T2-weighted magnetic resonance imaging, also have been described.[34] Outcomes of osteomyelitis caused by *B. henselae* generally have been excellent with or without antibiotic therapy or surgical intervention.

Bartonella spp. also have been reported as the cause of endocarditis in more than 100 cases[26] and accounted for 28 percent of culture-negative endocarditis cases in a series from a large referral laboratory in France.[19] In other series, *Bartonella* endocarditis accounted for only 3 percent of all cases. Endocarditis rarely is seen in young children, but cases in several adolescents have been reported. *B. quintana* predominates and accounts for roughly 75 percent, *B. henselae* causes most of the remaining cases, and other species (*Bartonella elizabethae* and *Bartonella vinsonii*) have been isolated in single reports. The epidemiologic characteristics of patients differ considerably between the main two causative species. *B. quintana* endocarditis is highly associated with homelessness, chronic alcoholism, and body lice and is less likely to occur in the setting of cat exposure and underlying valvular heart disease. In contrast, *B. henselae* endocarditis occurs most often in patients with underlying valvulopathy (90%) and clearly is linked to exposure to cats or their fleas.[12] *Bartonella* endocarditis generally is manifested subacutely as fever, heart murmur, and frequently evidence of heart failure. The aortic valve usually is affected; right heart or prosthetic valve involvement is an unusual finding. Valvular surgery is needed in most cases, probably because of frequent delay in diagnosis and treatment. Although the mortality rate in patients with *Bartonella* endocarditis has been reported to be as high as 30 percent, recent series have shown lower rates (7%).[19]

Patients with CSD also may have skin lesions, including maculopapular rash, erythema nodosum, and thrombocytopenic purpura. Other systemic manifestations include hepatitis, splenitis, hemolytic anemia, atypical pneumonia, pulmonary nodules, an infectious mononucleosis–like syndrome, and disseminated bartonellosis. Bacillary angiomatosis (mixed neovascular and inflammatory lesions in the skin or viscera caused by either *B. henselae* or *B. quintana*), bacillary peliosis (dilated capillaries or multiple blood-filled cavernous spaces in the liver, spleen, or lymph nodes), and relapsing fever with bacteremia can develop in immunocompromised subjects.[24]

DIAGNOSIS

Until recently, clinical diagnosis of CSD required the presence of at least three of the following: a history of contact with a cat and the presence of a scratch or a primary lesion, a positive skin test using material obtained from a purulent node from a patient with CSD, regional lymphadenopathy with negative studies for other potential causes of lymphadenopathy, and characteristic histopathologic findings on a biopsy specimen. The difficulty in isolating organisms from routine cultures of lymph nodes or other tissue specimens from patients with suspected CSD has created significant problems over the years. An intradermal skin test composed of heated purulent lymph node material from patients with CSD was used for many years to aid in establishing the diagnosis. Although the skin test was 90 to 98 percent sensi-

tive and specific for the diagnosis of CSD, the material was not readily available, was not standardized, and was not licensed for routine use. In addition, the potential for transmission of other infectious agents with this test currently prohibits its use.

Specific diagnostic tests to assess serum antibodies against *B. henselae* such as IFA and ELISA and PCR amplification to identify *B. henselae* DNA sequences in tissues have reduced the need for performing skin testing and invasive surgical diagnostic procedures. Giladi and colleagues[15] developed a new enzyme immunoassay for IgM and IgG that uses *N*-lauroylsarcosine–insoluble outer-membrane antigens from agar-grown *B. henselae* and demonstrated increased sensitivity of the test. An antibody titer greater than 1 : 64 is suggestive of recent infection, although some patients maintain a titer of this magnitude for a prolonged period after infection. Some authors have suggested that a single IgG titer of greater than 1 : 256 can reliably diagnose acute infection.[24] In the setting of endocarditis, a single IgG titer of 1 : 800 or higher has a 95.5 percent predictive value for *Bartonella* as the etiology.[19] For any manifestation of CSD, detection of a significant rise in titer between acute and convalescent sera is confirmatory. Cross-reaction between antibodies directed toward *B. henselae*, *B. quintana*, and *Chlamydia* spp. can render interpreting serology difficult in some circumstances. However, the cross-reactivity can be overcome by cross-adsorption and Western immunoblotting.[19]

When tissue is obtained for diagnostic purposes, a Warthin-Starry stain and culture (ideally plated on both chocolate and rabbit blood agar and co-cultivated with eukaryotic cells) may be performed, although neither has high sensitivity. Very sensitive species- and strain-specific assays involving PCR amplification of the 16S-23S intergenic spacer regions or the highly variable regions of the 16S ribosomal RNA gene sequence of *Bartonella* can be useful in establishing a diagnosis when purulent lymph node aspirates or other infected tissue is obtained. Because PCR of blood rarely is positive, PCR of valvular tissue is the most sensitive method to diagnose endocarditis.

The differential diagnosis of CSD includes various infections such as other forms of bacterial adenitis, typical or atypical mycobacterial infections, lymphogranuloma venereum, infectious mononucleosis, tularemia, plague, sporotrichosis, blastomycosis, histoplasmosis, syphilis, human immunodeficiency virus infection, neoplasm, and sarcoidosis.

TREATMENT

In an immunocompetent host, typical CSD is self-limited and resolves spontaneously in 1 to 2 months without antibiotics. However, conflicting data exist in the literature regarding whether antibiotic therapy is ever helpful in normal hosts. Macrolides, fluoroquinolones, trimethoprim-sulfamethoxazole (TMP-SMX), doxycycline, and β-lactam agents all have in vitro activity against the organism, but gentamicin and rifampin appear to be the only bactericidal agents. Because in vitro susceptibility testing is technically challenging, lacks standards for interpretation of results, and produces minimum inhibitory concentrations that have correlated poorly with clinical efficacy, it often is not useful clinically.[31] In Margileth's[23] retrospective review of 202 patients treated with antibiotics for CSD, rifampin was more effective than ciprofloxacin, gentamicin, or TMP-SMX. Another prospective, randomized, double-blind, placebo-controlled study using oral azithromycin for 5 days was effective in reducing lymph node volume measured by three-dimensional ultrasonography.[4] Adults and children weighing more than 100 lb were given an initial single dose of 500 mg azithromycin on day 1 of treatment and 250 mg on days 2 to 5 as single daily doses. Patients weighing less received the liquid preparation of 10 mg/kg on day 1 and 5 mg/kg on days 2 to 5.

No randomized, prospective, controlled studies have evaluated therapy for the systemic manifestations of CSD. In one retrospective review, children with hepatosplenic CSD who were given rifampin (20 mg/kg/day in two doses for 14 days), either alone or in combination with another agent, experienced a decreased duration of fever.[3] In the same retrospective review, gentamicin or TMP-SMX also led to defervescence within 5 days, but penicillins, cephalosporins, tetracycline, and erythromycin had minimal or no clinical efficacy. Recently, evidence-based treatment recommendations for *Bartonella* infections have been published, and no recommendations for typical CSD, hepatosplenic CSD, or osteomyelitis were presented.[31] For endocarditis, combination therapy with gentamicin (for 14 days) and either doxycycline or ceftriaxone (for 6 weeks) is recommended. Suggested therapy for central nervous system disease includes doxycycline and rifampin; however, no data suggest that antibiotic treatment of CSD encephalopathy is beneficial. Reports of the duration of antibiotic therapy have varied from 5 days in immunocompetent patients to 6 weeks in patients with atypical CSD or immunocompromised patients.

Corticosteroid therapy has been reported in a small number of cases, including patients with typical CSD, retinal involvement, hepatosplenic disease, or encephalopathy, as well as in a single immunocompromised patient with fever and diffuse lymphadenopathy.[6,7,22,36] Because the pathogenesis of CSD with prolonged symptoms may include a postinfectious, inflammatory process,[6,31] corticosteroids appear to have some theoretical role. Despite the reported anecdotal successes, however, steroids are not recommended for routine treatment of any manifestation of CSD.

Application of moist soaks and local heat, use of analgesics, limitation of activity of the affected limb, and aspiration of fluctuant material in the nodes (in some instances, done serially) may relieve the pain and resolve the inflammation. Excisional biopsy of chronically involved lymph nodes also is performed occasionally to rule out other treatable causes.

PROGNOSIS AND PREVENTION

Typically, the prognosis of CSD is excellent without any sequelae. Although patients with atypical findings and involvement of other organs may have a prolonged course and antibiotics may be used, the prognosis is good. Reinfection occurs only rarely. Because person-to-person transmission of *B. henselae* has not been shown to occur, hospitalized patients need only standard precautions. Currently, no vaccine is available for use in animals or humans. Routine veterinary visits, control of flea and tick infestations, and declawing of young kittens are the current practical preventive measures for CSD.

SUBSECTION 6

Treponemataceae

CHAPTER 152

BORRELIA (RELAPSING FEVER)

Kenneth M. Boyer

Relapsing fever is a vector-borne bacterial infection characterized by recurring febrile attacks separated by periods of relative well-being. Spirochetes of the genus *Borrelia* cause the disease. It may be transmitted by lice (epidemic, or louse-borne, relapsing fever) or ticks (endemic, or tick-borne, relapsing fever).

Relapsing fever was differentiated from other intermittently febrile conditions in 1868 by Obermeir,[9] who noted the presence of "myriads of living and actively motile spirilla in the blood of relapsing fever patients during the febrile attack." At the turn of the century, Mackie in India and Nicolle in Tunisia elucidated transmission of epidemic disease by the human body louse. Concurrently, in equatorial Africa, Dutton and Todd discovered that sporadic cases could be transmitted by argasid (soft) ticks.

Massive outbreaks of louse-borne relapsing fever accompanied the social and hygienic disruption in Europe and North Africa that occurred in the wake of both World Wars. At present, louse-borne disease is reported in appreciable numbers only from Ethiopia and Sudan. Tick-borne relapsing fever persists as an uncommon but widely dispersed infection in many countries, including the western portion of the United States.[23,25]

THE ORGANISM

The borreliae that cause relapsing fever differ from other pathogenic spirochetes (such as *Leptospira* and *Treponema*) in their loose-coiled morphology and ready staining by Wright or Giemsa stain. These two characteristics permit the organisms to be identified in blood smears, a diagnostic characteristic that is unique among bacterial diseases (Fig. 152–1). *Borrelia burgdorferi*, the

cause of Lyme disease, is not seen in peripheral smears, an important point in the differential diagnosis.

Borrelia microorganisms are extremely fastidious in cultivation, and taxonomic classification has depended on the specificity of strain-vector relationships.[28,67] *Borrelia recurrentis* is transmitted by the human body louse (*Pediculus humanus humanus*). The other species that cause relapsing fever are transmitted by argasid ticks of the genus *Ornithodoros* (Table 152–1).

Propagation of *B. recurrentis*, *Borrelia crocidurae*, *Borrelia hispanica*, *Borrelia hermsii*, and *Borrelia turicatae* in complex artificial media has been accomplished.[38] In common with other pathogenic spirochetes, borreliae require *N*-acetylglucosamine and long-chain fatty acids for growth. They are microaerophilic and metabolize glucose by glycolysis, with resulting accumulation of lactic acid. Further study of metabolism and DNA homology eventually may simplify their taxonomy. The guanine and cytosine content of borrelial genomic DNA is an exceptionally low 27 to 32 percent.[3] *B. burgdorferi* has 30 to 44 percent DNA homology with *B. hermsii*.[35] It clearly is a distinct species and perhaps a distinct genus. The 86 percent DNA homology between the two North American relapsing fever spirochetes *B. turicatae* and *B. hermsii*, however, suggests a close taxonomic and evolutionary relationship.[3] Analysis of DNA sequences, protein profiles, and reactivity with specific monoclonal antibodies now permits definitive speciation of isolates that have been recovered in culture.[1,64]

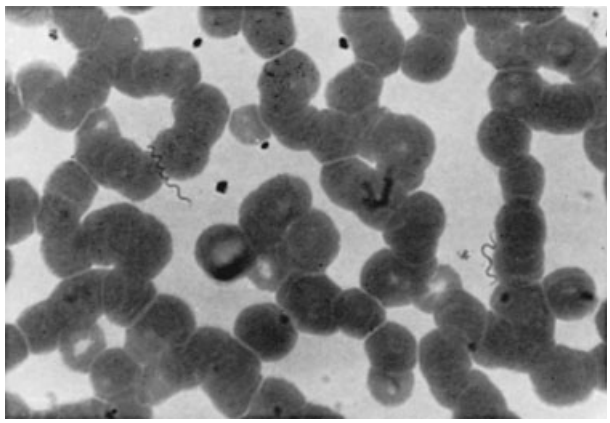

Figure 152–1 *Borrelia hermsii* spirochetes in the peripheral blood smear of a 20-year-old patient with tick-borne relapsing fever (Wright stain, ×1000). *(From Boyer, K. M., Munford, R. S., Maupin, G. O., et al.: Tick-borne relapsing fever: An interstate outbreak originating at Grand Canyon National Park. Am. J. Epidemiol.* 105*:469-479, 1977.)*

TRANSMISSION

Body lice that transmit relapsing fever become infected by feeding on a spirochetemic human. Ingested spirochetes enter the hemolymph through the gut epithelium and multiply there. Except for the central ganglion, other tissues such as the salivary glands and genital organs are not invaded. Once infected, lice remain so for their entire life but do not transmit the organism to their progeny. Transmission to other humans takes place by contamination of the bite wound with infectious hemolymph or feces when lice are crushed or wounded by scratching. Intermediate hosts for *B. recurrentis* other than humans are not known.[29]

The development of borreliae in *Ornithodoros* ticks differs from that in body lice. After the tick engorges on an infected host, spirochetes invade all tissues, including the salivary glands and, in most instances, the female genital tract. The latter phenomenon results in transovarial infection of progeny, an important survival mechanism. Once infected, ticks remain capable of transmitting infection for years via secretions of infectious saliva or coxal (analogous to urine) fluid. *Ornithodoros* ticks typically are night feeders and take blood meals lasting an average of 15 minutes, after which they detach themselves. Their bites usually are painless and are noted infrequently. With the exception of *Ornithodoros moubata*, ticks that transmit relapsing fever are maintained in nature by intermediate hosts. Rodents and other small mammals are the major reservoirs of both ticks and tick-borne borreliae.[14,28,29,68]

EPIDEMIOLOGY

The epidemiology of relapsing fever is determined by the habits of its vectors. Acquisition of louse-borne relapsing fever occurs under conditions of crowding, cold weather, and poor hygiene, which favor the spread of lice. Thus, epidemics have occurred in the setting of wars, earthquakes, famines, and floods, often in association with epidemic typhus. In Addis Ababa, Ethiopia, where an estimated 1000 cases of louse-borne relapsing fever occur each year, nomadic tribesmen, seasonal laborers, and their families, living in conditions of extreme poverty, are at risk.[12,50]

Most foci of tick-borne relapsing fever exist in nature in rather closed environments, such as rodent burrows, nests, or caves. In Africa, Asia, and South America, primitive dwellings with dirt floors, thatched roofs, and rodent nests often harbor endemic species of *Ornithodoros*. In more sophisticated societies, people become part of these ecologic systems only when "roughing it." In the western portion of the United States, for example, where *Ornithodoros hermsi* transmits most cases, a history of sleeping in

TABLE 152–1 Important Borreliae Causing Relapsing Fever, Their Vectors, and Their Current Geographic Distribution

Borrelia Species	Vector	Geographic Distribution
B. recurrentis	*Pediculus humanus humanus*	Ethiopia, Sudan
B. caucasica	*Ornithodoros verrucosus*	Iraq, southwestern former U.S.S.R.
B. crocidurae	*Ornithodoros erraticus* (small variant)	North Africa, Middle East
B. duttonii	*Ornithodoros moubata*	Eastern and Central Africa
B. hermsii	*Ornithodoros hermsi*	Western United States and Canada
B. hispanica	*Ornithodoros erraticus* (large variant)	Spain, western North Africa
B. latyschewii	*Ornithodoros tartakowskyi*	Iran, central Asia
B. mazzottii	*Ornithodoros talaje*	Mexico, Central America
B. parkeri	*Ornithodoros parkeri*	Western United States
B. persica	*Ornithodoros tholozani*	Middle East, western Asia
B. turicatae	*Ornithodoros turicata*	Southwestern United States, Mexico
B. venezuelensis	*Ornithodoros rudis*	Northern South America

Data from references 5, 13, 14, 26.

old summer cabins in forested mountain areas is the rule.[26,34,63,68] In well-studied outbreaks occurring at Browne Mountain, Spokane County, Washington,[62] Big Bear Lake, San Bernardino County, California,[19] North Rim, Grand Canyon National Park, Arizona,[10,20] and northern New Mexico,[21] cabins that were the sources of cases were found to contain large rodent nests from which infective ticks were recovered.

PATHOGENESIS AND PATHOLOGY

Borreliae undergo spontaneous antigenic variation both in vivo and in vitro.[53,60] Repeated episodes of dense spirochetemia (10^5 to 10^8 organisms/mL), each involving a different antigenic variant, account for the cyclic nature of relapsing fever in infected humans.[4,41,56] In relapsing fever *Borrelia* strains, the immunodominant surface protein is called variable major protein (VMP). In serial passage in mice, the progeny of a single organism can give rise to as many as 40 antigenically distinctive VMPs.[2,37,53] Different VMPs have some sequence homology but generally differ by considerably more than a single point mutation.[6,49] The VMP genes of *B. hermsii* are located on multiple copies of linear plasmids. Antigen variation is conferred by programmed, sequential recombination events in plasmid DNA analogous to those seen in African trypanosomiasis and falciparum malaria parasites.[3,5,39,45,49,53] With each remission of the disease, the antibodies produced against the variant strain result in immobilization, opsonization, and agglutination.[16,18,41] Agglutinated organisms are phagocytosed and cleared from the circulation. Experimental animal studies indicate that during remissions, borreliae persist in the central nervous system (CNS), bone marrow, spleen, and liver.[29]

An additional virulence factor that probably contributes to overcoming innate immunity to *B. hermsii* is its production of a surface protein that binds factor H, an important regulator of complement activation.[32]

Major pathologic findings in fatal cases include widespread petechial hemorrhaging of visceral surfaces, splenomegaly and hepatomegaly (often with multiple necrotic foci), and diffuse histiocytic interstitial myocarditis.[29,36] Other features in patients with a fatal outcome include intercurrent infections such as pneumonia, salmonellosis, or reactivated malaria; hemorrhages in the CNS; meningitis; disseminated intravascular coagulation; splenic rupture; hepatic coma; and cardiac arrhythmias.[29,36] Borreliae cross the placenta, and infection during pregnancy results in abortion or severe infection of live-born neonates.[30,59]

CLINICAL MANIFESTATIONS

After an incubation period of 5 to 11 days, relapsing fever has a sudden onset with high fever (39° C to 41° C [102.2° F to 105.8° F]), chills, headache, and myalgia.[25] An initial illness of 3 to 6 days' duration will be followed by approximately a week during which the patient is afebrile and feels weak but improved. Relapse occurs with "flulike" symptoms similar to those of the initial episode. As many as 10 febrile attacks have been recorded in untreated tick-borne cases, whereas 4 episodes is the usual maximum in louse-borne disease. Resolution of the febrile attacks, either spontaneously or after the administration of antibiotics, is by crisis. Relapses become progressively shorter and milder as the afebrile intervals lengthen (Fig. 152–2).[11]

Other clinical features are inconstant and reflect the nature of the infecting organism and the condition of the host. *B. recurrentis* and *B. duttonii* infections are uniformly severe; infections by other species tend to be somewhat milder. Splenomegaly and hepatomegaly, often with associated tenderness, are characteristic. A fleeting macular rash on the trunk, which may become generalized or petechial, is a common finding. Meningeal irritation, iridocyclitis, epistaxis, and myocarditis are more variable in their incidence but may be prominent features.[36,58] Unlike Lyme disease or tularemia, inflammation at the site of inoculation and regional lymphadenopathy are not seen. Thrombocytopenia, hyperbilirubinemia, and elevated liver enzymes are frequent laboratory abnormalities.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Although an appropriate history of exposure is by far the most helpful clue to the diagnosis of relapsing fever,[30,64] physicians caring for patients who have vacationed in distant endemic areas may not consider the possibility. Often, an alert hematology technician first makes the diagnosis by recognizing loosely coiled spirochetes in a Wright-stained smear of the patient's peripheral blood. Although routine smears usually are positive while the

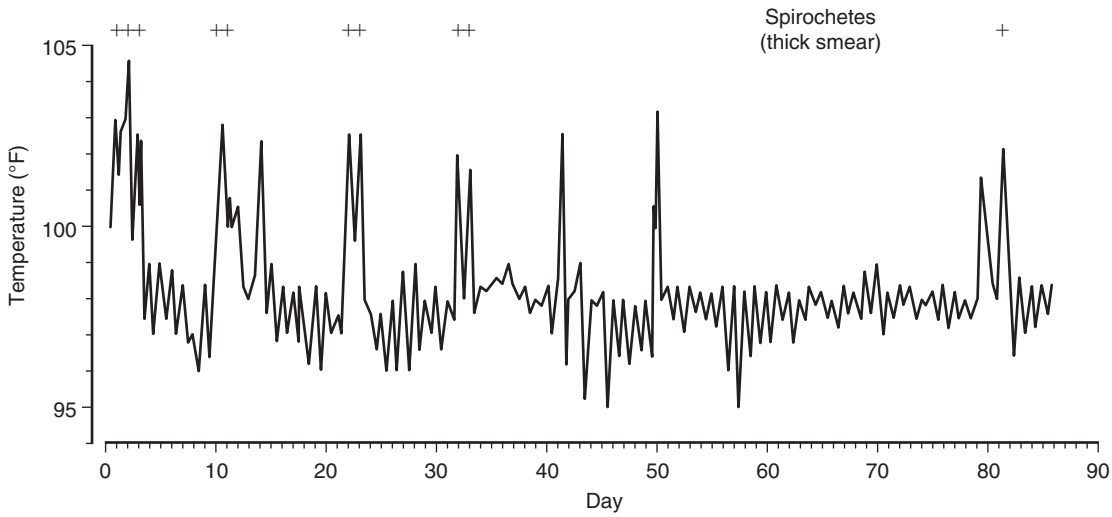

Figure 152–2 Febrile course of untreated tick-borne relapsing fever caused by *Borrelia duttonii*. Thick blood smears were examined for spirochetes on each day of illness, with positive results indicated by *plus signs*. *(Adapted from Breinl, A., Dutton, J. E., Kinghorn, A., et al.: An experimental study of the parasite of the African tick fever. Memoir XXI of the Liverpool School of Tropical Medicine. London, Williams & Norgate, 1906.)*

patient has fever, increased sensitivity is obtained by examination of dehemoglobinized thick smears or buffy coat preparations stained with Giemsa[31] or acridine orange.[57] Species-specific fluoresceinated monoclonal antibodies can enhance detection of borreliae in blood smears even further.[55] Immature laboratory mice, in which spirochetemia readily develops after intraperitoneal inoculation with infected blood, provide the most sensitive system for establishing a specific diagnosis during late relapses or remission periods.[28,67]

Because of the fastidiousness of *Borrelia*, routine blood cultures are helpful only in excluding other causes of bacteremia. A gene-specific polymerase chain reaction (PCR) developed for *B. burgdorferi*, with DNA sequence analysis of the amplicons, has been used to diagnose infection with *B. hermsii* associated with a well-documented family epidemic in Montana.[64]

Serologic diagnosis now can be achieved with indirect fluorescent antibody tests and confirmatory immunoblotting,[23] although these tests are limited by antigenic variability. False-positive results can occur in patients with Lyme disease and other spirochetal infections.[37] Conversely, enzyme-linked immunosorbent assays (ELISAs) and immunoblot serologic tests for Lyme disease may yield false-positive results in patients with relapsing fever.[23,52]

Because of its nonspecific initial symptoms and spontaneous remissions, relapsing fever may be misdiagnosed as influenza or enteroviral infection. The "saddleback" fever pattern of Colorado tick fever may resemble relapsing fever, but this condition can be recognized by its characteristic leukopenia. Other tick-transmitted illnesses, such as Lyme borreliosis, tularemia, Rocky Mountain spotted fever, and human ehrlichiosis, may be suggested by a history of exposure to ticks. In developing countries, malaria, typhoid fever, and rickettsial diseases may show similar clinical findings and are important to differentiate. The microgametocytes of *Plasmodium vivax* may look similar to borreliae in a peripheral blood smear.[24] The periodic fevers, such as familial Mediterranean fever, hyper-IgD syndrome, and the "PFAPA" syndrome (periodic fever, aphthous stomatitis, pharyngitis, and adenitis) may resemble relapsing fever but generally have longer intervals between febrile episodes.[42,46] Empiric treatment with broad-spectrum antibiotics may modify the characteristic pattern of relapsing fever or cure it before a diagnosis is made.

