Of interest is that the aforementioned recommendations differ considerably from recommendations made before the discontinuation of routine smallpox vaccination.[67] Specifically, dressings were not recommended for the reason that secondary infections were more likely to occur when dressings were used because the vaccine was not sterile. My opinion is that the present dressing recommendations prolong the duration of the vaccination lesion and, therefore, prolong the period of contagion. At present, care should be taken not to dress vaccination sites excessively, and sites should be examined daily for signs of maceration and possible secondary bacterial infections. The most important measure to prevent inadvertent implantation and contact transmission from vaccinia vaccination is thorough handwashing after changing the bandage or after any other contact with the vaccination site.

Treatment of Complications of Smallpox Vaccine

The only product currently available for the treatment of complications of smallpox vaccination is VIG. Cidofovir is being studied as a potential therapy.[18] VIG is an isotonic sterile solution of the immunoglobulin fraction of plasma from persons vaccinated with vaccinia vaccine. It is effective for the treatment of eczema vaccinatum and for some cases of progressive vaccinia, and it may be useful in the treatment of ocular vaccinia resulting from inadvertent implantation. However, VIG is not recommended for treating isolated keratitis. VIG also is recommended for treatment of severe generalized vaccinia if the patient has a toxic condition or a serious underlying disease. VIG is of no benefit in the treatment of post-vaccinial encephalitis and probably is of no benefit in vaccine-induced myocarditis.[10]

VIG is available as an intramuscular (VIGIM) and an intravenous (VIGIV) preparation.[18] It should be administered as early as possible after the onset of symptoms. Doses may be repeated, usually at intervals of 2 to 3 days, until recovery begins (e.g., no new lesions appear).[15]

The CDC is the only source of VIG for civilians. An adult patient with progressive vaccinia is reported to have benefited with the administration of ribavirin and VIG.[65]

Ocular vaccinia should be treated in conjunction with an ophthalmologist who performs serial slit-lamp examinations. Topical off-label use of ophthalmic trifluoride or vidarabine has been recommended by some ophthalmologists.

Cidofovir also may prove useful for the treatment of vaccinia complications. Cidofovir has been shown to be effective in treating other poxvirus infections in both humans and animal models.[27] At this time, use of this drug in treating complications of smallpox vaccination is recommended only under a research protocol sponsored by the CDC. Under this protocol, cidofovir may be released for civilian use by the CDC and for military use by the Department of Defense if (1) a patient fails to respond to VIG, (2) a patient is near death, or (3) all inventories of VIG have been exhausted.[18]

The drawbacks of cidofovir, including its poor oral bioavailability and nephrotoxicity, have encouraged research into other antiviral agents that could be used to treat orthopoxvirus infections, including vaccinia. Currently, promising research in mouse models shows effectiveness of experimental antiviral compounds that may one day be tested and used in humans.[86,87,105]

Misuse of Vaccinia Vaccine

Smallpox vaccine never should be used therapeutically for any reason. No evidence exists that it has any value in the treatment or prevention of recurrent herpes simplex virus infection, warts, or any disease other than that caused by human orthopoxviruses.[64] Misuse of vaccinia vaccine to treat herpesvirus infections has been associated with severe complications.[12,95]

Smallpox Vaccine Availability

The CDC is the only source of smallpox vaccine and VIG for civilians.

PASSIVE IMMUNIZATION AND ANTIVIRAL PROTECTION

Transient protection after exposure was provided by VIG when available.[63] Because this material often was in short supply, the use of methisazone was considered, although this drug was not licensed and was available only on special request. When used prophylactically, methisazone provided some measure of protection. Vomiting was a frequent side effect, and dosing presented problems in some persons.

CONTROL OF SOURCES OF INFECTION

All known contacts of persons with cases needed to be vaccinated or re-vaccinated promptly and kept under surveillance until at least 17 days transpired after the last contact with a known case. When fever developed in such persons, prompt isolation was required until the nature of the illness was determined. All personnel in contact with an index case or involved in the surveillance of contacts needed to be vaccinated or re-vaccinated.

Environmental isolation and disinfection precautions also were required because the virus persisted in crusts for many months. Proper double wrapping and disinfection of all articles leaving the patient's room were necessary. Precautions also were required to prevent transfer of crusts by the shoes or clothing of personnel to areas outside the isolation unit. Isolation precautions for the patient were necessary until all crusts had been shed. After recovery or death of the patient, terminal disinfection of the room was required.

CHAPTER 176

Monkeypox and Other Poxviruses

James D. Cherry ❂ Samantha Johnston

Smallpox, which is caused by variola virus (see Chapter 175), at one time was the most important human poxvirus disease, but this disease has been eradicated from the world. Today, only one human poxvirus, molluscum contagiosum virus, causes specific human illness. In addition, nine other poxviruses can cause human infections. Eight of these viruses are acquired zoonotically, and the other, vaccinia, is acquired by active immunization, or inadvertently by spread from a vaccinated person or laboratory accident.

PROPERTIES OF THE VIRUSES

CLASSIFICATION

The family *Poxviridae* has two subfamilies: *Chordopoxvirinae* (vertebrate poxviruses) and *Entomopoxvirinae* (insect poxviruses).[39,75] Eight genera are included in the *Chordopoxvirinae* subfamily, and four of these genera contain species that infect humans (Table 176–1).

STRUCTURE

Poxviruses are the largest animal viruses and are discernible by light microscopy.[8,75] In general, by electron microscopy, orthopoxviruses appear brick shaped, with a length of 350 nm and a width of 270 nm. They contain double-stranded DNA genomes that vary from 130 to 300 kbp, depending on the particular species. A 30-nm lipoprotein bilayer (envelope) surrounds the virus core. The envelope contains seven or more distinct glycoproteins. Parapoxvirus organisms have a different structure than do *Orthopoxvirus*, *Yatapoxvirus*, and *Molluscipoxvirus* organisms. They are ovoid and vary from 260 to 160 nm for orf virus to 300 to 190 nm for pseudocowpox virus.

TABLE 176–1 Poxviruses That Can Cause Human Illness

Genus	Species
Orthopoxvirus	Variola virus
	Monkeypox virus
	Vaccinia virus
	Cowpox virus
Parapoxvirus	Orf virus
	Bovine papular stomatitis virus
	Pseudocowpox virus
Yatapoxvirus	Tanapoxvirus
	Yabapoxvirus
Molluscipoxvirus	Molluscum contagiosum virus

SPECIFIC VIRUSES AND THEIR ILLNESSES

MONKEYPOX VIRUS*

Monkeypox virus was isolated first from sick laboratory primates in Copenhagen in 1958.[102] Human disease occurs in a large geographic area from Sierra Leone in the west to the Democratic Republic of Congo in the east.[58] The disease was not recognized as being distinct from smallpox until 1970, when, after smallpox had been eliminated, a similar illness continued to circulate in the Democratic Republic of Congo (formerly Zaire).[35,51,58,77] To understand the illness better, the World Health Organization (WHO) launched a surveillance campaign from 1981 to 1986 in that country. During this period and in the preceding 11 years, 338 cases, with an animal source of infection suspected in 245 and secondary transmission in 93 instances, were identified. Most cases were found in children (mean age, 4.4 years).[58,74,77] Since the WHO's initial efforts in monkeypox surveillance were initiated, several isolated outbreaks, mostly in the Democratic Republic of Congo, have been reported in the literature.

Epidemiology

Epidemiologic studies conducted since 1970 identified several outbreaks of human monkeypox, with most cases arising in the Democratic Republic of Congo. As immunity to smallpox waned, concerns were raised that person-to-person transmission could possibly allow monkeypox to replace a niche previously occupied by smallpox.[50] Between 1970 and 1979, 47 cases of human monkeypox were identified, 38 of which occurred in the Democratic Republic of Congo. Seven of these cases were fatal. Of the 47 reported cases, secondary transmission occurred in 4, for secondary attack rates of 3.3 percent among susceptible contacts.[7,50] From 1981 to 1986, Jezek and associates[63] studied 338 patients and found that among patients with primary cases, 50 percent were younger than 4 years of age, and 93 percent were younger than 14 years of age.[61] Ninety-six percent of these children were not vaccinated against smallpox.[6] Animal sources were suspected in 245 of 338 cases, and human-to-human transmission occurred in the remaining 93 cases. Analysis of unvaccinated contacts of

*See references 6, 7, 17-24, 35, 51, 53, 58, 62, 63, 65, 74, 76, 77, 86.

the patients showed a secondary attack rate of 9.3 percent.[6] The longest chain of infection was four generations.[61]

Reporting decreased in the late 1980s and early 1990s because of political instability in the region; from 1996 to 1998, 511 cases of human monkeypox were identified, again mostly in the Democratic Republic of Congo.[16,50] Analysis of 320 possible and probable cases showed attack rates of 18 percent in susceptible individuals, 3 percent if vaccinated and 26 percent if unvaccinated.[50] Eighty-five percent of cases occurred in patients younger than 16 years of age. The case-fatality rate was 1.5 percent, lower than the previously reported rate of 10 percent.[16] The definition of a case as fever and vesiculopustular rash possibly included numerous infections with varicella, thus artificially increasing the rates of reported secondary transmission as well as artificially decreasing the case-fatality rates.[35]

Meyer and colleagues[74] used viral isolation and amplification by polymerase chain reaction (PCR) to detect monkeypox after a 2001 outbreak in the Democratic Republic of Congo. The group found that co-infection and co-transmission of varicella could have misrepresented actual cases of monkeypox. Of the seven small outbreaks, two were proven to be the result of monkeypox (16 cases, 4 deaths); two showed evidence of co-circulating monkeypox and varicella (7 cases, 1 death); two outbreaks were the result of varicella-zoster virus (6 cases, 0 deaths); and neither virus was isolated in the final outbreak. Children were the principal victims.

Disease surveillance continues in the Democratic Republic of Congo, and reports indicate that many more cases occurred than those reported in the literature, with some 1265 cases noted between January 1998 and December 2002. Specimens were collected in 215 cases and showed evidence of human monkeypox infection in 88 cases. The ages of patients ranged from 10 months to 38 years, with mean age of 16.5 years.[77]

Of concern in the United States is that, in May of 2003, the Centers for Disease Control and Prevention (CDC) reported the first outbreak of monkeypox in humans in the Western Hemisphere among 72 patients, 37 of whom had laboratory-confirmed cases.[17-21,26] No case fatalities and no cases of secondary transmission occurred. Two severe cases in children required hospitalization: one girl developed encephalitis that resolved over the course of a 14-day hospitalization, and a second girl developed diffuse oral and pharyngeal lesions that impaired swallowing; she also recovered.[19] The outbreak was linked to the distribution of pet North American prairie dogs that had become ill after being housed with an infected rope squirrel and an infected giant pouched rat shipped from Ghana. Patients were identified in Illinois, Indiana, Kansas, Missouri, Ohio, and Wisconsin.[17-21,52,86] PCR analysis of tissue obtained from the prairie dogs revealed 100 percent similarity with the monkeypox virus strain Zaire 96-I-16 that had been isolated previously from the Democratic Republic of Congo.[67]

The virus is thought to spread to humans by handling of infected animals or by direct contact with an infected animal's body fluids or lesions. Person-to-person spread occurs by large respiratory droplets, although it is much less efficient than that for smallpox.[23,77,88] Risk factors for secondary transmission include close contact with a primary case. Evidence of previous vaccination is thought to be protective.[33] Mortality rates have varied between 0 and 17 percent among outbreaks.[1,6,35,42,53,58,60,62,74]

Modeling of attack rates with waning immunity from smallpox vaccination predicted a worst-case scenario of 147 cases causing 290 to 661 secondary outbreaks that could last as long as 14 generations. The estimated attack rates modeled were far less than for measles or chickenpox. Researchers suggested that 78 percent of primary cases would not result in secondary cases.[106] In light of this information, continued vaccination with vaccinia vaccine to prevent monkeypox has not been recommended, particularly considering the increasing prevalence of human immunodeficiency virus (HIV), which can result in serious adverse events on immunization with currently available vaccinia vaccine.[50]

Serologic evidence suggests that many animals, including rodents and nonhuman primates, are infected with monkeypox virus.[35,52] Epidemiologic studies from the Democratic Republic of Congo have implicated squirrels living in agricultural areas as primary candidates to sustain transmission among people in nearby settlements, although no definitive host has been identified. Concerns that monkeypox virus could spread through North American rodent populations and could serve as a vector for continued zoonotic exposure have not played out.[35]

Clinical Features

The clinical features of human monkeypox virus infection are similar to those of smallpox, but the overall illness tends to be less severe. The characterization of symptoms during outbreaks in Africa has been limited by poor access to medical care, retrospective identification, and civil unrest in areas of outbreaks. The outbreak reported in the midwestern United States allowed researches to describe clinical and laboratory parameters of disease.[51] Vaccinia vaccination markedly lessens the severity of the illness.

After a 10- to 14-day period of incubation (range, 1 to 31 days), a 2-day prodrome of fever, malaise, and lymphadenopathy precedes the manifestation of rash.[7,35,58] Lymphadenopathy occurs in 90 percent of unvaccinated individuals and is a key feature distinguishing monkeypox from smallpox because lymphadenopathy generally does not occur in smallpox. Affected lymph nodes may be unilateral or bilateral and include submandibular, cervical, postauricular, axillary, inguinal, or any combination of these locations.[6] Other signs and symptoms include chills, sweats, headache, backache, sore throat, cough, and shortness of breath.

The rash usually appears first on the face. As in smallpox, lesions develop and progress together in the same body region through the stages of macules, papules, vesicles, and pustules. Over the course of a 2- to 4-week period, the lesions progress until they finally scab over and desquamate. Most patients have discrete lesions, 23 percent have semiconfluent lesions, and 7 percent have confluent lesions. Mucous membrane involvement and conjunctivitis are common manifestations.[63,74] Lesions usually are found on the extremities, head, and trunk, as well as on the palms and soles.[51] During the first week of the rash, patients are considered to be infectious.[62]

Complications include the following: secondary bacterial infection of the skin; pneumonia; vomiting, diarrhea, and dehydration; keratitis and corneal ulceration; septicemia; and encephalitis. The death rate in non-vaccinated patients was 11 percent in the study reported by Jezek and associates,[63] and all deaths occurred in children aged 8 years or younger. Case-fatality rates reported in the 1996 to 1997 outbreak in the Democratic Republic of Congo were 1.5 percent, but this outbreak likely represented both chickenpox and monkeypox, and case-fatality rates probably were falsely low.[16] No fatalities were associated with the U.S. outbreak.

One case of congenital monkeypox infection has been reported.[58] This child's mother had typical illness on August 12, 1983, and the child was born prematurely on September 23, 1983. At birth, the child had generalized skin lesions and died 6 weeks later of malnutrition. No data are available on the clinical course of monkeypox in patients with HIV/AIDS (acquired immunodeficiency syndrome) or other immune compromised states.

Unlike African patients, most of the patients in the United States had a mild, self-limited febrile rash illness.[21] The majority of patients had localized lesions associated with direct contact with infected animals, and only one patient, a child, had a gen-

eralized rash. Differences in the severity of disease may result from differences in virulence among genetically distinct groups of monkeypox viruses: the West African monkeypox virus group and the Congo basin isolates. Isolates from the Congo basin are thought to be more virulent, based on epidemiologic and genetic sequence analyses.[27,39,58,71] The viral isolates involved in the U.S. outbreak were West African in origin.

Laboratory alterations noted in patients of the midwestern U.S. outbreak included elevated transaminases in 50 percent of patients, low blood urea nitrogen (61%), hypoalbuminemia (50%), leukocytosis (45%), and thrombocytopenia (35%).[51] The CDC defined guidelines for case definitions in 2004 (Table 176–2).

Diagnosis

All cases should be reported immediately to the local health department. Laboratory confirmation is required for establishing a definitive diagnosis. The CDC case definitions can help to guide clinicians.[24] Samples that may be used for diagnosis include blood and cutaneous tissue from at least two scabs that have been unroofed and collected in a sterile fashion. Once lesions have been unroofed, the base of the vesicle should be swabbed with sterile cotton or polyester swab and the material applied to a clean microscope slide and air-dried. The material should be sent to the CDC or national reference laboratory for diagnostic testing. Other specimens that can be analyzed include skin biopsy specimens, which may be indistinguishable from those of smallpox lesions, with necrosis of the stratum basale, adjacent dermal papillae, and stratum spinosum. Electron microscopy of the lesions shows abundant large, brick-shaped orthopoxvirus particles in the cytoplasm of infected epidermal cells.[94]

Blood samples may be analyzed for paired acute-phase and convalescent-phase serum samples; however, serology is limited because of the close antigenic relationship that exists among orthopoxviruses. More specific methods used by the CDC include cell culture or chick chorioallantoic membrane isolation along with PCR and sequencing to differentiate monkeypox virus from other orthopoxviruses.[32,70]

Treatment and Prevention

In 1968, investigators reported that monkeys could be immunized against monkeypox virus using smallpox vaccine.[72] In outbreaks in the Democratic Republic of Congo described by Jezek and colleagues,[63] prior smallpox inoculation was found to be protective and to result in a milder form of disease, often difficult to distinguish from chickenpox. However, the smallpox vaccination status did not alter either the severity of illness or hospitalization rates in the midwestern U.S. outbreak.[51] Hammarlund and associates[47] described protective immunity to monkeypox virus in persons previously vaccinated against smallpox. The CDC recommended vaccination with smallpox vaccine for healthcare workers and household contacts of patients with confirmed monkeypox cases. Whenever possible, care for patients with suspected or confirmed monkeypox should be given by vaccinated health care workers and those without contraindications to vaccination. Pre-exposure vaccination is preferred, but vaccination can be administered after laboratory confirmation of an infection is obtained and when vaccine is available. Vaccination should take place within 4 days but may be considered up to 14 days after exposure.[24]

Other researchers looked at the potential development of live virus vaccine against monkeypox and reported improved survival rates among vaccinated macaques. In light of the potential side effects of the current smallpox vaccine, perhaps developing safer vaccines for monkeypox would be useful.[49] Because of the high incidence of complications resulting from the vaccinia virus

TABLE 176–2 Centers for Disease Control and Prevention Case Definition for Human Cases of Monkeypox (January 2004)

Human Monkeypox Case Classification

Suspect Case

The patient meets one of the epidemiologic criteria and has fever or unexplained rash and two or more other signs or symptoms with onset of first sign or symptom within 21 days after the last exposure.

Probable Case

The patient meets one of the epidemiologic criteria and has fever and vesicular-pustular rash with onset of the first sign or symptom less than 21 days after the last exposure meeting epidemiologic criteria; or if rash is present but type is not described, the patient demonstrates elevated levels of IgM antibodies reactive with orthopoxvirus between at least 7 and 56 days after the rash onset.

Confirmed Case

The patient meets one of the laboratory criteria.

Clinical Criteria

Rash (macular, papular, vesicular, pustular, generalized or localized, discrete or confluent)
Fever (subjective or measured, ≥37.4° C)
Other signs and symptoms (chills and/or sweats, headache, backache, lymphadenopathy, sore throat, cough, shortness of breath)

Epidemiologic Criteria

Exposure (includes living in a household, petting or handling, or visiting a pet holding facility such as a pet store or veterinary clinic) to an exotic or wild mammalian pet (including prairie dogs, Gambian giant rats, and rope squirrels, among others to be considered on a case-by-case basis) obtained on or after April 15, 2003, with clinical signs of illness (e.g., conjunctivitis, respiratory symptoms, and/or rash)
Exposure (as described earlier) to an exotic or wild mammalian pet (as described earlier) with or without clinical signs of illness that has been in contact with either a mammalian pet (living in a household or originating from the same pet holding facility as another animal with monkeypox) or a human
Exposure (skin-to-skin or face-to-face contact) to a suspect, probable, or confirmed human case

Laboratory Criteria

Isolation of monkeypox virus in culture
Demonstration of monkeypox virus DNA by PCR testing of a clinical specimen
Demonstration of virus morphologically consistent with an orthopoxvirus by electron microscopy in the absence of exposure to another orthopoxvirus
Demonstration of presence of orthopoxvirus in tissue using immunohistochemical testing methods in the absence of exposure to another orthopoxvirus

Exclusion Criteria

An alternative diagnosis can explain the illness.
OR
The case was reported on the basis of primary or secondary exposure to an exotic or wild mammalian pet (as described earlier) or a human subsequently determined not to have monkeypox, provided other possible epidemiologic exposure criteria are not present.
OR
A patient without a rash does not develop a rash within 10 days of onset of clinical symptoms consistent with monkeypox.
The case is determined to be negative for non-variola generic orthopoxvirus by PCR testing of a well-sampled rash lesion by the approved protocol.
The case is determined to have undetectable levels of IgM antibody 7 to 56 days after rash onset.

IgM, immunoglobulin M; PCR, polymerase chain reaction.

Available at http://www.cdc.gov/ncidod/monkeypox/casedefinition.htm; and from Centers for Disease Control and Prevention: Update: Multistate outbreak of monkeypox: Illinois, Indiana, Kansas, Missouri, Ohio, and Wisconsin—2003. M. M. W. R. Morb. Mortal. Wkly. Rep. 52:561-564, 2003.

vaccine for smallpox, Stittelaar and colleagues[96] described the use of a modified vaccinia virus strain, Ankara, that protected macaques against lethal respiratory challenge with monkeypox virus, as a possible candidate for safer vaccine against smallpox. This vaccine candidate, MVA-BN, is undergoing phase I and II clinical trials in humans.

As a potentially preventive measure, in the Midwest outbreak, 28 residents (26 adults and 2 children) of the outbreak area received smallpox vaccine to try to prevent further transmission of monkeypox.[20] No data exist on the usefulness of vaccinia immune globulin, but this treatment can be considered in severe cases of monkeypox and for prophylaxis in exposed persons who are severely immunocompromised.[35]

Although cidofovir has in vitro activity against the virus,[33] no data have shown its effectiveness for treating human monkeypox virus. The CDC recommends that cidofovir be considered in severe monkeypox virus infections and in immunocompromised hosts, although the drug should not be used for prophylaxis because of its significant toxicities.[22] Studies in mouse models of oral cidofovir are ongoing,[83,84] and they may show some promise. ST-246, a compound with activity against orthopoxviruses, has shown promise in treating severe monkeypox virus infection in ground squirrels and may one day be available for use in people.[89]

Among hospitalized patients, isolation precautions should include standard, droplet, and contact, as well as airborne, precautions because the virus probably is transmitted by direct contact or by large respiratory droplets.[23] Isolation can be discontinued for patients with vesiculopustular rash after all the lesions have crusted; however, contact with immunocompromised persons should be limited until all the crusts have separated. For patients without rash, isolation should be continued for 7 days after the onset of fever. Affected individuals should not donate any body fluids or organs while they are ill.[24] Asymptomatic contacts should remain under symptom surveillance for 21 days after the last exposure, and temperature should be monitored twice daily.

Bioterrorism Concerns

Concern over use of monkeypox as an agent of bioterrorism was raised, but no evidence suggests that human monkeypox becomes more severe or that the virus becomes more virulent or easily transmissible after one or more passages through human hosts.[61] Furthermore, evidence that monkeypox evolved independently from smallpox alleviated some fears that the virus could "evolve back" into smallpox. The consensus is that monkeypox does not represent a serious bioterrorist threat because of low rates of primary infection, limited transmissibility, and low case fatality.[5] Some concerns remain about the potential of molecular biologic techniques to manipulate the virus genetically into a more lethal form.[55,90]

COWPOX VIRUS

In Europe, a disease with ulcers on the teats of cows (cowpox disease) has been recognized for hundreds of years.[39] Milkers who milked cows that were infected often developed similar ulcers on their hands, and milkmaids who had contracted cowpox were known to be immune to smallpox. This observation led Edward Jenner, in May of 1796, to inoculate James Phipps, an 8-year-old boy, with cowpox material obtained from a lesion on a local dairy maid.[4,56-58] After experimental challenge with material from a smallpox lesion, smallpox did not develop in Phipps.

Studies conducted since the 1970s indicate that bovine cowpox is not a common illness and cows are not the natural reservoir of the virus in nature.[2,4,8] The virus is distributed geographically throughout Western Europe, and the reservoir hosts are wild rodents.

Baxby[2] reported 12 human illnesses caused by cowpox virus. Five of the patients were exposed to infected cows, and the other 7 had no direct contact with cattle. All the patients, however, lived in or had visited a rural area before experiencing the onset of illness. Of 10 patients in whom lesions were described, 6 had lesions on the hand only, 3 had lesions on the chin or face only, and a single patient had involvement of both the face and hand. Most patients had local edema, lymphadenitis, and fever. The lesions were confused with anthrax in two instances.

Twelve cases of cowpox causing cutaneous infection, one with lethal outcome, were reported from various European countries. Most of the cases resolved between 3 weeks to 6 months, although the authors reported a 7-year-old girl with persistent lymph node involvement 2 years after the initial presentation. Infection developed after exposure to ill cats in nine cases, to ill dogs in two cases, and to a wild rat in one case.[79] The lethal outcome occurred in an immunocompromised 18-year-old man, who was thought to have acquired the infection from a cat with a skin lesion on the anterior paw.[30] Schupp and others[90] reported a case of cowpox virus causing necrotic ulcers on a 12-year-old boy in Germany. The virus was detected by PCR, and probably was transmitted from the patient's cat.

VACCINIA VIRUS

Vaccinia virus is the live immunizing antigen successfully used in the global program to eradicate smallpox. This orthopoxvirus is different from cowpox virus, the agent that Jenner and others used for vaccination in the early 19th century. Vaccinia virus has been used for vaccination for more than 100 years. Restriction endonuclease studies indicated that strains of vaccinia virus from different parts of the world are similar to each other and distinctly different from cowpox virus.[39] The origin of vaccinia virus is unknown.[8] Four hypotheses regarding its origin are that (1) it evolved from variola virus through continual passage in the skin of cows or humans, (2) it evolved from cowpox virus through continual passage in the skin of animals, (3) it is a hybrid between cowpox virus and variola virus, and (4) it is a virus from an animal (the natural host) that is now extinct.

Vaccinia virus causes outbreaks of disease in buffaloes in India.[8,39] However, the animal infection is thought to have resulted originally from contact of buffaloes with vaccinated humans during smallpox eradication programs, rather than from the virus' being a primary buffalo pathogen. More recently, in several Brazilian provinces, skin lesions on dairy cows and their milkers that resemble cowpox were caused by a variety of vaccinia virus strains belonging to two groups of vaccinia virus. All these cases were thought to have derived from repeated introduction of vaccinia virus during the 18th and 19th centuries.[98]

Because of the original success of the smallpox eradication program, routine vaccinia vaccination in the United States was discontinued in 1971.[10,15] In 1976, the recommendation for routine vaccination of health care workers also was discontinued.[11] In 1982, the only active licensed producer of vaccinia vaccine in the United States ceased production for general use, and distribution to civilian populations was discontinued in 1983.[14]

For several years, all military personnel continued to be vaccinated routinely. Although more recently only selected groups of military personnel were vaccinated against smallpox, with the initiation of action in Iraq and the concurrent threat of biologic warfare, all troops designated for military action in that area were

given smallpox vaccinations. Since January of 1982, smallpox vaccination has not been required for international travelers, and International Certificates of Vaccination no longer include smallpox vaccination.[107]

In 1980, the Advisory Committee on Immunization Practices (ACIP) recommended the use of vaccinia vaccine to protect laboratory workers from possible infection while working with nonvariola orthopoxviruses (e.g., vaccinia, monkeypox).[12] In 1984, these recommendations were included in guidelines for biosafety in microbiologic and biomedical laboratories.[99] These guidelines expanded the recommendation to include persons working in animal care areas where studies with orthopoxviruses were being conducted and recommended that these workers have documented evidence of satisfactory smallpox vaccination within the preceding 3 years. The CDC has provided vaccinia vaccine for these laboratory workers since 1983.[13] Because studies of recombinant vaccinia virus vaccines have advanced to the stage of clinical trials, health care workers (e.g., physicians, nurses) and veterinarians now may be exposed to vaccinia and recombinant vaccinia viruses and should be considered for vaccinia vaccination.[43,48]

Recombinant Vaccinia Virus

Vaccinia virus is the prototype of the genus *Orthopoxvirus*. It is a double-stranded DNA virus that has a broad host range under experimental conditions and rarely is isolated from animals outside the laboratory.[8,31,39,41,46,108] Many strains of vaccinia virus exist and have different levels of virulence for humans and animals. For example, the Temple of Heaven and Copenhagen vaccinia strains are highly pathogenic in animals, whereas the NYCBOH strain, from which the Wyeth vaccine was derived, has relatively low pathogenicity.[40]

Vaccinia virus can be engineered genetically to contain and express foreign DNA without impairing the ability of the virus to replicate. Such foreign DNA can encode protein antigens that induce protection against one or more infectious agents. Recombinant vaccinia viruses have been engineered to express the immunizing antigens of many viruses, bacteria, parasites, and tumors of veterinary and medical importance.[29,43,48,53,66,92,93,106]

Recombinant vaccinia viruses have been created from several strains of vaccinia virus. In the United States, recombinant viruses have been made from the NYCBOH strain or a mouse neuroadapted derivative, the WR strain. Some recombinant viruses have been made from the Copenhagen and Lister vaccinia strains, which are more pathogenic in animals than the NYCBOH strain is. More recently, studies using recombinant vaccinia to vaccinate against prostate cancer, malaria, tuberculosis, and HIV have used the vaccinia virus Ankara strain.[3,54,82] Animal studies generally suggest that recombinant viruses may be no more pathogenic than the parent strain of vaccinia virus is. However, no consistently reliable laboratory marker or animal test predicts the attenuation of vaccinia virus or a particular recombinant virus for humans.[85] Laboratory-acquired infections with vaccinia or recombinant viruses have been reported.[64,81,91] However, because no surveillance system has been established to monitor laboratory workers, the risk of acquiring infection in persons who handle virus cultures or materials contaminated with these viruses is not known.