TREATMENT

Because of difficulties in cultivation, no in vitro data are available to compare the efficacy of antimicrobial agents against relapsing fever borreliae. Oral or parenteral tetracycline, erythromycin, and chloramphenicol are effective clinically, whereas intramuscular procaine penicillin G and oral ampicillin result in relapse rates of approximately 5 and 30 percent, respectively. Probably, ceftriaxone and amoxicillin also are effective drugs, as indicated by anecdotal experience[34] and by analogy to their efficacy in Lyme disease. The newer macrolides clarithromycin and azithromycin may have efficacy as well. Doxycycline (100 mg orally), tetracycline (250 mg intravenously or 500 mg orally), and erythromycin (250 mg intravenously or 500 mg orally) have been used successfully as single-dose regimens for the treatment of adults with louse-borne relapsing fever in Ethiopia.[17,41,42,47] Such regimens have the advantages of low cost and at least partial efficacy against other louse-borne diseases such as typhus. Prophylaxis with a single dose of doxycycline has been shown to be effective in preventing tick-borne relapsing fever in exposed military personnel in Israel.[33]

Erythromycin is considered the drug of choice for children younger than 8 years old, whereas tetracycline is considered the drug of choice for older patients. For a febrile patient, however, oral phenoxymethyl penicillin (a single low dose of 7.5 mg/kg) or intravenous penicillin G (10,000 U/kg infused over a period of 30 minutes) is recommended as initial therapy. Either should lead to gradual clearance of circulating spirochetes and defervescence. Thereafter, a 10-day course of oral erythromycin or tetracycline (40 mg/kg/day of either drug divided every 6 hours) will eradicate tissue spirochetes and prevent relapse.[48] For an afebrile child between relapses, erythromycin or tetracycline may be given alone without initial penicillin therapy.

Other than the choice of antimicrobial therapy, the major concern in treating relapsing fever is the frequent occurrence of the Jarisch-Herxheimer reaction in the first hours after therapy has been initiated. This response, an exaggeration of the crisis that normally terminates febrile attacks, is characterized by rigors and hyperthermia followed by drenching sweats, hypotension, and prostration.[12] It may be fatal in louse-borne disease but generally is less severe in tick-borne cases. However, recent reports of acute respiratory distress syndrome (ARDS) with multiple organ dysfunction occurring after treatment of tick-borne relapsing fever in Nevada, California, and Washington emphasize this potential risk.[22] Rapid clearance of spirochetes in the bloodstream initiates the process.[12,17,61,66] Release of inflammatory mediators, such as tumor necrosis factor, interleukin-6, and interleukin-8, after bacterial lysis or phagocytosis probably is the major pathophysiologic mechanism.[7,15,16,18,44,51] Purified VMPs are potent triggers of the production of tumor necrosis factor by human monocytes.[65]

Three approaches to controlling this response have been tried—supportive measures, gradual killing of spirochetes, and pharmacologic blockade. The usual supportive measures involve volume expansion and antipyretics. Penicillins result in slower elimination of circulating borreliae and yield a more prolonged but less severe reaction than tetracycline or erythromycin does.[54,66] Steroids (e.g., hydrocortisone) and pure opioid antagonists (e.g., naloxone) do not block the reaction. The opioid antagonist and partial agonist meptazinol (available in Great Britain; not licensed in the United States) effectively blocks the reaction.[61] Fekade and colleagues[27] demonstrated that pretreatment with sheep anti–tumor necrosis factor-α Fab antibody fragments suppresses Jarisch-Herxheimer reactions and reduces the associated increases in plasma concentrations of interleukin-6 and interleukin-8.

At present, the most reasonable approach to limiting Jarisch-Herxheimer reactions is to provide close supervision (either in the hospital or in an office or emergency treatment room) during the first 12 hours after therapy has been initiated. During this period, intravenous access should be in place. The use of oral penicillin as initial therapy is recommended. Positioning, volume expansion, sponging, and antipyretics should be used to control changes in blood pressure, pulse, and temperature. More aggressive measures may be necessary for full-blown reactions.

PROGNOSIS

With current therapy, case-fatality rates from relapsing fever are less than 5 percent.[51] Without treatment, louse-borne disease, in particular, carries a much higher risk of fatality. Fatal cases of tick-borne disease in North America are rare occurrences. Late relapses may occur, particularly in patients with an incompletely treated CNS "sanctuary."[43] In untreated cases, immunity persists for several years. In treated cases, the duration of immunity is unknown.

PREVENTION

Louse-borne relapsing fever is internationally notifiable to the World Health Organization. Tick-borne relapsing fever is

reportable to state health authorities in 11 western states.[21] Its occurrence in national parks and other public recreational settings renders immediate reporting desirable.[10,20]

Prevention of relapsing fever is largely a problem of avoiding its vectors. In outbreaks of louse-borne disease, time-honored measures such as environmental dusting with insecticide, cutting hair short, laundering at 49° C (120° F), and applying residual insecticides to clothing and bedding have been effective.[8] In individual cases of louse-borne disease, eradication of pediculosis with 5 percent permethrin or 1 percent lindane is an essential adjunct to specific therapy.

In endemic foci of tick-borne disease, the habits of *Ornithodoros* and humans determine the environmental and personal measures necessary.[10,19,20] In the United States, increasing use of wilderness recreational areas by the public calls for increased awareness of relapsing fever and its potential transmission. Dwellings in endemic areas should be constructed with "rodent-proof" foundations and soffits. In unsatisfactory buildings, removal of rodent nesting material and liberal spraying of walls, floors, ceilings, and crawl spaces with 1.1 percent *o*-isopropoxyphenyl *N*-methylcarbamate (Baygon) or a similar residual insecticide are proven preventive measures.[10] The use of insect repellents such as DEET has been recommended in some instances, but their effectiveness is not established.

CHAPTER 153

Borrelia (Lyme Disease)

Barbara W. Stechenberg

Lyme disease, recognized initially in 1975, was brought to medical attention first through the concern of two mothers from Lyme, Connecticut; one contacted the Connecticut State Health Department, and the other contacted physicians at Yale about the unusual illness spreading through their community, a small town approximately 15 km north of Long Island Sound near the mouth of the Connecticut River. Their inquiries sparked an intensive clinical and epidemiologic investigation that has yielded much of the information about this disorder—its wide spectrum of clinical manifestations, etiology, pathogenesis, and treatment.

From these investigations, a distinct pattern of signs and symptoms emerged as a newly described disorder. Actually, the characteristic skin lesions soon were recognized as erythema (chronicum) migrans, a skin lesion that had been associated with a similar but more limited illness in Europe since the early 1920s.

THE ORGANISM

Because of certain epidemiologic characteristics, particularly the geographic and seasonal clustering of cases, an infectious etiology was sought, particularly one associated with an arthropod or other vector. Early speculation that Lyme disease might be caused by a virus diminished with the report of rapid resolution of erythema migrans and other symptoms if early treatment with penicillin or tetracycline was initiated.[103]

In 1982, Burgdorfer and associates[21] isolated a *Treponema*-like spirochete from the midgut of the tick *Ixodes scapularis* (also called *Ixodes dammini*). The spirochete has irregular coils ranging in size from 10 to 30 μm in length and 0.18 to 0.25 μm in diameter. Electron microscopy demonstrates their close association with the microvillar brush border of intestinal epithelium.

When infected *I. scapularis* ticks were allowed to feed on New Zealand white rabbits, no immediate adverse effect occurred. However, 10 to 12 weeks after tick engorgement occurred, small skin lesions developed that progressed into typical erythema migrans. Indirect immunofluorescence revealed that the sera of all exposed rabbits yielded high titers of antibody to the spirochetes. Sera from nine patients with clinically diagnosed Lyme disease also demonstrated positive reactions.[21]

The etiologic role of these spirochetes has been defined further. Steere and associates[115] isolated the spirochete from the blood, skin, and cerebrospinal fluid (CSF) of 3 of 56 patients with Lyme disease and from 21 of 110 *I. scapularis* ticks studied. More than 90 percent of the patients had a characteristic immunoglobulin M (IgM) and IgG antibody response; IgM antibody titers reached a peak between the third and sixth weeks after onset, and IgG antibodies rose slowly to reach a peak when arthritis was present. Benach and associates[16] isolated the same spirochete from 2 of 36 patients with Lyme disease in New York. These patients also had a similar rise in antispirochetal antibodies. Berger and his group[19] demonstrated the spirochete in 6 of 14 patients in whom the cutaneous lesions of erythema migrans were studied; four of the six positive specimens were obtained from the peripheries of lesions. Berger and colleagues[19] were able to demonstrate the organisms in secondary lesions.

Though morphologically similar to known pathogenic *Treponema* organisms, the spirochete found in the *I. scapularis* tick is distinctive because it grows on artificial media. Growth of this fastidious, microaerophilic organism occurs best at 33° C in a complex liquid medium called Barbour-Stoenner-Kelly medium.[11] The organism has an apparent slime layer, an outer membrane that is associated loosely with the underlying structures, flagella (7 to 11), a cell wall, and cytoplasmic constituents.[115] It is coiled more loosely and is longer than other spirochetes. It resembles

borreliae most closely and has been designated *Borrelia burgdorferi*.

B. burgdorferi contains many different proteins. Six outer-membrane proteins that act as surface antigens have been identified: outer-surface protein A (OspA, 30 to 32 kd), outer-surface protein B (OspB, 34 kd), outer-surface protein C (OspC, 22 to 25 kd), outer-surface protein D (OspD, 28 to 30 kd), outer-surface protein E (OspE, 19 kd), and outer-surface protein F (OspF, 26 kd). Other polypeptides include the 41-kd flagellar antigen, several heat shock proteins, and a 93-kd antigen that is part of the protoplasmic cylinder. A 49-kilobase linear plasmid contains genes that encode for the two major outer-surface proteins OspA and OspB.[13] In fact, all isolates of *B. burgdorferi* examined have had four to nine pieces of extrachromosomal plasmid DNA, both supercoiled and linear.[12] The complete genome of *B. burgdorferi* (strain B 31) has been sequenced and was found to consist of approximately 1.5 megabases.[45] The only known virulence factors of *B. burgdorferi* are the surface proteins that allow attachment to mammalian cells.

Strain differences in DNA and plasmid composition,[70] ultrastructure, and outer-surface proteins among American and European strains have been identified; the European strains generally are more diverse. Three genomic groups of the *B. burgdorferi* sensu lato complex have been identified with several methods. To date, all North American strains have belonged to group *B. burgdorferi* sensu stricto. All three groups have been found in Europe, but group 2, *Borrelia garinii*, and group 3, *Borrelia afzelii*, occur more commonly.[10,22] These differences may account for the variability in clinical expression.

EPIDEMIOLOGY

Evidence for a tick vector had accumulated early in the investigations. During 1977, the incidence of Lyme disease was 30 times greater on the eastern bank of the Connecticut River than on the western shore.[110,125] Case-control studies of patients, mainly children and young adults and their neighbors, revealed that patients did not participate in more outdoor activities but were more likely to have a cat or farm animal, a pet with ticks, or a tick bite in the year of the study. Ixodid ticks were identified as the probable vector. These ticks have a complex life cycle that spans 2 years, during which they feed once during each of their three stages. In the United States, the white-footed mouse is the preferred host for both the larval and nymph stages. The larvae feed in late summer, whereas the nymphs feed in spring or early summer. Of importance is that this animal is the host for both of these stages and that it is tolerant of infection. The host-seeking behavior of the nymphs in late May is what initiates the Lyme disease season each year. Although the prevalence of spirochetes in this stage (20-25%) is approximately half that found in the adult, nymphs are responsible for nearly 90 percent of Lyme disease cases,[44] which may be related to their smaller size, their greater abundance, and the coincidence of their peak feeding activity with human outdoor activity. The white-tailed deer is the preferred host for the adult stages and acts as the reservoir during the winter months. The adult tick feeds in the fall or winter.

Since the association of the *Ixodes* genus of ticks with a large number of cases was reported from the Lyme, Connecticut, area, Lyme disease has been identified in at least 46 states and now is the most common vector-borne disease in the United States. More than 15,000 cases have been reported each year, a 25-fold increase since national surveillance began in 1982; however, statistics from 2003 and 2004 have shown a decrease in reported cases.[26] The major geographic areas with clusters of cases include the eastern seaboard, the upper Midwest, and the West. In fact, more than 90 percent of the nationally reported cases come from 12 states: Maine, Massachusetts, New Hampshire, Rhode Island, Connecticut, New York, New Jersey, Pennsylvania, Delaware, Maryland, Wisconsin, and Minnesota. All have incidences of Lyme disease greater than the national rate (6.0 per 1000,000).[24] In the East, the tick associated with disease is the *I. scapularis* or *I. dammini* tick; in the West, it is *Ixodes pacificus*, which prefers to feed on lizards that are not susceptible to infection, thus accounting for the low frequency of disease. In the East and upper Midwest, these same ticks may be co-infected with *Babesia microti* and *Anaplasma phagocytophilum* (formerly *Ehrlichia phagocytophilia*).[124]

In Europe, cases of erythema migrans with and without meningopolyneuritis have occurred within the range of the *Ixodes ricinus* tick, although one case described outside the range of this vector has been ascribed to mosquito bites.[96] The highest frequencies of disease occur in middle Europe and Scandinavia. The infection has been documented in Russia, China, and Japan. In Asia, the vector is *Ixodes persulcatus*. Isolated cases distributed over a wide region, including Australia, where none of the vectors currently recognized are known to exist, suggest that the disease may be more widespread than first realized and may have a broader range of potential vectors. Mosquitoes and deer flies may become infected with the organism but do not appear to be able to transmit the organism to humans.[75]

B. burgdorferi is widespread in the animal kingdom. Virtually any feral or domestic animal can act as an intermediate host. Birds frequently are carriers, which may account for the unusual dispersal pattern of Lyme disease.[5] The greatest reservoir continues to be white-footed mice and deer. Wild animals are not susceptible to the development of illness; however, clinical Lyme disease may occur in domestic animals, such as dogs and horses.

As expected with this vector, the disease has a high incidence in the summer and early fall, with clustering of patients in wooded and sparsely settled areas. The age range of reported cases has been from 2 to 90 years, with a slight male preponderance. The incidence of reported disease peaks at ages 5 to 14 and 50 to 59.[26]

PATHOGENESIS

The organism must adapt to two major hosts, the ticks and mammalian hosts, to complete its enzootic cycle. In the tick midgut, OspA is expressed; when the tick feeds and a blood meal is taken, OspC is up-regulated. The spirochete is injected into the mammalian bloodstream through the saliva of the tick or deposited on the skin in fecal material.[17] Tick saliva may play a role in dissemination and survival of the spirochete.

During an incubation period of 3 to 32 days, the organism multiplies locally in the skin. It induces proinflammatory responses in the inflammatory cells of the erythema migrans lesions. Both innate and adaptive cellular elements are mobilized to fight infection. However, the organism has shown in vitro resistance to elimination by phagocytic cells, thereby increasing infectivity of the spirochete.[47] Several mechanisms may aid in dissemination of the organism to distant sites.[106] The sequences of OspC vary considerable among different strains, with a few particularly associated with dissemination. The organism binds plasminogen and its activators to its surface. Dissemination is primarily hematogenous. It has been isolated from the CSF of patients with neurologic symptoms up to 10 weeks after the initial tick bite. Success with antibiotic treatment provides evidence that the spirochete still is alive when arthritis is present.[114] The late complications probably are caused by a direct effect of infection with viable organisms and the immunologic response to them. The spirochete can adhere to many different types of mammalian cells and is a potent inducer of tumor necrosis factor, interleukin-1β, and interleukin-6.[54] In a rat model, permeability changes in the blood-brain barrier begin within 12 hours of inoculation of

the organism, and the spirochete can be cultured from CSF within 24 hours.[46]

Initially, the immune response seems to be suppressed, which may aid dissemination. However, during dissemination, adaptive T- and B-cell responses in lymph nodes lead to antibody production. The specific IgM response peaks between the third and sixth weeks of infection. It often is associated with polyclonal activation of B cells, which causes elevated total serum IgM levels, circulating immune complexes, and cryoglobulins.[57] The specific IgG response develops initially during the first 6 to 8 weeks but then matures for months with the development of a wide array of antibodies to both protein and nonprotein antigens. The unusual persistence of the IgM response in patients with severe disease suggests that such patients have a defect in their helper T-cell function needed to switch from IgM to IgG production.[115] Patients with severe and prolonged illness, particularly arthritis or neurologic disease, often have the B-cell alloantigens HLA-DR2 and HLA-DR4.[113]

Histologically, all affected tissues show infiltration of lymphocytes and plasma cells. Some degree of vascular damage may be seen in many sites, thus suggesting that the organism may have been in or around the vessels. *B. burgdorferi* seems to survive for long periods in certain areas, particularly the skin, nervous system, and joints. With the development of animal models, including hamsters, mice, dogs, and nonhuman primates, and expansion of knowledge about the immune response to this infection, new information is accumulating about the pathogenesis of this disease, which is described well in excellent reviews by Steere and colleagues.[106,111]

CLINICAL MANIFESTATIONS

The clinical findings in Lyme disease can be divided into three stages on the basis of the chronologic relationship to the original bite. In the first stage, the presence of the skin lesions is the most prominent symptom; in the second stage, cardiac and neurologic findings predominate; and in the third stage, arthritis is the most common symptom. Any of these findings may occur in isolation or recurrently. Asbrink and Hovmark[6] proposed a clinical classification analogous to that of syphilis, with early infection designated stage 1 (localized erythema migrans), followed days to weeks later by stage 2 (early disseminated infection), and then late or persistent infection designated stage 3.

The most common of the clinical manifestations is the rash erythema migrans (Fig. 153–1), seen in 70 to 80 percent of persons with Lyme disease. The rash usually begins 3 to 30 days after a tick bite, although only approximately a third of patients give a specific history of a bite, which may relate to the small size of the tick. An erythematous macule or papule forms at the site of the bite. It gradually enlarges to form a large, plaque-like, erythematous annular lesion. The median diameter is 16 cm, but it may reach 68 cm.[20] The outer border generally is erythematous and flat, although it may be indurated. The middle area may show clearing, but the center sometimes is indurated or erythematous or may have vesicles. In a study[105] of early microbiologically confirmed erythema migrans occurring within 3 days of the onset of symptoms, the lesions commonly had homogeneous or central redness associated with flu-like symptoms. The lesions often are hot to the touch and otherwise asymptomatic but may burn, prickle, or itch. They may occur on any area of the body; usual sites include the thighs, buttocks, and axillae; intertriginous areas; or places where underwear may be tight. Mucosal lesions do not occur. Multiple secondary annular lesions occur in 20 to 50 percent of patients, usually within a few days of appearance of the primary lesion. These secondary lesions are evidence of dissemination (stage 2).

The average duration of the initial skin lesion is approximately 3 weeks. It gradually resolves, sometimes with a bluish hue as it fades. Lesions can recur for up to a year or more, often coincident with subsequent attacks of arthritis. In patients treated with appropriate antibiotics, the lesions usually resolve within several days.

The skin lesions frequently are associated with systemic symptoms, most commonly malaise, fatigue, headache, stiff neck, and arthralgias; additionally, backache, myalgias, nausea, vomiting, and sore throat may be present. Fever usually is low-grade, but the patient's temperature can be as high as 40° C, with chills. Fever occurs more commonly in children than in adults.[112] Lymphadenopathy, usually regional and associated with erythema migrans but occasionally generalized, may occur. Occasionally, a malar rash, conjunctivitis, or pharyngitis is present. In

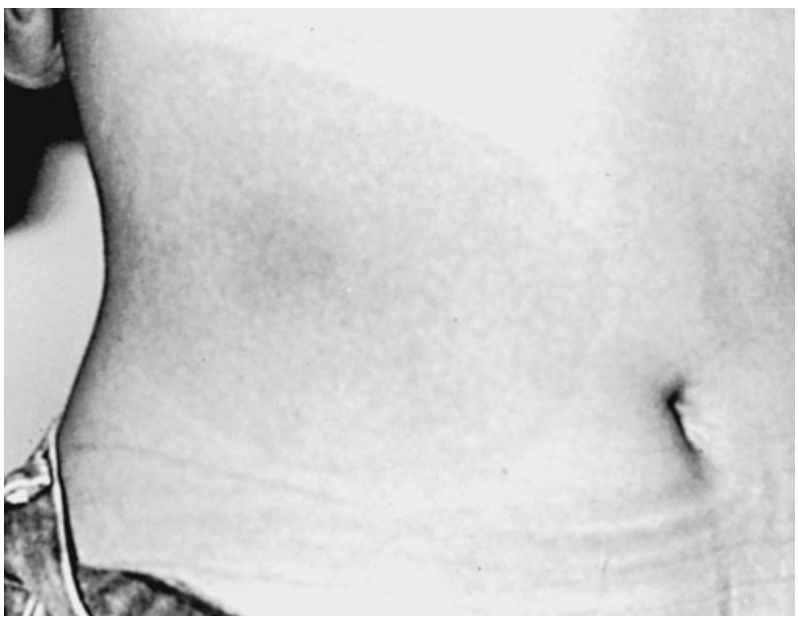

Figure 153–1 The typical skin lesion of Lyme disease, erythema (chronicum) migrans. The lesion had progressed from about 3 cm to this size within a week. *(Courtesy of Drs. Jane Grant-Kels and Nadine Wenner.)*

approximately 10 percent of patients, signs and symptoms consistent with anicteric hepatitis, including hepatomegaly and right upper quadrant tenderness are present. Most symptoms resolve over the course of a few days, but some patients experience intermittent and fluctuating symptoms for a period of several weeks. Feder and associates[42] described a group of five children with a flu-like illness but not erythema migrans that was documented serologically as Lyme disease.

Another skin lesion noted in early disseminated disease is *Borrelia* lymphocytoma. Seen in Europe in approximately 1 percent of cases of Lyme disease, it generally appears as a firm, red, red-brown, or red-purple nodule or papule, principally on the pinna of the ear in children or on the nipple or areola in adults.[76]

The late skin manifestation is acrodermatitis chronica atrophicans, a progressive dermatologic condition that develops slowly with increasing erythema and pigmentation changes of the skin of an extremity that spread over its extensor surface. After initial hyperpigmentation occurs, hypopigmented areas develop, and eventually the skin becomes frail. It is seen primarily in European cases. This condition has been associated with elevated antibodies to *B. burgdorferi* and response to antibiotic therapy.[79] Other associated lesions are fibrotic nodules, other sclerotic and atrophic lesions, and, rarely, eosinophilic fasciitis and progressive facial hemiatrophy.[52,76]

Although early Lyme disease can cause symptoms of meningeal irritation and headache, they usually are benign and self-limited. Neurologic abnormalities develop roughly within 4 weeks (range, 2 to 11 weeks, but can be up to months) after the tick bite occurs. The spectrum of involvement is wide and includes aseptic meningitis, meningoencephalitis, chorea, cerebellar ataxia, cranial neuritis, radiculopathies, mononeuritis multiplex, and myelitis.[31,55,88] The most common occurrence is aseptic meningitis, characterized by headache and stiff neck and often associated with nausea and vomiting, sensory disturbance, photophobia, and irritability. Findings in CSF are similar to those seen in patients with viral meningitis. The symptoms may occur intermittently for weeks, with mild headache persisting between attacks until spontaneous remission occurs. In a series comparing children with Lyme meningitis and children with viral meningitis, Eppes and associates[41] showed that those with Lyme meningitis were more likely to have a lower temperature, longer duration of symptoms, associated papilledema or cranial neuropathy, and milder pleocytosis. Further study by this group,[8] using a logistic regression model, showed a long duration of headache (7.5 days in Lyme meningitis versus 2.8 days in aseptic meningitis), the presence of cranial neuritis (56% vs. 3% for aseptic meningitis), and a predominance of CSF mononuclear cells as findings that differentiated Lyme meningitis from aseptic meningitis. As many as two thirds of adult patients exhibit subtle findings of parenchymal abnormality or encephalitis,[36] such as somnolence, emotional lability, memory loss, poor concentration, or behavioral changes. In a series of children with neurologic manifestations, changes in behavior that did not predate the Lyme disease occurred rarely, as did meningoradiculitis and peripheral neuropathy syndromes.[15]

The seventh cranial nerve is involved most frequently in Lyme disease; unilateral or bilateral facial palsies occur in as many as 11 percent of patients.[27] Seventh nerve palsy is seen in approximately 50 percent of patients with meningitis; it can occur alone as well. Other cranial nerves, particularly III and IV, are involved less frequently. Several children with pseudotumor cerebri in association with Lyme disease have been reported.[15,52,87] Rarely, opsoclonus-myoclonus may be seen.[83]

Neurologic involvement can develop in the third stage of illness months to years after the initial infection. These patients have neuropsychiatric symptoms, focal central nervous system disease, or, rarely, severe incapacitating fatigue.[55,82] These findings are extremely rare occurrences in children.[15,100]

Conjunctivitis is an infrequent early ophthalmologic manifestation that usually is transient.[107] A case of iritis progressing to panophthalmitis and unilateral blindness has been described.[112] Spirochetes consistent with *B. burgdorferi* were found in vitreous debris. Other eye manifestations include optic neuritis, iritis, and keratitis.[14] Rothermel and colleagues[92] described four cases of optic neuropathy in children with Lyme disease: two children had optic neuritis, one had papilledema, and one had both.

Cardiac abnormalities occur in approximately 10 percent of untreated patients, generally within several weeks after being bitten (average, 5 weeks; range, 3 to 21 weeks). Seen most commonly in young adult males, they range from fluctuating degrees of atrioventricular block to myopericarditis and left ventricular dysfunction.[78,108] Cardiac involvement usually is brief (3 days to 6 weeks). Recently, three children with a transient prolonged corrected QT interval and Lyme disease were described.[99] Patients with cardiac involvement generally have other evidence of more severe systemic disease, such as fever, rash, arthritis, or neurologic findings. Though described in children, these cardiac findings are uncommon occurrences in pediatric patients.

The second most common manifestation of Lyme disease after erythema migrans is arthritis, which occurs in approximately half of the patients without treatment.[32,38,118,129] It typically begins 4 weeks after the skin lesion (5 to 6 weeks after the bite) appears, although the time span can vary from less than 1 week to many months, and a small percentage of patients do not recall having any skin lesions. The arthritis usually is of sudden onset, monarticular or oligoarticular, and, occasionally, migratory. Large joints, often those closest to the initial rash, are affected most commonly. The knee is by far the joint involved most frequently, followed by the shoulder, elbow, temporomandibular joint, ankle, wrist, and hip.[36] They become swollen, warm, and painful but rarely red. The usual duration of the first episode is approximately 1 week, but sometimes the episode persists for several months.

Recurrent attacks of arthritis are common occurrences. Among the initial 51 patients studied, 35 (69%) had recurrent attacks.[107,118] The median number of recurrent attacks was three. During recurrences, usually more joints are involved than in the initial episode. These attacks last approximately 1 week, with intervals of 1 week to 2 years between attacks. Children experience complete remissions between attacks; however, adults often have persistent asymptomatic joint effusions or mild morning stiffness. A severe chronic erosive arthritis develops in approximately 10 percent of all patients with Lyme arthritis; it occurs approximately 1 year after the initial manifestations and often is associated with HLA-DR4.[113] A rare, unusual complication is rupture of a Baker cyst, which causes a pseudothrombophlebitis.

Other unusual manifestations of Lyme disease include recurrent hepatitis,[51] myositis,[7,59] eosinophilic lymphadenitis,[86] and adult respiratory distress syndrome.[66] Simultaneous co-infection with the agent of babesiosis or anaplasmosis may increase the severity of the initial illness or present a more confusing picture.[109] In particular, the associated fever and flu-like symptoms may be more severe.[69] The proportion of patients with co-infection varies greatly, with a range of 4 to 39 percent, depending on the population studied and the diagnostic measures used.[69,119]

Maternal-fetal transmission of *B. burgdorferi* has been documented in two infants, one with congenital heart disease[95] and the other with encephalitis.[127] Neither infant had evidence of tissue inflammation. A stillbirth that occurred after maternal Lyme disease also has been reported.[74] An analysis of 19 cases of Lyme disease occurring during pregnancy revealed five pregnancies (26%) with adverse outcomes. They occurred in all three trimesters, and no two were the same.[77] In a study of 463 infants, no association between congenital malformations and the presence of antibody to *B. burgdorferi* in cord blood or IgM antibody could be established.[128]

Strobino and associates,[122] in a prospective study of approximately 2000 pregnant women in an endemic area, found no evidence of fetal wasting, prematurity, or congenital malformations attributable to Lyme disease. In a follow-up study, they found no associated congenital heart disease.[121] Gerber and Zalneraitis[49] surveyed pediatric neurologists in a large endemic area to determine the prevalence of clinically significant nervous system disease that might be attributable to transplacental transmission; they found no cases that met their case definition.

The association of Lyme disease with adverse fetal outcomes appears to be unusual[128]; however, the importance of continued surveillance of pregnant women, as well as prompt diagnosis and treatment, should be emphasized.[126]

DIFFERENTIAL DIAGNOSIS

When the characteristic erythema migrans rash is present and recognized, identifying the etiology of subsequent symptoms should pose little problem. However, particularly when the clinical findings are atypical, the differential diagnosis is broad.

If the rash is not recognized as erythema migrans, it may be confused with streptococcal cellulitis. Erythema multiforme might be a consideration, but the lesions in that disorder often are smaller and urticarial or vesicular, are seen on mucosal surfaces, and frequently are associated with drug exposure. Erythema marginatum usually is smaller and less annular. If a necrotic or vesicular center is present in the erythema migrans lesion, it may resemble the lesion of tularemia, but the latter is not expansive and not associated with similar complications. Occasionally, a superficial reaction to a tick bite proves confusing, but generally the time course helps. A hiatus of at least 3 days should occur between the bite and development of erythema migrans.

Distinguishing Lyme disease from acute rheumatic fever is particularly important. If the skin lesion is misdiagnosed and migratory arthritis is noted in association with nonspecific electrocardiographic changes, such as a prolonged PR interval, one might assume erroneously that the modified Jones criteria have been fulfilled. Fortunately, in Lyme disease, usually no evidence of antecedent streptococcal infection is present, and the specific nature of rheumatologic involvement and cardiac involvement is different.

Other forms of arthritis that may be confused with Lyme disease include (1) pauciarticular juvenile rheumatoid arthritis; (2) psoriatic arthritis; (3) reactive arthritis associated with *Salmonella*, *Shigella*, or *Yersinia* infections; (4) Reiter syndrome; and (5) postinfectious or infectious arthritis, such as that associated with rubella, hepatitis B, or echoviruses. Several distinctive features usually allow prompt differentiation from Lyme disease.

The major neurologic manifestation of aseptic meningitis may be confused with enteroviral, leptospiral, or early tuberculous meningitis. When it becomes more chronic and relapsing, one must consider sarcoidosis, Mollaret meningitis, Behçet disease, and multiple sclerosis.

SPECIFIC DIAGNOSIS

The diagnosis of Lyme disease is made best on clinical and epidemiologic grounds and often can be established early in the course of illness from the gross appearance of erythema migrans.

Routine laboratory testing generally is nonspecific and not helpful. The sedimentation rate often is elevated. Leukocyte counts commonly are normal. Serum glutamic-oxaloacetic transaminase and serum glutamic-pyruvic transaminase levels may be elevated mildly early in the course of the disease. Complement studies may be normal, low, or high. Serum IgG and IgA typically are normal; however, IgM and cryoglobulin IgM often are elevated, particularly in patients with severe disease or in those in whom neurologic complications or arthritis develops later. Immune complexes as measured by Clq binding (or other methods) may be found in patients with Lyme disease and may be involved in the pathogenesis. They may be present at the time of diagnosis and then clear in patients without neurologic or cardiac involvement or localize to the synovium in those with arthritis.[57]

Examination of synovial fluid in patients with arthritis demonstrates leukocyte counts elevated from 500 to more than 100,000 cells/mm^3, with a predominance of polymorphonuclear leukocytes. Total protein usually is between 3 and 8 g/dL.

Patients with aseptic meningitis frequently have CSF pleocytosis, with counts ranging from 25 to 450 cells/mm^3 and lymphocytic predominance. Total protein may be elevated mildly, and glucose levels (CSF-to-blood ratio) usually are normal.

Culture of B. *burgdorferi* from specimens permits a definitive diagnosis to be established; however, the yield from culture is too low to render it practical for diagnosis. Therefore, serology currently is the only practical laboratory technique used for confirmation of the diagnosis. Although indirect immunofluorescence first was used to evaluate the immune response to *B. burgdorferi*, enzyme-linked immunosorbent assay (ELISA) appears to be more sensitive and specific.[29,93] However, because no standardization of testing has been established, interlaboratory variation in results may be marked.[58,65,68] Any serologic results must be interpreted with care. Serologic testing should be undertaken only when the clinical and epidemiologic investigations suggest Lyme disease as the diagnosis.

False-negative results are common occurrences early in the infection.[103] Only 20 to 30 percent of patients have positive responses, usually IgM, in the first few weeks of infection. However, Berardi and associates[18] have developed a sensitive capture IgM ELISA that demonstrates an IgM response in as many as 90 percent of patients with early stages of disease. Some patients treated with antibiotics early in the course of disease may not show an antibody response. In one study, 17 patients with a variety of symptoms were found to be seronegative but to have mononuclear cells with a proliferative response to *B. burgdorferi*.[33] The significance of such responses remains to be seen, but this finding should be considered extremely uncommon.

Techniques to increase sensitivity, specificity, or both include ELISA using flagellar antigen,[56] immunoblotting,[53] and polymerase chain reaction (PCR).[81] Immunoblotting, in particular, may be used to identify false-positive results.[91] Western blot or immunoblotting separates surface and subsurface proteins of *B. burgdorferi* by polyacrylamide gel electrophoresis, which then are reacted with patients' sera. This technique is more specific than is ELISA or immunofluorescent assay and is especially useful in identifying false-positive results.[48,53,91] False-positive results may be seen in patients with other spirochetal infections (e.g., syphilis, leptospirosis, relapsing fever), certain viral infections (e.g., varicella, herpes simplex virus, Epstein-Barr virus), or certain autoimmune diseases or in the presence of antibodies directed against spirochetes in normal oral flora.[4]

As a result of a national conference on serologic diagnosis of Lyme disease, the Centers for Disease Control and Prevention recommend a two-test approach for active disease and for previous infection that involves the use of a sensitive enzyme immunoassay or immunofluorescent assay followed by Western blot if the initial test is positive or the results are equivocal.[23] Negative results need not be validated. For Western blot in the first 4 weeks of disease, both IgM and IgG procedures should be performed. A positive IgM test result alone is not recommended for determining active disease in patients with illness of greater than 1 month's duration because of a high false-positive rate caused by the lower specificity of the IgM immunoblot.[130] If serologic

results in a patient with suspected early Lyme disease are negative, paired acute and convalescent specimens should be obtained. Serum samples from patients with disseminated or late-stage disease almost always have a strong IgG response to *B. burgdorferi* antigens. A recommendation is that an IgM immunoblot result be considered positive if two of the following three bands are present: 24 kd (OspC), 39 kd (BmpA), or 41 kd (Fla).[39] An IgG immunoblot result is considered positive if 5 of the following 10 bands are present: 18 kd, 21 kd (OspC), 28 kd, 30 kd, 39 kd (BmpA0), 41 kd (Fla), 45 kd, 58 kd, 66 kd, or 93 kd.[37]

In addition to having false-positive results, 5 to 10 percent of patients in the United States have asymptomatic *B. burgdorferi* infection; these serologic results may interfere with establishing the diagnosis of another significant illness. In fact, because IgM or IgG antibody responses to the organism may persist for 10 to 20 years after active disease, linking testing to appropriate clinical scenarios is important.[64]

PCR has been used to amplify and detect *B. burgdorferi* DNA in cultured spirochetes, infected animals, and patients with Lyme disease.[81,89,91] DNA sequences can be detected in blood, urine, CSF, skin, and synovial fluid.[97] *B. burgdorferi* DNA was identified in 75 of 88 synovial fluid samples from patients with Lyme disease.[81] The usefulness of PCR in clinical situations is an area of active research, but its use may be limited by problems with sensitivity and specificity.[81,89,91] Antibody response to recombinant VlsE1 antigen is promising as a sensitive and specific method of detecting an immune response.[9] The Lyme urine antigen test, immunofluorescent staining for cell wall–deficient forms of the organism, and lymphocyte transformation tests are unreliable for establishing the diagnosis of suspected Lyme disease.[25]

Diagnosing neurologic manifestations of Lyme disease is particularly difficult. Comparing intrathecal antibody assay results with serum results may be helpful.[109]

Because of the delay in specific antibody response and the possible ablation of this response in patients with localized disease who are treated early, recognition of the clinical picture—erythema migrans, a flu- or meningitis-like illness in the summer, or both—is essential for providing prompt diagnosis and treatment. Laboratory evaluation is unnecessary in early stages of the disease and should be used only to support a clinical diagnosis of Lyme disease in later stages. Overdiagnosis and overtreatment continue to be a concern in areas endemic for Lyme disease.[85]

TREATMENT

Even before the spirochete was identified as the causative agent of Lyme disease, treatment of adults with penicillin or tetracycline was associated with more rapid resolution of the rash and its associated symptoms.[117] Subsequent studies have confirmed that impression; tetracycline may be more effective in preventing late complications of the disease (meningoencephalitis, myocarditis, and arthritis).[116] In none of 88 patients treated with tetracycline did such complications develop, as compared with 7.5 percent (3 of 40) of a group of patients treated with penicillin. However, nearly half of all treated patients still had minor late symptoms such as headache, musculoskeletal pain, and lethargy. These complications correlated significantly with the initial severity of illness.

Antibiotic sensitivities to *B. burgdorferi* have been determined in vitro and in experimental animals.[60,61,63] Although the methods are not standardized, the consensus is that the organism is highly sensitive to tetracycline. It also is susceptible to ampicillin, ceftriaxone, and imipenem. Unlike *Treponema pallidum*, *B. burgdorferi* is only moderately sensitive to penicillin. Aminoglycosides and rifampin have no activity, whereas oxacillin and chloramphenicol are only moderately active. Erythromycin appears to be active in vitro but may be less so in vivo.

In fact, azithromycin and clarithromycin both are more active, although the clinical efficacy of either is controversial.[35] A trial comparing azithromycin and amoxicillin for the treatment of erythema migrans showed amoxicillin to be significantly more effective.[72] Newer oral cephalosporins, particularly cefixime and cefuroxime axetil, hold promise.[3,62] Cefuroxime axetil was comparable to doxycycline in a clinical trial in adults with early stages of Lyme disease.[73] In a similar trial comparing cefuroxime and amoxicillin in children, they were found to be equivalent.[40]

Recommendations for treatment continue to evolve. The Infectious Diseases Society of America recently presented evidence-based guidelines for treatment.[131] For early localized or disseminated Lyme disease, doxycycline, 100 mg twice a day (4 mg/kg/day to a maximum of 100 mg twice a day) for 14 to 21 days, is effective for adults and children older than 8 years. In younger children, amoxicillin, 50 mg/kg/day in three divided doses (maximum of 1.5 g/day) for the same duration, appears to be the best choice, with cefuroxime axetil, 30 mg/kg/day in two divided doses, as an alternative. For penicillin-allergic children who cannot tolerate a cephalosporin, erythromycin, 30 to 50 mg/kg/day in four divided doses for the same period, may be used, although its efficacy is less clear. The duration of treatment is based on clinical response. A recent study in adults actually demonstrated that a shorter course of 10 days may be adequate.[132] Multicenter studies of patients with early stages of disease show efficacy to be similar with doxycycline, amoxicillin, and cefuroxime axetil. Some patients may have subjective symptoms after receiving treatment, and it is important to caution families that resolution of nonspecific symptoms may continue slowly after treatment. Objective evidence of persistent infection or relapse is a very uncommon finding.

Patients with isolated seventh nerve palsy should be treated with oral regimens to prevent further complications. If the palsy is associated with other neurologic complications, parenteral therapy should be initiated.

Neurologic complications, particularly Lyme meningitis, have been treated successfully with large doses of penicillin G (20 million IU/day) in adults.[120] No large trials have been reported in children; however, penicillin, 300,000 IU/kg/day, appeared to be beneficial in two cases of pseudotumor cerebri.[87] The exquisite sensitivity of the organism to ceftriaxone renders it an attractive alternative for parenteral therapy, and it has become the drug of choice. The dose of ceftriaxone is 75 to 100 mg/kg/day, up to 2 g/day. In a study of 23 patients with late stages of Lyme disease, Dattwyler and associates[32] reported superior efficacy of ceftriaxone over penicillin. Cefotaxime is a reasonable alternative. The duration of parenteral therapy for neurologic or rheumatologic disease is not clear but should be a minimum of 14 days (as long as 4 weeks). The signs and symptoms of acute neuroborreliosis usually resolve within weeks. Even patients with late encephalopathy can be treated successfully with ceftriaxone.[71]

Patients with established Lyme arthritis also have been treated successfully with high-dose penicillin but without universal efficacy.[114] In an uncontrolled study of 33 children with arthritis, 31 were treated with oral therapy alone for 3 to 4 weeks, with elimination of synovitis and recurrent attacks.[30,38] Oral therapy with either doxycycline or amoxicillin for 4 weeks is a reasonable approach for children without neurologic involvement. Persistent or recurrent arthritis may be treated with a subsequent oral course or parenteral treatment with ceftriaxone.

The self-limited nature of the acute arthritis obviates the need for any analgesics other than acetaminophen or nonsteroidal anti-inflammatory agents. Patients with chronic arthritis generally have been treated with nonsteroidal anti-inflammatory agents.

Patients with cardiac complications usually do not require specific treatment other than an oral antibiotic regimen if they have first- or second-degree atrioventricular block. Patients with

third-degree block should be treated with parenteral therapy such as ceftriaxone, although no clinical data support this approach. Those with heart block may require temporary pacing.[108]

PROGNOSIS AND PREVENTION

Most patients with Lyme disease, particularly those treated promptly with an appropriate antibiotic, have an uncomplicated course. Series in children point to an excellent prognosis in most cases. A review of 65 children treated for erythema migrans and monitored for a mean of longer than 3 years found them all to be well and without findings of late Lyme disease.[94] Another prospective study of children with newly diagnosed disease of any stage found that all the children were cured.[100] Rose and associates[90] described 44 children with arthritis who all had an excellent prognosis. A study of cognitive sequelae in children treated for Lyme disease showed no differences between the Lyme disease and control groups.[1] In fact, a study of children with arthritis who initially were untreated for at least 4 years found few children with late or chronic problems.[123] Another study of 90 children also suggested an excellent prognosis.[50]

After receiving appropriate treatment of Lyme disease, a small percentage of patients continue to have subjective symptoms, mainly musculoskeletal pain, fatigue, and neurocognitive difficulties, sometimes called chronic Lyme disease. It is an extremely rare occurrence in children. A large study showed no difference in the frequency of pain and fatigue in adult patients who had had Lyme disease and age-matched controls.[98] In a recent study of adult patients with post-Lyme syndrome, comparison of treatment with intravenous ceftriaxone followed by doxycycline and treatment with appropriate placebos for a total of 3 months showed no significant differences between the groups.[67]

For the small percentage of patients with chronic arthritis, the course may be variable, although the illness may resolve after 12 to 16 months. With earlier treatment, this group should be held to a minimum.