With the initiation of human and veterinary trials of recombinant vaccines, physicians, nurses, veterinarians, and other personnel who are exposed to recipients of these vaccines could be exposed to both vaccinia and recombinant agents. This exposure could occur from contact with dressings contaminated with the virus or through exposure to the vaccine. The risk of transmission of recombinant viruses to exposed health care workers is unknown. To date, no reports of transmission to health care personnel from vaccine recipients have been published. If appropriate infection control precautions are observed, health care workers probably are at less risk of acquiring infection than are laboratory workers because of the smaller volume and lower titer of virus in clinical specimens than in laboratory material.[45,105] However, because of the potential for transmission of vaccinia or recombinant vaccinia viruses to such persons, the ACIP suggested that health care personnel who have direct contact with contaminated dressings or other infectious material from volunteers in clinical studies be considered for vaccination. Laboratory and other health care personnel who work with viral cultures or other infective material always should observe appropriate biosafety guidelines and should adhere to published infection control procedures.[45,100,105]

ORF VIRUS

Orf virus is a member of the genus *Parapoxvirus* (see Table 64–1 in Chapter 64). Infection with orf virus causes the disease by the same name (orf), which also is called *ecthyma contagiosum*.[39] The reservoir hosts of orf virus are sheep and goats, and the virus has worldwide distribution. Orf is an occupationally acquired disease, and most cases occur in adults.[44,68] Human disease is characterized by single or multiple lesions that most often are located on the hands. The lesions last approximately 35 to 40 days and progress through six stages[68]: maculopapular, 1 to 7 days; target, 7 to 14 days; acute, 14 to 21 days; regenerative, 21 to 28 days; papillomatous, 28 to 35 days; and regressive, 35 to 40 or more days. Patients may have low-grade fever, but regional lymphadenitis is an uncommon finding. Two patients with a widespread papulovesicular eruption, fever, malaise, and lymphadenopathy were described.[104] In addition, a giant orf granuloma developed at the site of a rope burn in a 12-year-old boy who lived on a farm.[80]

The CDC reported four unrelated cases of cutaneous, self-resolving orf virus infections in people exposed to sheep or goats that had either been vaccinated recently with live orf virus vaccine or exposed to animals with oral lesions. These cases occurred in New York, Illinois, California, and Tennessee. Patients' ages ranged from 11 to 51 years.[25] Uzel and colleagues[101] reported nine cases of orf virus infection in Turkey related to feasts of sacrifice. These cases occurred in adults involved in sacrifice or preparation of the animals for consumption.

Until recently, diagnosis of orf virus depended on electron microscopy or serology. In 2001, Torfason and Guonadottir[97] described a method of PCR to detect orf virus that helped to make identification of the virus more accessible.[78]

Orf virus has been shown to have antiviral activity against hepatitis B and herpes simplex virus in mice. By modulating the host innate immune system inducing phagocytosis, natural killer cell activity and release of interferon-α, tumor necrosis factor-α, interleukin-2, and granulocyte-macrophage colony-stimulating factor, it appears that orf virus protects mice from lethal herpes simplex virus type 1 infection, as well as guinea pigs from recurrent genital herpes disease. This finding may have implications for immune therapy for patients suffering serious infection from these viruses.[103] Treatment with imiquimod of complicated cases in immunocompetent hosts[38] and in immunocompromised patients has been reported.[69]

OTHER PARAPOXVIRUSES

Human infections with pseudocowpox virus and bovine papular stomatitis virus are, like orf, occupational diseases. Pseudocowpox infections occur on the hands of milkers, and infections with

bovine papular stomatitis virus become evident on the hands of veterinarians and others with close contact.[9,39,73] The lesions of milker's nodule are relatively painless, but they may be pruritic; they are red initially and then become purple. They are firm, do not ulcerate, and last 4 to 6 weeks. The lesions caused by bovine papular stomatitis virus are wartlike and last 3 to 4 weeks.

Humans also have been infected with the parapoxviruses of camels and seals.[87] One report noted human infection with sealpox virus resulting in an orflike lesion that resolved after biopsy specimens were obtained.[28]

YATAPOXVIRUSES

Tanapox virus, yaba-like disease virus (YLDV), and yaba monkey tumor virus (YMTV) are three monkey viruses that can cause human infection.[32,36,37,39,59] Tanapox in humans first was observed along the Tana River in Kenya in 1957, and outbreaks also were studied in the Democratic Republic of Congo.[39] DNA maps of tanapox virus and YLDV are extremely similar, a finding indicating that they may be the same agent. YMTV was isolated from tumors in monkeys in Nigeria. This virus has caused illness in animal handlers in centers for primates in the United States, but human infections have not been identified in the field in Africa.

Outbreaks of tanapox in Africa have involved both children and adults.[59] The illness associated with tanapox and YLDV starts with fever, headache, backache, and mild prostration. Skin lesions occur 2 to 4 days after the onset of illness. Individual lesions start with itching, followed by the development of a pocklike lesion. At 7 days, the lesion is approximately 10 mm in diameter with surrounding erythema. Lymphadenitis is both local and regional.

The lesions ulcerate during the second week of illness and last approximately 6 weeks. Most patients have a single lesion, but some have 2 to 10 lesions. The prognosis usually is good, although secondary bacterial infection can occur. YMTV produces epidermal histiocytomas, tumor-like masses of histiocytic polygonal mononuclear cell infiltrates that may advance to suppurative inflammation.[32]

Two cases of tanapox have been reported in the United States. A 51-year-old man developed papular lesions with general malaise after visiting Tanzania and being exposed to a cat.[95] A second case occurred in a 21-year-old female student from New Hampshire, who developed fever, headaches, malaise, and several papules after being exposed to chimpanzees in the Democratic Republic of Congo.[34] The symptoms of both patients were diagnosed using PCR techniques and resolved spontaneously. With increasing international travel, more case reports of such poxvirus illnesses may surface. PCR techniques to diagnose such infections quickly have been developed,[34,95,109] and these methods will assist in rapid diagnosis of poxvirus illnesses that may be confused with more serious illnesses as smallpox and monkeypox.

MOLLUSCUM CONTAGIOSUM VIRUS

In contrast to the other poxviruses discussed in this chapter, which are zoonotic agents, molluscum contagiosum virus is a human virus that is a common cause of human skin lesions[39] (see Chapter 67 and Table 64–1 in Chapter 64). The virus has not been grown in cell culture as yet, and it does not cause infection in experimental animals.

Although the virus has not been cultivated in the laboratory, large amounts of virus can be extracted from human lesions. Analysis of viral DNA from lesions in patients from different parts of the world indicates that two major subtypes and a third, rare subtype exist. The clinical aspects of molluscum contagiosum virus infection are presented in Chapter 67.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Because all but two viruses presented in this chapter are zoonotic agents, careful attention must be given to geographic location and animal exposure. All these diseases are characterized by local lesions, so virus is readily available for direct identification and culture. All poxviruses can be identified by examination of material from lesions by electron microscopy and by PCR. All viruses except molluscum contagiosum virus grow in one or more tissue culture systems, the chorioallantoic membrane of embryonated eggs, or both. Unusual agents should be referred to specific reference laboratories for species identification.

CHAPTER 177

MIMIVIRUSES

Ramya Ramraj

In 1992, while investigating the source of an outbreak of community-acquired pneumonia in northern England, investigators discovered a bizarre microorganism.[5,6] The microorganism, resembling a small gram-positive coccus, was found inside a free-living ameba in a water cooling tower. Researchers initially thought it was a bacterium, but subsequent analysis demonstrated a double-stranded DNA virus. Originally named *Mimivirus* because it resembled bacteria in Gram-stained smears, it now is designated officially as *Acanthamoeba polyphaga Mimivirus*.[7]

STRUCTURE AND PROPERTIES

A. polyphaga Mimivirus is a giant, double-stranded, icosahedral DNA virus.[18] With a diameter of approximately 650 nm, *Mimivirus* is the largest virus known to date. Morphologically, *Mimivirus* resembles nucleocytoplasmic large DNA viruses (NCLDVs) such as the *Iridovirus*, *Asfarvirus*, and *Phycodnavirus*.[3,17] However, evolutionary dissimilarities define a new family, the *Mimiviridae*.[5] The *Mimivirus* comprises a central dense core that is surrounded by two lipid membrane layers inside a capsid protein shell covered by fibrils. The 1.2-Mb genome sequence[10,12] is complex and possesses genes that are shared by the NCLDV families, as well as several that have not been identified previously in viruses. The origins and the various processes[1] involved in shaping gene content of the *Mimivirus* are not entirely clear at this time.[10,15]

VIRAL REPLICATION

In *A. polyphaga*, the replication cycle of the *Mimivirus* starts with entry of the virus by phagocytosis, followed by a 4-hour eclipse phase inside the nucleus,[5] then the formation of "virus factories"(VF) in the cytoplasmic space,[16] and ending with cell lysis and virus release 24 hours after infection (Fig. 177–1). The VF,[11] where virus replication and assembly occur, is the major site of production of *Mimivirus* DNA and induces profound alteration of the infected cell structure, such as by recruitment of organelles and organization of cellular compartments. Very specific mechanisms and complex interactions between viral and cellular factors that are not entirely clear at this time must be involved to build this remarkably large and efficient VF, which can generate this sophisticated microorganism rapidly.[16]

ANIMAL SUSCEPTIBILITY

An experimental model of infection[4] was developed to establish a possible role of *Mimivirus* as a human pathogen. Autopsy specimens of laboratory mice that were inoculated intracardially with infecting units of *Mimivirus* revealed histopathologic evidence of pneumonia and were re-isolated from samples from the lung. Inoculation of human macrophages with *Mimiviruses* showed evidence of infection, although no evidence of a lytic cycle was observed.[13] Efforts to induce infection in other cell lines were futile, and the target cell in mice remains to be identified.

MIMIVIRUS INFECTION IN HUMANS

In December 2004, a laboratory technician in France[14] developed subacute pneumonia with dry cough, fever, and chest pain. This technician was in charge of performing *Mimivirus* serologic testing and Western blot analysis and thus had handled relatively large amounts of *Mimivirus* antigens. Radiography of his chest revealed bilateral basilar infiltrates (Fig. 177–2). The illness did not respond to amoxicillin-clavulanate treatment prescribed on day 15 after the onset of symptoms, but after an additional 2

PloS ONE 2:e328, 2007.)*

Figure 177–2 Chest radiograph of a laboratory technician who was infected with *Mimivirus*, with bilateral basilar infiltrates evident. *(From Raoult, D., La Scola, B., Birtles, R., et al.: The discovery and characterization of Mimivirus, the largest known virus and putative pneumonia agent. Clin. Infect. Dis. 45:95-102, 2007.)*

weeks, the illness resolved, and the technician made a full recovery. Serum samples screened against pneumonia agents showed seroconversion (<1 : 50 to 1 : 3200) only for *Mimivirus*, which was confirmed by testing using two-dimensional Western blotting against 23 identified proteins of *Mimivirus*.

PREVALENCE OF ANTIBODIES TO *MIMIVIRUS* IN PATIENTS WITH PNEUMONIA

Three studies investigated the prevalence of antibodies to *Mimivirus* in specific human populations.[13] The first study tested serum samples obtained from 376 Canadian patients with community-acquired pneumonia and from 511 healthy subjects. A total of 9.66 percent of patients with pneumonia had antibodies to *Mimivirus*, compared with 2.3 percent of control subjects.[9] Patients with pneumonia who had antibodies to *Mimivirus* were more likely to be hospitalized from a nursing home and to be rehospitalized after discharge.[8] The second study included 26 patients from Marseille, France, who acquired pneumonia while in an intensive care unit, and 50 control serum samples (from blood donors). Antibodies to *Mimivirus* were detected in samples obtained from 5 patients but in none of the control samples.[8] The third serosurvey involved 157 patients in intensive care units who had pneumonia. Serum specimens obtained from these patients were tested against a panel of antigens from "conventional" pneumonia agents, as well as ameba-associated microorganisms, including *Mimivirus*.[2] Evidence of infection with "conventional" pathogens was found in 28 cases and with ameba-associated pathogens in 18 cases. In the group infected by ameba-associated pathogens, more patients had seroconversion to *Mimivirus* than to any other pathogen (5 cases), and seroconversion was more common among patients with ventilator-associated pneumonia than among those with community-acquired pneumonia (31.6% and 10.5% of patients, respectively). Taken

together, these three studies reveal a significant rate of seroconversion in patients with either community-acquired pneumonia (especially among patients who have been hospitalized from a nursing home) or nosocomial pneumonia.[13]

DIAGNOSTIC METHODS

Diagnostic strategies include collection of bronchoalveolar lavage (BAL) fluid and serologic samples. *Mimivirus* can be cultivated by co-culture with ameba or DNA extracted (QIAMP tissue kit, Qiagen, Hilden, Germany) from BAL samples for polymerase chain reaction (PCR) assay for enhanced detection.[2] Serologic testing includes immunofluorescence assay of samples of acute-phase and convalescent-phase serum for antibodies to proteins specific for *Mimivirus* (Becton Dickinson, Rutherford, NJ).[2] Strong evidence of infection includes positive BAL culture, positive PCR assays, or a fourfold increase in antibody titer between acute-phase and convalescent-phase serum samples or significant seroconversion for *Mimivirus*.[2]

MIMIVIRUS AS AN EMERGING PATHOGEN

Evidence indicates that *Mimivirus* is a new human pathogen that causes pneumonia. However, *Mimivirus* does not replicate efficiently in co-culture with any of the mammalian cells tested to date, and serologic cross-reactions among pathogens are observed commonly. Isolates of the virus from patients with pneumonia have not been obtained.[13] Prevalence data on infection with children with *Mimivirus* are unavailable as of this publication date.

RNA VIRUSES

SUBSECTION 1

Picornaviridae

CHAPTER 178

ENTEROVIRUSES AND PARECHOVIRUSES

James D. Cherry ✪ Paul Krogstad

Enteroviruses (EVs) and parechoviruses comprise two genera of the family *Picornaviridae*. These small RNA viruses are responsible for frequent and often significant human illnesses with protean manifestations.* To bring order to the growing list of poliovirus-like agents, coxsackieviruses, echoviruses, and polioviruses first were categorized together and named in 1957 by a committee sponsored by the National Foundation for Infantile Paralysis.[666] These viruses were grouped together because of similarities in their biophysical properties, shared features in their epidemiology and pathogenesis, and the many disease syndromes that they caused. The human alimentary tract was thought to be the natural habitat of these agents, and the term *enterovirus* was coined. Newer agents later assigned to the genus *Enterovirus* were simply numbered sequentially, and more than 100 distinct human EV (HEV) types now are recognized. The two viruses originally classified as echoviruses 22 and 23 were reclassified into a new

*See references 166, 168, 169, 233, 378, 525, 604, 658, 662, 864, 991-995.

genus *(Parechovirus)* within the *Picornaviridae* family because of features of their structure and replication that distinguish them from the EVs.[893]

HISTORY

Poliomyelitis, the first enteroviral disease to be recognized and the most important one, has a long history.[761] The earliest record is an Egyptian stele of the 18th dynasty (1403 BCE to 1365 CE), which shows a young man with a withered, shortened leg, the characteristic deformity of paralytic poliomyelitis.[431,659] Michael Underwood,[949] a London pediatrician, published the first medical description in 1789 in *A Treatise on Diseases of Children.* During the 19th century, many reports appeared in Europe and the United States describing small clusters of cases of "infantile paralysis." The authors were puzzled about the nature of the affliction; not until the 1860s and 1870s was the spinal cord firmly established as the seat of the pathologic process. The contagious nature of poliomyelitis was not appreciated until the late 19th century. Medin, a Swedish pediatrician, was the first to describe the epidemic nature of poliomyelitis (1890), and his pupil Wickman worked out the basic principles of the epidemiology.[998]

The virus was isolated first in monkeys by Landsteiner and Popper[567] in 1908. The availability of a laboratory animal assay system opened many avenues of research that in the ensuing decades led to the demonstration that an unrecognized intestinal infection was the usual manifestation and the paralytic disease was a relatively uncommon event.

Coxsackieviruses and echoviruses have had a shorter history. Epidemic pleurodynia was described clinically in 1735 by Hannaeus[392] more than 200 years before the coxsackieviral origin of this disease was discovered. In 1948, Dalldorf and Sickles[234] first reported the isolation of a coxsackievirus after inoculation of suckling mice.

In 1949, Enders and associates[276] described the growth of poliovirus 2 in tissue culture, and their techniques paved the way for recovery of a large number of other cytopathic viruses. Most of these "new" viruses failed to produce illness in laboratory animals. Because the relationships of many of these newly recovered agents with human disease were unknown, these agents were called *orphan viruses*.[658] Later, several agents were grouped together and were called *e*nteric *c*ytopathogenic *h*uman *o*rphan viruses, or echoviruses.

Live-attenuated poliovirus vaccines became available in the early 1960s, and the most notable advance since the late 1980s has been a dramatic reduction in worldwide poliomyelitis as a result of the global immunization initiative.[207,450,752,924] The last case of confirmed paralytic poliomyelitis in the Western Hemisphere caused by a wild-type virus strain occurred in 1991.[812]

THE VIRUSES

CLASSIFICATION[293,457,662-665,751,789,833,894]

EVs and parechoviruses are RNA viruses belonging to the family *Picornaviridae* (*pico*, "small"). These viruses are grouped together because they share certain physical, biochemical, and molecular properties. In electron micrographs, the viruses are seen as 30-nm particles that consist of naked (nonenveloped) protein capsids, constituting approximately 70 to 75 percent of the mass of particles, and dense central cores (nucleoid) of the genomic RNA.

The original classification of HEVs is shown in Table 178–1. The EVs originally were distributed into four groups based on their different effects in tissue culture and pattern of disease in experimentally infected animals: polioviruses (causal agents of poliomyelitis in humans and nonhuman primates), coxsackieviruses A (associated with herpangina, human central nervous system [CNS] disease, and flaccid paralysis in suckling mice), coxsackieviruses B (human CNS and cardiac disease, spastic paralysis in mice), and the echoviruses (nonpathogenic in mice and not linked to human disease at first).

Although this scheme was useful initially, many strains were isolated subsequently that do not conform to such rigid specificities. For example, several coxsackievirus A strains replicate and have a cytopathic effect in monkey kidney tissue cultures, and some echovirus strains cause paralysis in mice. For this reason, and to simplify the nomenclature, EVs subsequently were assigned sequential numbers. Following this convention, the prototype EV strains Fermon, Toluca-1, J 670/71, and BrCr (identified between 1959 and 1973) were designated EV 68 through EV 71, respectively. Additional EVs continued to be identified that could not be using antisera specific for the classic serotypes. More than 30 additional such EV types have been assigned provisionally, although many have not been linked to human disease.

Complicating matters somewhat, studies of echoviruses 22 and 23 found that these agents exhibited genomic and proteomic differences from other EVs, and hence they were reclassified in the new genus *Parechovirus* as parechovirus types 1 and 2.[789,893,895] Similarly, hepatitis A virus initially was assigned the designation EV 72, but it was reclassified as the sole member of the hepatovirus genus within the picornavirus family because of marked genetic and biologic distinctions from the EVs.

TABLE 178–1 Original Classification of Human Enteroviruses: Animal and Tissue Culture Spectrum*

Virus	Antigenic Types†	Cytopathic Effect		Illness and Pathology	
		Monkey Kidney Tissue Culture	Human Tissue Culture	Suckling Mouse	Monkey
Polioviruses	1-3	+	+	−	+
Coxsackieviruses A	1-24‡	−	−	+	−
Coxsackieviruses B	1-6	+	+	+	−
Echoviruses	1-34§	+	±	−	−

**Many enteroviral strains have been isolated that do not conform to these categories, leading to the revised classification scheme shown in Table 178–2.*
†New types, beginning with type 68, were assigned enterovirus type numbers instead of coxsackievirus or echovirus numbers. Types 68 through 71 were identified.
‡Type 23 was found to be the same as echovirus 9.
§Echovirus 10 was reclassified as a reovirus: echoviruses 22 and 23 were made the first members of the Parechovirus genus of Picornaviridae, and echovirus 28 was reclassified as a Rhinovirus.
+, present; −, absent; ±, variably present.
Modified from Cherry, J. D.: Enteroviruses. In *Remington, J. S., and Klein, J. O. (eds.): Infectious Diseases of the Fetus and Newborn Infant. 3rd ed. Philadelphia, W. B. Saunders, 1990, pp. 325-366.*

More recently, genetic, biologic, and molecular properties were used to revise picornavirus taxonomy and led to a reorganization of the HEVs into five groups: the polioviruses and four alphabetically designated HEV species (HEV-A, B, C, and D) (Table 178–2). Determining the nucleotide sequence encoding the viral VP1 capsid protein plays a major role in the approach to taxonomy and predictably identifies viruses originally classified by serologic means, thus leading to the term *molecular serotyping*.[734,735,778,785] This approach will, no doubt, dominate future phylogenetic studies. Additional reclassification of the EVs is likely. For example, some researchers proposed that the polioviruses be included as members of the HEV-C species because the three polioviruses appear not to have any poliovirus-specific nucleotides, amino acid sequence, or motif that allows them to be distinguished from current HEV-C members.[101] The application of molecular phylogenetic approaches also revealed that recombination between circulating EVs is a frequent event and is likely to increase their genetic diversity.[148,181,611-613,736,739,882] This propensity for recombination has played a role in more recent outbreaks of paralytic diseases involving vaccine-derived stains.[522]

MORPHOLOGY AND REPLICATION

The genome of EVs and parechoviruses is a single-stranded, positive-sense RNA molecule approximately 7.4 kb in length.[780] It consists of a 5′ noncoding region followed by a single long open-reading frame, a short 3′ noncoding region, and a polyA tail. The 5′ noncoding region contains an internal ribosome entry site, which is essential for the initiation of translation. The 3′ noncoding region folds into highly conserved secondary and tertiary structures that are thought to play a role in the initiation of the replication of the viral genome. This genome is packaged into naked capsids that exhibit icosahedral symmetry with 20 triangular faces and 12 vertices

TABLE 178–2 Genomic Classification of Enteroviruses

Species Designation	Original Enterovirus
Poliovirus	Poliovirus types 1-3
Human enterovirus A (HEV-A)	Coxsackievirus A types 2-8, 10, 12, 14, 16 Enterovirus types 71, 76, 89, 90, 91, 92
Human enterovirus B (HEV-B)	Coxsackievirus A9 Coxsackievirus B types 1-6 Echovirus types 1-9, 11-21, 24-27, 29-33 Enterovirus types 69, 73-75, 77-88, 93, 97, 98, 100, 101
Human enterovirus C (HEV-C)	Coxsackievirus A types 1, 11, 13, 17, 19, 20-22, 24 Enterovirus types 95, 96, 99, 102
Human enterovirus D (HEV-D)	Enterovirus types 68, 70, 94

Coxsackievirus (CV) A15 has been reclassified as a strain of CV A11, and CV A18 as a strain of CVA13.

From Fauquet, C. M., Mayo, M. A., Maniloff, J., et al. (eds.): Virus Taxonomy: VIIIth Report of the International Committee on Taxonomy of Viruses. London, Elsevier Academic Press, 2005.

Replication of EVs begins with the adsorption of virions to cell surface receptors, which, for the most part, are integrins or immunoglobulin-like proteins (Table 178–3). The virions penetrate the surface of cell and uncoat, and the viral genome functions as messenger RNA for the viral polyprotein. This polypeptide contains three domains, P1 to P3, which are cleaved into three to four proteins each. The P1 region is liberated from the polyprotein by the viral 2A protein, a chymotrypsin-like protease. P1 initially is split into three proteins, VP0, VP1, and VP3, by the viral 3C protease. VP0 then is processed further into two smaller proteins, VP4 and VP2. Portions of VP1, VP2, and VP3 are exposed at the surface of the virion, whereas VP4 is entirely internal. VP1, VP2, and VP3 have no sequence homology but share the same topology.[789] Specifically, they form an eight-stranded antiparallel β-barrel that is wedge shaped and is composed of two antiparallel β-sheets. The amino acid sequences in the loops that connect the β-strands and the N- and C-terminal sequences that extend from the β-barrel domain of VP1, VP2, and VP3 give each EV its distinct antigenicity. In contrast to the EVs, the parechovirus 2A protein does not function as a protease; viral capsids are composed of three proteins: VP2, VP3, and an uncleaved VP0 protein. Whereas parechoviruses appear structurally similar to other picornaviruses in electron micrographs, the structural arrangement of the three capsid proteins has not been established.

The replication of EVs typically occurs in the cytoplasm in membrane-associated replication complexes and is completed rapidly (5 to 10 hours). Studies of polioviruses and coxsackieviruses have shown that enteroviral replication is associated with disruption of cellular protein secretion, and host-cell protein synthesis is suppressed because of cleavage of eIF4G (human eukaryotic translation initiation factor 4G) by the enteroviral 2A protein. The coxsackievirus 2A protein also cleaves dystrophin, a cytoskeletal protein; this activity has been hypothesized to play a role in damage to the myocardium.[43,250]

The parechoviruses replicate in a similar fashion.[553] Integrins ($\alpha_v\beta_3$ and perhaps $\alpha_v\beta_{1)}$ are used as receptors, and replication occurs in cytoplasmic structures. However, as noted earlier, the P1 portion of the viral polyprotein is processed into only three capsid proteins, and only one protease has been identified in the parechoviruses. In addition, parechovirus replication occurs in small, discrete foci in the cytoplasm, rather than in large accumulations of membranous vesicles like the EVs. Moreover, transcription and translation do not appear to be disrupted by the parechoviruses, thus perhaps explaining their relatively mild and delayed cytopathic effect when they are grown in tissue culture.[893]

TABLE 178–3 Cellular Receptors and Cofactors for Infection of Representative Enteroviruses

Virus	HEV Species	Receptor	Cofactor for Infection*
Polioviruses 1-3	Poliovirus	CD155; Pvr	
Coxsackieviruses B1-6	HEV-B	CAR	Coxsackieviruses 1, 3, 5 may use CD55 (DAF)
Coxsackievirus A9 Echovirus 9	HEV-B	$\alpha_v\beta_3$ integrin (vitronectin receptor)	MAP-70
Echoviruses 1, 8	HEV-B	VLA-2 ($\alpha_2\beta_1$ integrin)	Heparan sulfate
Coxsackieviruses A13, 17, 20, 21, 24	HEV-C	ICAM-1	
Enterovirus 70	HEV-D	CD55 (DAF)	

**The cofactors generally facilitate adhesion to cells, but their sole expression is insufficient to permit infection to occur.*

CAR, coxsackie and adenovirus receptor; DAF, decay accelerating factor; HEV, human enterovirus; ICAM 1, intercellular adhesion molecule 1; MAP-70, microtubule-associated protein 70; Pvr, poliovirus receptor; VLA-2, a human integrin.

REPLICATION CHARACTERISTICS AND HOST SYSTEMS[662,664,751,819]

EVs and parechoviruses are relatively stable viruses in that they retain activity for several days at room temperature and can be stored indefinitely at ordinary freezer temperatures (–20° C). They are inactivated quickly by heat (>56° C), formaldehyde, chlorination, and ultraviolet light, but they are refractory to ether, ethanol, and isopropanol.

Enteroviral strains grow rapidly when adapted to susceptible host systems and cause cytopathologic features in 2 to 7 days. The typical tissue culture cytopathic effect is shown in Figure 178–1; characteristic pathologic findings in mice are shown in Figures 178–2 and 178–3. Final titers of virus recovered in the laboratory vary markedly among different viral strains and the host system used; typically, concentrations of 10^3 to 10^7 infectious doses per 0.1 mL of tissue culture fluid or tissue homogenate are obtained. Unadapted viral strains frequently require long periods of incubation. In both tissue culture and suckling mice, evidence of growth usually is visible. Blind passage occasionally is necessary for the cytopathologic features to become apparent.