Prompt recognition of this disease with its diverse manifestations should lead to early treatment and resolution. The best prevention is avoidance of contact with the tick vector.

Even in endemic areas where a large percentage of the ticks are infected, the chance of acquiring disease is not great and depends in part on the duration of attachment of the tick. Attachment for more than 24 hours is required.[84] A recent study using mice and nymphal *I. scapularis* revealed that no transmission occurred in the first 24 hours, with maximum transmission occurring between 48 and 72 hours.[34] A small study of prophylactic antibiotics for tick bites showed a low risk of acquiring disease, similar to the risk for an adverse reaction to penicillin.[28] In a study of prophylaxis after tick bites in a highly endemic area, the incidence of infection in the placebo-treated group was only 1.2 percent. The authors concluded that even in an endemic area, the use of routine prophylactic antibiotics is not indicated.[102] A recent trial demonstrated that a single 200-mg dose of doxycycline can effectively prevent Lyme disease if given within 72 hours of the tick bite.[80] One cannot generalize this finding to less endemic areas, other antibiotic regimens, or unidentified, unengorged ticks.[101] However, in certain situations, such as a highly engorged tick in a high-risk individual, prophylaxis might be considered. Data are insufficient to recommend amoxicillin prophylaxis. Analysis of ticks for spirochetal infection has poor predictive value and should be discouraged.

Important preventive measures include (1) avoiding high-risk areas, particularly wooded, grassy areas; (2) when walking in such areas, wearing light-colored, long pants tucked into socks, sneakers, and long-sleeved shirts; (3) using insect repellents such as DEET (for skin) and permethrin (for clothing); (4) most important, conducting careful "tick patrols" every day or after every potential exposure to look carefully for the ticks; and (5) removing ticks by pulling them straight out with tweezers or protected fingers.

Active immunization against *B. burgdorferi* consisting of recombinant OspA in adjuvant was available commercially in the United States for appropriate patients at least 15 years of age. In phase III efficacy and safety trials, the efficacy of the vaccine in preventing definite Lyme disease was 49 percent after two injections and 76 percent after three injections.[65] The most important factor in protection was the strength of the antibody response to the OspA epitope. The Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention advised consideration of vaccination for Lyme disease in people 15 to 70 years old who live or work in high-risk areas and who have frequent or prolonged exposure to the ticks.[2] A trial in children showed similar safety and higher geometric mean antibody titers than in adults.[104] However, this vaccine no longer is available. Studies of other vaccines are ongoing. Vigilance for tick bites will continue to be the most important preventive measure.

CHAPTER 154

LEPTOSPIROSIS

Ralph D. Feigin ✪ Adam W. Lowry

HISTORY

Weil[209] is credited with providing the first description of leptospirosis in 1886. Not until 1915, however, was the causal agent, "spirochaeta icterohaemorrhagiae," identified by Inada and associates.[97] Eight years earlier, Stimson[176] unknowingly had identified the same organism within sections of kidney obtained from a patient in whom yellow fever had been diagnosed incorrectly.

Noguchi[131] first recovered this organism from a Norway rat in 1917; in 1922, the first case of Weil disease in a person associated with rat exposure was identified.[204] For many years, the rat was considered the only animal host of *Leptospira icterohaemorrhagiae*. In 1944, Randall and Cooper[142] isolated this agent from a naturally infected dog, and *L. icterohaemorrhagiae* subsequently has been associated with many animal hosts, including goats, swine, cattle, and hamsters.

In 1938 and 1939, Meyer and associates[120] popularized the concept that infection with *Leptospira canicola* caused disease in dogs and humans in the United States. "Canicola fever" first was reported in Great Britain in 1946,[15] and in 1951, 40 percent of the dogs in Great Britain were noted to be seropositive.[36] Surveys have confirmed the presence of *L. canicola* infection in species other than dogs.[158,199]

In 1950, Gochenour and colleagues[83] identified *Leptospira pomona* as the agent responsible for leptospirosis in cows. Widespread *L. pomona* infection among cattle in the United States was recognized quickly, and in time this finding stimulated extensive epidemiologic investigations in livestock. Infections of cattle with *Leptospira hebdomidis* and *Leptospira grippotyphosa* were identified, and, concomitantly, infections of swine and horses with *L. pomona* were documented.[92] In Europe, *L. pomona* was identified as the agent responsible for "swineherd disease," and it was recovered from other domestic animals as well. In 1951, the first human cases of *L. pomona* infection were identified.

Many new serotypes of leptospires were recognized in the early 1950s after the establishment of serologic diagnostic services for leptospires by the Centers for Disease Control and Prevention (CDC) and the Walter Reed Army Institute of Research. Along with the identification of additional leptospiral serotypes, the spectrum of clinical disease associated with infection by leptospires was elucidated. Patients with autumnal fever (a disease in Japanese peasants and potters) and Fort Bragg fever (a febrile illness associated with pretibial eruptions described in army recruits) were shown to suffer from leptospirosis caused by *Leptospira autumnalis*.[82,154] "Mud fever," "pea-pickers disease," and "European swamp fever," terms that were used to describe a disease of undetermined etiology in eastern Germany, the Far East, and western Poland, were shown to be examples of leptospirosis caused by *L. grippotyphosa*.[42] Seven-day fever in Japan, Wycon fever and Bushy Creek fever in the United States, cane field fever in Australia, and swineherd disease in Europe were identified as examples of infection caused by *L. hebdomidis*, *L. canicola*, *L. pomona*, *Leptospira australis*, and *L. pomona*, respectively.[21,26,31,50,92]

Leptospirosis is a disease now thought to be caused most likely by a single family of organisms that has multiple serogroups and serotypes[3] and is characterized by a broad spectrum of clinical findings.[139] At least 180 strains, called serovars (serotypes), which are divided into serogroups on the basis of common antigens, have been identified.

EPIDEMIOLOGY

ANIMAL RESERVOIRS

Among mammals, rodents are the most important reservoir of leptospires, but nearly all mammals may be infected and can transmit the disease. In various parts of the world, rats, field mice, moles, gerbils, coypus, hedgehogs, shrews, dogs, foxes, jackals, mongooses, civets, skunks, raccoons, bandicoots, opossums, and cattle have been implicated as sources of human infection.* Leptospires also have been isolated in reptiles and birds, but the epidemiologic significance of these animals in terms of maintenance of the organism in nature or transmission of disease to humans is not clear. For many species, infectivity rates of 10 to 50 percent have been reported frequently.[92,145] During epizootics, the circulation of leptospires among many species of animals living within a given biocenosis has been well recognized.[56]

A biologic equilibrium whereby these organisms remain within the convoluted tubules of the kidneys of the host without producing any pathogenic effect on the tubular epithelium exists between some strains of leptospires and numerous species of animals. When this equilibrium is not established, the animal may become ill or may die.[16,69] Studies performed in skunks suggest that local resistance appears soon after infection occurs. The failure of leptospires to elicit a significant systemic antibody response in certain animal species may be due to the development of this local immunity.[182] Some animals fail to develop homologous antibody titers but harbor leptospires in their kidneys for extended periods.[182] Thus, lack of a positive titer to leptospires, as determined during the course of serologic surveys of animal populations, does not indicate absence of infection. For this reason, serologic surveys of animal populations cannot reflect the true incidence of leptospiral infection accurately.

A particular host species may serve as a reservoir for one or more serotypes of leptospires, and a particular serotype may be hosted by many different animal species. Turner[193,195] stressed that a particular animal species commonly serves as a reservoir for selected serotypes but temporarily may be infected and serve as an incidental host for other serotypes with which it usually is not infected. Two or more animal hosts for the same serotype may be present in the same geographic area. These newer insights have replaced earlier epidemiologic concepts of leptospirosis concerning a "host of election." Although any animal susceptible to infection by leptospires may become a urinary "shedder" of the organisms temporarily, only selected animal species with "biologic sympathy" for a particular strain of leptospires can become a principal or maintenance host of the serotype.[16]

TRANSMISSION OF LEPTOSPIRES TO HUMANS

Leptospires are transmitted to humans either by contact with blood, urine, tissues, or organs of infected animals or by exposure to an environment that has been contaminated by leptospires. Humans usually represent a dead end in the chain of infection because although person-to-person transmission is possible theoretically, it is rare. After direct exposure of humans to infected animals, leptospires may enter breaks in the skin or may penetrate the mucous membranes, including the conjunctiva, nasopharynx, and vagina.[21,59,153,193] Human-to-human transmission via human milk has been reported in a breast-fed infant from a lactating mother who was infected with *L. interrogans*.[30]

Indirect transmission of leptospires to humans (from soil or water) depends on the presence of an environment that favors the survival of leptospires outside the animal host. A warm climate (25° C [77° F]), the presence of moisture, and pH values of soil or surface water between 6.2 and 8.0 are optimal conditions for survival of leptospires. These conditions prevail in many tropical regions throughout the year and in temperate climates during the late spring, summer, and autumn months. Conversely, survival of leptospires outside the animal host is impeded by chemical pollution, salinity, and various absorptive properties of clay in soil.[59,193]

Smith and Self[167] demonstrated survival of leptospires in cultures of infected soil for 43 days. *L. icterohaemorrhagiae* recovered from the soil of lawns in suburban communities has been indicted in an epidemic of leptospirosis in Missouri,[43] and a case of human leptospirosis has been reported in a soil scientist who became infected after handling a soil sample that had been collected in North Queensland, Australia, and transported 1100 miles during a period of 48 hours.[188]

Fresh water, particularly that contaminated by rat urine, has been recognized as an important vehicle for transmission of leptospiral infection.[81,193] Drinking water from a fountain also has been associated with an outbreak of leptospirosis.[38] The urine of infected cows may contain as many as 100 million leptospires per milliliter. If conditions are favorable, surface water contaminated by the urine of infected cattle may remain infectious for several weeks.[39] The largest reported outbreak of leptospirosis in the United States occurred in 1998 in Springfield, Illinois, after a triathlon that was preceded by heavy rains. There were 66 laboratory-confirmed cases of leptospirosis after the event, which included a swimming portion in a lake that received runoff from

*See references 16, 59, 65, 69, 89, 154, 189, 193, 195, 197.

nearby livestock farms. Fifty-two of these cases occurred in triathlon participants, and 11 cases involved nonparticipants who came in contact with lake water near the event.[124]

Venereal transmission of leptospirosis is important in rodents and can occur in livestock. Leptospires have been recovered from the semen of bulls and have been transmitted by artificial insemination and by coitus. The possibility of seminal transmission in humans remains speculative. Transplacental infection of the fetus in utero is well documented in livestock and other animals and may occur in humans.[41,47,51,59,193,196]

The importance of occupation as related to the risk for leptospirosis was emphasized in 1965.[92] Disease appeared to occur most frequently in people with occupations that required exposure to cattle or swine or to water contaminated by rat urine. During the past several decades, the number of cases acquired during outdoor recreation has increased. In rural areas, the U.S. Department of Agriculture promoted and aided in the development of farm ponds. These ponds, along with streams and rivers, are used widely for recreation and as a water supply for livestock and wild animals.[138] That many outbreaks of human leptospirosis have been attributed to water used for dual purposes is not surprising.[26,78,146,154]

More recently, leptospirosis has become a more frequent occurrence in children, students, and housewives than in adults with occupational exposure; cases from urban and suburban communities have been reported more frequently than have cases from rural areas.[43] The dog has been incriminated increasingly as an important vector and as a reservoir of this disease. Although immunization of dogs against leptospirosis is possible, an important note to remember is that (1) immunization may not prevent the dog from having renal carriage and excreting the organism, (2) canine immunity after immunization may persist for just 1 year, and (3) immunity, when established, is effective only for serotypes present in the canine vaccine.[16] The immunized pet dog has been identified as a previously unrecognized threat to people.[16] The exact prevalence of immunized dogs in each community that excrete leptospires is unknown. In one survey of suburban and urban areas, however, between 15 and 40 percent of dogs were found to be infected.[25] These data are consistent with reports from the CDC; dogs were implicated in 58 percent of the 820 known cases of leptospirosis reported between 1962 and 1971.[43]

In a study performed in Detroit, 90 percent of rats carried *L. icterohemorrhagiae*.[62] Strain-specific tests comparing antibody titers in the sera of inner-city and suburban children were performed. Thirty-one percent of inner-city children had antibodies against *L. icterohaemorrhagiae*; 10 percent of suburban children also had antibodies to this organism.

PATHOPHYSIOLOGY

After penetrating the skin or mucous membranes, leptospires invade the bloodstream and spread throughout the body to produce the protean manifestation of the disease.[70,71,173] Stavitsky[173] has suggested that the speed with which the leptospire revolves in a corkscrew fashion enables it to bore through connective tissue. This suggestion correlates with observations in humans, which show that leptospires regularly invade the anterior chamber of the eye and the subarachnoid space without eliciting a significant inflammatory response.[88] Volland and Brede[203] detected hyaluronidase in fluid filtered from leptospiral cultures and cited it as a reason for the unusual invasive property of leptospires.

Specific factors responsible for the virulence of leptospires remain unknown. The possible role played by animal hosts in determining the virulence of leptospires for humans remains speculative. Faine[70] compared the fate of virulent and nonvirulent strains of *L. icterohaemorrhagiae* in guinea pigs. Both strains behaved similarly after intraperitoneal infection, but virulent organisms survived and multiplied, whereas avirulent strains did not. Both virulent and avirulent strains were taken up by fixed phagocytes in reticuloendothelial tissues in vivo. Phagocytosis or chemotaxis was not noted with either strain in vitro or in vivo. Virulent and avirulent strains appeared to be identical serologically. Faine[71] also showed that the severity of lesions correlated positively with the number of organisms present and that a discrete number of organisms were required to cause death. The logarithm of the dose for strains of a given virulence was related constantly to survival time after ingestion. This relationship was correlated with the growth rate in vivo. Faine[70] also suggested that the low proportion of virulent organisms within avirulent strains permits modification of the disease process by antibodies that have sufficient time to develop before the disease process becomes irreversible. He hypothesized that virulence results from the selective multiplication of virulent leptospires in vivo. This hypothesis was supported by the fact that maximum virulence can be regained after a single animal passage that follows isolation in culture. Virulence may be lost in culture by mutation to nonvirulent forms.

Nonspecific resistance to leptospirosis is not mediated by differences in phagocytosis of leptospires among animals. Specific resistance, however, apparently is mediated by antibody. Antibody increases the efficacy of clearance of leptospires from the bloodstream by enhancing opsonization and hence improving phagocytosis.[50] Wang and associates[205] demonstrated that polymorphonuclear leukocytes are not an efficient defense factor for pathogenic leptospires in nonimmune hosts. The virulence of leptospires appears to be related to their ability to resist killing both by serum and by neutrophils.

Clinical and histologic findings in human and animal leptospirosis have suggested that the pathogenicity of leptospirosis may be, in part, the result of enzyme, toxin, or other metabolites that are elaborated by or released from lysed leptospires.* Imamura and associates[96] demonstrated the presence of a thermostable dermal necrotizing toxin in extracts of a suspension of *L. icterohaemorrhagiae* by noting the necrotizing effects that occurred after intradermal injection into guinea pigs or rabbits. The skin-necrotizing effect was attributed to the presence of insoluble particles of leptospires in the sonification supernatant.[68]

The clinical and histologic findings observed in leptospirosis are similar to those noted in animals given endotoxin, which suggests that the endotoxin may be responsible in part for the pathogenic action of leptospires.[185] Arean and associates[12] were unable to demonstrate the presence of endotoxin in extracts of leptospires and concluded that *L. icterohaemorrhagiae* contained either no endotoxin or one that was labile and readily destroyed by chemical agents in the process of infection. Further study by Arean and Henry,[11] however, suggested the elaboration of some other undefined toxins that may play a role in the pathogenic action of leptospires. Inoculation of rabbits intravenously by Gourley and Low[86] with disintegrated cells or extracts of cells of *L. canicola* and *L. icterohaemorrhagiae* was followed by fever, leukopenia, thrombocytopenia, and later, leukocytosis. Their findings suggested the presence of endotoxin in these serotypes. Finco and Low,[74] using preparations of *L. canicola* organisms and several bioassay procedures, showed that *L. canicola* had little ability to elicit biologic responses characteristic of endotoxins. One thousand to 1 million more *L. canicola* organisms (on the basis of dry weight) were required to produce a febrile response in rabbits of a magnitude similar to that elicited by *Escherichia coli*. The results suggest that *L. canicola* contains material with weak endotoxin activity. Massive quantities of *L. canicola* would be required to produce endotoxin-related disease. Finco and

Low[74] concluded that (1) other factors related to leptospiral infection may increase the susceptibility of the host to endotoxin during leptospirosis or (2) endotoxin from the intestinal lumen may gain access to the bloodstream during the course of leptospirosis.

The development of hemolytic anemia and jaundice in patients with leptospirosis has suggested a role for hemolysis in the pathogenesis of this disease. Alexander and associates[5] reported the presence of a heat-labile, oxygen-stable, nondialyzable hemolysin in the supernate of leptospiral cultures; subsequently, Russell[149] noted that this hemolysin could be inhibited by leptospiral antiserum. Hemolysis may persist during leptospirosis despite the development of serum antibodies, which suggests that circulating hemolysin is adsorbed by erythrocytes early in the course of leptospirosis and that the erythrocytes lyse subsequently[24,126] despite the presence of circulating antibody. The hemolysin is thermolabile and can be inactivated by trypsin and precipitated by ammonium sulfates, which suggests that it is, in part, a protein moiety.[5,10] Lee and colleagues[110] cloned a hemolysin of *L. interrogans* serovar lai and demonstrated cell membrane pore-forming activity in vitro, in contrast to the sphingomyelinase and phospholipase activity demonstrated by other leptospiral hemolysins. The precise role of hemolysins in human disease remains unclear.

A toxic and pathogenic potential in vivo for lipid products of leptospiral metabolism has been suggested.[2] The cell wall of the leptospire is high in lipid content; component fatty acids vary among leptospiral strains. Lipids are used as a source of energy by leptospires.[2] Saprophytic leptospires invariably possess lipase activity, whereas pathogenic leptospires may be lipase-positive or lipase-negative.[2] Kasarov and Addamiano[103] investigated the lipolytic activity of leptospires on serum lipoproteins. On the basis of their ability to attack these lipoproteins, leptospires can be divided into three groups: (1) strains that degrade lecithin and sphingomyelin, (2) strains that degrade neither lecithin nor sphingomyelin, and (3) strains that degrade lecithin but not sphingomyelin. Virulent leptospires behaved as group 1 and 2 strains, whereas saprophytic leptospires behaved as a group 3 strain.

A prominent feature of experimental leptospirosis is a hemorrhagic diathesis that increases in severity before death.[9] Many investigators have attributed bleeding to depletion of serum prothrombin, to thrombocytopenia, or to both.[49,88,141] Rishavy and colleagues[147] sequenced an orthologue of vitamin K–dependent carboxylase from a pathogenic leptospiral strain and proposed that this acquired activity may result in depletion of host vitamin K. Prothrombin activity can be corrected in children and adults with leptospirosis by the administration of vitamin K; however, the overall severity of the hemorrhagic diathesis is unchanged.[9,80,176] Moreover, thrombocytopenia is not a consistent concomitant in patients who bleed during the course of leptospirosis. For these reasons, the hemorrhagic diathesis most likely reflects widespread damage to the capillary endothelium.[12,42,65,205] The precise mechanism of capillary injury is uncertain, but the damage has been suggested to be induced by toxin.[9] Generally, hemorrhage is restricted to the skin or mucosal surfaces, but rarely, death may follow the occurrence of a massive gastrointestinal hemorrhage or bleeding into a vital organ.[88]

In humans, profound derangement in hepatic function has been demonstrated. Liver cell necrosis, however, occurs infrequently, and, thus, the activity of aspartate aminotransferase and alanine aminotransferase generally is elevated only slightly.

The most striking clinical manifestation of hepatic dysfunction is jaundice. Laboratory evidence of hepatic involvement in human leptospirosis includes the following: impaired bromsulfophthalein excretion, positive cephalin flocculation reactions, reduced esterification of cholesterol, abnormal galactose tolerance test results, impaired production of the clotting factors dependent on vitamin K, decreased serum albumin, and increased serum globulins. These abnormalities have been noted in icteric and anicteric patients with leptospirosis.

Several theories attempt to explain the jaundice of leptospirosis. Early investigation suggested that hyperbilirubinemia was the result of hemolytic anemia.[23] Considerable evidence does not support the hemolytic theory; attempts to demonstrate elaboration of hemolysin by *L. icterohaemorrhagiae*, a serotype associated frequently with hyperbilirubinemia in humans, have failed repeatedly.[9] Variability in the presence of anemia, the poor temporal association between anemia (when present) and the development of icterus, the absence of hemoglobinuria and reticulocytosis, and generally normal fecal urobilinogen values provide evidence that hemolysis is not the cause of jaundice in many patients with leptospirosis.[141]

On the other hand, a significant hemolytic process can be documented in selected patients.[186] Hemoglobinuria has been documented early in the course of leptospirosis, even before the development of jaundice.[8,99] Significant anemia is a feature only of icteric cases of leptospirosis. Most likely, hemolysis occurs in selected cases of severe leptospirosis in humans, and it may contribute to the development of jaundice in some cases.[65,186]

One must conclude that the hepatic manifestations of leptospirosis, including jaundice, most likely are the result of hepatocellular injury because hemolysis is not a consistent finding and neither intrahepatic nor extrahepatic biliary stasis has been observed morphologically or clinically.[9,141,204] Although hepatocellular injury occurs, hepatocellular destruction is not significant, as reflected by complete recovery without residual hepatic dysfunction, even in survivors of severe icteric leptospirosis. Histologic changes that have been observed consistently include disorganization of liver cell plates; variations in the shape and size of parenchymal cells; large numbers of binucleated, trinucleated, and multinucleated cells with bizarre nuclei; proliferation of Kupffer cells with erythrophagocytosis; and cholestasis associated with scant infiltrates of round cells in the periportal spaces.[10,28,65] These changes also have been observed in anicteric patients.[28] Electron microscopy has demonstrated alterations in cell membranes, alteration or destruction of mitochondria, and a predominance of smooth over rough endoplasmic reticulum in hepatocytes because of altered protein turnover.[61]

Additional evidence of hepatocellular damage is provided by the histochemical demonstration of reduced activity of succinic, isocitric, glutamic, and lactate dehydrogenase concomitant with functional alteration,[11] findings suggesting that the fundamental hepatic lesion is subcellular and that critical cellular enzyme systems somehow are affected. Presumably, the hepatocellular damage is not caused by the direct action of leptospiral organisms because the most severe pathologic changes are noted at a time when leptospires are difficult to demonstrate in tissue section.[85] Moreover, leptospires rarely have been identified in sections of hepatic tissue. Elaboration of one or more toxins by leptospires or release of various products after lysis that may be injurious to hepatocytes is the most plausible explanation for hepatic injury at this time.

Renal failure is an important cause of death in patients with leptospirosis. In patients who have died during the first week of disease, renal changes included cloudy swelling or isolated tubular epithelial cell necrosis previously involving the distal convoluted tubule and the ascending loop of Henle, isolated foci of acute vasculitis, segmental thickening of the basement membrane, and isolated areas of mild interstitial edema with lymphocytic infiltrates. In patients who have died during the second week of the illness, numerous foci of tubular epithelial necrosis have been apparent. Interstitial edema and infiltrates of lymphocytes, monocytes, plasma cells, and neutrophils are more prominent. When patients die after the 12th day of illness, the inflammatory infiltrate is widespread and involves the medulla, as well as the cortex.

Foci of tubular necrosis and interstitial inflammation are large, irregular, and packed densely with plasma cells, monocytes, lymphocytes, and neutrophils. Cells lining the lumen of the renal tubules are distended and disorganized and contain hyaline, granular, epithelial, and even bile casts. The glomeruli show mesangial hyperplasia, focal fusion of the foot processes, moderate cloudy swelling of the epithelium in the Bowman capsule, and thickening of the basement membrane.[10,11,53,61,95,107,166,210] The changes seen in epithelial cells may be responsible for the protein leak observed clinically as proteinuria.[48] Leptospires have been demonstrated in the liver or renal tubules and less frequently in the interstices of the renal cortex.[10,65,107]

Hypokalemia may be noted in patients with leptospirosis and acute renal failure. Studies of Abdulkader and associates[1] suggest that these findings are a result of renal potassium wasting facilitated by increased secretion of aldosterone and cortisol.

Although some investigators[95] have emphasized that interstitial nephritis is the fundamental lesion of leptospirosis, renal failure primarily is the result of tubular damage. Interstitial nephritis occurs primarily in patients who have survived until inflammation has had an opportunity to develop. Interstitial nephritis frequently is absent in patients with fulminant disease.[10]

Hypoxia may contribute significantly to the pathogenesis of renal dysfunction in leptospirosis. The focal distribution of the lesions suggests a relationship to impaired renal blood flow. Even in relatively mild cases of leptospirosis in which glomerular function remains unaffected, tubular function as measured by the excretion of para-aminohippurate is reduced markedly.[53] In severe cases, the tubular maximum for para-aminohippurate becomes negligible, and glomerular filtration drops precipitously. On the basis of observations of this type, researchers have concluded that impaired renal blood flow is the fundamental alteration in the nephropathy of leptospirosis. Histochemical and enzymatic studies also demonstrate hypoxic damage and suggest renal ischemia.[11] Diminution of renal perfusion in leptospirosis also is suggested by the clinical occurrence of hypovolemia, hypotension, and circulatory collapse.[28,68,78,108] The reversible oliguria frequently observed during the course of leptospirosis has been attributed to reduced renal blood flow resulting from hypotension, a deficit of extracellular fluid, or both.[65] During periods of oliguria, decreased glomerular filtration rates have been noted. Renal function recovers first by restitution of glomerular function; subsequently, and more slowly, renal tubular function improves.[9]

Hypovolemia or hypotension in patients with leptospirosis may reflect dehydration secondary to vomiting, increased insensible water loss, diminished intake of fluid, and rarely, massive gastrointestinal or pulmonary hemorrhage.[14,65,75,137,211] A decrease in intravascular volume caused by a shift of fluid from the intravascular to the extracellular spaces as a result of severe endothelial injury also may occur.

Rarely during human leptospirosis, adrenal insufficiency occurs after hemorrhagic infarction of the adrenal glands.[170] The vascular collapse observed terminally in fatal cases may reflect, in part, adrenal insufficiency secondary to hemorrhage. However, it cannot be the cause of the reversible state of shock that is noted early during the course of leptospirosis.

Cardiac dysfunction also may lead to hypoperfusion in severe leptospirosis. Focal hemorrhagic myocarditis, acute coronary arteritis, pericarditis, aortitis, and cardiac arrhythmias have been documented. Rarely, sudden death results from congestive heart failure or arrhythmias.[10,60,161,170,181] Cardiac malfunction also may develop secondary to hypertension, hypovolemia, electrolyte imbalance, or uremia. Peripheral vascular collapse in leptospirosis most often occurs irrespective of any cardiac involvement, obvious dehydration, or massive hemorrhage. Regardless of the etiologic factor, shock is a common occurrence in the course of severe leptospirosis.

Pulmonary lesions in leptospirosis generally are the result of hemorrhage rather than acute inflammation. In selected cases, acute inflammation is noted but usually reflects a secondary pyogenic infection. Localized or confluent hemorrhagic pneumonitis may be noted, and petechial and ecchymotic hemorrhages are seen throughout the lungs, pleura, and tracheobronchial tree.[163] Acute hemorrhagic lobar pneumonia and massive hemoptysis have been observed in fatal cases.[13,137,211] Silverstein[163] suggested that pulmonary capillary damage was the result of a toxin because leptospires had not been demonstrated in the lung, although Yang and Hsu[211] subsequently reported a fatal case of pulmonary hemorrhage in which leptospires were visualized directly in the lung parenchyma by silver stain techniques. Alveolar septal deposition of immunoglobulin and complement may play a role in the pathogenesis of pulmonary hemorrhage.[130,211]

Central or peripheral nervous system involvement may be striking. Most investigators agree that signs of meningeal inflammation cannot be attributed to invasion of the meninges by leptospires. Leptospires frequently are isolated from cerebrospinal fluid (CSF) that otherwise is normal; thus, reaction to the presence of leptospires in the meninges appears to be minimal. The leptospires disappear rapidly after the onset of meningeal signs, usually during the second week of disease. Because meningeal reaction occurs only after the development of antibody, leptospiral meningitis has been suggested to be a reflection of an antigen-antibody reaction.[16,88] Meningitis as a result of hypersensitivity may explain the absence of pleocytosis in the early stages of meningeal involvement, the abrupt onset of meningitis at the end of the first week of leptospiral disease, and the good prognosis of patients with leptospirosis who have involvement of the central nervous system.

Pathologic examination of the meninges may reveal nothing[10] or may show thickening of the meninges, a slight increase in the number of arachnoid cells, and a predominance of mononuclear cells in the exudate.[13]

Uncommon features of leptospirosis include encephalitis, myelitis, radiculitis, and peripheral neuritis. When present, they occur during the second week of illness.[65] These neurologic findings also may be the result of hypersensitivity reactions similar to those seen in other postinfectious encephalitis syndromes.[121,122] Koppisch and Bond,[107] however, demonstrated perivascular infiltration of blood vessels in the spinal cord, basal ganglia, hippocampus, and white matter of the cerebellum and in the subcortical areas of the cerebrum; these changes are not pathologic features of postinfectious viral encephalitis.[10,84] In certain cases, neurologic manifestations have been attributed to subarachnoid, peripapillary, and subdural hemorrhages.[37,39]

The aqueous humor provides a protective environment for leptospires; despite the development of high antibody titers in serum, leptospires may remain viable in the anterior chamber of the eye for many months.[4] Persistence of leptospires in the aqueous humor may be responsible for the recurrent, chronic, or latent uveitis syndromes that have been seen in patients with leptospirosis. The acute ocular inflammatory response that occurs during the leptospiremic phase of the disease generally disappears without complications and with little or no opacification of the vitreous. Chronic ocular involvement occurs less commonly but is more significant because anterior uveal inflammation and vitreous opacification may occur. The development of hypopyon during the course of leptospirosis may be followed by loss of vision. Pathologic descriptions of ocular tissue from patients with leptospirosis are limited, which precludes a better understanding of the pathogenesis of the ocular involvement.

The myalgia reported so frequently in patients with leptospirosis most likely relates to the pathologic process that has been noted.[108] Biopsy specimens obtained early in the course of lepto-

spirosis have vacuoles within the cytoplasm of the myofibril. Subsequent focal cytoplasmic changes include fragmentation and loss of cellular detail, which results in homogeneous or irregular acidophilic masses. The polymorphonuclear infiltrates that may be seen in affected areas are minimal, even in muscle fibers that are affected severely. Infiltration by sarcoblasts, with new myofibril formation, ultimately leads to healing without significant fibrosis.[29,99] Histologic changes in the muscles of patients with mild infection generally are minimal.[65] Pathologic evidence of myopathy resolves completely and promptly in most cases; pathologic changes usually are absent in the muscles of patients dying in the second week of disease.[186]

The selective involvement of certain muscle groups in some patients with leptospirosis is not explained. Any or all muscles may be affected; generalized myalgia occurs commonly. Myalgia is an early clinical feature concurrent with leptospirosis, and these clinical findings are correlated with the timing of the histologic changes in muscle. Generally, muscle pain subsides promptly as leptospiral agglutinin titers develop and the septicemic stage of leptospirosis ends. These observations are consistent with active invasion of skeletal muscle by leptospires rather than a toxin-related effect.[108,171] Antigens of leptospires have been demonstrated by fluorescent antibody techniques in patients infected with *L. icterohemorrhagiae*.[162]

The epicardium, endocardium, and myocardium all may be involved during leptospirosis. Arean[9] described focal or diffuse epicardial hemorrhages with or without lymphocytic and monocytic infiltrates in 10 fatal cases. In four patients, mesothelial desquamation and fibrin formation in the pericardial cavity also were noted. Myocardial changes included focal or diffuse lesions characterized by interstitial edema with fragmented fibers and infiltrates of monocytes, lymphocytes, and plasma cells. Neutrophilic infiltrates also were observed in most necrotic foci. Aortic insufficiency caused by focal endocarditis involving the aortic valves likewise was noted.[10] Patchy interstitial edema, cellular infiltrates, necrosis, and focal hemorrhagic lesions have been detected in other patients.[84,186] In most cases, these findings are not mirrored by the clinical findings. Rarely, leptospires have been demonstrated in myocardium.[65]

Except for focal hemorrhages, no characteristic lesions have been noted in the adrenal glands, lymph nodes, spleen, gastrointestinal tract, pancreas, ureter, or bladder. Interstitial edema with monocytic and lymphocytic infiltrates has been found in testicular tissue associated with impaired spermatogenesis.[84] Bone involvement in leptospirosis is not a significant feature clinically or pathologically, and no explanation accounts for the apparent failure of leptospires to proliferate in bone.[98]

CLINICAL MANIFESTATIONS

Leptospirosis is an acute systemic infection characterized by extensive vasculitis. Serologic surveys in human populations indicate that a large number of subclinical infections also occur. Surveys of veterinarians and packinghouse and abattoir workers reveal positive leptospiral titers in 5 to 16 percent of people tested.[100,123,125,187]

A low index of suspicion for this disorder by physicians, coupled with the diversity and nonspecificity of its manifestations, accounts for the significant number of cases that go unrecognized. In one series of 483 proven cases, only 17 percent were diagnosed initially as leptospirosis.[26]

The incubation period generally is 7 to 12 days, but a range of 2 to 20 days has been noted.[156,173,197] The incubation period does not vary significantly among serotypes and is not of prognostic significance. Variability in incubation period may be attributed to the dose of virulent organisms to which the host is exposed and to the portal of entry of the organism.[156,173,197]

The clinical course of leptospirosis varies, but generally it is predictable: both anicteric and icteric leptospirosis follow a biphasic course (Fig. 154–1).

The first stage (septicemic phase) is characterized by acute systemic infection. The onset of symptoms is abrupt. This phase terminates after 4 to 7 days; symptomatic improvement and defervescence coincide with disappearance of leptospires from the blood, CSF, and all other tissues, with the exception of the aqueous humor and renal parenchyma. Antibody titers to leptospires develop rapidly; this immune response heralds the second, or "immune," stage of the illness.

The immune, or second, stage lasts 4 to 30 days. Leptospiruria is prevalent and continues for 1 week to 1 month; generally, it is unaffected by antibiotic therapy. Meningitis or hepatic or renal manifestations, when present, reach their peak intensity during this stage of the disease.

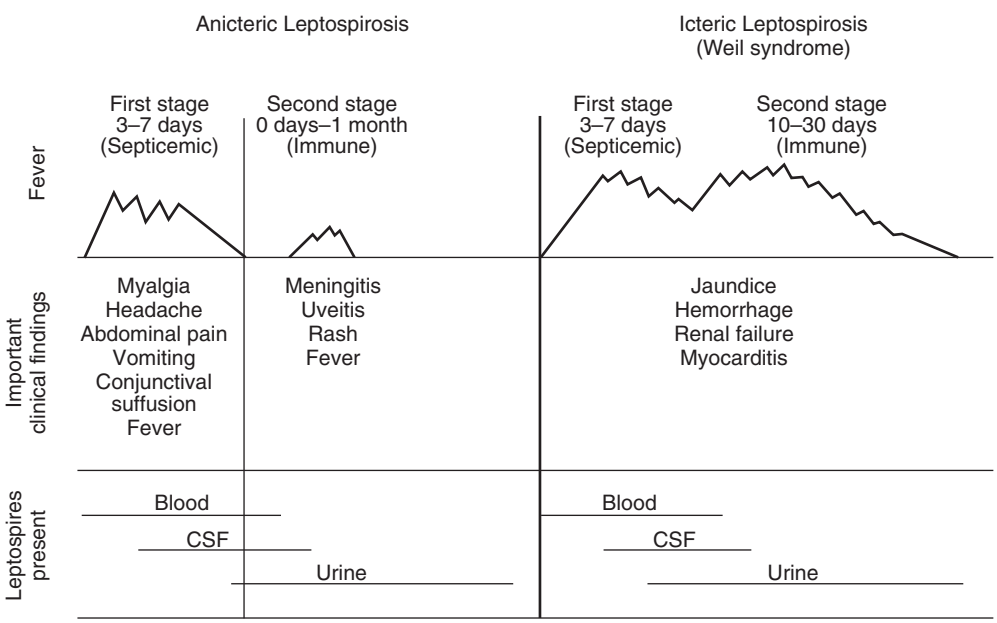

Figure 154–1 Clinical course of leptospirosis: anicteric and icteric disease.

ANICTERIC LEPTOSPIROSIS

Ninety percent or more of all patients with leptospirosis are anicteric. They frequently escape definitive diagnosis because jaundice and azotemia are absent. The onset of the septicemic phase of anicteric leptospirosis is abrupt[66] and heralded by fever, malaise, headache, myalgia, and occasionally, prostration and circulatory collapse.[116] Chills, remittent fever, headaches, severe myalgia, and abdominal pain are prominent for 4 to 7 days. Fever defervesces by lysis, and other symptoms resolve. Death is an extraordinarily rare occurrence in the first stage of anicteric illness. Some patients with anicteric leptospirosis do not experience a biphasic illness and remain asymptomatic after the first week.[66]

The second phase of anicteric disease may be characterized by fever, uveitis, rash, headache, and meningitis. If present, fever usually is of brief duration and has a lower peak than that of the septicemic phase.[65,66,92] Maximum temperatures range from 38.2° C to 40.6° C (100° F to 105° F), with one or more daily peaks. Recurrence of fever 2 or 3 weeks after leptospirosis resolves is not unusual, but no reports of the isolation of leptospires from blood document relapse on these occasions. Relapse generally occurs when the immune response of the host is peaking and at a time of maximal leptospiruria, which suggests an allergic or immune basis for the febrile episodes.[28] Headache may be intense and usually is not controlled well by analgesics. Typically, it is frontal in distribution and characterized as bitemporal or occipital. It may be associated with retrobulbar pain.[52,65,66] Persistence or recurrence of headache after termination of the septicemic phase of disease generally indicates the onset of meningitis. The factors responsible for headache in the septicemic phase of leptospirosis are unknown.

Restlessness, nocturnal confusion, mood disturbances, and mild alterations in consciousness usually occur briefly and commonly in both stages of leptospirosis.[65,92] Delirium, hallucinations, psychotic behavior, and suicidal tendencies have been reported.[65,92,160]

Anorexia, nausea, vomiting, and abdominal pain may be reported in both stages of anicteric disease. Constipation, diarrhea, and gastrointestinal hemorrhage also have been documented.[65,116,131] Generally, hemorrhagic complications are associated exclusively with icteric disease.

Physical examination during the septicemic stage may reveal dehydration, muscle tenderness, conjunctival suffusion, generalized lymphadenopathy, hepatosplenomegaly, and rashes that may be macular, maculopapular, erythematous, urticarial, petechial, purpuric, hemorrhagic, or desquamating. Skin lesions are most prominent over the trunk, but any area of the body may be affected. Pretibial eruptions have been noted in patients with infection caused by *L. autumnalis*, but other serotypes also may cause disease with pretibial eruptions. Recurrent, transient urticarial eruptions have appeared for many days after resolution of the other manifestations of leptospirosis. Pharyngitis, rales, arthritis, and nonpitting edema occur less commonly.* Tachycardia is a common occurrence, and cardiac arrhythmias are noted occasionally.[136,170] Hypotension rarely occurs in anicteric leptospirosis.[66]

Muscle pain and tenderness may be generalized, but the muscles of the calf, lumbosacral spine, and abdomen are affected most frequently. Tenderness and rigidity of the abdominal wall may suggest the possibility of an acute surgical abdomen. Tenderness of the muscles adjacent to the cervical spine often causes nuchal rigidity in patients without meningeal involvement. The muscle tenderness usually subsides with termination of the septicemic stage of the disease.

*See references 6, 10, 27, 52, 66, 92, 99, 116, 150, 191, 197.

Conjunctival suffusion, photophobia, ocular pain, and conjunctival hemorrhage are more specifically helpful diagnostic signs. Chemosis and inflammatory exudates generally are absent despite marked conjunctival infection. In anicteric disease, conjunctival infection involves primarily the bulbar conjunctiva only. It appears by the third day of illness and disappears 3 days to 3 weeks later.

Abdominal pain and tenderness, when associated with vomiting and hypoactive bowel sounds, clearly suggest the possibility of a surgical abdomen and present a challenging diagnostic problem because acute intra-abdominal catastrophes may complicate the natural history of this disease. Nonobstructive toxic dilation of the gallbladder requiring cholecystotomy has been noted repeatedly in children with leptospirosis (Fig. 154–2). Pain of this type must be differentiated from myositis, subperitoneal or subserosal hemorrhage, abdominal wall causalgia, or pancreatitis, all of which may occur in some children with anicteric or icteric disease.

Pulmonary involvement may be observed in anicteric patients, generally during the septicemic phase, and usually is manifested as a dry, hacking cough, occasionally productive of blood-stained sputum, or by the finding of infiltrates on a chest radiograph.[27,140,163] Hemoptysis, chest pain, respiratory distress, and cyanosis appear rarely during anicteric disease.[140] Hemoptysis, when present, clears in 3 to 5 days. Physical examination of the chest may reveal rales, evidence of consolidation, or a pleural or pericardial friction rub.

Chest radiographs may show (1) confluent infiltrates or massive consolidation representing larger areas of pulmonary hemorrhage; (2) small, patchy, snowflake-like lesions in the periphery of the lung fields that are restricted to a few intercostal spaces or disseminated widely; and (3) solitary, patchy lesions with ill-defined margins.[140,206] Of these radiographic appearances, the second is most common. Small pleural effusions are rare occurrences in anicteric disease,[206] and hilar adenopathy has not been described. Although the chest radiograph may help delineate the extent of pulmonary disease, it does not provide information that could be considered pathognomonic of leptospirosis.

Other signs and symptoms of the septicemic phase of anicteric leptospirosis that have been reported include parotitis,[23] orchitis,[177] epididymitis,[92] prostatitis,[92] otitis media,[27] arthralgia,[27,65,92] and monoarticular or polyarticular arthritis.[61]

The hallmark of the immune phase of anicteric leptospirosis is meningitis, and it is reflected by CSF pleocytosis with or without meningeal symptoms or signs. During the leptospiremic phase, leptospires may be found in the subarachnoid space unassociated with the presence of inflammatory cells. As an antibody titer develops, leptospires are cleared rapidly from CSF, and an inflammatory response develops.[65] If CSF is examined during the second week of illness in all patients with anicteric leptospirosis, a meningeal reaction can be demonstrated in more than 80 percent, but only 50 percent of these patients have clinical signs and symptoms of meningitis.[40,65] The severity of meningitis varies and does not correlate with the severity of other clinical manifestations of leptospirosis. Symptoms referable to the nervous system usually subside within 1 or 2 days but rarely persist for 2 or 3 weeks. The CSF pleocytosis may persist for 2 to 3 months but generally disappears within 7 to 21 days.[65] In some cases, patients are asymptomatic during the septicemic phase of leptospirosis but seek medical attention during the immune phase because of headache, vomiting, and nuchal rigidity. Papilledema rarely has been observed in patients with leptospirosis.[37]

Lumbar puncture may reveal CSF pressures varying from normal to 350 mm H_2O. Mean values generally are less than 200 mm H_2O.[94] Cell counts within CSF vary from normal to more than 500 cells/mm^3; generally, fewer than 500 cells have been reported.[65,92] Polymorphonuclear leukocytes predominate early in the immune phase, but mononuclear cells subsequently

Figure 154–2 Radiograph demonstrating a dilated, opaque gallbladder protruding from the inferior margin of the liver. Nonobstructed toxic dilation of the gallbladder is present in a child with leptospirosis.

predominate. Protein concentrations within CSF range from normal to 300 mg/dL. In some cases, protein values have been elevated in the absence of pleocytosis. Abnormal values may persist for several weeks after the clinical symptoms resolve.[27,40,92,117,118] Glucose concentrations within CSF generally are normal.[40,66,117]

Encephalitis, focal weakness, spasticity, paralysis, nystagmus, peripheral neuritis, cranial nerve paralysis, seizures, radiculitis, visual disturbances, myelitis, Guillain-Barré syndrome, or acute disseminated encephalomyelitis may appear with or subsequent to the immune stage of anicteric disease.* Generally, these symptoms resolve, but complete resolution may require several weeks to months. Neurologic sequelae secondary to central nervous system hemolysis may occur.[37,39]

The anterior uveal tract may be affected as early as the third week of illness, but symptoms may be found up to 1 year after the onset of leptospirosis. Conjunctival suffusion (characteristic during the septicemic phase) is not found in the immune stage of the disease. Rather, iritis, iridocyclitis, and, occasionally, chorioretinitis are noted.[26,65,66,92] Uveal involvement may be unilateral or bilateral and may occur as a single, self-limited episode, as recurrent episodes, or as a chronic unrelenting process.[33,65] The severity of the uveitis does not correlate with the severity of other clinical manifestations. When uveitis is transient or self-limited, complete healing is the rule, but in some cases, blindness and cataract formation are noted.