Although many different primary and secondary tissue culture systems support the growth of various EVs, primary rhesus monkey kidney cultures generally are accepted to have the most inclusive spectrum.[105] Other simian kidney tissue cultures, however, also have the same broad spectrum. Tissue cultures of human origin have a more limited spectrum, but several echovirus types have shown more consistent primary isolation in human than in monkey kidney culture. A satisfactory system for the primary recovery of EVs from clinical specimens would include the following: primary rhesus, cynomolgus, or African green monkey kidney; a diploid, human embryonic lung fibroblast cell strain; rhabdomyosarcoma cell line tissue cultures; and intraperitoneal and intracerebral inoculation of suckling mice younger than 24 hours.[62,399,412,662,664,819]

ANTIGENIC CHARACTERISTICS

Although some minor cross-reactions exist among several coxsackievirus and echovirus types, common group antigens of diagnostic importance have not been defined well.[659,661,662,664,751] Heat treatment of virions and the use of synthetic peptides have produced antigens with broad enteroviral reactivity.[926,927] These antigens have been used in enzyme-linked immunosorbent assay (ELISA) and complement-fixation (CF) tests to determine immunoglobulin G (IgG) and IgM enteroviral antibodies and for antigen detection. In one study, Terletskaia-Ladwig and colleagues[927] reported the identification of patients infected with EVs by the use of an IgM enzyme immunoassay (EIA). This test used heat-treated coxsackievirus B5 and echovirus 9 as antigens, and it identified patients infected with echoviruses 4, 11, and 30. The sensitivity of the test was 35 percent. In another study involving heat-treated virus or synthetic peptides, the respective sensitivities were 67 and 62 percent.[926] However, both tests lacked specificity. Intratypic strain differences are common findings, and some strains (prime strains) are neutralized poorly by antisera to prototype viruses. In animals, these prime strains induce antibodies that neutralize the specific prototype viruses, however.

The identification of polioviral, coxsackieviral, and echoviral types by neutralization in suckling mice or tissue culture with antiserum pools is relatively well defined. Neutralization is induced by the epitopes on structural proteins VP1, VP2, and VP3; in particular, several epitopes are clustered on VP1. Prime strains do cause diagnostic difficulty because frequently they are not neutralized by the reference antisera, a particular problem with echoviruses 4, 9, and 11 and EV 71. If these types are suspected, in some instances this problem can be overcome by using antisera in less diluted concentrations or antisera prepared against several different strains of problem viruses. Kubo and associates[555] were able to type enteroviral isolates not identified through

neutralization by nucleotide sequence analysis of the VP4 gene. They specifically identified prime strains of echovirus 18 and EV 71. Sequence analysis of the VP1 gene also is useful for typing enteroviral prime strains not identified by neutralization.[729]

HOST RANGE

Humans are the only natural hosts of polioviruses, coxsackieviruses, and echoviruses.[233,339,525,658,718,864,992,994] However, EVs have been recovered in nature from sewage, flies, swine, dogs, a calf, a budgerigar, a fox, mussels, and oysters.[168] In addition, serologic evidence of infection with EVs similar to human strains has been noted in chimpanzees, cattle, rabbits, a fox, a chipmunk, and a marmot.[168] Infection of these animals probably resulted from direct contact with an infected human or human excreta. Eighteen genetically distinct EVs have been isolated from nonhuman primates.[779] Of 10 of these strains, 7 were related closely genetically to HEVs, whereas the other 3 were related only distantly. Contamination of shellfish also is interesting because in addition to their possible role in human infection, shellfish offer a source of enteroviral storage during periods of cold weather.[168] Contaminated food is another possible source of human infection.[168]

EPIDEMIOLOGY

TRANSMISSION

The spread of HEVs and parechoviruses is from person to person by the fecal-oral and possibly the oral-oral (respiratory spread) route. Swimming and wading pools may serve as a means of spread of EVs during the summer.[518] Oral-oral transmission by way of the contaminated hands of health care personnel and transmission by fomites were documented in a chronic care pediatric ward.[482] EVs have been recovered from trapped flies, and such carriage probably contributes to the spread of human infection, particularly in lower socioeconomic populations with poor sanitary facilities.[168]

Children are the main susceptible cohort; they are immunologically susceptible, and their unhygienic habits facilitate the spread of infection. Spread is from child to child (from feces to skin to mouth) and then within family groups. Recovery of EVs is related inversely to age, but the prevalence of specific antibodies is related directly to age. The incidence of infection and the prevalence of antibodies do not differ between boys and girls.

GEOGRAPHIC DISTRIBUTION AND SEASON

EVs and parechoviruses have worldwide distribution.[168,304,339] Neutralizing antibodies for specific viral types have been noted in serologic surveys throughout the world, and most strains have been recovered in global isolation studies. In any given area, frequent fluctuations occur in predominant types. Epidemics probably depend on newly susceptible individuals in the population rather than on re-infection. Epidemics may be localized and sporadic, and they may vary in origin from place to place in the same year. Pandemic waves of infection also occur.

In temperate climates, enteroviral infections occur primarily in the summer and fall, but in the tropics, they are prevalent all year.[168,339,661] A basic concept in understanding the epidemiology of these illnesses concerns the far greater frequency of unrecognized infection than clinical disease, as illustrated by poliomyelitis, which remained an epidemiologic mystery until researchers appreciated that unrecognized infections were the main source of contagion. Serologic surveys were instrumental in elucidating the problem: in populations living in conditions of poor sanitation and hygiene, epidemics did not occur, but wide dissemination of polioviruses was confirmed by demonstrating the presence of specific antibodies to all three types in almost 100 percent of children by the time they reached 5 years of age.

Epidemics of poliomyelitis first began to appear in Europe and the United States during the latter part of the 19th century; they continued with increasing frequency in economically advanced countries until the introduction of effective vaccines in the 1950s and 1960s.[88,198,431,761] The evolution from endemic to epidemic follows a characteristic pattern beginning with collections of a few cases, then endemic rates that are higher than usual, followed by severe epidemics with high attack rates. The age group attacked in endemic areas and in early epidemics is the youngest; more than 90 percent of paralytic cases begin in children younger than 5 years of age. Once this pattern of epidemicity begins, it is irreversible unless preventive vaccination is performed.

As epidemics recur over a period of years, a shift in age incidence occurs whereby relatively fewer cases are seen in the youngest children; the peak often is in the 5- to 14-year-old group, and increasing percentages of cases develop in young adults. These changes are correlated with socioeconomic factors and improved standards of hygiene: when children are protected from immunizing infections in the first few years of life, the pool of susceptible persons builds up, and introduction of a virulent strain often is followed by an epidemic.[431] The extensive use of vaccines since the late 1950s resulted in the elimination of paralytic poliomyelitis from large geographic areas, but the disease remains endemic in various parts of the world. Although seasonal periodicity is distinct in temperate climates, some viral activity does take place during the winter months.[168] Infection and the acquisition of post-infection immunity occur with greater intensity and at earlier ages in crowded, economically deprived populations with less efficient sanitation.

Molecular techniques have allowed researchers to study the genotypes of specific viral types in populations over the course of time.[256,463,598,698] For example, Mulders and colleagues[698] studied the molecular epidemiology of wild poliovirus 1 in Europe, the Middle East, and the Indian subcontinent. These investigators found that four major genotypes were circulating. Two genotypes were found predominantly in eastern Europe, a third genotype was circulating mainly in Egypt, and the fourth genotype was dispersed widely. All four genotypes were present in Pakistan.

PREVALENCE OF DIFFERENT TYPES

The epidemiologic behavior of coxsackieviruses and echoviruses parallels that of polioviruses, in which unrecognized infections far outnumber infections with distinctive symptoms. The agents are disseminated widely throughout the world, and outbreaks caused by one or another type occur regularly. These outbreaks tend to be localized, with different agents prevalent in different years. In the late 1950s, however, echovirus 9 had a far wider circulation; it swept through a large part of the world and infected not only children but also young adults. This behavior has been repeated occasionally with other EVs: after a long absence, a particular agent returns and circulates among susceptible persons of different ages who have been born since the last epidemic. Other agents remain endemic in a given area and surface as sporadic cases and occasionally in small outbreaks. Multiple types frequently are active at the same time, although one agent commonly is predominant in a given locality.

Listed in Table 178–4 are the five most prevalent nonpolio enteroviral isolations per year in the United States from 1961

TABLE 178–4 Predominant Types of Nonpolio Enteroviral Isolations in the United States: 1961 to 2005*

	Five Most Common Viral Types Per Year

**The majority of patients from whom viruses were isolated had neurologic illnesses.*
†*Third and fourth place tie.*
Data from references 12, 129, 133, 134, 136, 139, 168, 329, and 905 and from personal communication from A. LaMonte-Fowlkes, Epidemiology Branch, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, for the 2005 data.

through 2005.[12,129,136,139,158,159,168,329,905*] Most patients from whom viruses were isolated had neurologic illnesses. Other EVs also possibly were prevalent but did not cause clinical disease sufficiently severe enough to induce physicians to submit specimens for study. In addition, probably many coxsackievirus A infections, even in epidemic situations, have gone undiagnosed because inoculation of suckling mice was not performed. Although more than 62 nonpolio enteroviral types and 4 parechovirus types have been identified, of interest is that in the 45 years covered in Table 178–4, only 24 different virus types are noted. Khetsuriani and associates[138] at the CDC presented an extensive report on enteroviral surveillance in the United States for the period from 1970 to 2005. During this period, the most common enteroviral isolates, in order, were echoviruses 9, 11, and 30, coxsackievirus B5, and echovirus 6. During the period from 2000 to 2005, the most common isolates, in order, were echoviruses 9, 30, 18, 13 and coxsackievirus B5.

Similar data for the most common enteroviral isolates in Spain from 1988 to 1997 and in Belgium from 1980 to 1994 are available.[259,941] The EV isolated most frequently in both countries was echovirus 30. In 1997 and 1998, major epidemic disease caused by EV 71 occurred in Taiwan, Malaysia, Australia, and Japan.[100,146,423,547,650]

Even though the use of live polioviral vaccine has eliminated epidemic poliomyelitis in the United States, determining the effect that polio vaccine viruses has had on enteroviral ecology

*Also personal communication from A. LaMonte-Fowlkes, Epidemiology Branch, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention (CDC).

has been difficult. In 1970, polioviruses accounted for only 6 percent of the total number of enteroviral isolations from patients with neurologic illnesses.[168] Although the numbers are not directly comparable, more than one third of the enteroviral isolations in 1962 from similar patients were polioviruses.[168] However, Horstmann and colleagues[432] studied specimens from sewage and from asymptomatic children during the early vaccine era and noted that the number of yearly polioviral isolations (presumably vaccine strains) was greater than the number of nonpolio EVs. The prevalence of vaccine viruses apparently did not affect the seasonal epidemiology of other EVs.

PATHOGENESIS AND PATHOLOGY

EVENTS DURING PATHOGENESIS[88,168,169,662,751,837]

Figure 178–4 diagrams the events in pathogenesis. After initial acquisition of virus by the oral or respiratory route, implantation occurs in the pharynx and the lower alimentary tract. Within 1 day, the infection extends to the regional lymph nodes. On approximately the third day, minor viremia develops and results in the involvement of many secondary infection sites. In congenital infections, infection is initiated during the minor viremia phase. Multiplication of virus in secondary infection sites coincides with the onset of clinical symptoms. Illness can vary from minor infection to fatal disease. Major viremia occurs during the period of multiplication of virus in secondary infection sites; this period usually lasts from the third to the seventh day of infection. In many echovirus and coxsackievirus infections, involvement of the CNS apparently occurs at the same time as does other secondary organ involvement. Occasionally, the CNS symptoms of enteroviral infections are delayed, thus suggesting that seeding occurred later in association with the major viremic phase.

Cessation of viremia correlates with the appearance of serum antibody. The viral concentration in secondary infection sites begins to diminish on approximately the seventh day. However, infection continues in the lower intestinal tract for prolonged periods.

In Figure 178–5, clinical and subclinical events in polioviral infections are presented. By 3 to 5 days after exposure, virus can be recovered from blood, the throat, and feces. This finding may be accompanied by symptoms of the "minor illness," or the infection may be unrecognized clinically. The end of the period of viremia coincides with the appearance of antibodies and the onset of clinical signs of CNS involvement. The available evidence favors blood as the main pathway of CNS invasion in natural disease, but experimental infections in monkeys indicated that the virus can travel along the axons of peripheral nerves. Possibly, when tonsillectomy is performed on a child with an inapparent poliovirus infection, the virus enters the nerve fibers exposed during surgery and spreads to the cranial nerve nuclei in the brain, thereby resulting in bulbar paralysis.

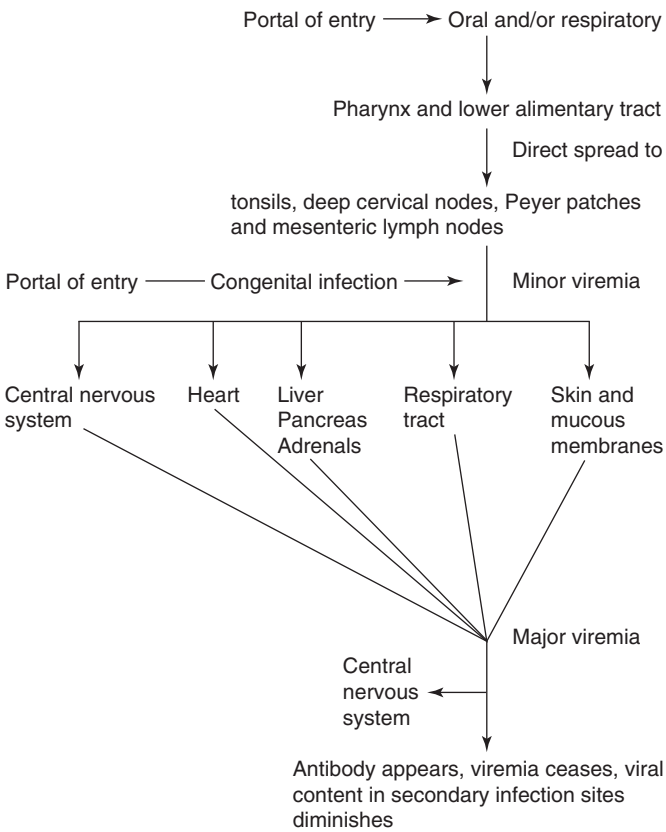

Figure 178–4 Pathogenesis of enteroviral infections. *(Modified from Cherry, J. D.: Enteroviruses.* In *Remington, J. S., and Klein, J. O. [eds.]: Infectious Diseases of the Fetus and Newborn Infant. Philadelphia, W. B. Saunders, 1976.)*

FACTORS THAT AFFECT PATHOGENESIS

The pathogenesis and pathology of enteroviral and parechoviral infections depend on the virulence, tropism, and inoculum concentration of virus, as well as on many specific host factors. EVs obviously have marked differences in both tropism and virulence. Although some generalizations can be made with regard to tropism, marked differences occur even among strains of specific viral types. Differences in the virulence of specific enteroviral types may be the result of recombination among EVs or point mutations.[795,810,849]

Van Eden and associates[955] studied 17 families during an outbreak of poliomyelitis caused by type 1 virus in the Netherlands. The findings suggested that human leukocyte antigen (HLA)–related genetic factors were important in the occurrence of paralytic disease.

Enteroviral infections in the fetus and neonate generally are thought to be more severe than are similar infections in older persons. This situation undoubtedly is the case with coxsackievirus B infection and probably also with coxsackievirus A and echovirus infections. Although the reasons for this increased severity are unknown, several aspects of neonatal immune mechanisms have been suggested. In addition, the similarity of coxsackievirus B infections in suckling mice to those in human neonates provided a useful animal model system. Heinberg and associates[406] compared coxsackievirus B1 infections in 24-hour-old suckling mice with similar infections in older mice. These investigators noted that adult mice produced interferon in all infected tissues, whereas suckling mice produced only small amounts of interferon in the liver. These researchers thought that the difference in outcome of coxsackievirus B1 infection in suckling and older mice could be explained by the inability of cells of the immature animals to elaborate interferon. Additional studies of abnormalities of innate immunity in neonates may enhance our understanding of the severity of enteroviral infections in newborns.[591]

Other researchers suggested that the increased susceptibility of suckling mice to severe coxsackievirus infections is related to the transplacentally acquired, increased concentrations of adrenocortical hormones.[60,89] Kunin[558] suggested that the difference in age-specific susceptibility could be explained at the cellular level. He showed that various tissues of newborn mice bind coxsackievirus B3, whereas tissues of adult mice are virtually inactive in this regard.[557,558] The progressive loss of receptor-containing

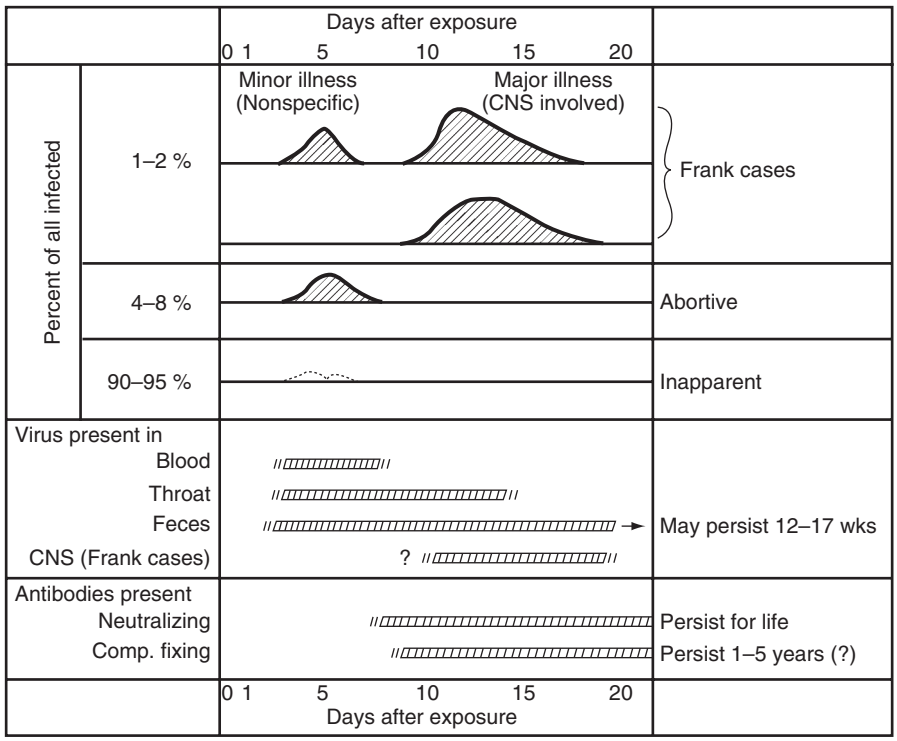

Figure 178–5 The course of clinical and subclinical forms of poliovirus infection in relation to the presence of virus and the development of antibodies. CNS, central nervous system. *(From Bodian, D., and Horstmann, D. M.: Poliomyelitis.* In *Horsfall, F. L., and Tamm, I. [eds.]: Viral and Rickettsial Infections of Man. 4th ed. Philadelphia, J. B. Lippincott, 1965, pp. 430-473.)*

cells with increasing age may be the mechanism that accounts for less severe infections in older animals. Supporting this suggestion, Ito and colleagues[466] showed that expression of coxsackievirus and adenovirus receptor (CAR) decreases with increasing age in rats. In the past, researchers assumed that specific disease in various organs and tissues in enteroviral infections was caused by the direct cytopathic effect and tropism of a particular virus. In more recent years, however, large numbers of studies using murine model systems suggested that host immune responses contribute to the pathologic process.* These studies suggested that T-cell–mediated processes and virus-induced autoimmunity cause both acute and chronic tissue damage. In contrast, other studies suggested that the primary viral cytopathic effect is responsible for the tissue damage and that the various T-cell responses are a reaction to the damage and not its cause.[648]

Since the early 1960s, the clinical manifestations caused by several enteroviral serotypes have changed. For example, echovirus 11 infection initially was noted in association with an outbreak of upper respiratory infection in a daycare center in 1958.[768] Then in the 1960s, this infection was found to be related to exanthem and aseptic meningitis.[172,177] Following this event and occurring at present is the association of echovirus 11 infection and severe sepsis-like illness with hepatitis in neonates.[90,168,169,386,491,675,693]

Another example relates to EV 71 infections. Initially, this virus was noted in association with aseptic meningitis, and only a few patients also had exanthem.[516,858] Since the late 1990s, severe epidemic disease with EV 71 has occurred in Taiwan, Singapore, Australia, Malaysia, and Japan. In these epidemics, hand, foot, and mouth syndrome is a major finding, and the neurologic disease is more severe than in the past.†

These phenotypic changes could be the result either of point mutations or of recombination among EVs.[148,181,520,611,612,736,849,882] Chan and AbuBakar[148] presented evidence indicating that a recombination event occurred between EV 71 and coxsackievirus A16.

PATHOLOGY

The clinical signs of enteroviral infection vary widely, so great variations in pathology also exist. Because pathologic material generally is available only from patients with fatal illness, this section discusses only the more severe manifestations. Worth emphasizing, however, is that these fatal infections account for just a small portion of all enteroviral infections. The pathologic findings in children with milder infections, such as nonspecific febrile illness, have not been described.

Coxsackieviruses A

Records of severe illness associated with coxsackieviruses A are rare. Gold and colleagues,[356] in a study of sudden unexpected death in infants, recovered coxsackievirus A4 from the brains of three children. In none of these patients were histologic abnormalities noted in the brain or spinal cord. An adult with a fatal coxsackievirus A7 infection had diffuse pancarditis and organized pneumonitis.[45]

Coxsackieviruses B

Of the nonpolio EVs, coxsackieviruses B have been associated most frequently with severe and catastrophic disease. The most common findings in these cases have been myocarditis, meningoencephalitis, or both. Involvement of the adrenals, pancreas, liver, and lungs also has been noted.

HEART[168,288,338,1011]

Grossly, the heart usually is enlarged, with dilation of the chambers and flabby musculature. Microscopically, the pericardium frequently contains some inflammatory cells along with thickening and edema, and the endocardium may have focal infiltrations of inflammatory cells. The myocardium (Fig. 178–6) is congested and contains infiltrations of inflammatory cells (lymphocytes, mononuclear cells, reticulum cells, histiocytes, plasma cells, and polymorphonuclear and eosinophil leukocytes). Involvement of the myocardium often is patchy and focal but occasionally diffuse. The muscle shows loss of striation as well as edema and eosinophilic degeneration. Muscle necrosis without extensive cellular infiltration is a common finding.

BRAIN AND SPINAL CORD[168,288,684,1011]

The meninges are congested, edematous, and occasionally mildly infiltrated with inflammatory cells. Lesions in the brain and spinal cord are focal rather than diffuse, but they frequently involve many different areas. The lesions consist of areas of eosinophilic degeneration of cortical cells, clusters of mononuclear and glial cells (Fig. 178–7), and perivascular cuffing. Two children with fatal coxsackieviral B infection (types 2 and 4) had, in addition to typical inflammatory encephalitic lesions, widespread multifocal areas of liquefaction necrosis without inflammation.[279]

OTHER ORGANS[11,101,168,336,684]

The lungs frequently have areas of mild focal pneumonitis with peribronchiolar mononuclear cellular infiltration. The liver often is engorged and occasionally contains isolated foci of liver cell necrosis and mononuclear infiltration. In the pancreas, occasional focal degeneration of islet cells occurs. Congestion has been observed in the adrenal glands, along with mild to severe cortical necrosis; inflammatory cells are present.

Echoviruses

Although frequently responsible for illness, echoviruses rarely were associated with fatal infection until relatively recently. In several different reports with eight different echovirus types, hepatic necrosis was a major pathologic finding.[83,168,341,386,675,693,1017] Massive hepatic necrosis has been seen with echoviruses 3, 6, 7, 9, 11, 14, 19, and 21. At autopsy, one infant with echovirus 6 infection had cloudy and thickened leptomeninges, liver necrosis, adrenal and renal hemorrhage, and mild interstitial pneumonitis.[168] One infant with echovirus 9 infection had an enlarged and congested liver with marked central necrosis,[168] and another with this virus had interstitial pneumonitis without liver involvement.[168] Three infants with echovirus 11 infection had renal and adrenal hemorrhage and small vessel thrombi in the renal medulla and in both the medulla and inner cortex of the adrenal glands.[702] These patients' livers were normal. Two infants, one with echovirus 6 and the other with echovirus 31 infection, had only extensive pneumonia.[97,168]

Enteroviruses

The brain of a child who died of acute encephalitis caused by EV 71 infection was examined.[1022] Grossly, the brain appeared normal, but microscopically, it revealed typical features of acute

encephalitis consisting of perivascular cuffing with mixed inflammatory cells, neuronophagia, and inflammatory nodules.

Polioviruses[88,198]

The neuropathy of poliomyelitis usually is pathognomonic; only certain cells and areas of the neuraxis are susceptible to the virus. Neuronal damage is caused directly by virus multiplication, but not all affected neurons are killed. The injury may be reversible, and function may be restored within 3 to 4 weeks after onset. Little histologic evidence of meningeal reaction exists. Perivascular cuffing and some interstitial glial infiltration are present. Histologic sections generally reveal more widespread lesions than would be estimated from the clinical findings. Scattered neurons may undergo considerable destruction without causing clinical disability.

Regions in which neuronal lesions occur are (1) the spinal cord (anterior horn cells chiefly and, to a lesser degree, the intermediate and dorsal horn and dorsal root ganglia), (2) the medulla (vestibular nuclei, cranial nerve nuclei, and the reticular formation that contains the vital centers), (3) the cerebellum (nuclei in the roof and vermis only), (4) the midbrain (chiefly the gray matter but also the substantia nigra and occasionally the red nucleus), (5) the thalamus and hypothalamus, (6) the pallidum, and (7) the cerebral cortex (motor cortex). The viruses spare the following areas: (1) the entire cerebral cortex except the motor area, (2) the cerebellum except the vermis and deep midline nuclei, and (3) the white matter of the spinal cord. This distribution of lesions permits the physician to establish a histologic diagnosis of poliomyelitis.

Extraneural disease usually is a secondary phenomenon. Bronchopulmonary changes such as aspiration pneumonia, atelectasis, and purulent bronchitis may occur because of impaired coughing and decreased thoracic movement. Cardiovascular changes may result in hypertension, cardiac failure, and pulmonary edema. Prolonged immobilization leads to negative nitrogen and calcium balance, along with urinary lithiasis, renal failure, hypertension with encephalopathy, and convulsions. Treatment itself may cause untoward complications, such as urinary tract infection (after catheterization), decubitus ulcers, and psychotic disturbances. Ulcerations in the alimentary tract may result in serious bleeding and occasional perforation. Respiratory failure culminates in respiratory acidosis and anoxic changes.

Parechoviruses

Although parechoviral infections have a broad spectrum of clinical manifestations, including encephalitis and sepsis-like neonatal disease, pathologic data are not available.[1,71,92,575,981]

CLINICAL MANIFESTATIONS: NONPOLIO ENTEROVIRUSES AND PARECHOVIRUSES

Nonpolio enteroviral and parechoviral infections are exceedingly common, and the spectrum of disease is protean (Tables 178–5 through 178–18). Many of the clinical-virologic associations listed in Tables 178–5 through 178–18 are based on a limited number of cases. Because EVs and parechoviruses frequently are carried asymptomatically in the gastrointestinal tract for relatively long periods of time, some of the observed illnesses and the viruses concomitantly recovered may not have a cause-and-effect relationship. However, repeated observations since the 1960s have supported many virus-illness associations, even though their occurrence has been sporadic.

*++++ = *most common*; ± = *rare*.

Few specific EV or parechovirus diseases exist, but, rather, various interrelated syndromes and anatomically associated illnesses are reported. Many illnesses and syndromes can be caused by different viral types, and most types are capable of inducing a variety of clinical syndromes. Conversely, certain specific coxsackieviral and echoviral types have clinical characteristics that facilitate an etiologic diagnosis.

Since the late 1980s, few careful studies have been conducted in which specific clinical findings were correlated with individual enteroviral types. This paucity was fostered by the expense of serotyping and the lack of using inoculation of suckling mice for isolation of virus. The increased use of polymerase chain reaction (PCR) also has contributed to the lack of identification of manifestations of disease by specific viral type. This situation is unfortunate because the clinical manifestations caused by specific viral types are not constant, and disease severity varies by specific enteroviral type.

ASYMPTOMATIC INFECTION

Because researchers have known that 90 to 95 percent of poliovirus infections are not recognized clinically, they have assumed that most infections with EVs and parechoviruses are asymptomatic. This opinion is strengthened by the finding that these viruses can be recovered frequently from the stools of healthy children. However, relatively few data are available on the rate of asymptomatic infection with nonpolio EVs and parechoviruses. All too frequently, isolation of EVs and parechoviruses from stool is equated with asymptomatic infection. This assumption is an error because illness, if it takes place, occurs shortly after the acquisition of virus and is short-lived; a particular infection may have been associated with a nonspecific illness 2 or 3 months before a stool specimen is obtained in a surveillance program. Unfortunately, in several studies involving controlled population groups in which accurate clinical expression rates could have been determined, clinical observations apparently were of secondary importance to the investigators.[168,339,340,342,546] The data available suggest differences in clinical expression among coxsackieviral and echoviral types.

Table 178–5 lists the approximate frequency of asymptomatic infections with selected coxsackieviruses and echoviruses. As can be seen, the rates vary among the group as a whole and even within specific types. Overall, approximately half, and perhaps more, of all nonpolio enteroviral infections appear to be associated with clinical manifestations. In general, the more carefully clinical symptoms are examined, the smaller is the percentage of truly asymptomatic infections. Clinical expression also is related inversely to age. With coxsackievirus A16, asymptomatic infection occurs in only approximately 10 percent of children younger than 5 years old, whereas rates are higher in older children and adults.[9,168] Sabin[836] reported no asymptomatic infections in infants with echovirus 18, and Nishmi and Yodfat[726] noted fewer than 20 percent of infections without illness in children younger than 8 years during an echovirus 4 epidemic. At the other extreme, Clemmer and associates[206] reported that 96 percent of infections with coxsackievirus B3 were asymptomatic. In other studies, the illness rate of coxsackievirus B3 was 60 to 75 percent.