The precise incidence of involvement of the uveal tract is unclear because symptoms may be minimal or may not appear until after other clinical manifestations have resolved completely. The generally benign course of uveitis may be attributable to the capacity of leptospires to survive in the aqueous humor without eliciting an intense inflammatory response.[66] Despite the presence of high titers of specific antibodies to leptospires in serum, antibodies to leptospires are absent or found in low titer in the aqueous humor.

*See references 7, 20, 44, 65, 68, 92, 117, 121, 146, 200.

Leptospiruria is the rule during the immune stage of anicteric leptospirosis, and it is not associated with impaired renal function. In contrast to many animal species, humans do not serve as a reservoir for leptospires; leptospiruria is transient. In anicteric patients, proteinuria, pyuria, microscopic hematuria, and mild to moderate azotemia may be observed.[27]

The white blood cell count may be low, normal, or elevated. Neutrophilia is the rule, regardless of the total white blood cell count. Leukocytosis generally is associated with hepatic involvement. Anemia is an inconsistent finding; when present, it may be attributable to blood loss, vascular damage, or hemolysis. In the absence of blood loss, significant anemia is not a manifestation of anicteric cases. The erythrocyte sedimentation rate consistently is elevated.

ICTERIC LEPTOSPIROSIS (WEIL SYNDROME)

The term *Weil syndrome* should be applied to define a form of leptospirosis that is distinctive in clinical expression but nonspecific with respect to serotypic etiologic agents. In addition to having the symptoms and signs of anicteric leptospirosis, Weil syndrome is set apart by the presence of impaired hepatic and renal function, vascular collapse, hemorrhage, severe alterations in consciousness, and a high mortality rate.

Weil syndrome may be heterogeneous in its manifestations, and the course may be dominated by symptoms of renal, hepatic, or vascular dysfunction. Jaundice and azotemia may be so severe that the biphasic course of illness is not observed. Fever may persist without defervescence between the septicemic and immune stages and is more prominent and of longer duration during the immune stage than in anicteric cases. The mortality rate, despite adequate supportive care, is between 5 and 10 percent.

Jaundice remains the hallmark of Weil syndrome. The intensity of jaundice varies; a maximum total serum bilirubin concentration in the range of 60 to 80 mg/dL has been reported.[117] Usually, the bilirubin concentration is less than 20 mg/dL. Both

direct- and indirect-reacting bilirubin levels increase, but an increase in the direct fraction usually accounts for most of the elevation in bilirubin.[174] Jaundice may occur as early as the third day of illness or may not appear until the second week.[13,66] The serum bilirubin concentration peaks within the first 7 days after the onset of jaundice in 85 percent of cases.[141]

Modest elevations in serum alkaline phosphatase and depressed activity of plasma prothrombin are noted occasionally.[141] Hypoprothrombinemia responds uniformly to parenteral administration of vitamin K. Serum albumin may be depressed; concentrations of 2 to 2.5 g are not uncommon.[174] Aspartate aminotransferase and alanine aminotransferase are elevated minimally; these values rarely exceed 100 and 200 units, respectively. The urine may contain bilirubin and urobilinogen.

Hepatomegaly is found in approximately 24 percent of patients, a frequency that is no greater than that in anicteric cases.[65] Transient biliary obstruction, probably intrahepatic, may occur, but no evidence that obstructive phenomena are the primary mechanism of impaired hepatic function exists. Even in severely icteric cases, acholic stools generally are not observed.[65,92] Pruritus has been reported rarely in patients with leptospirosis.[65] The presence of abnormal urinary urobilinogen values in the absence of acholic stools suggests patency of the biliary tract in most cases.[141]

In some reports of children with leptospirosis, acalculous cholecystitis has been seen in 55 percent of cases.[175] In these patients, right upper quadrant pain, tenderness, and a palpable mass were present. Abdominal radiographs confirmed the presence of a mass in the region of the gallbladder. When cholecystotomy was performed, a massively distended gallbladder containing colorless bile was noted. Routine aerobic and anaerobic cultures of bile were negative, but cultures for leptospires were positive.

Hepatic dysfunction is not an important cause of death in patients with leptospirosis. It is present, however, in most patients who die of this disease, and, conversely, a fatal outcome is extremely rare in the absence of hepatic dysfunction.[27] Renal dysfunction, cardiovascular collapse, and hemorrhagic complications occur most often in patients whose icterus is most prominent.

Renal dysfunction may be observed in all forms of leptospirosis, regardless of the severity of disease or the serotype causing infection.[27,65,92] Symptoms attributable to functional renal impairment generally are observed only during icteric leptospirosis.[13,27,65,66,197] In the leptospiremic phase, abnormal urinalysis results are noted in as many as 80 percent of cases.[27,65,175] Proteinuria is the most frequent abnormality and generally is mild. Hyaline or granular casts and cellular elements (red and white blood cells) may be found in the urinary sediment. Microscopic or gross hematuria is seen in many patients and most likely reflects the presence of a hemorrhagic diathesis rather than glomerular injury.[200]

Fatal cases of icteric leptospirosis in which urinalysis results were normal have been reported.[13] The abnormalities in urinary sediment and proteinuria may persist for weeks in patients without significant azotemia.[22]

Oliguria or anuria may be noted as early as the third day of illness but occurs more commonly after the first week. Generally, blood urea nitrogen values remain below 100 mg/dL, but values may exceed 300 mg/dL in some cases.[92,132] The height of the blood urea nitrogen value is not of prognostic value in individual cases, although in groups of patients, it correlates well with outcome.[186]

Azotemic patients with leptospirosis can be divided into two groups: (1) those with decreased renal perfusion (ratio of urine osmolality [U_{Osm}] to plasma osmolality [P_{Osm}] of about 2:1) and a good response to fluid administration and (2) those with a U_{Osm}-to-P_{Osm} ratio close to 1:1, with impaired resorption of sodium and water from the renal tubules and no response to administration of fluids. The manifestations of the second group of patients are those of acute tubular necrosis. The factors responsible for oliguria in the first group of patients (those with prerenal azotemia), including hypotension, shock, and volume depletion, if uncorrected, ultimately may progress to acute tubular necrosis as well.

Anuria is an ominous sign, whereas diuresis is a good prognostic omen.[13] The impairment in renal function may persist, and fatalities have been recorded after the onset of diuresis.[132] Hyposthenuria can persist for months in some cases.[66] Some evidence of renal disease has been demonstrated by renal function tests and renal biopsies for as long as 6 months after the onset of leptospirosis.[18] Renal failure is the principal cause of death in patients with leptospirosis, but it generally is reversible in time. Usually, renal function improves by 6 months after acute infection.[57]

Cardiac involvement is a relatively infrequent occurrence, but when present, congestive heart failure and cardiovascular collapse may occur.[66,99] Electrocardiographic changes are seen in all forms of leptospirosis.[136] In one series of patients, electrocardiograms obtained during the first week of illness were abnormal in 90 percent of patients at a time when none had signs or symptoms of congestive failure, pericarditis, or hypotension.[136] The electrocardiographic abnormalities disappeared by 10 days in most cases. The electrocardiographic changes that have been described often are nonspecific findings common to many infectious diseases or attributable to fever alone.[136,151]

Cerebrovascular accidents may occur in patients with leptospirosis.[111] In a study of 21 cases in which postmortem examination was performed, subarachnoid hemorrhage was described in 1 case, cerebral hemorrhage in 2, and recent cerebral infarction in 1.

Hyponatremia is a rather consistent finding in patients with severe icteric leptospirosis. The hyponatremia appears to be the result of (1) failure of the sodium pump, which causes sodium to move intracellularly in exchange for potassium, and (2) redistribution of fluid such that the extracellular fluid space is expanded at the expense of the intracellular space. Hyponatremia in these patients may be unresponsive to either sodium replacement or fluid restriction. It is treated best by fluid restriction, which can be continued unless systemic blood pressure falls. Clinical improvement in the patient generally follows a spontaneous increase in serum sodium, which may occur before any other evidence of clinical improvement is noted.

INDICATORS OF PROGNOSIS

Attempts have been made to identify prognostic factors associated with leptospirosis. Such studies, which aimed to evaluate the prognostic significance of certain clinical and laboratory variables at different stages of disease, have produced variable results. Hypotension, oliguria, hyperkalemia, the development of pulmonary rales, crackles, or rhonchi, and electrocardiographic repolarization abnormalities each have been associated with a poor prognosis,[58,64,114,134,184] although conflicting data exist about the implications of hypotension.[64] In a small series of 12 patients, Truccolo and colleagues[192] reported death of all patients with a leptospiral load greater than 10^4 organisms per milliliter as determined by quantitative polymerase chain reaction (PCR). Chang and colleagues,[45] in a series of 11 patients with late leptospirosis, reported mortality in all patients with hepatitis and a disproportionate aspartate transaminase level, as defined by a ratio of peak aspartate transaminase to peak alanine transaminase greater than 3. Respiratory failure, hemoptysis, metabolic acidosis, and throm-

bocytopenia also have been associated with increased mortality rates.[184]

LABORATORY DIAGNOSIS

Whenever possible, the physician should use laboratory facilities in which culture and serologic tests for leptospirosis are performed routinely. We recommend that specimens be sent to the standard reference laboratory, the National Leptospirosis Laboratory at the CDC in Atlanta. Despite proper collection and handling of specimens, obtaining laboratory confirmation of cases of leptospirosis may be difficult, even for facilities with skill in this area.

A confirmed case of leptospirosis, as defined by the U.S. Department of Health and Human Services, fulfills one of the following criteria: (1) clinical specimens that are culture-positive for leptospires or (2) clinical symptoms compatible with leptospirosis and either seroconversion or a fourfold or greater rise in the microscopic agglutination titer between acute and convalescent serum specimens obtained 2 or more weeks apart and studied at the same laboratory.

Presumptive leptospirosis is defined as the presence of clinical symptoms that are compatible with leptospirosis and a microscopic agglutination titer of 1:100 or greater, a positive macroscopic agglutination slide test reaction on a single serum specimen obtained after the onset of symptoms, or a stable microscopic agglutination titer of 1:100 or greater in two or more serum specimens obtained after the onset of symptoms.

IDENTIFICATION BY CULTURE

Leptospires can be recovered from blood or CSF obtained from patients during the septicemic stage of illness or from urine during the immune stage. Other than these body fluids, only tissue sections obtained by biopsy or at necropsy are sources from which organisms can be recovered. Rarely, organisms are isolated from intraocular fluid obtained during convalescence.[4]

Media for the cultivation of leptospires generally contain a buffered solution, with or without peptone and with or without 0.1 to 0.2 percent agar to which rabbit serum has been added to provide a final concentration in the medium of 5 to 10 percent. In addition, a pH between 7.2 and 7.8 appears to be essential. Clinical material obtained for culture frequently is contaminated; antimicrobial agents, including neomycin, vancomycin, or bacitracin, added to leptospiral media in low concentration have been found to be effective in reducing contamination and exert little if any effect on leptospires.

For routine use, Fletcher semisolid medium[76] or EMJH semisolid medium[101,173] is recommended. Stuart medium[178] has been used to prepare and maintain antigens for serologic tests. Tween 80–albumin medium (OAC) was developed not long ago and is available commercially. This medium seems to be superior for primary isolation of leptospires.

Several solid media are available but appear to be most useful for isolation and purification of leptospires from contaminated natural material such as water.[179,196] Preparation, use, and maintenance of these solid media and other media are described in other works.[119,179,196]

Multiple cultures should be obtained from patients with leptospirosis because the concentration of organisms in blood at any point in time is low.[101] Freshly drawn blood is most desirable, but leptospires may remain viable in anticoagulated blood for as long as 11 days.[178] Blood should be inoculated into several tubes of semisolid media. The number of drops of blood placed into each tube should be varied (one to four drops). Excessive amounts of blood inhibit the growth of leptospires; hence, a small inoculum yields the best results.[76] Cultures are incubated at 28° C to 30° C (82.4° F to 86° F) in the dark for 6 weeks or longer.

In semisolid media, leptospires grow in a concentrated ring about 0.5 to 1 cm below the surface. Growth may not be detected in Fletcher semisolid medium for several weeks but may occur earlier in polysorbate medium.

Contaminated specimens or suspensions of primary cultures in which contamination is suspected may be inoculated into hamsters. Upon death of any animal, phlebotomy or necropsy is performed, and sections of liver, kidney, and brain then are recultured in appropriate semisolid media.

If collected during the septicemic phase, CSF may be cultured in the same manner as blood.

Urine serves as the main source from which leptospires can be isolated during the immune and convalescent phases of leptospirosis. Clean-voided urine may be inoculated directly into an appropriate semisolid medium. Urine specimens must be diluted with sterile, buffered saline solution to ensure growth.[186] Best results are obtained by adding 0.1 mL of urine to 0.9 mL of buffered saline before inoculation into 5 mL of semisolid medium. This procedure can be continued with four additional dilutions. Other bacterial contaminants that may be present in undiluted urine cultures generally do not survive in these cultures after dilution.[179]

IDENTIFICATION BY MEANS OTHER THAN CULTURE

The morphologic appearance of all members of the genus *Leptospira* is similar. They are slender, threadlike organisms about 0.1 μm in diameter and 6 to 12 μm in length, tightly coiled on their long axis. Like other spirochetes, they cannot be seen in wet preparations by lightfield microscopy, but on darkfield examination they may be observed readily. For the detection of one leptospire per high-power field by darkfield examination, a concentration of 10,000 to 20,000 leptospires per milliliter of fluid is needed.[196] At best, darkfield examination should be considered an aid that may suggest but not establish a diagnosis of leptospirosis.

Leptospires can be stained by several silver impregnation techniques.[35,105,119,179,196] The modified method of Van Orden has been used at the CDC for demonstrating organisms in sections of liver, kidney, or other tissues. Infecting serotypes cannot be differentiated by silver impregnation techniques. Leptospiral antigen also has been detected with the use of an immunoperoxidase staining procedure.[73]

Fluorescent antibody techniques may be applied successfully to the detection of leptospires in urine or tissue.[127,128,179,196] This test is based on specific antigen-antibody reactions using fluorescence-tagged antisera. In theory, the fluorescent antibody reaction should demonstrate distorted and fragmented, as well as whole, organisms, but caution is required. Control specimens that have been treated with unlabeled antiserum before the addition of fluorescein-labeled antiserum should be used.[119] The control specimen should not fluoresce. The fluorescent antibody technique may provide the physician with useful information in the course of the disease in some patients. Positive results, however, are considered only presumptive evidence of infection.

In addition to this technique, DNA hybridization techniques or nucleic acid amplification procedures, including PCR protocols using leptospiral-specific cDNA probes or oligonucleotide primers, can be used to detect the presence of leptospires in body fluids or culture supernatants. These techniques are being developed in the laboratories of the Leptospirosis Branch at the CDC, but proof of their superiority in terms of sensitivity or specificity

in detecting leptospiral organisms in body fluids or other clinical samples has not been established yet.

SEROLOGIC TESTS

Evaluation of serologic findings to supplement clinical and epidemiologic information generally is recommended as a first step in establishing a diagnosis of leptospirosis. One of the most widely used specific serologic tests for leptospirosis has been the microscopic agglutination test (MAT), in which live antigen is used. This test is time-consuming and potentially hazardous to the technician but is considered the reference test against which all other tests are evaluated. Formalinized antigens can be used for the MAT, and they are preferred in some laboratories, but the titers obtained are lower than those obtained with live antigen, and more cross-reactions with heterologous serotypes occur. Generally, serum is used for the MAT or other agglutination tests, but CSF, urine, bile, or aqueous humor may be used as well.[119]

The CDC uses a standard panel of commonly occurring serovars representing 20 serogroups for routine performance of the MAT. However, because of geographic differences in serovar distribution, serovars are added or changed depending on the region where exposure occurred and the location from which specimens were obtained. Killed antigens remain stable for at least 12 months and are available commercially either individually or in pools. Sulzer and associates[179] have provided detailed descriptions of methods for performance of the MAT. Modifications of the MAT have been developed and include the semimicromethod and microtiter techniques.[79]

A newer serologic test involving diffusion in gel, the enzyme-linked immunosorbent assay (ELISA), has been compared with the MAT for the serologic diagnosis of leptospirosis.[56,202] The results suggest that this test is a viable alternative to the MAT because of its sensitivity, potential for standardization, and simplicity. Variations of this test have been developed; rapid serodiagnosis of leptospirosis with the use of an IgM-specific dot ELISA has proved to be as sensitive and specific as MATs.[201,207] The dot ELISAs are inexpensive and simple to perform, and they use minute volumes of leptospiral antigens.

The IgM-PK ELISA, an assay for IgM using a proteinase K–treated antigen, was compared with the Leptoteste-S macroagglutination test (CDC, Atlanta, GA) and with the MAT for the diagnosis of leptospirosis. All three tests were comparable in their ability to detect the presence of leptospirosis. Both the IgM-PK ELISA and the Leptoteste-S differed statistically from the MAT in terms of the positivity of acute-phase sera. Thirty-eight percent of patients with leptospirosis were identified earlier with either test than when the MAT was used. The IgM-PK ELISA, which had a sensitivity of 89.9 percent and a specificity of 97.4 percent, has been suggested as the test of choice for laboratories that are equipped to perform ELISA.[144]

A slide agglutination test available commercially has been compared with the ELISA IgM and has yielded equivalent results for the diagnosis of leptospirosis. The slide agglutination test is inexpensive and can be performed more quickly and more easily than ELISA, thus rendering it a useful test for laboratories that are less well equipped than those in which IgM ELISA currently is performed.[34]

Lepto Dipstick (Royal Tropical Institute, Amsterdam, The Netherlands), a dipstick assay for detection of *Leptospira*-specific IgM antibodies in serum, has been studied as a method for the diagnosis of leptospirosis in situations in which laboratory facilities may not be available.[168] Lepto Dipstick results correlated well (80% to 96.7% observed agreement, kappa value of 0.62 to 0.92) with results obtained by the IgM ELISA leptospiral antigen detection method.[19,90] A 93.2 percent agreement (kappa value of 0.66) was reported between the Lepto Dipstick and MAT, along with a high number of false-positive results as well.[19] The dipstick test is a valuable and useful tool for rapid screening for leptospirosis and may be useful in the field for detecting and monitoring outbreaks of leptospirosis.

Other tests that may be used for the serologic diagnosis of leptospirosis include a complement-fixation assay,[46] a hemolytic test,[46] an indirect immunofluorescent test,[190] an erythrocyte-sensitizing substance test,[46] countercurrent immunoelectrophoresis,[129] and flow cytometry light scatter analysis.[212] These tests are genus-specific and may yield positive results earlier in the course of leptospirosis than the agglutination tests do. Their results also revert to negative earlier; therefore, these tests are of little value for serologic surveys. They may be of value in distinguishing current from past infections when agglutination test results are equivocal.[178,179] Other works[46,55,143,190,196] provide specific details concerning the use of these techniques.

An indirect hemagglutination test offers the advantage of detecting antibodies as early as the fourth day after the onset of illness. It is genus-specific, is less time-consuming, and requires just one antigen in the test system. It has excellent sensitivity and specificity, and some investigators have suggested that it may replace the MAT as the screening test of choice.[179] Effler and colleagues,[67] however, reported discouraging results when this test was used for the diagnosis of leptospirosis in Hawaii.

Agglutination tests have been considered to be serotype-specific. Because of the antigenic complexity of leptospires, however, cross-agglutination reactions occur; serotypes that belong to the same serogroup cross-react at high titers. Early in the course of leptospirosis, heterologous reactions may be stronger than homologous reactions. Because of these paradoxical cross-reactions, one should not depend on serologic determination alone to define the infecting serotype. When agglutination tests are performed on serial specimens over the course of time, the homologous reaction becomes the dominant one in most cases. Performance of agglutination absorption studies may be necessary to define the infecting serotype in some cases. The antigen (serotype) that absorbs out agglutinin to all the serotypes in a serogroup most likely is the infecting serotype.[119,174,194]

A passive microcapsule agglutination test that uses chemically stable microcapsules instead of sheep erythrocytes has been developed.[13] When compared with the MAT, the passive microcapsule agglutination test showed a relatively greater degree of genus specificity and 4- to 32-fold higher titers. The sensitized microcapsules were stable for at least 1 year. This test is simple to perform and reproducible and can be used readily in the routine laboratory. Moreover, the test appears to be more sensitive than is the MAT in the early stages of leptospirosis.[159]

A positive leptospiral agglutination reaction generally is not found until the 6th to 12th day of illness, and maximal levels are reached between 21 and 28 days. After recovery, low titers may persist for many years. One blood sample should be obtained early in the course of illness, and a second one should be obtained at the end of 1 month. Negative reactions in serial samples do not exclude the possibility of leptospirosis because patients may be infected with a serotype not included in the battery of test antigens or with a previously unrecognized serotype. Moreover, the titer may have peaked before the acute-phase specimen was collected. Antibiotic therapy also may suppress the development of positive titers or delay their appearance.[89,119] Peak microscopic agglutination titers of 1:3000 to 1:100,000 usually are reached during the third week of illness.[65,194] An unchanging titer of 1:100 on two successive serum specimens has been defined as sufficient for making a presumptive diagnosis of leptospirosis. A fourfold increase in titer between acute and convalescent sera is indisputable evidence of active leptospirosis.

Leptospira DNA may be detected by PCR at a minimum detection limit of two to three cells per sample.[113,169] Nonradioac-

tive, arbitrarily primed PCR assays can be used to discriminate species of *Leptospira*.[148] Romero and colleagues[148] reported that PCR was more likely to facilitate the early diagnosis of leptospiral aseptic meningitis than was either the IgM ELISA or the MAT test.

PCR, IgM ELISA, latex agglutination, the Lepto Dipstick assay, and an antibody-based urine antigen assay each may be more sensitive than the MAT early in the course of disease.[104,133,152]

TREATMENT

To be of maximum therapeutic benefit, an antimicrobial agent would have to be administered before invading organisms damage the endothelium of blood vessels and various organs or tissues. One of the problems in evaluating the efficacy of treatment is the fact that generally, leptospirosis is a self-limited disease with a favorable prognosis. Even patients with severe icteric leptospirosis may recover without specific treatment.

Most claims of the beneficial value of antimicrobial agents in human leptospirosis are based on the response of individual patients rather than on controlled studies. Hall and associates[91] compared the effects of penicillin, chloramphenicol, chlortetracycline (Aureomycin), and oxytetracycline (Terramycin) with placebo in 67 confirmed cases of leptospirosis. No appreciable effect of antibiotics could be demonstrated on the duration or severity of illness or on the prevention or amelioration of central nervous system, hepatic, renal, or hemorrhagic complications of this disease. Moreover, the duration of leptospiremia and the persistence of organisms in CSF were not altered by treatment. Kocen[106] compared the effects of penicillin administered on the fourth day of illness to 28 patients with a control group of 33 who were given only supportive care and reported that the duration of fever was shorter and the incidence of jaundice, meningismus, renal involvement, and hemorrhagic manifestations was diminished in the treated group.[106] None of these controlled studies was entirely satisfactory with respect to randomization of patients.

McClain and associates[115] studied the therapeutic efficacy of doxycycline in military recruits who contracted leptospirosis while training at the Jungle Operations Training Center in Panama. Twenty-nine patients with anicteric disease were treated in a randomized, double-blinded fashion with doxycycline, 100 mg orally twice a day, or with placebo. Therapy was administered for 7 days in the hospital, after which patients were monitored for 3 weeks. The duration of illness before therapy and the severity of illness were similar in both study groups. Doxycycline shortened the duration of illness by 2 days and favorably influenced fever, malaise, headache, and myalgias. Treatment also prevented leptospiruria, and no significant adverse effects of doxycycline administration were observed.

In another randomized, double-blinded, placebo-controlled field trial at the same military training site, Takafuji and associates[183] demonstrated that doxycycline (200-mg oral dose) given weekly or at the completion of jungle training was highly effective in preventing the onset of clinical leptospirosis. Twenty cases of disease were documented in the placebo group (attack rate, 4.2%) as opposed to only one case in the treatment group (attack rate, 0.2%), findings supporting the prophylactic utility of doxycycline in this setting.

Watt and associates[208] reported the results of a trial in which a 7-day course of intravenous penicillin (6 million units per day) was compared with placebo in a randomized, double-blinded trial involving 42 patients. All the patients had severe, advanced disease. Every measurable aspect of the disease was affected favorably by penicillin. The duration of fever was shortened significantly ($p < 0.005$) in the group receiving penicillin. Penicillin therapy decreased the number of days of hospitalization and prevented the development of leptospiruria. These investigators concluded that intravenous penicillin should be given to patients with severe leptospirosis, even if therapy can be initiated only late in the course of their disease. Subsequently, Costa and associates[54] reported the contrary. Two hundred fifty-three patients with leptospirosis and longer than 4 days of symptoms were randomized to receive 6 million units of penicillin for 7 days or placebo (mean pretreatment duration of symptoms, 6.6 days and 6.5 days, respectively). Neither the number of days of hospitalization nor the in-hospital case-fatality rate differed significantly between the two groups.

Limited data exist comparing the use of alternative antimicrobial agents with penicillin. Panaphut and colleagues[135] reported no difference in time to resolution of fever, mortality, or duration of organ dysfunction between patients randomized to receive a 7-day course of penicillin or intravenous ceftriaxone. A subsequent study[180] comparing penicillin, doxycycline, and cefotaxime reported no significant differences among the three groups with regard to mortality, time to defervescence, or time to resolution of abnormal laboratory test results.

Nonetheless, we favor treatment with penicillin or tetracycline (to be avoided in children younger than 9 years) *early* in the course of disease if a diagnosis of leptospirosis is suspected. Parenteral aqueous penicillin G, 6 to 8 million U/m^2/day in six divided doses, should provide optimal blood and tissue concentrations of penicillin. For patients sensitive to penicillin, tetracycline, 10 to 20 mg/kg/day intravenously or 25 to 50 mg/kg/day orally in four divided doses for 1 week, should be provided.

Management of leptospirosis requires careful attention to supportive care. Fluid and electrolyte balance requires meticulous attention. Dehydration, cardiovascular collapse, and acute renal failure may necessitate prompt and specific treatment. In some cases, acute renal failure may be prevented by ensuring adequate renal perfusion and appropriate fluid administration early in the course of disease, when prerenal azotemia and shock may be seen.[22,164] If prerenal azotemia is suspected, diuresis should be attempted promptly with administration of a fluid or colloid load designed to expand extracellular volume and replace extracellular fluid deficits.[22] In patients who do not respond to such therapy, acute tubular necrosis may be suspected, and appropriate fluid restriction should be initiated. If azotemia is severe or prolonged, peritoneal dialysis or hemodialysis should be instituted.[72,198] The use of exchange transfusion has been suggested in patients with marked hyperbilirubinemia.[128,132,165]

The use of corticosteroids in the treatment of severe cases has not been evaluated critically, but their use in patients with impending hepatic coma has been suggested.[66] Anecdotal reports also suggest that corticosteroids may be of value in patients with profound hypotension or shock.

PREVENTION

Benches in rat-infested, fish-gutting sheds and sewers may be decontaminated. Hygienic conditions should be encouraged in slaughterhouses, farmyard buildings, and bathing pools. In addition to hygiene, prevention of leptospirosis primarily depends on immunization of animals. Immunization of workers at high risk for acquiring leptospirosis has been used successfully in mines in Japan and Poland and in rice fields in Italy and Spain.[193]

Leptospire bacterins are available commercially and have been evaluated for safety and efficacy in laboratory animals and domestic livestock.[32,102,155,172] The degree of protection attained depends largely on the antigenic potential of the immunizing agent. Requirements for the *L. pomona* vaccine used in cattle are such that not more than one eight-hundredth of the dose recommended for cattle must protect 80 percent of hamsters challenged

intraperitoneally 14 to 18 days after vaccination with a dose of 100 hamster LD_{50}s. In contrast, most dogs are immunized with a vaccine that is but one tenth of the potency of that used for cattle. Most dogs thus immunized have been protected against disease but not necessarily from carrying and excreting leptospires in their urine. Trends documenting that many cases of leptospirosis in children have been associated with contact with dogs suggest that more stringent requirements for the immunization of pet dogs are needed.

A randomized trial of doxycycline versus placebo was undertaken to assess the efficacy of doxycycline prophylaxis in the prevention of infection and disease caused by leptospires during outbreaks in North Andaman.[157] Leptospiral infection was not prevented, but the patients who received doxycycline and in whom disease subsequently developed had lower morbidity and mortality rates.

CHAPTER 155

SPIRILLUM MINUS (RAT-BITE FEVER)

Carrie L. Byington ❂ Robert D. Basow

Spirillum minus is one of the causative agents of rat-bite fever, or sodoku. Rat-bite fever also may be caused by *Streptobacillus moniliformis* (see Chapter 150). *S. minus* is a spirochete that was isolated first by Futaki and associates in 1917.[5] The original name for the organism was *Spirochaeta morsus muris*. *S. minus* is the most frequent cause of rat-bite fever in Asia.[9] Only one case of spirillary rat-bite fever has been reported in the American literature in the past 4 decades.[3]

BACTERIOLOGY

S. minus is a short, rigid, aerobic, gram-negative, flagellated spirochete measuring 2 to 5 μm in length. The organism is thicker than *Treponema pallidum* and usually contains two to five regular sharp turns along its length. On darkfield microscopy, the organism moves quickly with the use of a terminal flagellum.[5] In general, the thought is that *S. minus*, like other spirochetes, does not grow on artificial media and requires animal inoculation for successful isolation.[15] However, two reports in the literature describe the isolation of *S. minus* in broth,[8,14] but these cases may have represented other infectious illnesses.

EPIDEMIOLOGY AND PATHOLOGY

The epidemiology of spirillary rat-bite fever is similar to that of the streptobacillary form. Disease appears to be transmitted primarily through rat bites. Approximately 25 percent of rats are carriers of *S. minus* in the nasopharynx, and rats with conjunctivitis have been shown to have *S. minus* in the eye discharge that drains into their mouths.[11] Disease has not been reported after oral ingestion of the organism. Human-to-human transmission has not been reported but conceivably could occur during blood transfusions.

Gunning has given an excellent description of the pathologic changes associated with *S. minus* infection.[6] The infection provokes edema, mononuclear leukocyte infiltration, and necrosis at the site of inoculation. Regional lymph nodes are hyperplastic. The relapsing symptoms are associated with invasion of the blood by spirilla. Toxic, hemorrhagic, or necrotic changes may occur in the liver and kidney.

CLINICAL MANIFESTATIONS

The incubation period of spirillary rat-bite fever typically is longer than that of the streptobacillary form, with an average of 14 to 18 days and a range of 1 to 36 days.[2] The disease is heralded by the appearance of an indurated lesion at the site of the initially healed bite, which coincides with the onset of fever and chills. Chancre formation or ulceration may occur at the site, and regional lymphadenopathy is a common finding. The temperature may reach 41° C in a stepwise fashion over the course of 2 to 4 days and then fall abruptly.[6] Six to eight regularly occurring relapses of fever, separated by afebrile periods lasting 3 to 7 days, may occur. During febrile periods, the patient also may experience myalgia, headache, and vomiting. In approximately 50 percent of patients, a purple to red-brown rash develops and consists of large macules with occasional indurated erythematous plaques or urticarial lesions.[15] As opposed to streptobacillary rat-bite fever, joint manifestations are rare occurrences. In untreated cases, the illness may persist for 3 to 8 weeks, but relapses have occurred after months or years.[13]

Spontaneous cure is the general rule, but several untreated cases have persisted for more than 1 year.[15] The untreated mortality rate is reported to be 6.5 percent.[2] In protracted, untreated cases, severe complications include endocarditis,[8] meningitis,[10] myocarditis, hepatitis, and nephritis.[4] Anemia, weight loss, and severe diarrhea are common complications in infants and chil-

dren. Epididymitis, nuchal rigidity, headache, pleurisy, pleural effusion, and splenomegaly also have been reported.[12]

The differential diagnosis includes streptobacillary rat-bite fever, as well as many other infectious and noninfectious diseases (see Chapter 150 for details).

DIAGNOSIS

Definitive diagnosis requires isolation and identification of the spirochete. Although the organism rarely may be seen on a peripheral blood smear[1] or darkfield examination of ulcer exudate,[7] animal inoculation usually is required for isolation. Blood or wound aspirates are injected intraperitoneally into guinea pigs or mice. The spirochetes then may be recovered in 5 to 15 days from the animals' blood, which is examined under darkfield microscopy. This process is time-consuming and may not be available in most centers. In addition, the inoculated animals must be screened carefully for previous *Spirillum* carriage.

Nonspecific diagnostic criteria include a false-positive test for syphilis in 50 percent of patients, white blood cell count between 10,000 and 20,000 cells/mm,[3] and moderate anemia.[2,15] There are no specific serologic tests for *S. minus*. Molecular methods, such as polymerase chain reaction, may offer hope in the future for detection of *S. minus*.[4]

TREATMENT

S. minus is considerably more sensitive to penicillin than *S. moniliformis* is. In one study, a dosage as low as 24,000 U/day for 5 days was shown to be effective.[13] However, because distinguishing spirillary disease from streptobacillary disease is difficult, the two may coexist, and it is important in the acute stage to treat with dosages effective against *S. moniliformis* (see Chapter 150 for further details).

CHAPTER 156

SYPHILIS

Simon R. Dobson ❂ Pablo J. Sánchez

Syphilis was recognized first at the end of the 15th century in Europe, where it appeared seemingly as an emerging infectious disease. It rapidly spread to reach epidemic proportions. Its European origins are a mystery that will not be solved easily, with theories ranging from its being a disease introduced from the New World by the returning crew of Columbus to its being a virulent form of the endemic yaws and bejel of African peoples that appeared later as virulent syphilis in a susceptible European population.

Syphilis initially was called the *Italian disease*, the *French disease*, and the *great pox* (as distinguished from smallpox). Its venereal transmission was not recognized until the 18th century. Delineation of characteristics of syphilis was hindered by the confusion of its symptoms with those of gonorrhea. In 1767, Hunter, a great English experimental biologist and physician, inoculated himself with urethral exudate from a patient with gonorrhea. The patient also had syphilis, and the subsequent symptoms experienced by Hunter convinced two generations of physicians of the unity of gonorrhea and syphilis. The separate natures of gonorrhea and syphilis were shown in 1838 by Ricord, who reported his observations on more than 2500 human inoculations. Recognition of the stages of syphilis followed, and in 1905, Schaudinn and Hoffman discovered the causative agent. The following year, Wassermann introduced the diagnostic blood test that bears his name.

ORGANISM

Morphologic characteristics are the primary features by which members of the family Spirochaetaceae are placed into a single taxon. Spirochetes are helix-shaped, heterotrophic bacteria. These organisms are slender, coiled, and flexible, with one or more complete turns in the helix. Spirochetes are motile, their corkscrew motility resulting from the action of axial fibrils known as *endoflagella*. The family Spirochaetaceae has five genera, of which only *Treponema*, *Borrelia*, and *Leptospira* spp. cause major human illnesses. Differentiation among genera of the family Spirochaetaceae is based primarily on the morphology of the organism.

The name *Treponema* is derived from the Greek words meaning, "turning thread." Individual organisms are 5 to 15 μm in length and 0.092 to 0.5 μm in diameter and have finely tapered ends. Whole cells appear to have a flat wave with one or more planes per cell, giving the appearance of a helical coil. Each cell has 8 to 14 evenly distributed waves. They exhibit a sluggish mobility, with drifting motion and graceful flexuous movements.[71] The internal structure of *Treponema pallidum* subsp. *pallidum* generally is similar to that of other spirochetes. An outermost thin three-layered membrane surrounds the protoplasmic cylinder of the cell. Intracytoplasmic microtubules have been described, and such structures may be specific for *Treponema* spp.

The six axial fibrils or endoflagella are long, flagella-like, intracellular organelles that originate at either end of the cell from knoblike structures and extend toward the other end. Axial fibrils vary in length but overlap one another near the middle of the cell. These fibrils are thought to determine the spiral shape of the cells and are responsible for the characteristic motility along the longitudinal axis exhibited by members of Spirochaetaceae.

The complete genome of *T. pallidum* subsp. *pallidum* (Nichols strain) was sequenced by the whole-genome rapid sequencing method.[47] The *T. pallidum* genome is a circular chromosome and is small compared with most bacteria at 1.14 Mb encoding 1041 predicted proteins. By polyacrylamide gel electrophoresis technique, the major constituent proteins of *T. pallidum* have been characterized and include integral membrane proteins with apparent molecular masses of 47 kd, 34 kd, 17 kd, and 15 kd.[98] These lipoprotein antigens are highly immunogenic in laboratory animals and humans.[7,66]

Virulent strains of *T. pallidum* are propagated by intratesticular inoculation of rabbits, and the inability to propagate the organisms in vitro has hampered study of these microorganisms. The time required for division of the organism to occur in rabbits is slow, at approximately 30 hours. Velocity sedimentation employing discontinuous gradients of radiocontrast medium (Hypaque) successfully has purified and concentrated treponemes extracted from infected rabbit testes. These organisms retain the antigens for the fluorescence test, although motility is lost.

Limited cultivation of *T. pallidum* on monolayers of baby hamster kidney cells in 7 percent carbon dioxide has been reported. Research with in vitro characteristics of these organisms also has resulted in the description of adherence of virulent *T. pallidum* to primary cell cultures of rabbit testicular cells and to an established continuous line of human epithelial cells (HEp-2). To date, however, direct in vitro culture for establishing the diagnosis of *T. pallidum* disease has not been possible. In vitro growth is hindered by the reliance of *T. pallidum* on glycolysis alone for adenosine triphosphate synthesis, its sensitivity to oxygen, and its sensitivity to growth temperature.[71]

Other pathogenic *Treponema* organisms cause characteristic clinical diseases and now are known to be genetically different from *T. pallidum* subsp. *pallidum*. These are *T. pallidum* subsp. *carateum* (pinta), *T. pallidum* subsp. *endemicum* (bejel or endemic syphilis), and *T. pallidum* subsp. *pertenue* (yaws). Several nonpathogenic treponemes also inhabit the oral cavity and intestinal tract.[18]

TRANSMISSION

ACQUIRED SYPHILIS

Syphilis is not a highly contagious disease. An individual who has had sexual contact with an infected partner has approximately a 30 percent chance of acquiring disease. The median infective dose to humans experimentally has been estimated to be 57 organisms. *T. pallidum* has the capability to invade the intact mucous membrane or microabrasions of the skin. Direct inoculation from contact with an infected individual is necessary for infection to occur because survival of the organism outside the host is very limited. The organism is killed easily by heat, drying, soap, and water. Sexual contact is the common method of transmission of acquired disease, and the site of inoculation usually is on the genital organs—the vagina or cervix in females and the penis in males. Other sites include lips, breast, tongue, and abraded areas of the skin. Examining physicians and pathologists may be infected by contact if appropriate barrier protection is not used.

CONGENITAL SYPHILIS

Congenital syphilis usually results from transplacental infection of the developing fetus from spirochetes in the maternal bloodstream. *T. pallidum* becomes widely disseminated to many tissues in an adult soon after initial infection occurs even if clinical manifestations are delayed by months. Maternal spirochetemia and placental infection are not surprising findings.[10] A newborn occasionally may be infected at delivery by contact with an infectious lesion present in the birth canal or perineum. Intrauterine transmission is supported by isolation of the organism from umbilical cord blood and amniotic fluid,[52,96,122,147] detection of spirochetes in the placenta and umbilical cord in association with typical histopathologic changes,[46,41,107] and detection of specific IgM antibody to *T. pallidum* in neonatal serum obtained at birth.[79,88,120,125] The isolation of *T. pallidum* from 74 percent of amniotic fluid specimens obtained from women with early syphilis also suggests that the organism is capable of traversing the fetal membranes, gaining access to the amniotic fluid and resulting in fetal infection.[80] Breast-feeding is not associated with transmission of syphilis, unless the mother has a chancre on her breast.

Transmission of syphilis to the fetus can occur throughout pregnancy. Occasional reports in the literature describing treponemes in fetal tissue or placentas before the fifth month of gestation were disputed for decades.[38] The thought was that the Langhans cell layer of the cytotrophoblast formed a placental barrier against treponemal invasion of the fetus. Researchers subsequently showed, however, that the layer of Langhans cells in the placenta persisted throughout pregnancy.

In 1976, Harter and Benirschke[57] visualized spirochetes by Warthin-Starry silver stain and immunofluorescence in tissue from two aborted fetuses at gestational ages of 9 and 10 weeks. The expected inflammatory response was not observed in these two fetuses, but such changes have been found in infected fetuses after the 15th week of pregnancy. These investigators noted that researchers describing syphilitic fetuses or placentas in the older literature worked with the products of spontaneous abortions. Such fetal loss caused by syphilis occurred only after 18 weeks of gestation, implying that the fetal loss was a reflection of damage incurred as a result of the host response to the organism. The observation of sequential acquisition by the fetus of the ability to respond to a variety of antigens suggests that inflammation can be present only after the fetus acquires the immunologic ability to recognize the treponeme.[132] The more recent detection of spirochetes in amniotic fluid obtained by amniocentesis from a woman with early syphilis at 14 weeks of pregnancy has shown that the fetus can be infected with *T. pallidum* in early pregnancy.[95] The rate of vertical transmission does increase with advancing gestation, however.

Vertical transmission is related directly to the maternal stage of syphilis, with early syphilis resulting in significantly higher transmission rates than late latent infection. Generally, the greater the time that has elapsed since the woman's primary or secondary infection, the less likely she is to transmit disease to the fetus. Ingraham[62] reported in 1950 that among 251 women with syphilis having a duration of 4 years or less, 41 percent of their infants were born alive and had congenital syphilis; 25 percent were stillborn; 14 percent died in the neonatal period; 21 percent had low birth weight, but no evidence of syphilis; and 18 percent were normal full-term infants. In contrast, only 2 percent of infants born to mothers with late disease had congenital syphilis. In 1952, Fiumara and colleagues[44] reported that untreated primary or secondary syphilis resulted in 50 percent of infants having congenital syphilis, whereas the other half were stillborn or premature or died in the neonatal period. With early latent infection, 40 percent of the infants had congenital syphilis, whereas only 10 percent with late latent disease developed syphi-

lis. These data are supported by a more recent study of Sheffield and colleagues,[128] in which mothers with primary, secondary, early latent, and late latent infection had transmission rates of 29, 59, 50, and 13 percent.

Syphilis is an ulcer-causing disease that is associated with increased sexual transmission of human immunodeficiency virus (HIV). In this regard, increasing numbers of newborns who are infected with congenital syphilis also are born to mothers with HIV, and vice versa. The contribution of maternal co-infection with *T. pallidum* and HIV to vertical transmission of either syphilis or HIV has not been elucidated fully. Virulent *T. pallidum* can promote the induction of HIV gene expression in macrophages, possibly resulting in increased systemic HIV levels and more rapid progression of the HIV infection.[141] A more recent study noted higher rates of congenital syphilis in infants born to co-infected mothers, but the diagnosis of congenital syphilis was based on a surveillance definition used by the Centers for Disease Control and Prevention (CDC) and not on strict diagnostic criteria.[126]

EPIDEMIOLOGY

The introduction of penicillin in 1942, and its subsequent widespread use in the 1950s, resulted in a marked decline in the occurrence of syphilis in the United States. After an increase in the number of cases occurred in the early 1960s, the rates again declined in the 1970s, only to have a dramatic resurgence from 1986 to 1991.[21,29,113] The rapid increase during these years in the rate and numbers of cases of primary and secondary syphilis in adults, specifically among women of child-bearing age, resulted in a significant increase in rates of congenital syphilis. Rates of syphilis were greatest among blacks and Hispanics residing in large urban centers. The disease was centered in populations in which substance abuse, particularly crack cocaine, was common, and where there was involvement with the sex trade industry often in exchange for drugs.[21]

Other factors that may have contributed to the increased rates of syphilis included underfunded and overwhelmed public health resources; use of spectinomycin for treatment of penicillinase-producing *Neisseria gonorrhoeae* because spectinomycin is ineffective against incubating syphilis; and failure to implement safer sexual practices, especially among adolescents and young adults. Generally, individuals who acquire syphilis characteristically are young and often have had contact with an average of five individuals during the incubation period. Because of the high rate of dual infection (8%) with *N. gonorrhoeae*, some individuals identified and treated for gonorrhea with ceftriaxone also are treated for syphilis while in the pre-primary stage of disease.