NONSPECIFIC FEBRILE ILLNESS

Nonspecific febrile illness is the most common manifestation of coxsackieviral and echoviral infection (see Table 178–6). All viral types cause this clinical finding, but its frequency varies considerably among the individual viruses.

The onset of illness usually is abrupt, without a prodrome. In young children, the initial finding is fever and associated malaise. In older children, headache generally is noted. The temperature ranges between 38.3° C and 40° C (101° F and 104° F) and has a mean duration of 3 days. In some instances, the fever is biphasic: it occurs for 1 day, is absent for 2 to 3 days, and then recurs for an additional 2 to 4 days. In many young children, the only manifestation of illness is fever, and its presence is discovered by chance by a parent.

Malaise and anorexia often are related to the degree of temperature elevation, as is headache in older patients. Sore throat is a common complaint, but an inflamed pharynx is not seen on examination. Nausea and vomiting occasionally occur at the onset of illness, as does mild abdominal discomfort. One or two

loose stools may be noted. Generalized myalgia also is observed, and children complain of a scratchy feeling in the throat.

Physical examination usually yields benign findings. Minimal conjunctivitis, infection of the pharynx, and cervical lymphadenitis may be present. The duration of illness varies from 24 hours to approximately 6 days, with an average of 3 to 4 days. The white blood cell count (WBC) count is normal. EVs, particularly coxsackieviruses A, are significant causes of febrile convulsions in young children.[437]

RESPIRATORY MANIFESTATIONS

Common Cold

Although numerous coxsackieviruses and echoviruses have been recovered from children with mild upper respiratory infections, only rarely do the illnesses qualify as common colds (see Table 178–6). (The common cold is an acute illness with nasal stuffiness, rhinitis, no objective evidence of pharyngitis, and no or minimal fever.) In most instances, significant fever (temperature >38.3° C [>101° F]) is associated with enteroviral infections and usually some degree of pharyngitis.

Coxsackievirus A21 is the only EV that clearly qualifies as a common cold virus.[168,484] This agent has produced epidemics of mild respiratory illness in military populations. In adult volunteers, instillation of this virus in the nose has resulted in the common cold syndrome. Epidemic disease has not been observed in children. Other viruses that have been associated with the common cold syndrome include echoviruses 2 and 20 and coxsackieviruses B1, B2, B3, B4, B5, and A24.[168]

Pharyngitis (Pharyngitis, Tonsillitis, Tonsillopharyngitis, and Nasopharyngitis)

Pharyngitis is a common clinical manifestation of coxsackieviral and echoviral infection. Probably all EVs on occasion cause mild pharyngitis. The most common coxsackieviruses and echoviruses associated with pharyngitis are as follows: coxsackieviruses A9, B1, B2, B3, B4, and B5; echoviruses 2, 4, 6, 9, 11, 16, 19, 25, and 30; and EV 71.*

TABLE 178–15 Signs and Symptoms in Echovirus 9 Disease*

Sign or Symptom	Percentage of Cases (%)
Fever	92
Headache	85
Nuchal rigidity	83
Nausea and vomiting	71
Pain (neck, back, trunk)	44
Exanthem	35
Nonexudative pharyngitis	28
Cough	24
Sore throat	20
Cervical lymphadenopathy	18
Coryza	18
Abdominal pain	17
Photophobia	16

From Cherry, J. D.: Newer viral exanthems. Adv. Pediatr. 16:233-286, 1969.

Pharyngitis in coxsackievirus and echovirus infections frequently is associated with other clinical findings such as meningitis, pleurodynia, and exanthem. These other manifestations become more important than pharyngitis in individual cases in the minds of parents as well as clinicians.

Pharyngitis caused by coxsackieviruses and echoviruses usually is abrupt in onset, without a prodrome. Although pharyngeal involvement is present at the onset of disease, the initial complaint usually is fever. The temperature usually ranges between 38.3° C and 40° C (101° F and 104° F), but higher temperatures are not unusual symptoms. In general, fever tends to be more pronounced in younger patients. Young children have malaise and anorexia. School-age children complain of headache and myalgia. Sore throat, coryza and vomiting, diarrhea, or a combination thereof also may be noted.

Examination of the tonsils and pharynx shows varying degrees of erythema. In some cases, only infection is noted, whereas in others, severe pharyngitis with patches of exudate is seen. The usual duration of uncomplicated coxsackieviral or echoviral pharyngitis is 3 to 6 days. Routine laboratory study is of minimal value in enteroviral pharyngitis; the total WBC count may be normal or slightly elevated with a normal differential determination. Throat culture rules out disease caused by group A streptococci.

Other Intraoral Manifestations

HERPANGINA (See Chapter 11)

ACUTE LYMPHONODULAR PHARYNGITIS

In 1962, Steigman and colleagues[898] reported a unique enanthem associated with coxsackievirus A10 infection. The lesions had the typical distribution of herpangina; they were papular, discrete, 3 mm in diameter, and surrounded by a zone of erythema. The lesions were white to yellow and persisted for 6 to 10 days. This entity has not been reported again, although coxsackievirus A10 has been noted in association with hand, foot, and mouth syndrome.[168,865]

STOMATITIS AND OTHER LESIONS IN THE ANTERIOR OF THE MOUTH

The main enteroviral cause of stomatitis and ulcerative lesions in the anterior of the mouth is coxsackievirus A16, and the clinical

entity is the hand, foot, and mouth syndrome. This condition is presented in detail later in this chapter. Worth mentioning here, however, is that occasionally, enanthem occurs without the exanthem, and this enanthem also has been associated with other coxsackieviruses (A5, A9, A10, B2, B5), echovirus 33, and EV 71.[168,239,260,298,603,865]

In echovirus 9 infection, Tyrrell and colleagues[948] reported six children with a unique enanthem: painless whitish dots, ulcers, or vesicles on the buccal surfaces near the Stensen duct. These investigators also noted the occasional occurrence of similar lesions under the tongue.

Deseda-Tous and colleagues[246] reported an adolescent with hemorrhagic vesicular lesions on the pharynx, mucosal surfaces, and tongue in association with an echovirus 11 infection. Clarke and Stott[201] observed reddish macules on the buccal mucosa of a patient with echovirus 20 infection, and Cherry and Jahn[171] noted a child with hand, foot, and mouth syndrome in whom the buccal lesions suggested Koplik spots, although the lesions were larger and yellower in this patient.

Parotitis

Parotitis in association with herpangina and coxsackievirus A infection was reported in 1957 by Howlett and associates.[440] In 1960, Kraus[552] described two additional cases, and Bertaggia and associates[84] and Winsser and Altieri[1009] noted parotitis in association with coxsackieviruses B3 and B4, respectively. Three patients with acute hemorrhagic conjunctivitis and parotitis caused by EV 70 also have been reported.[854]

Croup

In large studies of respiratory illness in young children, croup is associated sporadically with coxsackieviral and echoviral infection.[156,168,308,347,996] In general, these illnesses are mild when compared with croup caused by parainfluenza and influenza viruses.

An outbreak of croup associated with echovirus 11 in a daycare center was reported.[768] In this instance, 17 of 53 ill children were found to be infected with the U strain of echovirus 11. A subsequent study noted the same virus in 4 children with croup.[769] Croup also was reported in outbreaks of coxsackievirus B5 infection.[42,216] Other specific agents associated with croup include coxsackieviruses A9 and B4 and echoviruses 4 and 21.[168]

Bronchitis

An acute febrile illness with cough, rhonchi, and referred breath sounds occasionally is a sporadic manifestation of enteroviral infection. A specific association of coxsackieviruses B1 and B4, echoviruses 8, 12, 13, and 14, and parechovirus 1 has been found.[156,168,216,267,269]

Bronchiolitis and Infectious Asthma

Coxsackieviruses and echoviruses have been associated sporadically with bronchiolitis, infectious asthma, and the precipitation of asthmatic attacks in atopic children.[156,168,267,308,347,369,427,996] Epidemic disease has not been observed, and the illnesses usually have been mild.

Pneumonia

In general studies of respiratory infections in children, sporadic coxsackieviruses and echoviruses have been noted in 1 to 7 percent of patients with pneumonia and positive viral cultures.[156,168,308,347] Specific virus types include the following: coxsackieviruses A9, A16, B1, B2, B3, B4, B5, and B6; echoviruses 6, 7, 9, 11, 12, 19, 20, and 30; and EV 71.*

In only three instances can an outbreak of pneumonia caused by specific viruses be suggested to have occurred. During the summer of 1959, Lerner and colleagues[587] noted that 3 of 15 children infected with coxsackievirus A9 had pneumonia. The patients with pneumonia had a vesicular rash, and one of these children died.

Eckert and associates[267] observed 6 children with coxsackievirus B1 infection and pneumonia during the summer of 1963. These illnesses were not described further, although the mean WBC count in 12 children who had lower respiratory infections with coxsackieviruses B was reported as 11,383 with a normal differential. All children were hospitalized.

Goldwater[357] reported a coxsackievirus B6 outbreak in south Australia during the summer of 1992 to 1993. Twenty-seven patients had pneumonia associated with high fever and severe cough that lasted several weeks. In addition to the fatal case of coxsackievirus A9 infection described by Lerner and colleagues,[587] deaths have resulted from infection with coxsackieviruses B1, B5, and A16.[297,471,1018]

Pleurodynia (Bornholm Disease)

Epidemic pleurodynia[44,168,233,362,378,525,682,913,980] is an illness that was noted first in 1735 by Hannaeus, a Danish physician.[392] Not until the late 19th century, however, did the illness receive further attention in the medical literature. At this time, several epidemics in Scandinavian countries were described.[168,225,296] Although Finsen referred to the disease as *pleurodynia*, others who designated outbreaks used geographic names, such as Skien disease, Bamle disease, Drangedral disease, and Bornholm disease, or

*See references 168, 218, 267, 297, 343, 471, 505, 587, 683, 855, 880, 993.

descriptive names such as epidemic myalgia, devil's grippe, epidemic diaphragmatic spasm, or epidemic benign pleurisy.[362] In 1933, Sylvest[913] published the classic monograph on the subject, and from this publication the name Bornholm disease (from Bornholm Island, a Danish island in the Baltic Sea) came to be associated with the illness. The enteroviral origin of epidemic pleurodynia was established in 1949.[224,989]

Historically, pleurodynia is an epidemic disease, but sporadic cases do occur. A characteristic incubation period of approximately 4 days is followed by the sudden onset of fever and pain. The pain typically is located in the chest or upper part of the abdomen and is muscular in origin and of variable intensity. Occasionally, the pain occurs in other areas of the body. Frequently, the pain is excruciatingly severe and sudden and is associated with profuse sweating, so the patient may appear pale and as though in shock. The pain is spasmodic, with durations varying from a few minutes to several hours. Most commonly, the spasmodic periods last approximately 15 to 30 minutes. During spasms, respirations usually are rapid, shallow, and grunting, suggestive of pneumonia or pleural inflammation. Coughing, sneezing, or deep breathing makes the pain worse. Older children and adults describe the pain as stabbing or knifelike. An older person often fears that a heart attack is occurring.

When pain localizes in the abdomen, it frequently is crampy and suggests colic in a younger child. The child may double over and refuse to walk or move. Occasionally, the abdominal pain in association with a pale, sweaty, shocklike appearance suggests acute intestinal obstruction. Splinting and guarding of the abdomen also lead to consideration of appendicitis and peritonitis.

The fever and pain usually last 1 to 2 days. Frequently, however, the illness is biphasic; after the initial febrile period, the patient is asymptomatic for several days, and then the pain and fever recur. Rarely, patients have several recurrent episodes over the course of several weeks. In these patients, fever is less prominent.

Some degree of tenderness is present in the areas of pain, but frank myositis with muscle swelling is not observed. Pleural friction rubs may be noted on auscultation, and they may appear and disappear with the coming and going of episodes of pain.

In epidemics, both children and adults are afflicted, but most cases occur in persons younger than 30 years. Most children have other symptoms of enteroviral infection, such as anorexia, nausea, vomiting, headache, and sore throat. Routine laboratory study is not very helpful. The WBC count varies considerably, but increased percentages of polymorphonuclear neutrophils and band forms are frequent findings. The erythrocyte sedimentation rate also is inconsistent; normal to extremely high values may be observed. The chest radiograph usually is normal.

Complications in pleurodynia seldom develop. Aseptic meningitis has been noted in some patients, and men have experienced orchitis. Cardiac involvement, in the form of myocarditis and pericarditis, also may complicate pleurodynia.

The major etiologic agents in epidemic pleurodynia are coxsackieviruses B3 and B5.[44,168,447,835,861,880] Other viruses associated with epidemic disease include coxsackieviruses B1 and B2 and echoviruses 1 and 6.[31,168,262] Agents associated with sporadic occurrences of pleurodynia include the following: coxsackieviruses A1, A2, A4, A6, A9, A16, B1, B2, B3, B4, B5, and B6; echoviruses 1, 2, 3, 6, 7, 8, 9, 11, 12, 14, 16, 17, 18, 19, 24, 25, and 30; and parechovirus 2.*

Pleurodynia rarely is reported today. Because the EVs that cause pleurodynia still circulate, cases probably are overlooked or misdiagnosed. An outbreak caused by coxsackievirus B1 in football players at a public high school was reported.[458] Unfortunately, no clinical data were presented.

*See references 63, 168, 216, 262, 388, 499, 530, 647, 682, 911.

GASTROINTESTINAL MANIFESTATIONS

Gastrointestinal manifestations occur commonly in coxsackieviral and echoviral infections.* Clinical manifestations in addition to vomiting and diarrhea are varied (see Table 178–7).

Early studies paid particular attention to diarrheal disease in children. However, when specific studies of infantile diarrhea were undertaken, the enteroviral association was far from clear.[61,168,361,757,891,1032] The correlation of infection and disease in these studies was compromised by the problem that the main source of culture in study patients and controls was from stool; persistent infection in the bowel rendered separation of controls and ill patients impossible.

Infections with all coxsackieviruses and echoviruses frequently have one or more gastrointestinal symptoms as part of the general illness. The intensity and spectrum do vary among the specific agents, however, and also among strains of particular viral types. In a review of World Health Organization (WHO) virus reports covering a 4-year period, Assaad and Cockburn[34] found that the main clinical sign or symptom was gastrointestinal in 12 percent of coxsackieviral infections and in 6.8 percent of echoviral infections. In another analysis, Assaad and Borecka[33] noted 16 deaths during the period 1967 to 1975 in patients with coxsackievirus and echovirus infections in whom the principal clinical association was gastrointestinal.

In a 20-year survey in Wisconsin, Nelson and colleagues[712] noted that gastrointestinal symptoms occurred in approximately one third of all patients from whom these investigators recovered nonpolio EVs. Morens and colleagues[686] reported that in 4 percent of patients from whom nonpolio EVs were recovered during the 1971 to 1975 period, gastrointestinal disease was the major diagnosis. Horn and coworkers,[427] studying respiratory viral infections, noted that 21.2 percent of subjects from whom EVs were recovered had gastrointestinal complaints.

Vomiting

Vomiting is a common manifestation of infection with many coxsackieviral and echoviral types, but it rarely is the major complaint of the patient or the parent.† The frequency of vomiting during outbreaks of illness caused by coxsackieviruses and echoviruses depends on the specific types of virus and on the major manifestation during a particular outbreak. Table 178–8 presents the frequency of vomiting by viral type. In 14 different enteroviral types, vomiting has been noted as a significant aspect of the illness during disease outbreaks. Except for coxsackievirus A16 infections (hand, foot, and mouth syndrome), in which it is an uncommon complaint, vomiting occurs in approximately 50 percent of all patients with epidemic enteroviral disease. Vomiting is noted most commonly in meningitis and least commonly in pleurodynia and uncomplicated exanthematous disease.

Diarrhea

Diarrhea occurs commonly in coxsackieviral and echoviral infections, but it usually is just one of many manifestations of systemic

†See references 9, 32, 168, 175, 176, 186, 218, 219, 244, 291, 292, 362, 381, 387, 388, 394, 502, 505, 506, 515, 528, 538, 584, 626, 629, 726, 771, 777, 799, 813, 832, 836, 839, 848, 880, 899, 935, 980, 986, 997, 1005, 1006.

illness.* Specific studies of diarrheal disease in infants and children have had varied results; some studies indicated an enteroviral origin, whereas others revealed that coxsackieviruses and echoviruses were recovered from well children at the same prevalence.

Ramos-Alvarez and Olarte[793] carried out an extensive study of diarrheal disease in Mexico City and noted that echoviruses were recovered eight times more frequently from children with diarrhea than from control children without diarrhea. These investigators found that echoviruses 6 and 19 predominated, but types 3, 7, 9, 12, 14, 18, and 21 also were recovered. Pelon and colleagues[762] noted an association between coxsackieviruses B4 and B5 and acute diarrhea; they observed a 42 percent coxsackievirus B isolation rate in children with acute diarrhea and a corresponding rate of only 12 percent in those without diarrhea. Goodwin and associates[361] noted echoviruses in the stools of children with diarrhea at twice the rate observed in healthy children. In a study by Yow and colleagues,[1032,1033] no association was found between EVs and infantile diarrhea. Echoviruses were recovered twice as frequently from children ill with diarrhea as from children without gastrointestinal illness.[1033] In Canada, McLean and colleagues[644] could find no association between enteroviral infection and gastroenteritis. In a large study of diarrhea in India, coxsackieviruses A9, B3, and B6 and echoviruses 12 and 21 were recovered more commonly from ill patients than from children without diarrhea.[704]

In several studies of specific diarrhea outbreaks, afflicted persons were noted to be actively infected with a particular virus type. Goldwater and Laws[358] observed three children younger than 6 months who were infected with echovirus 19 and who had gastroenteritis without other signs or symptoms. Klein and colleagues[538] recovered echovirus 11 from the blood of two laboratory workers with acute gastroenteritis. Diarrhea occurred in three of nine volunteers given echovirus 11.[106] Eichenwald and associates[271] and Cramblett and colleagues[216] reported epidemic diarrhea caused by echovirus 18 in neonates. An outbreak of diarrhea associated with coxsackievirus A1 was noted in 7 of 14 bone marrow transplant recipients during a 3-week period.[937]

Table 178–9 presents the frequency of diarrhea in outbreaks of specific coxsackieviral and echoviral illnesses. Diarrhea varied with regard to the viruses represented and in different studies with the same agents. Diarrhea in enteroviral disease rarely is severe. In most instances, loose stools occur for a 2- to 4-day period. The stools rarely are watery, never are bloody, and at most number six to eight per day.

Constipation

Some degree of constipation is a rather frequent occurrence in many acute infectious illnesses, but evaluation is rendered difficult by the subjective nature of the complaint. In coxsackieviral and echoviral diseases, a short period of constipation may be associated with fever, vomiting, and anorexia early in the course of the illness. This period frequently is followed by mild diarrhea.[106] As noted in Table 178–7, constipation has been reported specifically as a symptom with four coxsackieviral and four echoviral types. Constipation is a particularly common event in children with enteroviral meningitis; it occurs in 10 to 40 percent of cases.[168,291,292,505,506,561]

*See references 9, 31, 32, 78, 103, 106, 168, 171, 216-219, 244, 291, 292, 358, 362, 378, 387, 388, 394, 505, 506, 515, 525, 538, 563, 577, 584, 626, 636, 639, 644, 704, 758, 762, 771, 775, 782, 792-794, 813, 835, 836, 864, 891, 892, 922, 935, 992, 994, 1006, 1032, 1033.

Abdominal Pain

Abdominal pain is a common complaint in many coxsackieviral and echoviral infections. Table 178–10 lists the frequency of occurrence of abdominal pain and the main characteristic of the illness by virus type. Approximately 10 percent of patients with coxsackievirus A16 hand, foot, and mouth syndrome complain of abdominal pain. In approximately one fourth of patients, many coxsackieviruses and echoviruses associated with meningitis cause abdominal pain.

The magnitude of abdominal pain as a clinical complaint in coxsackieviral and echoviral infections varies considerably. For example, in aseptic meningitis, headache and other neurologic complaints overshadow the abdominal symptoms. In other situations, fever and abdominal pain are diagnostically troublesome because of the possible presence of a surgical abdomen (discussed further in the next paragraph). The pain most frequently is periumbilical; it may be either constant or colicky. The fever is most often higher than 38.3° C (101° F).

Peritonitis, Pseudoperitonitis, Appendicitis, Pseudo-obstruction, Mesenteric Adenitis, and Intussusception

Occasionally, coxsackieviruses and echoviruses are associated with illnesses that suggest severe abdominal involvement. Liebman and St. Geme[595] described two children with abdominal findings suggestive of acute appendicitis (semirigid, tender abdomen, rebound tenderness, rectal tenderness) who had associated infections with echoviruses 1 and 14. McLean[643] described a surgical abdomen in one child with coxsackievirus B1 infection. In this case, virus was recovered from the peritoneal exudate; at surgery, this boy was found to have peritonitis, but his appendix was normal. Thomas[928] reported a 5-year-old boy with coxsackievirus B5 infection who at surgery was found to have excessive clear peritoneal fluid and markedly enlarged mesenteric lymph nodes. A pregnant woman with acute abdominal pain and rebound tenderness associated with echovirus 8 infection was described.[760]

In immunofluorescence studies, Tobe[933] showed the presence of coxsackievirus B2 and B5 antigens in the mucous membranes and mesenteric lymph nodes of patients with appendicitis more often than in similar studies in control subjects. He suggested that the viral infection acts as a trigger for appendicitis. Bell and Steyn[68] recovered echoviruses 7 and 9 from the mesenteric lymph nodes of children with intussusception.

Hepatitis*

Marked liver involvement is not a rare finding in disseminated coxsackieviral and echoviral infections in neonates.[169] The association of hepatitis and enteroviral infection in older children is defined less clearly but probably occurs more commonly than generally realized, based on the number of individual cases reported. Caution must be exercised in accepting EVs as the exclusive etiologic agent of hepatitis, however, because hepatitis A virus infection has been ruled out in only a few of the available studies.

Morris and associates[691] described an illness suggestive of a coxsackieviral or echoviral infection in an 18-month-old child who had hyperbilirubinemia and abnormal liver function test results. From this child, coxsackievirus A4 was recovered from blood during the acute illness, and a rise in neutralizing antibody titer to the isolated virus was demonstrated. Chang and Wein-

*See references 10, 142, 151, 233, 435, 525, 570, 576, 629, 685, 686, 691, 748, 855, 862, 864, 880, 909, 962, 977.

stein[151] reported a 3-year-old boy with pharyngitis, urinary abnormalities, and neurologic symptoms who had elevated liver enzyme values (aspartate transaminase value of 1600 and alanine transaminase value of 1180). Coxsackievirus A9 was recovered from this child's cerebrospinal fluid (CSF), and the child's antibody response to this agent was significant. Coxsackievirus A20 has been associated with clinical hepatitis, and simultaneous infections with coxsackievirus A24 and hepatitis A virus have been demonstrated.[862]

An adult with a coxsackievirus B1 infection had both myocarditis and liver involvement.[10] A similar illness caused by coxsackievirus B3 in a 19-year-old woman was described.[909] An 11-month-old boy had a Reye-like syndrome in conjunction with coxsackievirus B2 infection.[509] Reye syndrome has been associated with echovirus 3 infection.[400] Siegel and colleagues[880] described a hepatosplenic syndrome in which 15 patients had hepatomegaly and coxsackievirus B5 infection. These patients, most of whom were children, had otherwise typical enteroviral illnesses. Liver function studies were performed in only three instances, and the results were normal.

Echoviruses 1, 3, 4, 6, 7, 9, 11, 14, 20, 21, and 30 have been associated with hepatitis.[168,448,525,624,682,855] Hepatomegaly occurs commonly in enteroviral infections.[168,171,290,563,587] During the period from 1971 through 1975, more than 7000 cases of nonpolio enteroviral infection were reported to the Viral Diseases Division at the CDC.[686] In this group were 13 cases of hepatitis and 6 of Reye syndrome; coxsackieviruses A2 and B4 and echoviruses 14 and 22 were associated with Reye syndrome.

Pancreatitis

One of the effects of coxsackievirus B in suckling mice is extensive infection in the pancreas. As with other similarities of infection between suckling mice and human neonates, generalized coxsackievirus B infection in neonates also is accompanied frequently by extensive pancreatic damage. In contrast, pancreatic involvement in older children and adults is not a common occurrence.[117,700,705,951] Coxsackieviruses B3, B4, B5, and A9 have been noted.

Diabetes Mellitus

A possible relationship between juvenile diabetes mellitus and the seasonal occurrence of coxsackievirus B4 was suggested in 1969 by Gamble and Taylor.[326] In a second study, Gamble and associates[327] noted that titers of coxsackievirus B4 antibodies in patients with insulin-dependent diabetes mellitus (IDDM) within 3 months of the onset of disease were higher than those in physiologically normal subjects or in patients with chronic diabetes.

Since the 1960s, many studies in animal models and children have looked at the relationship between juvenile-onset, type 1 IDDM and coxsackieviruses B.* Between 1973 and 1984, 10 case-control studies examined the prevalence of antibody to various coxsackieviruses B in patients with IDDM and controls. In 8 of these studies, the prevalence was greater in the patients with IDDM. In 3 of these studies, IgM antibody to the coxsackieviruses B was examined, and the prevalence in each was greater in the patients with IDDM than in controls. A Finnish study noted that patients with IDDM were more likely to have IgA antibodies to coxsackievirus B4 than were controls.[454]

Helfand and associates[407] performed a well-done case-control study of IDDM. These investigators found that new-onset cases of IDDM in patients 13 to 18 years of age were more likely than were controls to be IgM antibody-positive for 9 of 14 EV serotypes. The serotypes were as follows: coxsackieviruses B2, B3, B4, B5, and B6; coxsackievirus A9; and echoviruses 9, 30, and 34. Green and associates[368] performed a systematic review of published case-control studies relating to coxsackievirus B serology and IDDM. In 13 studies that looked at antibody to all coxsackievirus B types, 7 (54%) had significantly more positive antibody values in the cases than in the controls. The findings were less impressive when rates of antibody by specific coxsackievirus B serotypes were compared. However, with coxsackievirus B4, the odds ratio was higher than 1 in 9 of 17 (53%) comparisons, and this difference was significant in 6 (35%) of the studies.

In an extensive study, Skarsvik and colleagues[886] noted that children with IDDM had an impaired type 1 T-cell response against coxsackievirus B4 compared with the response in healthy children. The findings led these investigators to suggest that the defect in T-cell function delayed clearance of coxsackievirus B4 and made damage to beta cells more likely. In another study involving adults, Varela-Calvino and coworkers[958] noted that T-cell proliferative responses against the VP2 protein of coxsackievirus B4 was significantly reduced in patients with IDDM compared with the responses in control subjects.

Cudworth and colleagues[222] noted a correlation between HLA type BW15 and coxsackieviruses B1, B2, B3, and B4 antibodies in patients with IDDM. In 1979, Yoon and colleagues[1029] reported the recovery of coxsackievirus B4 from the pancreas of a previously healthy 10-year-old boy who died after being in a diabetic coma. Maria and coworkers[627] noted the simultaneous onset of type 1 IDDM in a mother and her 10 year-old son coincident with a coxsackievirus B5 infection.

Clements and coworkers[204] noted that 9 of 14 serum samples from children with new-onset IDDM were positive for EV RNA by PCR. In contrast, only 4 percent of serum samples from control children had evidence of EV RNA.

In a murine model, See and Tilles[866] found that a diabetogenic strain of coxsackievirus B4 infection resulted in persistent detection of viral RNA in the pancreases of most infected mice. This persistence of antigen was associated with chronic islet cell inflammation and elevated islet cell antibody levels. Stimulated peritoneal macrophages caused lysis of islet cells either directly or by an antibody-dependent mechanism. A study in prediabetic children found that the presence of EV RNA in serum was a risk factor for development of beta-cell autoimmunity and IDDM.[609] Glutamic acid decarboxylase (GAD_{65}) is one of the major beta-cell target antigens in the autoimmune beta-cell damaging process that leads to the development of IDDM.[607] Antibody and cellular immunity cross-reactivity exists between GAD_{65} and the 2C protein of coxsackievirus B4.[35,607] The results of several studies suggest that enteroviral infections are associated with the development of beta-cell autoimmunity and the eventual destruction of islet cells.[113,421,608] Time periods from enteroviral infection to the development of beta-cell autoimmunity and the eventual development of IDDM from beta-cell destruction have a great range that perhaps explains the lack of a more specific seasonally related onset of IDDM. A case of neonatal IDDM associated with a maternal echovirus 6 infection has been reported.[749]

EYE FINDINGS

Acute Hemorrhagic Conjunctivitis*

Although conjunctivitis has been a frequent finding in nonpolio enteroviral illnesses since the 1950s, its occurrence as a dominant complaint has been observed only since the 1960s. In June of

*See references 22, 35, 47, 48, 143, 204, 222, 249, 313, 314, 368, 397, 407, 416, 421, 434, 495, 498, 533, 607-609, 627, 672, 749, 860, 866, 886, 931, 953, 958, 1004.

*See references 82, 124, 130, 137, 168, 353, 367, 378, 417, 548, 756, 852, 923.

1969, Chatterjee and associates[157] noted an epidemic of acute hemorrhagic conjunctivitis in Accra, Ghana. This disease was nicknamed Apollo 11 disease because it coincided with the time of the Apollo 11 moon landing. Since 1969, many epidemics of acute hemorrhagic conjunctivitis have been described. In most epidemics, EV 70 has been the etiologic agent, but similar epidemics have been caused by a variant of coxsackievirus A24.[199] More recently, this virus has been the cause of more epidemics than has EV 70.[130,137,205,353,756,799,923] Most epidemics have occurred in tropical and semitropical countries; however, outbreaks have been observed in Minnesota, as well as in Moscow, London, and other European cities.[560,1027] In the continental United States, epidemic disease has occurred in Florida and North Carolina.[128] During epidemics, all age groups are affected, but the highest attack rate is in school-age children.[982]

Acute hemorrhagic conjunctivitis has a sudden onset, with severe eye pain and associated photophobia, blurred vision, lacrimation, erythema, and congestion of the eye, as well as edema and chemosis of the lids.[417] Subconjunctival hemorrhages of varying size, and frequently transient punctate epithelial keratitis, conjunctival follicles, and preauricular lymphadenopathy are present. The eye discharge initially is serous but becomes mucopurulent with secondary bacterial infection. Systemic symptoms, including fever, are rare manifestations. Within 2 to 3 days after the onset of illness, patients note some improvement, and recovery is usually complete in 7 to 12 days. In a study in American Samoa, researchers found that illness caused by coxsackievirus A24 was somewhat different from that caused by EV 70.[852] In cases caused by coxsackievirus A24, conjunctival hemorrhage was less severe, and upper respiratory and systemic symptoms occurred more frequently. In a study in American Samoa of disease caused by EV 70, researchers found that children 2 to 10 years of age had the highest attack rate, and antibody from previous infection gave only partial protection against symptomatic re-infection.[82]

Occasionally, findings suggestive of pharyngoconjunctival fever have been noted. A few patients have had a poliomyelitis-like illness or polyradiculomyeloneuropathy after EV 70 acute hemorrhagic conjunctivitis.[367,969] Epidemics are explosive, with spread mainly by the eye-hand-fomite-eye route.

Conjunctivitis Associated with Other Enteroviral Illness

Conjunctivitis is a common minor manifestation of enteroviral illness with several specific agents. Table 178–11 presents the frequency of occurrence of conjunctivitis in selected outbreaks of disease caused by coxsackieviruses and echoviruses. Conjunctivitis was most prevalent in coxsackievirus B3 and B5 and echovirus 9 and 30 infections. In addition to the outbreaks reported in Table 178–11, conjunctivitis has been noted in isolated illnesses associated with echoviruses 1, 6, and 20.[525]

Photophobia

As would be expected, photophobia occurs commonly in aseptic meningitis caused by coxsackieviruses and echoviruses. During epidemic meningitis, researchers have noted it with the following viruses: coxsackievirus A9 and echoviruses 3, 4, 6, 7, 9, 19, and 30.* It is a most common occurrence with echovirus 9 and 30 infections, but the incidence of this complaint varies greatly in different reports. In one echovirus 30 outbreak, 80 percent of the patients studied had photophobia.[935] On average, 20 percent of patients with meningitis have remarkable photophobia. Photophobia also is associated with pleurodynia caused by coxsackievirus B infections.[835,980]

*See references 67, 168, 362, 369, 501, 502, 505, 506, 528, 584, 624, 771, 935.

Other Eye Findings

Nodular lesions on the palpebral conjunctiva were observed in some patients with coxsackievirus A10 infection and lymphonodular pharyngitis.[898] A corneal ulcer occurred in one patient with hand, foot, and mouth syndrome.[619] Optic neuritis was described in a boy with pleurodynia, although the enteroviral origin of the illness was not confirmed in the laboratory.[946] Keratoconjunctivitis was noted in two boys with echovirus 13 infections.[532] Periorbital edema was observed in one patient with echovirus 9 meningitis. A woman with panuveitis associated with coxsackievirus B3 infection was described.[303] One report detailed monofocal outer retinitis in a 36-year-old man with hand, foot, and mouth syndrome.[382] Five extensive outbreaks of uveitis caused by echoviruses 11 and 19 in hospitalized young children were noted in three Siberian cities.[959] These cases occurred predominately in infants hospitalized for other illnesses such as bronchitis, pneumonia, gastroenteritis, sepsis, dystrophy, and premature birth. Sore eyes and other unspecified eye complaints also have been noted frequently in patients with coxsackieviral and echoviral infections.[168,286,301,381,577,618,714,850,856]

CARDIOVASCULAR MANIFESTATIONS

Pericarditis, Myocarditis, and Dilated Cardiomyopathy

Pericarditis or myocarditis or both have been noted in association with 27 different nonpolio EVs. The relative importance of the different serotypes is presented in Table 178–12. The coxsackieviruses B have been implicated most frequently in heart disease. Coxsackievirus B5 has been the most common causative agent, but types 2, 3, and 4 also have been reported frequently. Of the echoviruses, type 6 has been associated most often with cardiac involvement, but the clinical findings with this agent have been described in only a few cases.

In patients with coxsackievirus B cardiac disease, hepatitis, pneumonia, nephritis, meningitis, and orchitis have been occasional associated findings. Sometimes, arrhythmias are the only clinical manifestations of myocarditis.[174,945] Constrictive pericarditis occurs occasionally.[637] The mortality rate for acute coxsackieviral and echoviral heart disease is unknown, but it is significant. Unfortunately, proper virologic study rarely is performed in nonfatal disease. In the only published follow-up study, researchers found that patients who survived acute coxsackievirus myocarditis usually recovered completely, without any residual disability.[907]

The early descriptions of coxsackievirus B infection with myocarditis in the 1950s and early 1960s indicated acute, usually fulminant illnesses in which a coxsackievirus B serotype could be recovered from multiple sites such as the throat, stool, and CSF, as well as from the heart and other organs at autopsy.[338,376,524,526,954] Coxsackieviruses B originally were isolated from suckling mice, and the infection in these mice caused acute, overwhelming fatal infections involving multiple organs, including the heart.[233,488] Coxsackievirus B infections in mice were studied in mouse model systems in the 1950s and 1960s, and researchers found that infections in older mice were affected markedly by the virus strain, mouse genetics, and drugs.[89,439,531] Since the 1970s, studies in mouse model systems have become more sophisticated, but they still depend on specific coxsackievirus B strains and specific mouse strains.*

*See references 20, 112, 116, 195, 331, 332, 334, 335, 338, 350, 410, 413, 424, 445, 446, 497, 523, 529, 537, 568, 617, 635, 648, 713, 740, 754, 787, 802, 805, 806, 814, 867, 868, 939, 942, 1010.

More recent studies in mouse model systems noted the progression of acute coxsackievirus B infection to chronic infection and cardiomyopathy.[20,424,497,635,787,802] Since the mid-1980s, acute, subacute, and chronic cardiomyopathy in patients has been studied by antigen-detection techniques and newer serologic methods.*

Bowles and colleagues[96] found coxsackievirus B nucleic acid sequences in myocardial biopsy samples from several patients with cardiomyopathy. Muir and colleagues[697] detected EV-specific IgM antibodies in the sera of nine patients with chronic relapsing pericarditis. Fujioka and coworkers[319] reported positive enteroviral PCR results from endomyocardial biopsy specimens in 6 of 31 patients (19%) with dilated cardiomyopathy (DCM). Andréoletti and collaborators[23] noted EV RNA in 18 of 25 samples from the heart tissue of patients with DCM or ischemic cardiomyopathy. However, in two other well-controlled studies, enteroviral RNA could not be identified in endomyocardial biopsy samples or in heart tissue from patients undergoing heart transplantation.[208,596] In 1994, Muir and Archard[694] and Melchers and associates[656] reviewed the evidence for persistent enteroviral infection in chronic medical conditions, including idiopathic DCM. Muir and Archard concluded that persistent enteroviral infection is associated causally with chronic medical conditions, whereas Melchers and colleagues found no clear evidence for enteroviral persistence and the subsequent development of chronic medical conditions.

Since the mid-1990s, additional studies in humans have been performed, and they again have had mixed results with regard to the role of coxsackievirus B in the origin of chronic cardiomyopathy. Bowles and associates[95] studied cardiac samples for PCR analysis from 624 patients of all ages with myocarditis and 149 patients with DCM. Enteroviral genome was found in the cardiac samples of 85 patients with myocarditis and in the samples from 12 patients with DCM. The histopathologic findings in 9 of these 12 patients demonstrated borderline or mild findings of inflammatory infiltrates. Another study by investigators in the same group examined 80 explanted hearts from children with end-stage heart disease, and an enteroviral genome was not detected.[309] In another study, Zhang and coworkers[1037] found evidence of enteroviral capsid protein VP1 by immunohistochemical staining in 47 of 89 patients with DCM. In a study performed in Japan, Fujioka and associates[318] detected EV RNA in 7 of 30 American patients (23%) and in 15 of 47 Japanese patients (32%) with DCM. In our opinion, the data in these studies suggest that EVs have a role in some patients with DCM.

The general theme in most contemporary mouse model studies is that damage to the myocardium is not caused by the direct cytopathic effect of the virus, but rather is caused by the cellular immune response of the host. Unfortunately, the mouse model data and the less than definitive data from human studies have led cardiologists and others to think that the model systems are representative of human disease.[289,605] No adequate follow-up studies of survivors of acute enteroviral myocarditis or pericarditis have been conducted. Levi and colleagues[589] compared follow-up cardiac data on 10 adults who had acute myocarditis associated with coxsackieviral infections 42 to 68 months previously with similar cardiac data from normal age- and sex-matched subjects. No statistically significant differences in the two groups were found in the seven tests evaluated.

Orinius[747] performed cardiac examinations on 53 adults who had coxsackievirus B infections 2 to 11 years previously. The initial diagnoses in these 53 patients were meningitis in 33 cases, encephalitis in 3 cases, pleurodynia in 6 cases, pericarditis in 2 cases, and nonspecific complaints in 9 cases. Of this group, the "possibility of cardiomyopathy was established" in 2 (4%) cases. Two patients who had had pericarditis were normal at follow-up.

Sainani and associates[840] performed follow-up studies on 20 adults and 2 teenagers who had coxsackievirus B myocarditis or pericarditis and found that 5 (23%) patients had chronic heart failure. Unfortunately, the duration of time since the primary illness of the patients was not reported.

Bergström and colleagues[77] performed follow-up examinations on five patients (two teenagers and three adults) who had had enteroviral myopericarditis and found that none had significant complaints or physical signs. No follow-up data are available for neonates, infants, and children who have had enteroviral myocarditis.

In 1954, Stürup[907] reported a follow-up study of patients admitted to the hospital in 1930 to 1932 with pleurodynia. Of nine patients evaluated, including four who had a history of acute pericarditis, none had constructive pericarditis.

Other Cardiac Manifestations

Several investigators have studied the possible association of coxsackievirus B infection and myocardial infarction.[370,376,572-574,679,719,724,774,1013,1015] In many instances, patients with infarction have been demonstrated to have concomitant coxsackievirus B infection.* In controlled studies, the results have varied. Nikoskelainen and associates[724] noted that 9 of 59 patients with acute myocardial infarction had coxsackievirus B infection, whereas in the control group of 38 patients without infarction, only 1 patient had evidence of infection. Similarly, Nicholls and Thomas[719] found that 26 percent of patients had infections, but no infections were found in the control subjects.

In contrast, five other studies failed to show an increased rate of infection in patients with myocardial infarction when compared with controls.[370,376,742,774,1013] However, two of these studies were performed during a nonenteroviral season,[774,1013] and in a third study, little coxsackievirus B activity occurred in the community during the study period.[370] Analysis of the available studies indicates that coxsackievirus B infection would appear to have a role in myocardial infarction. In one coxsackievirus B5 infection, inferolateral wall myocardial necrosis occurred, but coronary arteriography did not demonstrate obstruction.[245]

Chandy and associates[149] presented data in which antibody to group B coxsackieviruses was related to rheumatic-like valvular heart disease, and Burch and associates[109] demonstrated coxsackievirus B antigens in rheumatic lesions of the heart. Limson and colleagues[597] could find no association between group B coxsackieviruses and rheumatic fever. Soboleva and associates[888] noted an association between coxsackievirus A13 and rheumatic fever; they reported seven children with concomitant streptococcal and coxsackievirus A13 infection. Children with fulminant EV 71 infection have been noted to have acute left ventricular dysfunction.[146,150,442]

GENITOURINARY MANIFESTATIONS

Orchitis and Epididymitis

Group B coxsackieviruses are second only to mumps as causative agents of orchitis.† Coxsackievirus B5 is the virus associated most commonly with this disease, although coxsackieviruses B2 and B4 also have been implicated on many occasions. In almost all instances, orchitis is a secondary event in enteroviral infections.

*See references 19, 21, 23, 29, 95, 208, 241, 309, 318, 319, 405, 594, 596, 656, 694, 695, 697, 1037.

*See references 370, 376, 572, 573, 679, 719, 724, 742, 1013, 1015.
†See references 31, 168, 214, 311, 378, 525, 686, 864, 911, 992.

The most common association is with pleurodynia. The illness frequently is biphasic: fever and pleurodynia develop initially, and then apparent recovery is followed by orchitis approximately 2 weeks after onset. Many patients also have epididymitis. In epidemics of disease caused by group B coxsackieviruses, the occurrence of testicular involvement varies considerably. Generally, orchitis occurs infrequently, but in one outbreak of coxsackievirus B2, 17 percent of postpubertal male patients had orchitis, and 7 percent also had epididymitis.[168] Orchitis also is associated frequently with pericarditis and myocarditis. In one instance, coxsackievirus B5 was recovered from a testicular biopsy specimen.[214]

In virtually all instances, testicular involvement has occurred in postpubertal patients, mostly in young adults. In addition to coxsackieviruses B2, B4, and B5, other EVs have been implicated: coxsackieviruses B1 and B3[168,525] and echoviruses 6, 9, and 11.[525,990] Meningitis and exanthem have been associated with orchitis.

Nephritis

Scattered cases of nephritis associated with nonpolio enteroviral infections have been reported. Bayatpour and colleagues[58] noted acute glomerulonephritis in a 9-year-old boy with an extensive coxsackievirus B4 infection. This child had a concomitant rise in anti-streptolysin O titer. Yuceoglu and associates[1034] reported twins with echovirus 9 infection and acute glomerulonephritis; Burch and Colcolough[107] observed a patient with progressive fatal pancarditis and nephritis in whom coxsackievirus B4 antigen was found in the kidneys. Mesangiolytic glomerulonephritis associated with an echovirus 6 infection was described in an infant with immune deficiency.[444]

Other Genitourinary Findings

Hemolytic-uremic syndrome has been associated with virologic or serologic evidence of infection with coxsackieviruses A2, 4, 9, 10, 16, 21, and B1 to B6, echoviruses 4, 6, and 7, and parechovirus 1.[36,242,346,743,800,801] De Petris and colleagues[242] demonstrated titer rises to various EVs in patients with hemolytic-uremic syndrome who were both positive or negative for infections with verocytotoxin-producing *Escherichia coli*. Other abnormal renal or urinary findings in nonpolio enteroviral infections include the following: acute oliguric renal failure with coxsackievirus B5[30]; pyuria, hematuria, or proteinuria with echoviruses 1, 6, and 9 and coxsackievirus B5[168,505,584,839,856]; and hemorrhagic cystitis.[686] A 7-year-old girl with coxsackievirus A10 infection had vaginal ulcerative lesions,[673] and Wassermann test results have been falsely positive in patients with echovirus 9 and coxsackievirus B5 infections.[786]

HEMATOLOGIC FINDINGS

In 1968, Horwitz and Moore[433] described an outbreak of infectious lymphocytosis during which 27 mentally retarded children were studied. The mean WBC count of the study group patients was 57,200; lymphocytes accounted for at least 50 percent of the total in all cases. Approximately half the patients had low-grade fever, and 15 of 27 had moderate diarrhea. A nontypeable EV suggestive of coxsackievirus group A was recovered from the ill patients, and neutralizing antibody to a strain (EVU-16) of the isolated virus developed in 31 percent of the patients in whom serologic studies were performed.[379,433]

Letsas and colleagues[588] reported a 17-year-old-boy with fulminant myocarditis and hemophagocytic syndrome. Over the course of a 3-day period, his hematocrit decreased from 40.9 to 31.7 percent, and his platelet count went from 90,000 to 38,000/mm^3. Examination of the bone marrow revealed many mature histiocytes with active hemophagocytosis. The patient improved dramatically with inotropic and intravenous immunoglobulin (IVIG) treatment.

MUSCLE AND JOINT MANIFESTATIONS

Arthritis

During the period from 1971 to 1975, during which EVs were recovered from 7075 persons in the United States, 9 instances of rheumatic disease were reported[686]; although not clearly specified, 3 patients apparently had arthritis. Blotzer and Myers[86] noted an adult with echovirus 9 infection and the concomitant onset of arthritis that persisted for 3 months. Echovirus 9 was recovered from the synovial fluid of a man with acute monocytic arthritis,[556] and one adult and one adolescent had serologic evidence of coxsackievirus B4 infection in association with the onset of rheumatoid arthritis–like illness.[453]

Myositis

Because group A coxsackieviruses routinely cause myositis in suckling mice, a reasonable approach is to suspect a similar clinical manifestation in people. Myalgia also is a common complaint in illnesses caused by many coxsackieviruses and echoviruses.[31,168,311,388,562,647] However, almost no direct (demonstration of virus in muscle) or indirect (elevations in muscle enzymes) evidence of muscle involvement in routine enteroviral illnesses exists. Of the nine patients with rheumatic disease described by Morens and colleagues,[686] six apparently had myositis; in one instance, coxsackievirus A2 was implicated, and in another patient with polymyositis, coxsackievirus A9 was the related agent. Three patients with echovirus 18 infection and polymyositis have been reported.[517] Acute rhabdomyolysis in one adult and myositis, myoglobinemia, and myoglobinuria in another adult have been associated with echovirus 9 infection.[477,492] Christensen and associates[197] noted that children with dermatomyositis were more likely to have serum antibody to one or more coxsackieviruses B than were control children. Chou and Gutmann[193] noted EV-like particles in the muscles of two patients with fatal dermatomyositis; Tang and colleagues[920] demonstrated coxsackievirus A9 in the muscles of an 11-year-old girl with chronic myopathy. Using both PCR and dot-blot hybridization assays, Fox and colleagues[307] could not find evidence of persistent enteroviral infection in 32 adults with inflammatory muscle disease (1 patient with dermatomyositis and 31 patients with polymyositis).

Yousef and coworkers[1031] reported EV RNA in biopsy specimens from 6 of 13 patients (46%) with idiopathic polymyositis or dermatomyositis but in no samples from 13 patients with other muscle disorders. Behan and associates[59] looked for picornavirus RNA in biopsy specimens from 41 patients with inflammatory myopathy, but all results were negative.

Dekel and associates[240] reported a 4-year-old girl with localized thigh swelling caused by coxsackievirus A21. On muscle biopsy, perivascular infiltrates were noted, but the muscle fibers were not affected. Widespread edema was found in the muscle.

SKIN MANIFESTATIONS

Nonpolio EVs as a group are a common cause of a variety of skin manifestations.[166,993,997] In the summer and fall, these viruses are the leading cause of exanthems. Variation in the clinical expression rate of exanthem and in the age of the host is marked among the various viral types. In general, dermatologic expression is

related inversely to the age of the infected patient. The frequency of exanthem and common associated illnesses by viral type are presented in Table 178–13.

Coxsackievirus A2

Rash associated with coxsackievirus A2 has occurred rarely. Febrile illness with exanthem in conjunction with coxsackievirus A2 infection was observed in Cincinnati in 1957; no details of this outbreak were presented.[836] Assaad and Cockburn[34] reviewed approximately 15,000 enteroviral illnesses for the period from 1967 to 1970 that were reported to the WHO and noted that in 45 instances, skin or mucous membrane lesions associated with coxsackievirus A2 infection were the main clinical manifestations.

Coxsackievirus A3

One case was reported, but no details are available.[682]

Coxsackievirus A4

Exanthem has been noted infrequently with coxsackievirus A4 infection.[34,172,302,691,1036] However, many cases may be missed because this virus grows poorly in tissue culture, and suckling mouse inoculation rarely is used in diagnostic laboratories. Six children were observed in one outbreak.[302] All patients initially had herpangina, and then the exanthem appeared concurrently with or after defervescence. It initially was erythematous, maculopapular, and discrete. In some children, the rash resolved within 4 days, but in others it progressed and became vesicular. The vesicular lesions occurred in crops, spread to the extremities but not the palms and soles, and were yellowish, opaque, and 5 to 10 mm in size. They persisted for 1 to 2 weeks and regressed, with a brownish discoloration. The lesions easily were confused with resolving bug bites. Other manifestations of coxsackievirus A4 infection include an exanthem suggesting combined scarlet fever and rubella,[337] a maculopapular rash that clears with desquamation,[691] and an anaphylactoid, purpura-like rash (see Fig. 64–15).[172]

Coxsackievirus A5

During the 4-year period studied by Assaad and Cockburn,[34] coxsackievirus A5 was second only to coxsackievirus A16 in the number of instances for which exanthem or mucous membrane involvement was the main clinical manifestation. Even with this apparent frequency, most instances of exanthem have been sporadic rather than part of an outbreak of exanthematous disease. The most common finding is the hand, foot, and mouth syndrome, which is not clinically discernible from that caused by coxsackievirus A16.[221,298,302] In one patient, the virus was recovered from vesicular fluid.[298]

Coxsackievirus A7

Coxsackievirus A7 was recovered from one child with a morbilliform rash and aseptic meningitis.[372] An adult with a fatal coxsackievirus 7 infection had pancarditis, pneumonia, and hand, foot, and mouth syndrome.[45]

Coxsackievirus A9

Coxsackievirus A9 is a common cause of exanthem (see Figs. 64–12 and 64–14).* In contrast to coxsackievirus A16 and echovirus 9, in which rates of clinical exanthem expression are high, the rate of skin manifestations in coxsackievirus A9 infection is low. A review of 259 coxsackievirus A9 infections in 1970 revealed an exanthem rate of 4 percent.[168] Most cases of coxsackievirus A9 exanthem occur sporadically, although a few outbreaks have been described.[175,586,732]

Skin manifestations in coxsackievirus A9 infection have been interesting and varied. The most common rash illness is characterized by fever and an erythematous, maculopapular rash that starts on the face and neck and spreads to the trunk and extremities. Aseptic meningitis is a common associated finding.

In 1960, Lerner and colleagues[587] reported on 11 children with exanthem associated with coxsackievirus A9 infection. Six had vesicular lesions, and 2 patients had associated viral pneumonia. Since 1960, vesicular exanthem has been noted on several occasions.[168,175,449] Most commonly, illnesses have been described as hand, foot, and mouth syndrome, but when the reports were analyzed, the rashes were vesicular but not always in a peripheral pattern.

Papular urticaria and large urticarial lesions have been an occasional manifestation of coxsackievirus A9 infection (see Fig. 64–12).[172,175] Other manifestations include Stevens-Johnson syndrome and a severe illness simulating meningococcemia (see Fig. 64–14).[172,686]

Coxsackievirus A10

The most common exanthematous illness associated with coxsackievirus A10 infection is the hand, foot, and mouth syndrome.[110,168,203,260,465,590] Stevens-Johnson syndrome was associated with coxsackievirus A10 infection in one instance,[168] and a child with ulcerative genital lesions also was reported.[673]

Coxsackievirus A16

In the WHO review of enteroviral infections for the 4-year period from 1967 through 1970, coxsackievirus A16 was associated with almost half of all skin or mucous membrane diseases. Coxsackievirus A16 is the major cause of hand, foot, and mouth syndrome (see Figs. 64–9 through 64–11 and 64–16). Of historical interest is that hand, foot, and mouth syndrome apparently was a new clinical entity in 1956.[731] It was noted in sporadic outbreaks until approximately 1963, and since that time it has been a regularly recurring disease throughout the world.* Serologic data suggest that coxsackievirus A16 was not in wide circulation until approximately 1963.[171]

The symptoms and signs of coxsackievirus A16 hand, foot, and mouth syndrome are recorded in Table 178–14. All illnesses have a typically enteroviral pattern with a short incubation period (4 to 6 days) and a summer and fall seasonal pattern. The clinical expression rate of the enanthem-exanthem complex is high: close to 100 percent in young children, 38 percent in schoolchildren, and 11 percent in adults.[687] Exanthem occurs more commonly in children, but in adults, the rash occurs more frequently with coxsackievirus A16 than with any of the other enteroviral agents.

Illness is ushered in with a mild prodromal fever, anorexia, malaise, and frequently a sore mouth. Enanthem occurs 1 to 2 days after the onset of fever, and the exanthem appears shortly thereafter. Of the cutaneous lesions, oral lesions are present more consistently than lesions of the skin. Because of this prevalence, illness, particularly in adults, is identified mistakenly as aphthous stomatitis (canker sores) or herpes simplex virus (HSV) infection. The intraoral lesions are ulcerative and average approximately 4

*See references 34, 168, 172, 175, 429, 449, 487, 490, 530, 587, 686, 732, 1003.

*See references 9, 15, 26, 31, 103, 168, 171, 196, 281, 302, 315, 337, 352, 354, 355, 418, 420, 590, 619, 620, 652, 687, 710, 809, 813, 932.

to 8 mm in size. The tongue and buccal mucosa are involved most frequently.

As noted in Table 178–14, the hands are involved more commonly than are the feet. Buttock lesions also occur frequently, but they usually do not progress to vesiculation. The lesions on the hands and feet generally are vesicular and vary in size from 3 to 7 mm; they typically occur more commonly on the dorsal surfaces but frequently on the palms and soles as well. The vesicles contain virus, but cytologic examination usually does not reveal diagnostic findings. These lesions clear by absorption of the fluid in approximately 1 week.

Of considerable interest is the frequent association of coxsackievirus A16 with subacute, chronic, and recurring skin lesions.[281,710] Evans and Waddington[281] described an 84-year-old woman with chronic recurring skin lesions of more than 2 years' duration. Nankervis and associates[710] noted both subacute and recurring lesions in children. Higgins and Crow[418] reported a 31-year-old woman with Darier disease who had a Kaposi varicelliform eruption caused by coxsackievirus A16, and a similar illness was noted in a 1-year-old boy with eczema.[703] One child with a Gianotti-Crosti–like eruption (papular acrodermatitis of childhood) associated with coxsackievirus A16 infection was described.[472]

Coxsackievirus B1

Exanthem occasionally occurs in coxsackievirus B1 infections.[34,168,170,172,239,616] The most common cutaneous finding is an erythematous maculopapular eruption that is discrete. Two children with illnesses suggestive of hand, foot, and mouth syndrome have been observed.[172]

Coxsackievirus B2

Coxsackievirus B2–associated exanthem is a rare occurrence. Maculopapular, vesicular, and petechial lesions have been noted.[31,34,302]

Coxsackievirus B3

Exanthem occasionally is reported as a sporadic event in coxsackievirus B3 infections, and a small outbreak occurred in one instance.[31,34,115,212,292,395,447,586,1035] Erythematous maculopapular eruptions occur most commonly, but petechial rash illnesses suggestive of meningococcemia also have been observed. Hand, foot, and mouth syndrome was reported in one child,[586] and another child had a more generalized vesicular eruption. An adult with recurrent hand, foot, and mouth syndrome had a rise in neutralizing antibody titer to coxsackievirus B3.[212]

Coxsackievirus B4

Although cutaneous manifestations with coxsackievirus B4 were noted as frequently as were those associated with coxsackieviruses B1, B2, and B3,[34,168] few clinical descriptions exist.[506,527] Morbilliform, petechial, and urticarial rashes have been described.

Coxsackievirus B5

Of the group B coxsackieviruses, type B5 is noted most frequently to have skin manifestations.* The rash usually is maculopapular; petechial lesions are observed occasionally, and one child with urticaria was reported.[176] Several children studied by Cherry and colleagues[176] had a roseola-like illness pattern. During outbreaks of coxsackievirus B5 illness, approximately 10 percent of young children have an exanthem. Many patients have concomitant aseptic meningitis. One adult patient with recurrent hand, foot, and mouth syndrome had serologic evidence of coxsackievirus B5 infection.

Coxsackievirus B6

Goldwater[357] identified 97 children and adults with coxsackievirus B6 infection. The most prominent finding in these cases was cough and pneumonia. Twenty patients had exanthems; the rash was morbilliform and was associated with high fever and cough.

Echovirus 1

Exanthem and conjunctivitis have been associated with echovirus 1 infection in several children.[638]

Echovirus 2

Exanthem occasionally occurs with echovirus 2 infection.[168,839,896] The rash has been erythematous macular in some instances but usually is maculopapular and discrete. Most children have had associated fever and pharyngitis.