Strenuous attempts were made to control syphilis, and the lowest rate ever reported in the United States was reached in 2000, with the rate of primary and secondary syphilis declining by 90 percent between 1990 and 2000 to 2.1 per 100,000 population.[23] The reasons for this decline included (1) wider screening practices secondary to medical and public awareness of the syphilis epidemic of the late 1980s that led to identification and treatment of infected individuals; (2) increased state and local funding for syphilis control programs such as partner notification, community-based screening and presumptive treatment strategies, and risk-reduction counseling; (3) introduction of HIV prevention programs that target prevention of other sexually transmitted diseases (STDs); and (4) decrease in crack cocaine use and trading sex for drug behaviors; and possibly (5) development of acquired immunity to syphilis among high-risk populations that resulted in less reacquisition of infectious syphilis.

The concentration of cases in the United States to a few geographic areas, especially in the southeastern United States, led to an optimistic "National Plan to Eliminate Syphilis" announced by the CDC in 1999.[135] The plan had to be restated in 2006 in the face of resurgent rates.[23] A gender gap has been noted, with rates of primary and secondary syphilis in men increasing from 3 per 100,000 in 2001 to 5.7 per 100,000 in 2006, whereas a sustained increase in rates in women has been from 0.8 per 100,000 in 2004 to 1 per 100,000 in 2006. The increase in male rates has been explained partly by cases in men who have sex with men and attributed to high-risk sexual behaviors and co-infection with HIV. With the rates also increasing in heterosexuals, the rates of congenital syphilis also have rebounded.

In 1987, the reported rate of congenital syphilis was 10.5 cases per 100,000 live births. By 1991, there were 4398 cases of congenital syphilis (107 per 100,000 live births). These rates reflect a reporting case definition that was changed in 1988[21,152] and resulted in an almost fourfold increase in the number of cases reported to the CDC.[29] There also was a genuine increase, however, in the number of actual cases and case rates secondary to the increase in early syphilis among women.[68] Case rates of congenital syphilis were greatest in the Northeast (186.2 cases per 100,000) and least in the Midwest (54.8 per 100,000).[39]

In 1988, investigators recognized that prior definitions of congenital syphilis that had been used for surveillance and for treatment decisions had been difficult to apply to the clinical setting because they required a diagnosis that often could be established only over weeks or months. During that period, many children were lost to follow-up and were neither treated nor reported.[29] Because of the high incidence of congenital disease in infants born to inadequately treated mothers, current definitions of congenital syphilis for a presumptive case (which should be reported and treated) require only (1) that the infant be born to a mother with untreated or inadequately treated syphilis or (2) that the child have physical or laboratory signs of congenital syphilis. A summary of the surveillance case definition used since 1988 is provided in Table 156–1.

TABLE 156–1 Surveillance Case Definition for Congenital Syphilis

A *confirmed case* of congenital syphilis is an infant in whom *Treponema pallidum* is identified by darkfield microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, umbilical cord, amniotic fluid, or autopsy material

A *presumptive case* of congenital syphilis is either of the following:

A. Any infant whose mother had untreated or inadequately treated* syphilis at delivery, regardless of findings in the infant; *or*

B. Any infant or child who has a reactive treponemal test for syphilis and any one of the following:
   1. Any evidence of congenital syphilis on physical examination; *or*
   2. Any evidence of congenital syphilis on long bone radiograph; *or*
   3. Reactive cerebrospinal fluid VDRL; *or*
   4. Elevated cerebrospinal fluid cell count or protein (without other cause); *or*
   5. Quantitative non-treponemal serologic titers that are fourfold higher than the mother's (both drawn at birth); *or*
   6. Reactive test for FTA-ABS-19S-IgM antibody

A *syphilitic stillbirth* is defined as a death of a fetus weighing >500 g or having a gestational age >20 weeks in which the mother had untreated or inadequately treated syphilis at delivery

**Inadequate treatment consists of any non-penicillin therapy or penicillin given <30 days before delivery.*

FTA-ABS, fluorescent treponemal antibody absorption; VDRL, Venereal Disease Research Laboratory.

Adapted from Centers for Disease Control: Congenital syphilis, New York City, 1986-1988. M. M. W. R. Morb. Mortal. Wkly. Rep. 38:*828, 1989.*

Minor differences exist among case definitions of congenital syphilis as formulated by several agencies and experts.[118] Some experts would consider as a presumptive case a newborn who is well clinically but was born to a mother who had contact within 90 days before delivery with an individual with primary or secondary syphilis and who had not been treated or had been treated inadequately, even if the mother has nonreactive serology. Although recommendations for therapy commonly have assumed that adequate therapy given to a mother with primary or secondary syphilis during pregnancy would prevent congenital syphilis with a high degree of reliability, reasons to doubt this premise have emerged.[3,86,151] In particular, treatment failures in which the infant developed syphilis despite maternal therapy have been reported when the mother was treated first within 30 days of delivery.[12,14,84,85,117]

An infant born to a mother who was treated within 30 days of delivery is considered to have been treated inadequately, and the infant should receive appropriate therapy. Table 156–2 lists the various circumstances in which maternal therapy may be presumed to be subtherapeutic. The consequences of inadequate therapy of the mother are shown in data in Table 156–3. In that experience, 13 percent of children born to inadequately treated mothers had congenital syphilis, all of which was neurosyphilis.[116]

Substantial underreporting of infected infants did occur previously,[151] but the revised surveillance definition does not represent diagnostic criteria. Rather, it reflects the public health burden of the disease because these infants require medical and public health interventions. Notwithstanding this change in reporting guidelines, the number of cases of congenital syphilis had continued to decline from a peak of 107 per 100,000 live births in 1991, but after 14 consecutive years of decline, the rates increased 3.7 percent between 2005 and 2006 (8.2 to 8.5 per 100,000 live births).[23]

Worldwide syphilis remains a considerable public health problem. Russia reported 730 cases in 2001, an increase from 15 cases in 1991. Russia and countries of the former Soviet Union have rates of syphilis in pregnancy of 1 to 2 percent. In the Caribbean and Latin America, these rates are 2 to 7 percent, but they are even worse in Southern Africa, with 2 to 17 percent of all pregnancies occurring in women with syphilis.[143] The toll of untreated maternal syphilis on the outcomes of pregnancy is severe. An estimated one fourth of all stillbirths and 10 percent of neonatal deaths in Southern Africa are caused by congenital syphilis.[140] The World Health Organization (WHO) reckons that every year, 1 million pregnancies are complicated by syphilis, with half resulting in early pregnancy abortion or perinatal death, a quarter resulting in low birth weight or premature birth, and a final quarter resulting in overt congenital syphilis.[143]

Congenital syphilis is a disease that should be amenable almost fully to eradication if currently available prenatal health measures were implemented completely. Table 156–4 presents two studies in the United States of prenatal care of women who delivered infants with congenital syphilis and indicates the hurdles that control of the disease will have to overcome.[30,86] Lack of prenatal care is the most important one.[34,87,145] National surveillance data analyzed by the CDC in 2002 highlight the fact that cases of congenital syphilis still occur even when prenatal care is implemented if the mother's response to treatment is inadequate or if the infant's evaluation is not thorough (Fig. 156–1).[22]

Penicillin was a major reason for the decline of the treponematoses seen in the early 1950s.[41] Other factors must be considered in the attempted eradication of these infections. Nonvenereal endemic treponemal infections (endemic syphilis, bejel, yaws, pinta) have continued to flourish in underdeveloped areas of the world where hygiene is poor, despite the introduction of penicillin. Progress in control of these diseases requires that mass treatment programs be coupled with efforts to improve local living conditions. In areas where this goal could be accomplished, a resulting decline in endemic treponematoses occurred.

TABLE 156–2 Circumstances in Which Maternal Therapy for Syphilis May Be Subtherapeutic or Inadequate

Treatment with a non-penicillin regimen (including macrolide antibiotics)
History of maternal treatment was not documented fully or verifiable
Treatment during the month before delivery
Treatment in HIV-infected women
Serial post-therapy assays of maternal non-treponemal antibody titers were not performed
Serial post-therapy assays of maternal non-treponemal antibody titers did not show a fourfold decline in titers after treatment of early syphilis, not permitting assessment of adequacy of therapy, and suggesting possibility of failure to eradicate infection
Serial post-therapy assays of maternal non-treponemal antibody titers show a fourfold increase in titers, suggesting re-infection or relapse

HIV, human immunodeficiency virus.

PATHOLOGY

Syphilis often is a lifelong infection that progresses in three clear characteristic stages (Fig. 156–2). After initial invasion occurs through mucous membranes or skin, the organism undergoes rapid multiplication and is disseminated widely. Spread through the perivascular lymphatics and then through the systemic circulation probably occurs even before the clinical development of the primary lesion. Ten to 90 days later, usually within 3 to 4 weeks, the patient manifests an inflammatory response to the infection at the site of the inoculation. The resulting lesion, the chancre, is characterized by the profuse discharge of spirochetes; accumulation of mononuclear leukocytes, lymphocytes, and plasma cells; and the swelling of capillary endothelia. The regional lymph nodes are enlarged, and the cellular infiltrate resembles that of the primary lesions. Resolution of the primary lesion occurs by fibrosis.

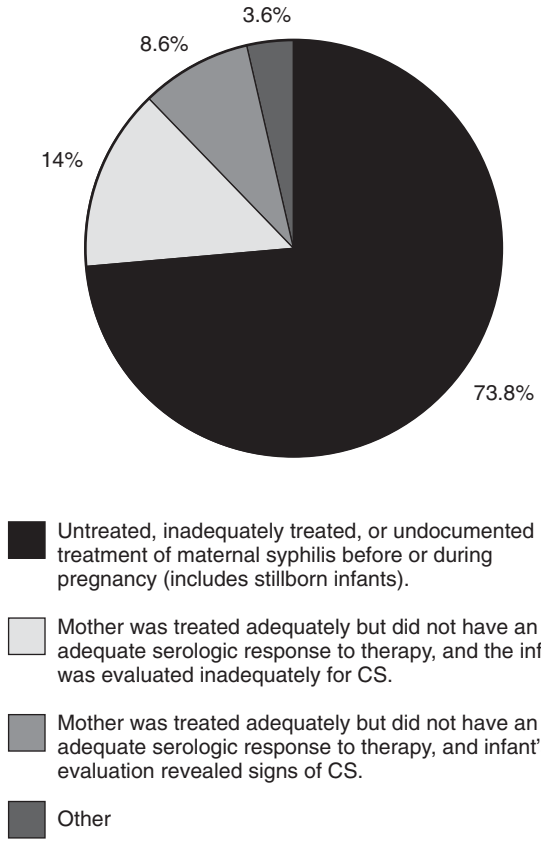

Figure 156–1 Maternal treatment history of 451 cases of congenital syphilis (CS) reported in 2002. *(From Centers for Disease Control and Prevention: Congenital syphilis—United States, 2002. M. M. W. R. Morb. Mortal. Wkly. Rep. 53:716-719, 2004.)*

Secondary lesions develop when tissues of ectodermal origin, such as skin, mucous membranes, and central nervous system (CNS), participate in an inflammatory response. Mucous patches in the mouth are caused by local vasculitis. The cellular infiltrate resembles that of the primary lesion, with the predominance of plasma cells. Little or no necrosis is present, and healing is without scarring but may include pigmentary changes.

Tertiary syphilis may involve any organ system and often is asymmetric. Gummata are lesions typified by extensive necrosis, a few giant cells, and a paucity of organisms. They commonly occur in internal organs, bone, and skin. The other major form of tertiary lesion is a diffuse chronic inflammation, with plasma cells and lymphocytes but without caseation, which may result in an aneurysm of the aorta, paralytic dementia, or tabes dorsalis. Chronic swelling of the capillary endothelium and fibrosis result in the characteristic tissue changes.

Congenital syphilis is a result of hematogenous infection and the disseminated involvement of almost all viscera. The intense inflammatory response occurs in the perivascular framework and interstitial stroma, rather than in the parenchyma.[94] Bone, liver, pancreas, intestine, kidney, and spleen are involved most reproducibly and severely. Other tissues, such as the brain, pituitary gland,[14] lymph nodes, and lungs, also may be infected. The gastrointestinal tract shows a pattern of mononuclear cell infiltration in the mucosa and submucosa, with subsequent widening of the submucosa by the ensuing fibrosis. This event is most prominent in the small bowel. In the kidney, a perivascular inflammation, particularly in the juxtamedullary region, is evident. The basic architecture of the tissue influences the ultimate pattern of involvement. The deposition of collagen around arteries of the spleen produces a typical onion-skin appearance. Periosteum and epiphyses are the most affected portions of bone, and syphilitic granulation tissue may interfere with bone forma-

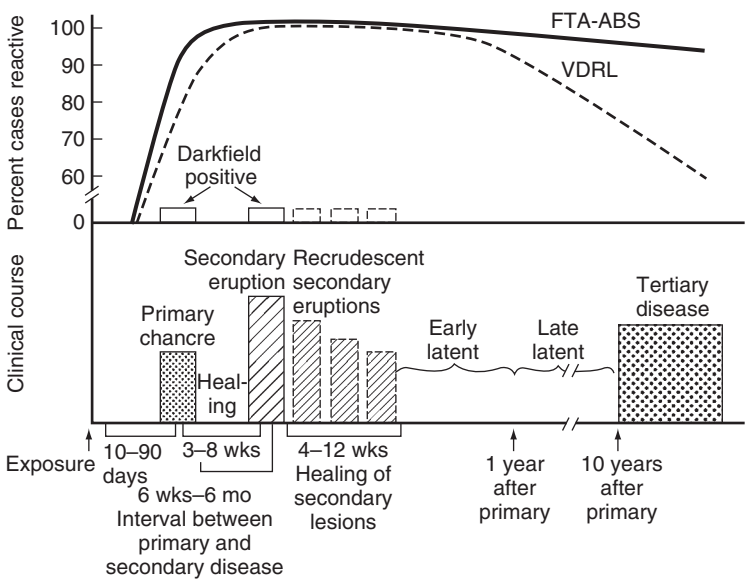

Figure 156–2 The course of untreated syphilis. FTA-ABS, fluorescent treponemal antibody absorption; VDRL, Venereal Disease Research Laboratory.

tion. Pancreatitis also is observed, with typical inflammation and fibrosis.

The fetus or newborn shows diffuse extramedullary hematopoiesis in many tissues. The placenta of infants with congenital syphilis often is large, thick, and pale. Three histopathologic features commonly are seen: enlarged and hypercellular villi, proliferative fetal vascular changes, and acute and chronic inflammation of the villi.[50,129] Erythroblastosis involving the placenta has been seen more frequently among stillborn infants with congenital syphilis than in live-born infants with or without syphilis.[129]

Spirochetes may be identified in placental tissue using conventional staining, although they may be difficult to visualize. Nucleic acid amplification methods also have been used to identify *T. pallidum* genome in involved placental specimens.[50] In addition, the umbilical cord may exhibit significant inflammation, with abscess-like foci of necrosis located within Wharton jelly and centered around the umbilical vessels, which is termed *necrotizing funisitis*.[46,129] Macroscopically, the umbilical cord resembles a "barber's pole"; the edematous portions have a spiral striped zone of red and pale blue discoloration, interspersed with streaks of chalky white. Histochemical staining may show spirochetes within the wall of the umbilical vessels. Placental and umbilical cord histopathology should be performed on every case of suspected syphilis.[129]

PATHOGENESIS AND IMMUNE RESPONSE

The host immune response to syphilis is vigorous and is responsible for many of the clinical manifestations seen in the disease. Despite this immune response, the infection may persist for life. In addition, prior infection does not confer resistance to re-infection. Researchers continue to try to explain this contradiction.[102]

TREPONEMAL VIRULENCE–ASSOCIATED FACTORS

Virulent *T. pallidum* attach to host cells during parasitism and are oriented by the proximal hook to the host cell surface. There seems to be a ligand-receptor adherence mechanism involving the treponemal outer-membrane proteins. Virulent strains attach to metabolically active mammalian cells, and treponemes are capable of multiplication only during attachment. Fetal and infant cells seem to support treponemal growth maximally, and capillary cells are the prime target of parasitism. Virulent treponemal strains produce hyaluronidase, which may facilitate the perivascular infiltration that is apparent by histopathologic study. These strains also may invade the ground substance that joins capillary endothelial cells.

Virulent *T. pallidum* is coated with fibronectin having host origin. This coating seems to protect the organism from antibody-mediated phagocytosis; allows the organism to adhere to the surface of host phagocytes with only limited ingestion of the organisms; may block complement-mediated lysis of the coated treponemes; and, finally, may allow the treponemes additionally to acquire physiologically active host proteins, such as ceruloplasmin and transferrin, on which they are dependent.[103]

HOST RESPONSE

Treponemes seem to persist in extracellular loci with little or no inflammatory response elicited. Polymorphonuclear leukocytes ingest virulent treponemes, incorporate them into phagocytic vacuoles, degranulate, and digest *T. pallidum*. In addition, phagocytosis occurs slowly and is facilitated by the presence of immune serum.[2] Large numbers of treponemes are needed to elicit this response, however, and small numbers may escape recognition.[91] Although there are few surface-exposed transmembrane proteins, one more recently described, Tpr K, seems to act as a porin.[25] It has been shown to elicit an opsonic antibody response in the rabbit model. Variable regions of the protein are explained by diversity in the encoding genes. This antigenic variation could explain the success of the treponeme in evading the host response.[24,75,89] Innate immunity through Toll-like receptor 4 is activated by lipoproteins under the outer membrane and may be important in orchestrating the overall immune response to *T. pallidum*.[16,109,119]

Alterations in host cell-mediated immunity occur during primary and secondary stages of syphilis. During early stages of disease, all aspects of cell-mediated immunity, including responses to nonspecific T-cell mitogens, are suppressed. Blastogenesis to treponemal antigens is not demonstrable until late in the course of secondary disease. Natural killer cell activity is increased during early primary syphilis and depressed in secondary and latent syphilis.[65] Some evidence supports the idea that lymphocytes from previously infected animals confer moderate protection to nonimmune animals. In human disease, $CD4^+$ T cells and macrophages predominate in primary chancres, whereas $CD8^+$ cells predominate in secondary syphilis lesions. In primary and secondary syphilis lesions, T_H1 cytokines are present.[105,119,142] Some investigators have suggested that increased apoptosis of peripheral blood lymphocytes and $CD4^+$ cells by a Fas-mediated pathway that occurs during the secondary stage of infection may explain the failure to clear the organism and set up a chronic infection.[40] Alterations in the immune environment of the mother during pregnancy may alter the balance of containment of the organism, allowing transplacental passage to the fetus.[150]

During the initial infection with *T. pallidum*, humoral IgG and IgM antibodies are detectable by the time the chancre appears. In primary syphilis, the main IgG subclass is IgG1, whereas IgG1 and IgG3 predominate in secondary syphilis.[9] If the patient is treated adequately, IgM antibody declines during the next 1 to 2 years, but IgG antibody usually persists through the lifetime of the patient. The stages of syphilis evolve, despite humoral antibody response.

Individuals with untreated syphilis have only a relative resistance to re-infection, so the development of a chancre with re-infection is unusual and probably depends on the challenge inoculum. After re-exposure, untreated individuals may develop an increased humoral antibody level.

In individuals who have been treated for syphilis, especially if treatment was provided during the secondary or earlier stages, the protective effect of prior disease is minor, and active disease frequently occurs after re-infection, regardless of whether the patient maintains a reactive non-treponemal antibody test (serofast) or is seronoreactive. Patients who have been treated for congenital syphilis also may acquire symptomatic disease.[43,101] Although active or prior syphilis modifies the response of a patient to subsequent re-infection, protection is only relative and is unreliable.

Secondary syphilis and congenital infection may be accompanied by the nephrotic syndrome. The nephrosis characteristically responds rapidly to penicillin, and light microscopy reveals membranous glomerulonephritis with glomerular mesangial cell proliferation. The subendothelial basement membrane deposits contain IgG and C3 or only globulin. Acute syphilitic glomerulonephritis seems to be an immune complex disease.[15,48,67] In infants with congenital syphilis, analysis of circulating immune complexes using immunoblotting methods showed the presence of an 83-kd *T. pallidum* antigen.[35] Findings have been similar with secondary syphilis.

CLINICAL MANIFESTATIONS

The course of untreated syphilis characteristically progresses through three or four stages over many years. Information on the natural history of untreated syphilis comes primarily from follow-up studies of almost 2000 untreated syphilitic patients who were seen initially between 1891 and 1910 in the clinic of Boeck. The subsequent studies of these patients by Bruusgaard and by other epidemiologists later provided the basis for most of our concepts of the consequences of syphilis. Clark and Danbolt[28] published a summary of some of these studies. Figure 156–2 depicts some of the characteristics of an untreated course of disease.

ACQUIRED SYPHILIS

Most recognized syphilitic disease in children is congenital. Acquired syphilis in prepubertal children seldom is reported and is assumed to resemble the clinical course of acquired syphilis in adulthood. Children with acquired syphilis should be assumed to have been infected through contact during child sexual abuse, unless another method of transmission is identified. All patients with syphilis should be tested for HIV infection.[20]

The decision to screen for syphilis during the medical evaluation of a child who is suspected to have been sexually abused should be made on an individual basis because the prevalence of STDs is low in these circumstances. Situations in which screening is recommended include the following: The perpetrator has an STD or is at high risk of having one, such as residing in a community or being of a social setting in which the prevalence of STDs is high; multiple perpetrators are involved; the child is infected with another STD, such as HIV infection, or has physical signs of sexual abuse; STDs have been diagnosed in siblings, other children, or adults in the household; the patient is postpubertal; or screening is a matter of patient or family preference.[11,70,72,130,131] A difficult aspect of the follow-up is the requirement of repeat serologic assays in 3 to 6 months because the initial test may not detect incubating syphilis.

Primary Disease

The chancre of primary syphilis typically is a single lesion, nontender and firm, with a clean surface, raised border, and reddish color. It may be overlooked by women because it frequently is situated on the cervix or vaginal wall. Systemic signs or symptoms are absent, but adjacent lymph nodes frequently are enlarged and nontender. Gutman[54] provides depictions of children with acquired primary syphilis.

Secondary Disease