Echovirus 3

Exanthem was noted in 2 of 29 children with echovirus 3 infection.[400] In both instances, the rashes were petechial; most patients in this outbreak had aseptic meningitis. Details of other echovirus 3 infections and exanthems are lacking.[34,430]

Echovirus 4

Echovirus 4 is a common cause of epidemic aseptic meningitis, and exanthem is an associated finding in 10 to 20 percent of pediatric cases.[172,300,324,506,577,624,726,799,892] The rash usually is macular or maculopapular, has its onset 1 to 3 days after the initial fever, and lasts 1 to 2 days. A child with a petechial rash was noted.[506]

Echovirus 5

One major outbreak of echovirus 5 infection with exanthem was described.[342] This outbreak, which involved a maternity unit, resulted in a macular rash in 36 percent of the infants and in 14 percent of the mothers. The rash was most prominent on the limbs and buttocks, appeared 24 to 36 hours after the onset of fever, and lasted 2 days. Selwyn and Howitt[870] reported a child who had a macular rash with a zoster distribution. A neonate with sepsis-like illness and exanthem was described.[384]

Echovirus 6

Although echovirus 6 has been one of the more prevalent EVs since the late 1970s, it has been associated only sporadically with exanthematous disease. The following manifestations have been observed: morbilliform,[963] maculopapular,[646,1006] macular,[632] and papulopustular exanthems[505]; Stevens-Johnson syndrome[966]; and pityriasis rosea in an adult and a child.[505] Meade and Chang[651] reported an interesting zoster-like eruption in a 7-year-old boy in whom echovirus 6 was recovered from several bullae.

Echovirus 7

Echovirus 7 has been associated occasionally with exanthem.[34,226,475,682] In one outbreak of aseptic meningitis, 5 of 13

*See references 34, 91, 168, 176, 212, 244, 381, 403, 727, 773, 775, 848, 880, 902, 906, 912, 1006.

patients had erythematous maculopapular rashes that occurred during fever.[475] One child with a discrete maculopapular rash and thrombocytopenia was described.[638] The case of a 37-year-old woman with echovirus 7 infection, leukocytoclastic vasculitis, and palpable purpura was reported.[184]

Echovirus 9

Since the 1960s, echovirus 9 has been the most prevalent nonpolio EV, and exanthem is a common clinical manifestation (Table 178–15; see Fig. 64–13).* Nonspecific febrile illness and aseptic meningitis are the usual major manifestations of echovirus 9 infection. Exanthem occurs in approximately one third of cases. The prevalence of exanthem is related inversely to age; 57 percent of children younger than 5 years of age have a rash, whereas only 6 percent of those older than 10 years have similar cutaneous findings.[584] The rash usually is rubelliform, but in addition or as the sole manifestation, petechiae are common findings. Rash and fever generally appear at approximately the same time, and frequently the illness closely mimics meningococcemia. The rash usually lasts approximately 3 to 5 days. In one instance, the rash progressed to a vesicular stage.[581]

Echovirus 11

Exanthem occasionally occurs with echovirus 11 infection, and it varies considerably in appearance.[34,106,168,177,246,864] The most notable lesions have been bug bite–like vesicles and urticaria.[177] A child with subacute recurrent vesicular lesions[177] and a woman with a disseminated vesicular eruption were reported.[246]

Echovirus 13

One child with a maculopapular eruption was described.[426] During an outbreak of echovirus 13 aseptic meningitis in Israel, 15 patients had a concomitant exanthem.[890]

Echovirus 14

Echovirus 14 is a rare cause of exanthem, and few details are available.[34,839] One child with a scarlatiniform eruption and aseptic meningitis was reported.[839]

Echovirus 16

The first of the enteroviral exanthematous diseases to be described was that caused by echovirus 16. It initially was studied by Neva and Enders[715] and, later, Enders and colleagues,[717] and the illness was called *Boston exanthem*. Two outbreaks of echovirus 16 infection with exanthem were documented by Neva[714] in 1951 and by Neva and Zuffante[716] in 1954, and another occurred in Paris in 1960.[213] Since then, Boston exanthem has been reported only once. Seven cases were observed in 1974.[387]

The exanthem associated with echovirus 16 infection is erythematous, maculopapular, and discrete and is similar to that of other enteroviral infections. What has been unique with echovirus 16 infection is the relationship of rash with fever. Frequently, the illness resembles roseola in that the rash occurs at the time of or after defervescence.[166,387] Ulcerative lesions on the soft palate and tonsillar pillars (herpangina) sometimes have been observed.

*See references 34, 75, 168, 202, 210, 219, 237, 286, 299, 316, 325, 328, 359, 401, 429, 473, 487, 496, 525, 527, 540, 561, 581, 618, 645, 686, 723, 777, 784, 797, 831, 839, 889, 903, 916, 997.

Echovirus 17

Rash is an occasional occurrence in echovirus 17 infection.[34,103,172,178] In one outbreak, transient erythematous rashes were noted.[103] In cases that I (J. D. C.) studied, papular, maculopapular, and papulovesicular lesions were noted; two patients had herpangitic enanthems, and one had aseptic meningitis.[172,178]

Echovirus 18

Kennett and associates[517] described an extensive epidemic of echovirus 18 infection in which aseptic meningitis with or without exanthem was the major finding. In 15 patients, exanthem was the chief complaint. The rash was described as rubelliform. Most patients were children, but adults also had exanthem.

Echovirus 19

In one extensive epidemic of echovirus 19 infection, exanthem was a common occurrence.[209] Fifty percent of children younger than 6 months old had exanthem, and many of these infants presented a picture of septicemia with peripheral circulatory failure. Rash occurred in adults and older children, but the percentage decreased with age. The rash usually was erythematous, maculopapular, and discrete. It started on the face and upper part of the trunk and spread to the extremities. Fever occurred in all cases, and meningitis and signs of upper respiratory tract involvement were noted frequently. In another outbreak of echovirus 19 infection, 33 percent of those infected had exanthem,[358] whereas in an outbreak studied by Cramblett and colleagues,[217] exanthem was a rare finding.

Echovirus 21

A 19-day-old infant with aseptic meningitis and rash was reported.[191]

Echovirus 24

A 4-month-old infant had rash and aseptic meningitis as a result of echovirus 24 infection.[191]

Echovirus 25

Echovirus 25 has been associated with an array of different skin manifestations.[64,173,380,690,708] In one epidemic of febrile pharyngitis, approximately one third of the patients had exanthem.[690] The rash usually was maculopapular and discrete, but occasionally it displayed a morbilliform confluence. The rash most frequently occurred during the period of defervescence.

Of considerable interest are two children with acute hemangioma-like lesions.[173] The lesions were erythematous and papular and surrounded by a 1- to 4-mm-wide halo of blanched-appearing skin. The center of each lesion had a bright red dot that suggested a dilated capillary or terminal arteriole. The whole lesion blanched with pinpoint pressure in its middle.

Echovirus 30

Echovirus 30 is a common cause of epidemic aseptic meningitis, and exanthem occasionally is noted concomitantly. The rash is macular or maculopapular.[34,168,460,502,579,935,1021]

Echovirus 32

Two children with echovirus 32 infection and hemangioma-like lesions were described by Cherry and colleagues.[173] Some lesions

seemed to be composed of many dilated capillaries; they easily blanched with pressure.

Echovirus 33

Four patients with aseptic meningitis and echovirus 33 infection also had exanthem.[504,514] Two adults had vesicular lesions that suggested HSV infection.[239]

Enterovirus 71

Kennett and associates[516] studied 49 patients with EV 71 infection and noted exanthem in 11. Six patients had aseptic meningitis, and rash was the predominant complaint in 5 patients. The exanthems varied: some were erythematous maculopapular, some vesicular, and some a combination of lesions. Two children had hand, foot, and mouth syndrome, and a single child had a florid, diffuse erythematous rash. Outbreaks of hand, foot, and mouth syndrome caused by EV 71 have been observed in Japan, Sweden, Australia, the United States, Taiwan, and Malaysia.* In many cases, varied neurologic manifestations also occurred.

Parechovirus 1

A morbilliform rash was noted in three infants with respiratory disease and parechovirus 1 infection.[79]

Clinical Exanthematous Manifestations and Syndromes

The major clinical exanthematous manifestations and syndromes of coxsackieviruses and echoviruses are presented in Table 178–16. Unusual findings include hemangioma-like lesions with echoviruses 25 and 32, anaphylactoid purpura with coxsackievirus A4 and echoviruses 9 and 18, zoster-like rash with echoviruses 5 and 6, pityriasis-like rash with echovirus 6, and chronic or recurrent rash with coxsackievirus A16 and echovirus 11.

NEUROLOGIC MANIFESTATIONS

Neurologic illness is a frequent manifestation of infection with most EVs and parechoviruses. The most common illness is aseptic meningitis, but encephalitis and other manifestations also occur. The prevalence of nonpolio EVs and parechoviruses in the various clinical syndromes is presented in Table 178–17.

Aseptic Meningitis

Aseptic meningitis caused by EVs occurs both in epidemics and as isolated cases. The etiologic agents most often associated with epidemic disease are presented in Table 178–18. Epidemic disease has occurred most commonly with coxsackievirus B5 and echoviruses 4, 6, 9, 13, and 30. In general, illness occurs more frequently in children, but if a specific outbreak is large, adults also are involved. Virtually all patients have fever and pharyngitis; other respiratory manifestations occur commonly. Rash is a frequent occurrence but varies with the specific viral agents. Between one third and one half of all patients with echovirus 9 meningitis have exanthem. Abdominal pain is a common complaint in patients with epidemic enteroviral aseptic meningitis.

Except for rash, herpangina, pleurodynia, or myocarditis, little else occurs clinically to help identify the origin in a sporadic case of aseptic meningitis. Initial symptoms include fever, headache, malaise, nausea, and vomiting. The headache usually is frontal or generalized; adolescents and adults frequently note retrobulbar pain. Pain in the neck, back, and legs occurs commonly. Abdominal pain is noted in approximately one fifth of patients, but this symptom varies with the specific etiologic viral type. Photophobia is a common occurrence.

Physical examination reveals a temperature in the range of 38° C to 40° C (100.4° F to 104° F). Skin rash occurs often and usually is erythematous, maculopapular, and discrete. Frequently, particularly with echovirus 9 infection, the rash is petechial and suggests meningococcemia. Hand, foot, and mouth syndrome is a common event in cases of aseptic meningitis caused by EV 71 infection.[146,150,423,547,650] Pharyngitis occurs frequently. Generalized muscle stiffness or spasm usually is observed, although the degree varies considerably; the Kernig and Brudzinski signs are positive in fewer than half the cases. Deep tendon reflexes usually are normal. In one study, 9 percent of children with enteroviral meningitis had the syndrome of inappropriate secretion of antidiuretic hormone.[161] The onset of this syndrome was noted 36 hours after admission to the hospital, and it usually lasted less than 2 days.

Examination of CSF reveals considerable variation among patients and in the same patient on repeated examination. CSF leukocyte counts vary from a few cells to a few thousand per cubic millimeter; the median is in the range of 100 to 500 cells/mm^3. The percentage of neutrophils also varies greatly. Initial examinations frequently reveal a predominance of neutrophils, but rarely more than 90 percent, as seen in bacterial disease. Usually, a range between 30 and 60 percent neutrophils is found on initial examination. Repeated examinations of CSF demonstrate an increasing percentage of mononuclear cells. Dagan and colleagues[227] observed that the rate of isolation of virus from the CSF in enteroviral meningitis was directly proportional to the number of leukocytes in the fluid. Dalal and associates[232] found that children with echovirus 4 meningitis had elevated values of interleukin 6 and interferon in the CSF and that the interleukin 6 value correlated with the CSF leukocyte values.

CSF protein levels usually are elevated mildly, and glucose concentrations usually are normal; hypoglycorrhachia rarely occurs.* Occasionally, the CSF findings suggest tuberculosis meningitis with mononuclear pleocytosis, hypoglycorrhachia, and elevated protein levels.[623] A child with coxsackievirus B4 meningitis had eosinophils in the CSF.[179] The results of other routine laboratory studies such as the WBC count occasionally are abnormal but are not helpful diagnostically.

The duration of illness varies significantly. In most patients, the temperature returns to normal within 4 to 6 days, and disability as a result of neurologic involvement lasts 1 to 2 weeks. Occasionally, the pattern of illness is biphasic: an initial period with fever, headache, nausea, vomiting, and muscle aches and pains of a few days' duration is followed by general recovery and then a return to the same symptoms in addition to more pronounced neurologic involvement.

Wilfert and associates[1000] performed a longitudinal assessment of children who had enteroviral meningitis early in life and found that receptive language functioning was significantly worse than that of children in a control group without meningitis. In another study, Sells and colleagues[869] examined the long-term effects of CNS enteroviral infection in 19 children. Of this group, 11 were free of detectable abnormalities, 5 had possible defects, and 3 had definite neurologic sequelae. In more recent studies, patients who have had meningitis have

performed as well as controls in follow-up developmental evaluations.[76,820,825]

Encephalitis

In the United States, approximately 2500 cases of encephalitis per year, on average, are reported to the CDC.[127] Of this group, only approximately 2 percent of these patients demonstrate an enteroviral origin. However, the seasonal pattern of disease and the absence of arboviral activity in many geographic locations suggest that 500 to 1000 cases of enteroviral encephalitis actually occur each year in the United States. The prevalence of coxsackieviruses and echoviruses as etiologic agents in encephalitis is presented in Table 178–17. Echovirus 9 is the most frequent cause of enteroviral encephalitis. Other enteroviral types commonly associated are echoviruses 4, 6, 11, and 30 and coxsackievirus B5. Echoviruses 4, 6, and 11 have been noted most frequently over a long period.

In general, the prognosis in encephalitis caused by enteroviral infection is good, but fatalities do occur. The viral types that have been isolated from the brain or CSF in fatal cases are as follows: coxsackieviruses B3 and B6; echoviruses 2, 9, 17, and 25; and EV 71.[378,525] Since the mid-1980s, outbreaks of disease caused by EV 71 have occurred in Southeast Asia.* These outbreaks have been characterized by hand, foot, and mouth syndrome, herpangina, and a spectrum of neurologic diseases including severe, often fatal, encephalitis.

In an outbreak in Taiwan in 1998, 30 of 78 (38%) patients with severe illness had encephalitis, and 25 of these patients with encephalitis also had pulmonary edema or hemorrhage, 2 had myocarditis, and a single patient had acute flaccid paralysis.[423] In another study, 30 of 34 children with CNS involvement had brain stem encephalitis, and 9 of this group (30%) died.[976] Children who recovered from EV 71 encephalitis associated with cardiopulmonary failure often had neurologic sequelae with delayed neurodevelopment and reduced cognitive function.[155,781]

Paralysis

Paralysis caused by anterior horn cell disease occasionally results from infection with nonpolio EVs. In contrast to the prevalence of poliovirus, which in the pre-vaccine era resulted in epidemic paralytic disease, paralysis caused by nonpolio EVs usually is a sporadic event. Coxsackievirus A7 has been associated with outbreaks of paralytic disease on three occasions.[375,377,967] Many cases of illness similar to poliomyelitis have occurred during outbreaks and epidemics of illness caused by EV 71.[13,235,343,402,464,660,845] Paralytic disease also has been noted during epidemics of acute hemorrhagic conjunctivitis caused by EV 70.[969,1027]

Guillain-Barré Syndrome and Transverse Myelitis

As Table 178–17 shows, many coxsackieviruses and echoviruses apparently have been associated with Guillain-Barré syndrome. In general, no specific viral types appear to cause the disease. Rather, the disease occurs sporadically in association with the prevalent enteroviral types.

Other Neurologic Illnesses

Cerebellar ataxia has been associated with coxsackieviruses A4, A7, A9, B3, and B4 and echoviruses 6, 9, and 16 (see Table 178–17). Scott[864] specifically commented on peripheral neuritis with echovirus 9 infection. Coxsackievirus A9 has been associated with focal encephalitis and acute hemiplegia on two occasions,[141,168] and echovirus 25 infection was noted in a 5-year-old boy with focal encephalitis and subacute hemichorea.[764] Coxsackievirus B4 was isolated from the CSF of a 22-year-old woman with intracranial hypertension,[1016] and postencephalitis Parkinson syndrome occurring after an episode of coxsackievirus B2 meningoencephalitis was described.[970] Two children with coxsackievirus B3 infections had a syndrome of opsoclonus-myoclonus.[554] The case of a 4-year-old boy with "Alice in Wonderland" syndrome (complex symptoms of perceptual distortion) associated with coxsackievirus B1 infection was described.[975]

Phillips and colleagues[770] and Barrett and associates[51] noted the simultaneous occurrence of enteroviral and St. Louis encephalitis viral infection in the same community. In six instances, dual infections occurred, and the afflicted children tended to have more serious illnesses. Ribai and colleagues[807] noted an 18 month-old boy with transient cerebral arteriopathy and an enteroviral infection. The child had aphasia, right hemiplegia, and seizures, which occurred intermittently over a 3-day period.

Ergul and associates[277] described a 7-year-old boy with vestibular neuritis from whom enteroviral RNA was found in both the CSF and a nasopharyngeal sample. Multiple attacks of enteroviral aseptic meningitis in the same individuals have been noted occasionally.[541,707]

Woodall and associates[1014] found conserved enteroviral sequences in spinal cords from subjects with sporadic motor neuron disease and from one patient with possible familial motor neuron disease. Berger and associates[74] noted EV RNA sequences in spinal cord specimens from 13 of 17 patients with amyotrophic lateral sclerosis, but Walker and colleagues[776] could not duplicate these findings in a study of 20 spinal cord specimens from similar patients. Simonsen and coworkers[883] noted an outbreak of vertigo in Wyoming in August of 1992 in which IgM antibody studies suggested an enteroviral origin.

CHRONIC FATIGUE SYNDROME/FIBROMYALGIA

From molecular techniques and antibody prevalence data, chronic enteroviral infections have been suggested to play a role in the chronic fatigue and postviral fatigue syndromes.[25,114,205,694,1030] However, these findings have not been confirmed by other investigators.[656,670,910] More recently, Douche-Aourik and associates[253] found enteroviral RNA in muscle biopsies from 4 of 30 (13%) patients with fibromyalgia/chronic fatigue syndrome but in no biopsy samples from 29 healthy subjects. However, in none of the 4 positive samples could the presence of VP1 enteroviral capsid protein be demonstrated using a specific monoclonal antibody. In another study, Lane and colleagues[569] found enteroviral RNA in muscle biopsy samples of 10 of 48 patients (20.8%) with chronic fatigue syndrome and in no samples from 29 controls. These investigators also found that 9 of the 10 subjects with positive muscle biopsies had abnormal lactate responses to exercise in the subanaerobic threshold exercise test (SATET). In an editorial relating to these data, Dalakas[229] warned that similar findings in the past were "epiphenomenal" because EVs are ubiquitous in humans and technical flaws inherently connected to contamination in laboratories working with these viruses are inevitable.

The biggest proponents for a causal role of EV in chronic fatigue syndrome are Chia and Chia.[183,185] Although they have extensive experience with chronic fatigue syndrome and have conducted several studies, none of their data has been controlled or subjected to peer review.[545]

*See references 118, 145, 146, 150, 153-155, 164, 189, 317, 423, 436, 441-443, 464, 500, 547, 593, 599-602, 610, 634, 649, 650, 728, 744, 745, 781, 972-974, 1024.

SUDDEN INFANT DEATH

Balduzzi and Greendyke[46] recovered coxsackievirus A5 from the stool of a 1-month-old child who experienced sudden infant death. In a similar investigation of sudden infant death, Gold and associates[356] recovered coxsackievirus A4 from the brains of three babies. Coxsackievirus A8 also was recovered from the stool of a child in whom anorexia was noted on the day before death. Coxsackievirus B3 was recovered at the autopsy of an infant who died suddenly on the eighth day of life.[46] Morens and colleagues[686] noted sudden infant death eight times in association with enteroviral infection; parechovirus was found on two occasions. In a subgroup of infants with sudden unexplained death in whom the "clinical, biologic, and histologic" findings suggested viral infection, evidence of enteroviral infection was found more frequently than in infants without findings of viral infection.[365] Specifically, enteroviral RNA was detected in the respiratory tract in 54 percent of the viral infection group and in none of the group without findings suggestive of viral infection. These results were supported by IgM antibodies to coxsackieviruses B in 56 percent of the first group and in none of the second group. Four infants with suspected sudden infant death syndrome were found to have coxsackievirus B3 myocarditis with minimal histopathologic changes.[248] In five instances of crib death in one study, echovirus 11 was isolated from the lungs in two cases, from the myocardium in one case, and from the nose or feces in the other two cases.[83]

CHRONIC ENTEROVIRAL INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

Patients with cell-mediated and combined immunodeficiencies are susceptible to chronic and often fatal infections with many viruses.[321] Patients with agammaglobulinemia and normal cell-mediated function generally survive infections with these same viruses. EVs are the exception, however, in that chronic, unusual infections with a variety of EVs have been reported.* The most common illness is meningoencephalitis, but arthritis and polymyositis are other frequent findings. Echovirus 11 has been the most common cause of chronic infection, but the following other EVs also have been causative: echoviruses 2, 3, 5, 6, 7, 9, 13, 14, 15, 17, 18, 19, 21, 24, 25, 26, 29, 30, and 33; coxsackieviruses A11, A15, B1, B2, and B3; and parechovirus 1.[642] EVs have been recovered from many other body sites, such as the liver, heart, lung, pancreas, lymph nodes, bone marrow, muscle, throat, and stool, in addition to the CSF.

Several patients with X-linked agammaglobulinemia have had polymyositis-like or dermatomyositis-like syndromes caused by echovirus infections; the following echoviruses have been implicated: types 2, 3, 5, 9, 11, 17, 19, 24, 25, 30, and 33.[50,220,653] The case of a 15-year-old boy with X-linked agammaglobulinemia and chronic arthritis caused by echovirus 11 was reported.[8] Three children with X-linked hyper-IgM syndrome and persistent enteroviral meningoencephalitis were described.[223] Persistent enteroviral infections of the CNS were reported in pediatric and adult patients infected with human immunodeficiency virus (HIV).[265,753] In addition, enteroviral infections caused deaths in bone marrow transplant recipients.[24,322]

CONGENITAL INFECTIONS

Abortion

Landsman and associates[566] studied 2631 pregnancies during an epidemic of echovirus 9 and could find no difference in antibody to echovirus 9 in women who aborted and in those who delivered term infants. A similar study in Finland revealed no increase in the abortion rate in women infected in early pregnancy with echovirus 9.[797] Although coxsackieviral infections occur commonly, epidemics with specific viral types involving large populations have not been studied.

Two women with coxsackievirus A16 hand, foot, and mouth syndrome had spontaneous abortions.[741] In one instance, coxsackievirus A16 was recovered from the products of conception. Frisk and Diderholm[312] found that 33 percent of women with abortions had IgM antibody to coxsackieviruses B, whereas only 8 percent of controls had similar antibody. In a second, larger study, the same research group confirmed their original findings.[39]

Congenital Malformations

In a large prospective study, Brown and Karunas[102] made a serologic search for selected maternal enteroviral infections in association with congenital malformations. Sera from 630 mothers of infants with anomalies and from 1164 mothers of children without defects were studied carefully. Specifically, serologic evidence of infection with coxsackieviruses B1, B2, B3, B4, B5, and A9 and with echoviruses 6 and 9 was sought during the first trimester and during the last 6 months of pregnancy. In this study, infants were examined for 113 specific abnormalities; these anomalies were grouped into 12 categories for analysis. The investigators demonstrated a positive correlation between maternal infection and infant anomaly with coxsackieviruses B2, B3, B4, and A9. The overall anomaly rate associated with first-trimester infection with coxsackievirus B4 was significantly higher than that in controls. Maternal coxsackievirus B2 infection throughout pregnancy, coxsackievirus B4 infection during the first trimester of pregnancy, and infection with at least one of the five group B coxsackieviruses during pregnancy all were associated with urogenital anomalies when compared with controls. Coxsackievirus A9 infection was associated with digestive anomalies and coxsackieviruses B3 and B4 with cardiovascular defects. When coxsackieviruses B were analyzed as a group (B1 to B5), an overall association with congenital heart disease was found; the likelihood of having cardiovascular anomalies was increased when maternal infection with two or more coxsackieviruses B occurred.

Gauntt and colleagues[333] found that ventricular fluid from 4 of 28 babies with severe anatomic defects contained neutralizing antibody to one or more coxsackievirus B types. In one case, specific IgM antibody to coxsackievirus B6 was demonstrated.

In a serologic study in Scotland, Ross and colleagues[821] found no association between maternal coxsackievirus B infection and fetal developmental anomalies. Elizan and associates[273] were unable to find any relationship between maternal infection with coxsackieviruses B and congenital CNS malformations. In three studies, no association between maternal echovirus 9 infection and congenital malformation was noted.[540,566,797]

Prematurity and Stillbirth

Bates[55] reported an 8-month-old stillborn fetus with calcific pancarditis and hydrops fetalis at autopsy. Fluorescent antibody study revealed coxsackievirus B3 antigen in the myocardium. Burch and colleagues[108] reported three stillborn infants who had fluorescent antibody evidence of coxsackievirus B myocarditis, one each with coxsackieviruses B2, B3, and B4. These investigators also described a premature boy who had histologic and immunofluorescent evidence of cardiac infection with coxsackieviruses B2, B3, and B4; he lived only 24 hours.

Freedman[310] reported the occurrence of a full-term stillbirth in a woman infected with echovirus 11. Because the baby had no

*See references 8, 83, 87, 211, 220, 223, 261, 264, 278, 385, 389, 414, 507, 642, 828, 957, 985, 987, 999.

pathologic or virologic evidence of infection, Freedman attributed the event to a secondary consequence of maternal infection caused by fever and dehydration rather than primary transplacental infection. In another stillbirth in which echovirus 11 was recovered from amniotic fluid, the fetus was found to have evidence of focal encephalitis, massive adrenal hemorrhage, and diffuse subarachnoid hemorrhage.[887] Echovirus 27 was recovered from amniotic fluid in an intrauterine fetal death at 28 weeks' gestation.[719] A 26-week, 1300-g stillborn fetus with hydrocephalus, fibrotic peritonitis, and hepatosplenomegaly was found by PCR and immunohistochemical study to have an EV 71 infection.[194] A baby of 26 weeks' gestation with non-immune hydrops fetalis with an intrauterine infection with coxsackievirus B3 was reported by Ouellet and coworkers.[750]

NEONATAL INFECTIONS

Epidemiology and Pathogenesis

Neonatal infection with coxsackieviruses and echoviruses can result from transplacental viral transmission, contact infection during birth, and human-to-human contact after birth. Transplacental passage of coxsackieviruses and echoviruses at term has been noted on many occasions. Benirschke[69] studied the placentas in three cases of congenital coxsackievirus B disease and could find no histologic evidence of infection. In 1956, Kibrick and Benirschke[526] reported the first case of intrauterine infection with coxsackievirus B3. In this instance, the infant was delivered by cesarean section and became symptomatic several hours after birth. Brightman and associates[98] recovered coxsackievirus B5 from the placenta and rectum of a premature infant. No histologic abnormalities of the placenta were noted.

Berkovich and Smithwick[80] noted an asymptomatic neonate who had specific IgM parechovirus 1 antibody in cord blood, thus suggesting intrauterine infection with this virus. Hughes and colleagues[448] reported a newborn infant with echovirus 14 infection who had markedly elevated IgM (190 mg/dL) on the sixth day of life. This child probably also was infected in utero. In addition, echovirus 19 has been noted in a transplacentally acquired infection.[767] Other evidence of intrauterine infection has been presented for coxsackieviruses A4, B1, B2, B3, B4, and B5 and echoviruses 9, 11, and 19.[55,70,90,168,178,280,395,491,503,622,750,767,925]

Little definitive evidence exists for either ascending infection or contact infection with coxsackieviruses or echoviruses during birth. However, transmission of infection during the birth process seems probable.[165,178,503] The fecal carriage rate of EVs in asymptomatic adult patients varies between 0 and 6 percent or higher in different population groups.[168] Cherry and colleagues[178] reported that in 2 of 55 mothers (4%), EVs were present in feces shortly after delivery.

Coxsackievirus B5 was recovered from the cervices of four women with febrile illnesses during the third trimester of pregnancy.[804] Echovirus 11 was isolated from the cervix of a mother whose baby became ill on the third day of life with fatal echovirus 11 necrotizing hepatitis.[803] Chang and colleagues[152] detected coxsackievirus B3 in breast milk of two symptomatic mothers, and their babies both suffered severe illnesses with hepatic necrosis and meningitis caused by coxsackievirus B3.

Several epidemics with coxsackieviruses and echoviruses in newborn nurseries have been studied.[98,119,667,702] Brightman and associates[98] observed an epidemic of coxsackievirus B5 in a premature nursery. Their data suggested that the virus was introduced into this nursery by an asymptomatic infant who had been infected in utero. Secondary infections occurred in 12 babies and 2 nurses. The timing of the secondary cases suggested that three generations had occurred and that the nurses had been infected during the second generation. The investigators suggested that the infection had spread from infant to infant and from infant to nurse.

Javett and associates[476] reported an acute epidemic of myocarditis associated with coxsackievirus B3 infection in a Johannesburg maternity home. Unfortunately, no epidemiologic investigation or search for asymptomatic infected infants was performed. However, in analyzing the dates of onset of the illnesses, single infections apparently occurred for five generations, and then five children became ill within a 3-day period.

Kipps and colleagues[535] carried out epidemiologic investigations in two coxsackievirus B3 nursery epidemics. In the first epidemic, the initial infection probably was transmitted from a mother to her baby; this baby then was the source of five secondary cases in newborn infants and one illness in a nurse. Four of the five secondary cases were located on one side of the nursery, but only one crib was close to that of the index baby, and this crib did not adjoin the cribs of the three other contact cases. In the second outbreak, a baby who also was infected by his mother probably introduced the virus into the nursery. The three secondary cases were geographically far removed from the primary case.

Cramblett and colleagues[215] reported an outbreak of echovirus 11 disease in four infants in an intensive care nursery. All infants were in enclosed incubators, and three patients became ill within 24 hours; the fourth child became ill 4 days later. Echovirus 11 was recovered from two members of the nursery staff. These data suggest that transmission from personnel to infants occurred because of inadequate washing of hands.

In another outbreak in an intensive care unit, the initial patient was transferred to the nursery because of severe echovirus 11 disease.[702] After transfer, the senior house officer and a psychologist in the unit were infected. The investigators inferred that these infected personnel spread the disease by respiratory droplet to nine other babies. In another nursery outbreak of echovirus 11, Mertens and colleagues[667] found that the infection spread through close contact between infected newborns and the nurses in the unit. Spread of infection was interrupted with the installation of vigorous hygienic and isolation measures. In an outbreak of echovirus 11 in an intermediate care unit, Kinney and colleagues[534] found that gavage feeding, mouth care, and being a twin were risk factors for acquiring illness.

Many other instances of isolated nursery infections and small outbreaks with coxsackieviruses and echoviruses have been reported. The most consistent source of original nursery infection seems to be transmission from a mother to her baby,* but virus can be introduced into the nursery by hospital personnel.[461,571,912]

In a longitudinal study of neonatal enteroviral infections carried out during the summer and fall of 1981, Jenista and associates[478] found that the nonpolio enteroviral infection rate was 12.8 percent. Lower socioeconomic status and lack of breastfeeding were found to be risk factors for acquiring infection. Nonpolio enteroviral infections were determined to be a significant cause for re-admission of the cohort neonates to the hospital. During a community outbreak of echovirus 11 disease, Modlin and colleagues[678] found that passive transplacental passage of antibody to neonates prevented the development of severe disease but not mucosal infection.

Clinical Manifestations

Coxsackieviral and echoviral infections in neonates result in a wide variety of clinical manifestations ranging from asymptomatic infection to fatal encephalitis and myocarditis.[169] Unfortunately, in more recent years, enteroviral illnesses have not been examined by specific viral type, but rather have been evaluated in a more generic fashion.[5,6,857] An overview by illness category and prevalence is presented in Table 178–19.

Cox, coxsackievirus; echo, echovirus.

INAPPARENT INFECTION

Although inapparent infection probably occurs occasionally with many different EVs, little documentation of this assumption exists. Cherry and colleagues[178] studied 590 normal neonates during a 6-month period and noted only a single asymptomatic infection. This child was infected in utero or immediately thereafter with coxsackievirus B2. The mother had an upper respiratory illness 10 days before delivery.

During a survey of perinatal viral infections, 44 babies were found to be infected with parechovirus 1 in the study period May to December of 1966.[468] The prevalence of virus and the incidence of new infections during this period were fairly uniform. No illness was attributed to parechovirus 1 infection, and the virus disappeared from the nursery in mid-December. Asymptomatic infections with parechovirus 1 were noted on two other occasions.[79,709] Infections without evidence of illness also have been noted with coxsackieviruses A9, B1, B4, and B5 and echoviruses 3, 5, 9, 11, 13, 14, 20, 30, and 31.[168,169,270,283,342,467,478,692]

MILD, NONSPECIFIC FEBRILE ILLNESS

In a review of 338 enteroviral infections in early infancy, 9 percent were classified as nonspecific febrile illnesses.[685] Illness may be sporadic or part of an outbreak with a specific viral type. When the illness is part of an outbreak, the clinical manifestations vary, depending on the viral type: some infants have aseptic meningitis and other signs and symptoms, whereas others simply have nonspecific fever. Specific viruses related to nonspecific fever are listed in Table 178–19. Although by definition illness in this category is mild, awareness that viral infection may be extensive is important. When sought, virus may be isolated from the blood, urine, and CSF of infants with mild illnesses.[53,470] In an outbreak in six neonates of relatively benign illness caused by echovirus 7, all the infants were found to have high C-reactive protein values.[226]

SEPSIS-LIKE ILLNESS

The main diagnostic problem in neonatal enteroviral infections is differentiation of bacterial from viral disease. Even in an infant with mild, nonspecific fever, bacterial disease must be considered strongly. The sepsis-like illness described here always is alarming. Illness is characterized by fever, poor feeding, abdominal distention, irritability, rash, lethargy, and hypotonia.[387,563] Other findings include diarrhea, vomiting, seizures, and apnea. In severe, frequently fatal illnesses, most often caused by echovirus 11 infection, jaundice, hepatitis, disseminated intravascular coagulation (DIC), thrombocytopenia, and hypotension occur.[491,675,693,803]

Sepsis-like illness is a common occurrence. Morens[685] noted its presence in one fifth of 338 enteroviral infections in infants. In an attempt to differentiate bacterial from viral disease, Lake and associates[563] studied 27 infants with enteroviral infection. WBC counts were not helpful because the total count, the number of neutrophils, and the number of band-form neutrophils were elevated in most cases. Of most importance were historical data. Most mothers had suffered a recent, febrile, viral-like illness. In addition, other factors often associated with bacterial sepsis, such as prolonged rupture of membranes, prematurity, and low Apgar scores, were unusual findings in the enteroviral infection group. Bone marrow failure developed in a newborn baby boy with a sepsis-like illness caused by echovirus 11 infection.[921] The neutropenia resolved spontaneously, and the thrombocytopenia normalized after treatment with IVIG.

Abzug[4] reviewed the prognosis in 16 neonates who had a sepsis-like illness with hepatitis and coagulopathy. The case-fatality rate was 31 percent. In addition to having hepatitis and coagulopathy, the 5 patients with fatal cases had myocarditis, and 3 patients had encephalitis. The follow-up of 6 survivors noted normalization of liver function and platelet counts and the absence of subsequent significant medical problems.

RESPIRATORY ILLNESS

Respiratory complaints generally are overshadowed by other manifestations of neonatal enteroviral disease. Only 7 percent of 338 enteroviral infections in early infancy were classified as respiratory illness in one study.[685] Herpangina has been observed and photographed only once; Chawareewong and associates[159] noted several infants with herpangina and coxsackievirus A5 infection.

Hercík and colleagues[411] reported an epidemic of respiratory illness in 22 neonates associated with echovirus 11 infection. All these infants had rhinitis and pharyngitis, 50 percent had laryngitis, and 32 percent had interstitial pneumonitis. Berkovich and Pangan[79] studied respiratory illnesses in premature infants and reported 64 babies with illness, 18 of whom had virologic or serologic evidence of parechovirus 1 infection. In addition, many had high but constant levels of serum antibody to parechovirus 1. Some of the infants with high antibody levels probably also were infected with parechovirus 1. The children with proven parechovirus 1 infection could not be differentiated clinically from those without evidence of such infection. Ninety percent of the infants had coryza, and 39 percent had radiographic evidence of pneumonia.

Except for echoviruses 11 and parechovirus 1, respiratory illness associated with EVs has occurred sporadically. The following other viruses have been noted: coxsackieviruses A5, A9, B1, B4, and B5 and echoviruses 9, 17, 18, 19, 20, 22, and 31. In the review by Morens,[685] only 7 of 338 enteroviral infections of infancy were classified as pneumonia. A newborn with an echovirus 11 infection developed meningitis, DIC, and persistent pulmonary hypertension.[1002] Postmortem examination revealed pneumonia, hyaline membranes, pulmonary interstitial emphysema, meningitis, and DIC.

Eichenwald and Kostevalov[271] recovered echovirus 20 from four full-term infants younger than 8 days old. Although these infants were asymptomatic, they were found to be colonized extensively with staphylococci, and they disseminated these organisms into the air around them. Because of this ability to disseminate staphylococci, they were called *cloud babies*. The investigators thought that these cloud babies contributed to the epidemic spread of staphylococci in the nursery. Because active staphylococcal dissemination occurred only when echovirus 20 could be recovered from the nasopharynx, viral-bacterial synergistic activity was thought to be present.

GASTROINTESTINAL MANIFESTATIONS

Significant gastrointestinal illness occurs in approximately 7 percent of enteroviral infections of infancy.[685] Vomiting and diarrhea occur commonly but usually are only part of the overall illness complex and not the major manifestations. In 1958, Eichenwald and associates[270] described epidemic diarrhea associated with echovirus 18 infection. In a nursery unit of premature infants, 12 of 21 babies were mildly ill. Neither temperature elevation nor hypothermia occurred. Six infants were lethargic and listless, and moderate abdominal distention developed in 2 infants. The diarrhea lasted from 1 to 5 days; these infants had five or six watery, greenish stools per day, occasionally expelled explosively. Two infants had a small amount of blood, but no mucus or pus cells, noted in their stools. Five other babies in another nursery also had similar diarrheal illness. Echovirus 18 was recovered from all ill infants.

In 22 infants with epidemic respiratory disease caused by echovirus 11, all had vomiting as a manifestation of the illness.[411] Linnemann and colleagues[604] reported vomiting in 36 percent and diarrhea in 7 percent of neonates with echoviral infection. In another study, Lake and associates[563] found diarrhea in 81 percent and vomiting in 33 percent of neonates with nonpolio enteroviral infections.

Hepatitis is an important neonatal nonpolio enteroviral illness. Morens[685] reported that 2 percent of neonates with clinically severe enteroviral disease had hepatitis. Lake and colleagues[563] observed that hepatomegaly was present in 37 percent of neonates with enteroviral infection, and hepatosplenomegaly was observed by Hercík and associates[411] in 12 of 22 newborns with echovirus 11 respiratory illness.

Severe hepatitis, frequently with hepatic necrosis, has been noted with echoviruses 6, 9, 11, 14, 19, and 21.* Echovirus 11 most often has been associated with severe and usually fatal hepatitis; findings include DIC and thrombocytopenia, as well as apnea, lethargy, poor feeding, and jaundice.

Philip and Larson[767] reported three catastrophic neonatal echovirus 19 infections that resulted in hepatic necrosis and

*See references 78, 90, 168, 169, 386, 448, 491, 675, 693, 767.

massive terminal hemorrhage. One infant, infected in utero, was symptomatic at birth. The Apgar score was 3, and multiple petechiae were observed. Generalized ecchymoses and apneic episodes occurred, and the infant died at 3.5 hours of age. Thrombocytopenia was noted, and echovirus 19 was isolated from the brain, liver, spleen, and lymph nodes. The other two infants who died of echovirus 19 infection were twins. They were normal during the first 3 days of life but then became mildly cyanotic and lethargic. Shortly thereafter, apneic episodes occurred, and jaundice and petechiae developed. Both twins became oliguric, and they died on the eighth and ninth days of life with severe, terminal gastrointestinal bleeding. Both twins were thrombocytopenic, and virus was recovered from systemic sites in both.

Pancreatitis was found in three of four newborns with coxsackievirus B5 meningitis[544] and in a coxsackievirus B4 infection at autopsy.[1009] In other fatal coxsackievirus B infections, pancreatic involvement has been detected, but clinical manifestations rarely have been observed.

Lake and associates[563] reported three infants with necrotizing enterocolitis. Coxsackievirus B3 was recovered from two of these infants, and coxsackievirus B2 was recovered from the third.

CARDIOVASCULAR MANIFESTATIONS

In contrast to enteroviral cardiac disease in children and adults, in which pericarditis is a common finding, neonatal disease almost always involves the heart muscle. Most cases of neonatal myocarditis are caused by coxsackievirus B infection, and nursery outbreaks have occurred on several occasions. In 1961, Kibrick[524] reviewed the clinical findings in 45 cases of neonatal myocarditis; his findings are summarized in Table 178–20. Of interest is that many of the early experiences, particularly in South Africa, involved catastrophic nursery epidemics. Since the observation in 1972 of five newborns with echovirus 11 infection and myocarditis, no other nursery epidemics have been reported.[257]

The illness caused by coxsackieviruses B most commonly was abrupt in onset, with symptoms of listlessness, anorexia, and fever. A biphasic pattern was noted in approximately one third of the patients. Progression was rapid, and signs of circulatory failure appeared in a 2-day period. If death did not occur, recovery occasionally was rapid but usually took place gradually over an extended period. Most patients had cardiac findings such as tachycardia, cardiomegaly, electrocardiographic changes, and transitory systolic murmurs. Many patients showed signs of respiratory distress and cyanosis. Approximately one third of the infants had signs suggesting neurologic involvement. Of the 45 cases analyzed by Kibrick,[524] only 12 patients survived.

TABLE 178–20 Signs and Symptoms of Neonatal Coxsackievirus B Myocarditis

Category	Frequency (%)
Feeding difficulty	84

Central nervous system signs	27
Hemorrhage	13
Jaundice	13
Diarrhea	8

Modified from Kibrick, S.: Viral infections of the fetus and newborn. Perspect. Virol. 2:140-159, 1961.

In an echovirus 11 nursery outbreak reported by Drew,[257] 5 of 10 babies had tachycardia out of proportion to their fever. Three of these babies had electrocardiograms; supraventricular tachycardia was noted in all, and ST-segment depression was observed in 2 patients' records. Supraventricular tachycardia also has occurred with coxsackievirus B infection.[467] Echovirus 19 has been associated with myocarditis, and coxsackievirus A9 was noted in a child with pericarditis.[217,917]

In the 1970s, neonatal myocarditis caused by EVs was seen less commonly than it was in the 1950s and early 1960s. In his review, Morens[685] noted only 2 instances among 248 severe neonatal enteroviral illnesses. Chan and Lun[147] reported a neonate with coxsackievirus B4 myocarditis who developed a ventricular aneurysm.

EXANTHEM

Exanthem as a manifestation of neonatal enteroviral infection has been reported with coxsackieviruses B1, B3, and B5, with echoviruses 4, 5, 7, 9, 11, 16, 17, and 18, and with parechovirus 1. In most instances, rash is just a minor manifestation of severe neonatal disease. In 27 infants studied by Lake and colleagues,[563] 41 percent had exanthem. Cutaneous manifestations generally commence between the third and fifth days of illness. The rash usually is macular or maculopapular. Petechial lesions are noted occasionally. Surprisingly, vesicular lesions have not been described, nor has any rash illness in neonates been associated with coxsackievirus A16. Hall and associates[387] reported two neonates with echovirus 16 infections in which the illnesses resembled roseola. These patients had fever for 2 and 3 days, defervescence, and then the appearance of a maculopapular rash.

A newborn with a vesiculopapular-crusted rash on the face, trunk, and extremities caused by coxsackievirus B3 was reported by Theodoridou and associates.[925] It was a congenital infection in which new lesions appeared over the course of a 5-day period, and the total duration of the rash was 10 days.

NEUROLOGIC MANIFESTATIONS

As noted in Table 178–19, neurologic illness has been associated with coxsackieviruses B1, B2, B3, B4, and B5 and with many echoviruses as well. In neonates, differentiating meningitis from meningoencephalitis usually is difficult. Meningoencephalitis occurs commonly in infants with sepsis-like illness, and postmortem studies revealed many infants with disseminated viral disease (heart, liver, adrenal glands) in addition to CNS involvement. In Morens' review,[685] 50 percent of the patients with enteroviral infection who were analyzed had encephalitis or meningitis.

The initial clinical findings in neonatal meningitis or meningoencephalitis are similar to those in nonspecific febrile illness or sepsis-like illness. Most often, the child is normal and then becomes febrile, anorectic, and lethargic. Jaundice frequently is noted in newborns, and vomiting occurs in neonates of all ages. Less common findings include apnea, tremulousness, and general increased tonicity. Seizures occur occasionally.

Examination of CSF reveals considerable variation in protein, glucose, and cellular values. In seven newborns with meningitis caused by coxsackievirus B5 studied by Swender and colleagues,[912] the mean CSF protein value was 244 mg/dL, and the highest value was 480 mg/dL. The mean CSF glucose value was 57 mg/dL, and one of the seven infants had pronounced hypoglycorrhachia (a value of 12 mg/dL). The mean CSF leukocyte count in the seven babies was 1069 cells/mm^3, with 67 percent polymorphonuclear cells. The highest cell count was 4526 cells/mm^3, with 85 percent polymorphonuclear cells. In another study involving 28 children younger than 2 months in which coxsackievirus B5 was the implicated pathogen, 36 percent of the infants had CSF leukocyte counts of 500 cells/mm^3 or greater.[628] In this

same study, only 13 percent of the infants had CSF protein values of 120 mg/dL or greater; 12 percent of the infants had glucose values lower than 40 mg/dL.

In summary, the CSF findings in neonatal nonpolio enteroviral infections frequently are similar to those in bacterial disease. In particular, the most consistent finding in bacterial disease, hypoglycorrhachia, is noted in approximately 10 percent of newborns with enteroviral meningitis.[180,272,563,628,912]

Johnson and associates[487] reported a 1-month-old boy with right-sided facial paralysis and loss of abdominal reflexes. The facial paralysis persisted through convalescence; the reflexes returned to normal within 2 weeks. The boy was infected with coxsackievirus B2.

Euscher and associates[280] detected coxsackievirus RNA in placental tissue from six of seven newborn infants with respiratory difficulties and other manifestations at birth. Of these infants, one died shortly after birth, and the other six suffered neurodevelopmental delays.

CLINICAL MANIFESTATIONS: POLIOVIRUSES[16,88,167,169,198,438]

When a susceptible person has had effective contact with a poliovirus, one of several responses may occur, in the following order of frequency: (1) inapparent infection, (2) minor illness (abortive poliomyelitis), (3) nonparalytic poliomyelitis (aseptic meningitis), and (4) paralytic poliomyelitis. Paralytic poliomyelitis is the most dramatic expression of the infection and the only one clinically recognizable as caused by a poliovirus; it accounts for not more than 1 to 2 percent of infections during epidemics and considerably less under endemic conditions (see Fig. 178–5). The aseptic meningitis syndrome is similarly infrequent; nonspecific "minor illness" is estimated to occur in 4 to 8 percent, and 90 to 95 percent of those infected have inapparent infections. Factors that determine the type of clinical response are poorly understood, but the degree of virulence of the virus and certain host characteristics are important.

Age has a significant effect on patterns of infection; older patients are more likely to have severe paralytic disease and a higher mortality rate. Pregnancy increases the risk, probably primarily because of hormonal factors but also because pregnant women may be exposed more to young children, who are the main sources of contagion. Tonsillectomy in the presence of inapparent infection can precipitate bulbar poliomyelitis; evidence also suggests that tonsillectomy at any time in the past results in enhanced susceptibility to the bulbar form of the disease. Recent diphtheria-tetanus-pertussis vaccination increases the likelihood of development of paralysis; the site of injection and the site of paralysis appear to be correlated. Physical exertion and trauma around the time of onset also increase the risk of severe paralysis, especially in adults.

MINOR ILLNESS (ABORTIVE POLIOMYELITIS)

The minor illness is mild and nonspecific, with low-grade fever, malaise, anorexia, and sore throat. Physical examination reveals no significant abnormalities, CSF is normal, and recovery occurs within 24 to 72 hours. The illness often is so mild that it goes unrecognized, and patients rarely are seen by a physician.

NONPARALYTIC POLIOMYELITIS (ASEPTIC MENINGITIS)

The onset of nonparalytic poliomyelitis is associated with vague malaise followed by fever, headache, aching of the muscles, and sometimes hyperesthesia and paresthesia. Anorexia, nausea, vomiting, constipation, or diarrhea also may be present. The temperature rises to 37.8° C to 39.5° C (101° F to 103° F); stiffness of the neck, back, and hamstrings soon appears.

Approximately two thirds of affected children have a short, symptom-free interlude between the first phase (minor illness) and the second phase (CNS or major illness). This two-phase course occurs less commonly in adults, in whom the evolution of symptoms is more insidious. Nuchal and spinal rigidity is necessary for establishing the diagnosis of nonparalytic poliomyelitis during the second phase.

Physical examination reveals nuchal-spinal signs and changes in superficial and deep reflexes. With cooperative patients, the nuchal-spinal signs are sought first by active tests. The child is asked to sit up unassisted. If doing so causes undue effort, if the knees flex upward, and if the patient writhes a bit from side to side while sitting up and uses the hands on the bed for the tripod supporting position, unmistakable spinal rigidity is present. Still sitting, the patient is asked to flex chin to chest and is observed for nuchal rigidity. Alternatively, from the supine position with the knees held down gently, the patient is asked to sit up and kiss the knees. If the knees draw up sharply or if the maneuver cannot be completed adequately, the patient has stiffness of the spine caused by muscle spasm. If the diagnosis still is uncertain, attempts should be made to elicit the Kernig and Brudzinski signs. Gentle forward flexion of the occiput and neck elicits nuchal rigidity, which may precede spinal rigidity. Head drop may be demonstrated by placing the hands under the patient's shoulders and raising the trunk. Normally, the head follows the plane of the trunk, but in poliomyelitis, it often falls backward limply. The frequency of the head-drop sign, even in nonparalytic poliomyelitis, with no subsequent residuals indicates that it is not caused by true paresis of the neck flexors. In struggling infants, distinguishing voluntary resistance from clinically important involuntary nuchal rigidity may be difficult. One may place the infant's shoulders flush with the edge of the table, support the weight of the occiput in the hand, and then flex the head anteriorly. Nuchal rigidity that persists during this maneuver may be interpreted as involuntary. When not closed, the anterior fontanelle also may be tense or bulging.

In the early stages, the reflexes are normally active and remain so unless paralysis supervenes. Changes in reflexes, either increased or depressed, may precede the onset of weakness by 12 to 24 hours; hence, detecting such changes is important, especially in nonparalytic patients managed at home. The superficial reflexes (i.e., cremasteric and abdominal and the reflexes of the spinal and gluteal muscles) are usually the first to be diminished. The spinal and gluteal reflexes are elicited by tapping segmentally downward on each side of the spine and buttocks. These reflexes may disappear before the abdominal and cremasteric ones do. Changes in the deep tendon reflexes, whether exaggerated or depressed, generally occur 8 to 24 hours after depression of the superficial reflexes and indicate impending paresis of the extremities.

Laboratory findings consist of a normal or slightly elevated WBC count and the characteristic CSF changes of aseptic meningitis: approximately 20 to 300 cells, predominantly lymphocytes, a normal glucose level, and a normal or slightly elevated protein level. If a spinal tap is performed in the first few hours after onset, a predominance of polymorphonuclear leukocytes may be seen, but it shifts in 6 to 12 hours to more than 90 percent lymphocytes. If no further progression of clinical signs occurs, the disease remains nonparalytic, the temperature falls to normal, and signs of meningeal irritation gradually disappear. Recovery ensues in 3 to 10 days, depending on the severity of the illness.

PARALYTIC POLIOMYELITIS

The manifestations of paralytic poliomyelitis are those enumerated earlier for nonparalytic poliomyelitis in addition to weakness in one or more muscle groups, either skeletal or cranial. Patients in whom paralysis is destined to develop often wear an anxious expression; they are extremely alert, restless, and flushed and appear acutely ill. The fever is higher than that in abortive disease,

and the patient may have intense muscle pain. Shortly before actual muscle weakness is detected, the superficial and deep reflexes often diminish or disappear on the affected side. Frequently, a symptom-free interlude of several days occurs between the initial illness phase and the recurrence of symptoms that culminate in paralysis.

The onset of paralysis may be extraordinarily sudden and may progress in a few hours to complete loss of motion in one or more extremities. Asymmetric involvement is typical in milder cases. More gradual spread of weakness also occurs and may continue over a period of 3 to 5 days. Bladder paralysis of 1 to 3 days' duration develops in approximately 20 percent of patients, and bowel atony frequently is noted, occasionally to the point of paralytic ileus. In general, when the fever subsides, no further paralysis is likely to occur. The lower limbs are affected more commonly than are the upper, but in severe cases, quadriplegia and loss of function of the intercostal, abdominal, and trunk muscles with resultant respiratory difficulty may ensue. The superficial and deep reflexes in the affected limbs are lost; twitching of the muscles and diffuse fasciculations may be seen transiently. Sensory abnormalities are rare occurrences.

Flaccid paralysis is the most obvious clinical expression of the neuronal changes. The ensuing muscular atrophy is caused by denervation in addition to the atrophy of disuse. The pain, spasticity, nuchal and spinal rigidity, and hypertonia early in the illness probably are caused by lesions in the brain stem, spinal ganglia, and posterior columns. Respiratory and cardiac arrhythmias, blood pressure and vasomotor changes, and similar manifestations reflect damage to vital centers in the medulla.

On physical examination, the distribution of paralysis characteristically is spotty. To detect mild muscular weakness, one often must apply gentle resistance in opposition to the muscle group being tested. The spinal form has weakness of some of the muscles of the neck, abdomen, trunk, diaphragm, thorax, or extremities. The bulbar form is characterized by weakness in the motor distribution of one or more cranial nerves, with or without dysfunction of the vital centers of respiration and circulation. Patients with bulbar disease often are extremely agitated, even delirious, or they may become stuporous. The 10th cranial nerve nuclei are involved most commonly and result in paralysis of the pharynx, soft palate, and vocal cords. Facial paralysis occurs less commonly; it usually is asymmetric and involves only selected muscle groups. Ocular palsies are unusual findings.

Components of both the bulbar and spinal forms occur together in bulbospinal poliomyelitis. In the encephalitic form of the disease, irritability, disorientation, drowsiness, and coarse tremors not explained by inadequate ventilation are noted. Even during epidemics of poliomyelitis, this form can be recognized only if some peripheral or cranial nerve paralysis coexists or ensues. Hypoxia and hypercapnia caused by inadequate ventilation from respiratory insufficiency may produce disorientation without true encephalitis.

Numerous components acting together may result in insufficiency in ventilation (Table 178–21). The most serious consequences are hypoxia and hypercapnia, which may produce profound effects on many other systems. Respiratory insufficiency should be detected early to diminish its widespread effects, and because the situation may shift rapidly, continued clinical evaluation is essential. Despite weakness of the respiratory muscles, the patient may respond with so much respiratory effort that normal alveolar ventilation is maintained. In fact, the increased effort (associated with anxiety and fear) actually may produce overventilation at the outset and may result in respiratory alkalosis. Such effort is fatiguing and soon leads to respiratory failure.

For clarity, certain terms characterizing patterns of disease need definition. First, *pure spinal poliomyelitis with respiratory insufficiency* refers to tightness, weakness, or paralysis of the respiratory muscles (chiefly the diaphragm and intercostals) without discernible clinical involvement of the cranial nerves or vital centers. The cervical and thoracic spinal cord segments chiefly are involved. Second, *pure bulbar poliomyelitis* refers to paralysis of the motor cranial nerve nuclei with or without involvement of the vital centers that control respiration, circulation, and body temperature. Involvement of the 9th, 10th, and 12th cranial nerves is most important because it results in paralysis of the pharynx, tongue, and larynx, with consequent airway obstruction. Third, *bulbospinal poliomyelitis with respiratory insufficiency* refers to involvement of the respiratory muscles with coexisting bulbar paralysis.

TABLE 178–21 Common Sources of Hypoxia and Hypercapnia in Poliomyelitis

1. Cranial nerves IX to XII involved with
   a. Pharyngeal paralysis and pooling of secretions
   b. Laryngeal involvement, either spasm of laryngeal muscles or paralysis of vocal cords
   c. Lingual paralysis
   d. Tracheal accumulation of secretions from inability to cough
   e. Aspiration of vomitus
2. Vital center involvement with
   a. Inefficient, irregular respiration
   b. Cardiovascular disturbance
   c. Hyperpyrexia causing increased oxygen consumption
3. Cervical and spinal cord involvement causing paresis of the primary and accessory muscles of respiration
4. Pulmonary complications (e.g., pneumonia, atelectasis, and edema)
5. Contributory factors
   a. Panic
   b. Gastric dilation
   c. Sedation
   d. Inadequate equipment (e.g., small-bore tracheostomy tubes, unsuitable respirator settings)

From Cherry, J. D.: Enteroviruses. In *Behrman, R. E., and Vaughan, V. C. (eds.): Nelson Textbook of Pediatrics. 12th ed. Philadelphia, W. B. Saunders, 1983, pp. 791-804.*

The clinical findings resulting from involvement of the respiratory muscles are as follows: (1) an anxious expression; (2) inability to speak without frequent pauses, a situation resulting in short, jerky, "breathless" sentences that can be demonstrated by asking the child to count numbers serially; (3) increased respiratory rate; (4) movement of the alae nasi and the accessory muscles of respiration; (5) inability to cough or sniff with full depth; (6) paradoxical abdominal movements caused by diaphragmatic immobility from spasm or weakness of one or both leaves; and (7) relative immobility of the intercostal spaces, whether segmental, unilateral, or bilateral. When the arms are weak and especially when deltoid paralysis occurs, one should beware of impending respiratory paralysis because the phrenic nerve nuclei are in adjacent areas of the spinal cord. Observing the patient's capacity for thoracic breathing while the abdominal muscles are splinted manually can be performed to assess minor degrees of paresis. Light manual splinting of the thoracic cage helps in evaluating the effectiveness of diaphragmatic movement.

The clinical findings of bulbar poliomyelitis with respiratory difficulty (other than paralysis of the extraocular, facial, and masticatory muscles) include the following: (1) a nasal twang to the voice or cry as a result of palatal and pharyngeal weakness (hard consonant words such as "cookie" or "candy" bring out this condition best); (2) an inability to swallow smoothly that results in an accumulation of saliva in the pharynx and indicates partial immobility (holding the larynx lightly and asking the patient to swallow confirms the immobility); (3) accumulated pharyngeal secretions, which may cause irregular respiration because each inspiration must be "planned" and cannot be "subconscious" in view of the risk of aspirating; the respirations thus may appear interrupted and abnormal even to the point of falsely simulating intercostal or diaphragmatic weakness; (4) the impossibility of

effective coughing, with resultant constant and fatiguing efforts to clear the throat; (5) nasal regurgitation of saliva and fluids caused by palatal paralysis, with an inability to separate the oropharynx from the nasopharynx during swallowing; (6) deviation of the palate, uvula, or tongue; (7) involvement of vital centers, as manifested by an irregularity in the rate, depth, and rhythm of respiration; by cardiovascular alterations that include changes in blood pressure (especially increased), alternate flushing and mottling of the skin, and cardiac arrhythmias; and by rapid changes in body temperature; (8) paralysis of one or both vocal cords that causes hoarseness, aphonia, and, ultimately, asphyxia unless recognized by laryngoscopy and managed by immediate tracheostomy; and (9) the "rope sign," an acute angulation between the chin and larynx caused by weakness of the hyoid muscles (the hyoid bone is pulled posteriorly, thus narrowing the hypopharyngeal inlet). Myocardial failure sometimes develops secondary to pulmonary complications or as a result of acute myocarditis. The initial manifestation of poliovirus infection on occasion can resemble that of Guillain-Barré syndrome.[1028]

Congenital Infections

ABORTION

Poliomyelitis is associated with an increased incidence of abortion. Horn[428] noted 43 abortions in 325 pregnancies complicated by maternal poliomyelitis. Abortion was related directly to the severity of the maternal illness, including the degree of fever during the acute phase of illness. However, abortion also has occurred in association with mild nonparalytic poliomyelitis. Siegel and Greenberg[879] noted that fetal death occurred in 14 of 30 instances (46.7%) of maternal poliomyelitis during the first trimester. Kaye and associates[510] reviewed the literature in 1953 and recorded 19 abortions in 101 cases of poliomyelitis in pregnancy. In a small study in Evanston Hospital in Illinois, the abortion rate in maternal poliomyelitis was little different from the expected rate.[94]

CONGENITAL MALFORMATIONS

Although isolated instances of congenital malformation and maternal poliomyelitis have been noted, little statistical evidence supports the suggestion that polioviruses are teratogens. In their review of the literature, Kaye and colleagues[510] noted 6 anomalies in 101 infants born to mothers with poliomyelitis during pregnancy. In the reviews of Horn,[428] Bates,[56] and Siegel and Greenberg,[879] no evidence of maternal polioviral infection–induced anomalies was found. Similarly, no evidence suggests that infection with poliovirus vaccine during pregnancy causes congenital malformations.[396]

PREMATURITY AND STILLBIRTH

In Horn's study[428] of 325 pregnancies, 9 infants died in utero. In each instance, the mother was critically ill with poliomyelitis. Horn[428] also noted that 45 infants weighed less than 6 lb, and 17 of them had a birth weight less than 5 lb. These low-birth-weight infants were born predominantly to mothers who had poliomyelitis early in pregnancy. In New York City, Siegel and Greenberg[879] also noted an increase in prematurity after maternal poliomyelitis infection. It was related specifically to maternal paralytic poliomyelitis.

Neonatal Infections

GENERAL

In the excellent review by Bates[56] in 1955, 58 cases of poliomyelitis in infants younger than 1 month were described. Although complete data were not available on many of the cases, 51 had paralysis, died of their disease, or both. Of the total number of infants on whom these investigators had clinical data, only one infant had nonparalytic disease. More than half the cases were secondary to maternal disease. Because other investigators have noted congenital infection without symptomatic maternal infection, infection in the mother probably was the source for an even greater percentage of the neonatal illnesses. The incubation period of neonatal poliomyelitis has not been established, and, therefore, determining how many of the babies were infected in utero is difficult. Probably, most illnesses that occurred within the first 5 days of life were congenital. Most of the neonates had symptoms of fever, anorexia or dysphagia, and listlessness. Almost half the infants noted in this review died, and of those surviving, 48 percent had residual paralysis.

INFECTION ACQUIRED IN UTERO

Elliott and associates[274] described an infant girl in whom "complete flaccidity" was noted at birth. This child's mother had had mild paralytic poliomyelitis, with the onset of minor illness occurring 19 days before the infant's birth. Fetal movements had ceased 6 days before delivery, a finding suggesting that paralysis had occurred at this time. On examination, the baby was severely atonic; when supported under the back, she was passively opisthotonic. Respiratory efforts were abortive and were confined to the accessory muscles; laryngoscopy revealed complete flaccidity in the larynx.

Johnson and Stimson[483] reported a case in which the mother's probable abortive infection occurred 6 weeks before the birth of the baby. The baby initially was thought to be normal but apparently underwent no medical examination until the fourth day of life. At this time, the physician noted right hemiplegia. On the following day, a more complete examination revealed lateral bulging of the right side of the abdomen accompanied by crying and maintenance of the lower extremities in a frog leg position. Adduction and flexion at the hips were weak, and the knee and ankle jerks were absent. Laboratory studies were unremarkable except for examination of CSF. It revealed 20 lymphocytes and a protein level of 169 mg/dL. During a 6-month period, this child's paralysis gradually improved and resulted in only residual weakness of the left lower extremity.

Paresis of the left arm was noted shortly after birth in another child with apparent transplacentally acquired poliomyelitis.[615] At 2 days of age, the baby was quadriplegic, but patellar reflexes were present, and the child had no respiratory or swallowing difficulties. This child had pneumonia at 3 weeks of age, but otherwise, general neurologic improvement occurred. Examination at 8 weeks of age revealed bilateral atrophy of the shoulder girdle muscles. The CSF from this patient had 63 leukocytes/mm^3, 29 percent of them polymorphonuclear cells, and a protein concentration of 128 mg/dL.

All three of the infants just discussed apparently were infected in utero several days before birth. Their symptoms were exclusively neurologic; fever, irritability, and vomiting did not occur.

POSTNATALLY ACQUIRED INFECTION

In contrast to infections acquired in utero, those acquired postnatally are more typical of classic poliomyelitis. Shelokov and Weinstein[876] described a child who was asymptomatic at birth. The onset of minor symptoms in the mother occurred 3 weeks before delivery, and the onset of major symptoms occurred 1 day before delivery. On the sixth day of life, the infant suddenly became ill with watery diarrhea. He looked grayish and pale. On the following day, he was irritable, lethargic, and limp and had a temperature of 38° C. Mild opisthotonos and weakness of both lower extremities developed. He was responsive to sound, light, and touch. The CSF had an elevated protein level and an increased

number of leukocytes. His condition worsened during a total period of 3 days, and then gradual improvement began. At 1 year of age, he had severe residual paralysis of the right leg and moderate weakness in the left leg.

Baskin and associates[54] described two infants with neonatal poliomyelitis. The first child, whose mother had severe poliomyelitis at the time of delivery, was well for 3 days and then had a temperature of 38.3° C. On the fifth day of life, the boy became listless and cyanotic. Examination of CSF revealed a protein level of 300 mg/dL and 108 leukocytes/mm^3. His condition worsened, and extreme flaccidity, irregular respiration, and progressive cyanosis developed; he died on the seventh day of life. The second infant was a boy who was well until he was 8 days old but then became listless, with a temperature of 38.38° C. During the next 5 days, flaccid quadriplegia developed, as did irregular, rapid, and shallow respirations and an inability to swallow. The child died on the 14th day of life. Acute poliomyelitis had developed in his mother 6 days before the onset of his symptoms.

Abramson and colleagues[3] reported four children with neonatal poliomyelitis, two of whom died. In three of the children, the illnesses were typical of acute poliomyelitis in older children. The other child died at 13 days of age with generalized paralysis. The onset of his illness was difficult to define, and he was never febrile. Bates[56] described infants with acute poliomyelitis and clinical illnesses similar to those that occur in older persons.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

CLINICAL DIAGNOSIS

Clinical differentiation of enteroviral disease frequently is thought to be impossible. Although treatable bacterial illnesses always should be considered and treated first, also true is that when all the circumstances of a particular illness are considered, enteroviral diseases can be suspected on clinical grounds. The most important factors in clinical diagnosis are the season of the year, geographic location, exposure, incubation period, and clinical symptoms.

In temperate climates, prevalence of EVs is distinctly seasonal, so disease usually is seen in the summer and fall. Enteroviral disease is less likely to occur in the winter. In the tropics, EVs are prevalent throughout the year, and the season, therefore, is not diagnostically helpful.

As with all infectious illnesses, knowledge of exposure and incubation time is important. A careful history of maternal illness is critical in neonatal disease. For example, nonspecific, mild febrile illness in a mother that occurs in the summer and fall should warn of the possibility of severe neonatal illness. Specific findings (i.e., aseptic meningitis, pleurodynia, herpangina, pericarditis, myocarditis) should alert the clinician to enteroviral illnesses. The short incubation period of enteroviral infections should be considered.

LABORATORY DIAGNOSIS

Virus Isolation and Detection Techniques

Most viral diagnostic laboratories have facilities for the recovery of most EVs that cause illness. A three-tissue culture system that includes primary monkey kidney, a diploid, human embryonic lung fibroblast cell strain, and the RD cell line will allow the isolation of virtually all coxsackieviruses B and echoviruses and some coxsackieviruses A (e.g., coxsackieviruses A9 and A16). In a study in which Buffalo green monkey kidney cells and subpassage of primary human embryonic kidney cells were used in addition to primary monkey kidney and human diploid fibroblast (MRC-5) cells, the recovery rate of EVs was increased 11 percent.[190] For a complete diagnostic isolation spectrum, suckling mouse inoculation also should be performed.

Proper selection and handling of specimens are most important in the isolation of viruses. Enteroviral infections tend to be generalized, so collection of material from multiple sites is important; specimens should be collected from any or all of the following: nasopharynx, throat, stool, blood, urine, CSF, and any other body fluids that are available. Swabs from the nose, throat, and rectum should be placed in a carrying medium containing a small amount of protein. Hanks balanced salt solution with 2 percent agamma calf serum and antibiotics is satisfactory. Fluid specimens should be collected in sterile vials; specimens of postmortem material are collected best in vials that contain carrying medium. In general, specimens should be refrigerated immediately after collection and during transportation to the laboratory. The specimens must not be exposed to sunlight during transportation. If an extended period will elapse before a specimen is processed in the laboratory, shipping and storing it frozen are advisable.

Contrary to popular belief, tissue culture evidence of enteroviral growth takes only a few days in many cases and less than a week in most.[366] The use of spin amplification, the shell vial technique, and monoclonal antibodies has been shown to reduce the time of detection in enteroviral cultures significantly.[542,763,874,938] After an EV has been isolated, type identification is performed conventionally by neutralization, and this process, unfortunately, frequently takes a long time.

Nucleic acid techniques with cDNA and RNA probes have been shown to be useful for direct identification of EVs.[120,238,455,765,823,824,827] Most important, however, has been the development of numerous PCR techniques. Since 1990, many reports have described enteroviral PCR methods and their use in identifying EV RNA in clinical specimens.* PCR has proved most useful for the direct identification of EVs in the CSF of patients with meningitis.[830,853,918,929,1026] When compared with culture of CSF specimens, PCR is faster and more sensitive, and the specificity is equal.

PCR also has proved useful in the identification of EVs in blood, urine, and throat specimens.[7,18,111,720,721,873] Particularly impressive are the findings of Byington and associates.[111,811] Using PCR on specimens of blood and CSF, these investigators found that more than 25 percent of infants admitted to the hospital for suspected sepsis in 1997 had nonpolio enteroviral infections. Based on this study and the work of Andréoletti and coworkers,[18] we consider that the general work-up for febrile children hospitalized for possible sepsis should include PCR for EVs in both blood and CSF, if available. A shortcoming of PCR is that EV RNA is identified, but a specific enteroviral type is not. Because of this shortcoming, we recommend that conventional culture be performed in addition to PCR.

EV RNA also has been identified in numerous tissue specimens from patients with chronic medical conditions such as idiopathic DCM. However, as discussed earlier ("Cardiovascular Manifestations"), the possibility of a lack of specificity (false-positive results) is a concern. Polioviruses can be separated from other EVs, and poliovirus vaccine strains can be identified rapidly by PCR.[2,182,268,1023]

Serology

Except in special circumstances, the use of serologic techniques for establishing the primary diagnosis of suspected enteroviral

*See references 2, 7, 18, 23, 41, 111, 182, 204, 205, 208, 268, 307, 319, 363, 390, 456, 559, 564, 596, 631, 656, 694, 720, 738, 790, 811, 815, 822, 825, 830, 850, 857, 872, 873, 877, 885, 901, 910, 918, 929, 943, 961, 964, 968, 1012, 1023, 1026.

infection is impractical. Standard serologic study depends on the demonstration of a rise in antibody titer to a specific virus as an indication of infection with that agent. Although ELISA, hemagglutination inhibition, and CF take only a short time to perform, these tests can be carried out only after a second, convalescent-phase blood specimen has been collected. These tests also are impractical in searching for the cause of a specific illness in a child because of the existence of so many antigenically different EVs. As noted previously ("Antigenic Characteristics"), group antigens can be produced that allow one to establish a serologic diagnosis by IgM EIA and CF, but these tests lack specificity.[846,926,927]

In the evaluation of a patient with a suspected enteroviral infection, serum should be collected as soon as possible after the onset of illness and then again 2 to 4 weeks later. This serum should be stored frozen. In most clinical situations, performing serologic tests on the collected serum is not necessary because demonstration of a rise in antibody titer in the serum of an infant from whom a specific virus has been isolated from a body fluid obviously is superfluous. However, collected serum can be useful diagnostically if the prevalence of specific EVs in a community is known. In this situation, looking for antibody titer changes to a selected number of viral types is relatively easy. Faster diagnosis can be made with a single serum sample if a search for specific IgM enteroviral antibody is made.[144,188,330,348,349,360,878,944,1038]

Unfortunately, no EV IgM antibody tests are commercially available in the United States. Commercial laboratories do offer enteroviral CF antibody panels. However, these tests are expensive, and their results in the clinical setting almost always are meaningless unless acute-phase and convalescent-phase sera are analyzed.

Histology

Enteroviral infections have no specific histologic findings such as those seen in cytomegalovirus or HSV infection. However, tissues can be examined for specific enteroviral antigens by immunofluorescence and for RNA by PCR.[108,142,630]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of enteroviral infection depends on the clinical manifestations. In general, the most important considerations relate to bacterial diseases such as those commonly associated with pharyngitis, pneumonia, pericarditis, meningitis, and septicemia. Other viruses must be considered with upper respiratory illnesses, gastrointestinal infections, rashes, encephalitis, and neonatal illness.

Paralytic poliomyelitis usually presents no diagnostic problem in the presence of an outbreak, but sporadic cases are another matter, especially in countries such as the United States, where the disease (except for the vaccine-associated form) has disappeared and many pediatricians have never seen a case. Rarely, other EVs have been shown to cause paralytic syndromes that are indistinguishable from poliomyelitis.

Several other diseases must be considered in the differential diagnosis of sporadic cases of paralytic illness. Guillain-Barré syndrome is the most common and difficult differential diagnostic problem. Fever, headache, and meningeal signs usually occur less commonly in Guillain-Barré syndrome; the paralysis characteristically is symmetric, and sensory changes are common findings. Also in Guillain-Barré syndrome, the CSF contains few cells but a significant elevation in protein concentration. Other illnesses confused with paralytic poliomyelitis include peripheral neuritis (post-injection, toxic, herpes zoster), arboviral infection, rabies, tetanus, botulism, and tick paralysis.

TREATMENT

SPECIFIC THERAPY

No specific therapy for any enteroviral infection is approved for use in the United States. In severe, catastrophic, and generalized neonatal infection, in all probability the baby received no specific antibody for the particular virus from the mother. In this situation, administering immunoglobulin to the infant probably is advisable because high titers of neutralizing antibody to many EVs frequently are present in immunoglobulin.[194,228] Little evidence supports the claim that this therapy is beneficial; however, it can be expected to stop further organ seeding secondary to continued viremia. Intravenous or intraventricular injection of immunoglobulin with IVIG and administration of hyperimmune plasma have been useful on some occasions and not others in the treatment of enteroviral infection in patients with agammaglobulinemia.*

Abzug and associates[5] performed a small but controlled study in which nine EV-infected neonates received IVIG and seven similarly infected infants received supportive care. In this study, no significant difference was found in clinical scores, antibody values, or the magnitude of viremia and viruria in those treated versus control infants. However, five infants received IVIG with a high neutralizing antibody titer (>1:800) to their individual viral isolates, and they experienced faster cessation of viremia and viruria. A neonate with disseminated echovirus 11 infection and hepatitis, pneumonitis, meningitis, DIC, decreased renal function, and anemia who survived after receiving a large dose of IVIG and supportive care was described.[489] Administering IVIG to older children with life-threatening enteroviral infection also seems reasonable. A specific recommended dosage is unknown, but 400 mg/kg/day for 4 days or 2 g/kg in one dose has been used.

Jantausch and associates[474] reported an infant with a disseminated echovirus 11 infection who survived after receiving maternal plasma transfusions. A neonate with fulminant echovirus 11 infection survived after undergoing orthotopic liver transplantation.[200]

The antiviral drug pleconaril offers promise for the treatment of enteroviral infections.[57,104,247,511,766,826,829,984] This drug is a novel compound that integrates into the capsid of EVs. It prevents the virus from attachment to cellular receptors and the uncoating and subsequent release of viral RNA into the host cell. In a double-blinded, placebo-controlled study of 39 patients with enteroviral meningitis, a statistically significant shortening of duration of disease was noted: from 9.5 days in controls to 4.0 days in drug recipients.[829] Pleconaril also has been used on a compassionate-release basis for the treatment of patients with life-threatening infection.[57,104,826] The following categories of enteroviral illness have been treated: chronic meningoencephalitis in patients with agammaglobulinemia or hypogammaglobulinemia, neonatal sepsis, myocarditis, poliomyelitis (wild type or vaccine associated), and encephalitis, as well as in bone marrow transplant recipients. Although these treatment studies have not had control arms, favorable clinical responses have been observed in 26 of 50 treated patients, including 12 of 18 patients with chronic meningoencephalitis. Pleconaril is not available in the United States.

In severe illnesses such as neonatal myocarditis or encephalitis, one frequently is tempted to administer corticosteroids. Although some workers have thought that this therapy is beneficial in treating coxsackieviral myocarditis, we recommend that corticosteroids should not be given during acute enteroviral infection. The deleterious effects of these agents in coxsackieviral

*See references 8, 87, 220, 264, 278, 323, 385, 414, 642, 653, 657, 957, 987.

infection of mice are particularly persuasive factors in this opinion.[89,531] Immunosuppressive therapy for myocarditis of unknown origin with prednisone and cyclosporine or azathioprine was evaluated in a controlled trial of 111 adults, but no beneficial effect was observed.[633]

Because the possibility of bacterial sepsis cannot be ruled out in many instances of enteroviral infection, antibiotics frequently should be administered for the most likely potential pathogens. Care in the selection and administration of antibiotics is urged so that drug toxicity is not added to the problems of the patient.

NONSPECIFIC THERAPY

Mild, Nonspecific Febrile Illness

In patients in whom fever is the only symptom, careful observation is important. Many patients who eventually become severely ill initially have 2 to 3 days of fever without other localized findings. Care should be taken to administer adequate fluids to febrile infants, and excessive elevation of temperature should be prevented if possible.

Myocarditis

Myocarditis has no specific therapy. However, congestive heart failure and arrhythmias occur, and they should be treated by the usual methods. In administering digitalis to patients with enteroviral myocarditis, paying careful attention to the initial dosage is most important because the heart often is extremely sensitive; frequently, only small amounts of digoxin are necessary.

Meningoencephalitis

In patients with meningoencephalitis, convulsions, cerebral edema, and disturbances in fluid and electrolyte balance all occur frequently and respond to treatment. Seizures are treated best with phenobarbital, phenytoin, or lorazepam. Cerebral edema can be treated with urea, mannitol, or large doses of corticosteroids. As noted, the use of corticosteroids in patients with active enteroviral infection seems unwise because the local benefit may be outweighed by the overall deleterious effects. Fluids should be monitored closely, and serum electrolyte levels should be determined frequently because inappropriate antidiuretic hormone secretion is a common occurrence.

Poliomyelitis

The broad principles of management are to allay fear, to minimize the ensuing skeletal deformities, to anticipate and meet complications in addition to the neuromusculoskeletal ones, and to prepare the child and family for the prolonged treatment that may be required and for permanent disability when it seems likely. Patients with the nonparalytic and mildly paralytic forms of the disease may be treated at home.

Most patients with paralytic poliomyelitis require hospitalization. A calm atmosphere is desired. Suitable body alignment is necessary to avoid excessive skeletal deformity. A neutral position with the feet at a right angle, knees slightly flexed, and hips and spine straight is achieved by the use of boards, sandbags, and occasionally, light splint shells. Active and passive motion is indicated as soon as the pain has disappeared. The orthopedist and physiatrist should see these patients as early in the illness as possible and should assume responsibility before fixed deformities develop.

Management of pure bulbar poliomyelitis consists essentially of maintaining the airway and avoiding all risks of inhalation of saliva, food, or vomitus. Gravity drainage of accumulated secretions is favored by the head-low (foot of the bed elevated 20 to 25 degrees), prone position with the face to one side. Aspirators with rigid or semirigid tips are preferred for direct oral and pharyngeal use, and soft flexible catheters may be used for nasopharyngeal aspiration. Fluid and electrolyte balance is maintained best by intravenous infusion because tube or oral feeding in the first few days may incite vomiting. After the initial few days, sips of sterile water may be given from a spoon, with increments as indicated by the child's ability to swallow. In addition to close observation for respiratory insufficiency, blood pressure should be recorded at least twice daily. Hypertension is not an uncommon occurrence and occasionally leads to hypertensive encephalopathy. Patients with pure bulbar poliomyelitis may require tracheostomy because of paralysis of the vocal cords or constriction of the hypopharynx. Most patients with pure bulbar poliomyelitis who recover have little residual impairment; some patients exhibit mild dysphagia and occasional vocal fatigue with slurring of speech.

Impaired ventilation must be recognized early; mounting anxiety, restlessness, and fatigue are early indications for prompt intervention. Tracheostomy is indicated for some patients with pure bulbar poliomyelitis, spinal respiratory muscle paralysis, and bulbospinal paralysis. Unlike other patients on whom tracheostomy is performed, these patients generally are unable to cough, sometimes for many months. Frequent and swift endotracheal aspiration under aseptic conditions is necessary. Mechanical ventilation often is needed. Patients are fully conscious and aware; terrifying procedures are performed best with an outward atmosphere of calm. Explaining the procedure and having the parents on hand may be helpful. A reduction in thoracic compliance occurs early, and higher than expected pressure gradients may be required to achieve adequate ventilation. Weaning a patient from dependency on respiratory assistance is a torturous process, as is total musculoskeletal rehabilitation. Motivation of the patient and the team of personnel is paramount.

PROGNOSIS

The prognosis for nonpolio enteroviral infections is excellent in most instances. Virtually all morbidity and mortality are related to cardiac and neurologic disease in older children and to these diseases in addition to general disseminated infection with hepatitis in neonates.

The prognosis for poliomyelitis varies with the degree of muscle involvement. In patients with mild muscle weakness, complete recovery is the rule. If paralysis is present, recovery of muscle function continues for a period of approximately 18 months to 2 years. By 3 months, approximately 60 percent of the ultimate improvement has been achieved, and by 6 months, 80 percent. The final result depends on the extent and localization of nerve cell damage.

Respiratory failure is responsible for most of the deaths in paralytic poliomyelitis. With the many improvements in techniques for handling this complication, the overall mortality rate has been reduced to approximately 4 percent; with the bulbar form and in adults, it still may be as high as 10 percent.

Occasionally, new neuromuscular symptoms develop later in life in patients who have had paralytic poliomyelitis.[121,230,231,485,791,930,1007,1008] Although the cause of this late-onset weakness and muscle atrophy (post-polio syndrome) is not understood completely, it most likely is the result of routine attrition of anterior horn cells associated with aging rather than persistent neural infection with polioviruses. However, specific immunopathologic mechanisms possibly play a role in some instances.[345]

Leparc-Goffart and associates[580] presented data suggesting the presence of poliovirus-specific genomic sequences in the CSF of

patients with post-polio syndrome. However, Muir and colleagues,[696] who performed similar studies, found no association of chronic neurologic disease with the presence of enteroviral RNA in CSF.

PREVENTION

NONPOLIO ENTEROVIRAL INFECTIONS

Attenuated and inactivated viral vaccines for EVs other than polioviruses are not available. However, if a virulent enteroviral type were to emerge, a specific vaccine for active immunization probably could be developed.

Passive protection with IVIG may be useful in preventing disease. In practice, however, it would seem worthwhile only for sudden and virulent nursery outbreaks. For example, if several cases of myocarditis occurred in a nursery, administering IVIG to all babies in the nursery would seem reasonable. Pooled human immunoglobulin in most instances can be expected to contain antibodies against coxsackieviruses B1, B2, B3, B4, and B5, as well as several coxsackieviruses A and echoviruses.[228] Therefore, this procedure would offer protection to infants without transplacentally acquired specific antibody who had not become infected yet. Immune serum was useful in the management of three nursery enteroviral outbreaks.[119,701,759]

POLIOVIRAL INFECTIONS

In the United States, the total annual number of paralytic cases fell from an average of 16,000 in the 5 years before the introduction of vaccine to approximately 10 cases per year between 1980 and 1984. The experience in 1979, however, when 26 paralytic cases were reported, served as a reminder that virulent polioviruses still could surface in susceptible persons.[125,126] Most of the 1979 cases occurred in Pennsylvania and several other states in Amish population groups who had not been immunized. A similar epidemic in Connecticut in 1972 involved a pocket of unimmunized students in a Christian Science school.[122] These outbreaks reflected the reality that poliomyelitis was still occurring in many parts of the world. The possibility of the introduction of virulent strains was ever present, and only through continued and extensive immunization programs could the disease be prevented from reappearing in epidemic form.[431]

The remarkable overall record of the decline in paralytic poliomyelitis in the United States was a result of the development and use of two effective vaccines.[431] Inactivated poliovirus vaccine, the first to be licensed, was used extensively beginning in 1955 and considerably reduced the incidence of the disease, although epidemics continued to occur. Live-attenuated oral poliovirus vaccine, licensed in 1961 and 1962, subsequently was recommended as the method of choice in the United States based on its superiority in terms of immunogenic capacity, ability to induce local IgA antibody in the oropharynx and intestinal tract and thus provide greater resistance to re-infection, and ease of administration. Oral poliovirus vaccine gradually supplanted inactivated poliovirus vaccine, and between 1973 and 1978, it was the only vaccine available. Its extraordinary effectiveness at that time, despite reaching only 65 percent of children younger than 5 years of age with the recommended three doses, suggested that the capacity of the attenuated strains to spread contributed to a much higher immunization rate than was indicated by vaccination statistics. The potential impact of such spread on the immunity of the population was illustrated by the observations of Fox and Hall,[306] who conducted long-term virologic surveillance of middle-income families in Seattle. Polioviruses (vaccine strains) accounted for 50 percent of the 2937 viral isolates from healthy children, their parents, and others in the community. In an analysis of 611 of the poliovirus isolates, researchers found that 75.6 percent were from vaccinees, 10.5 percent were from vaccinee contacts, and 14 percent were from persons without recent known contact with vaccine or a vaccinee. These findings provided a vivid picture of the pervasiveness of the attenuated strains and their continuous circulation in the population. This feature also was supported by the almost invariable recovery of polioviruses from weekly samples of sewage that were collected throughout the year, in the early vaccine era, in urban communities.[432]

Despite its striking success, the oral vaccine had some problems. One was greatly reduced seroconversion rates when the vaccine was given to children living in the tropics: as few as 50 percent had satisfactory responses, in contrast to the more than 95 percent response rate in the United States and similar countries.[252,661] Viral interference from other EVs played some role, and the presence of an inhibitory substance in the oropharynx that prevented significant multiplication of the vaccine strains also was involved. The seroconversion problem was lessened by using pulse immunization programs.[480,838] For example, the strategy of national annual vaccination days twice a year, 2 months apart, has been successful in developing countries.

Another problem with oral poliovirus vaccine—and the major problem in the United States—was the occurrence of a small number of vaccine-associated cases of poliomyelitis.[431,661] The immunogenic effectiveness of the vaccine depends on multiplication of the attenuated strains in the intestinal tract. Because no poliovirus strain is completely stable, the progeny of vaccine strains underwent a certain degree of mutation, which rarely resulted in increased virulence and vaccine-associated cases in recipients and their contacts, most often their parents.

Since 1980, no indigenous cases of wild poliovirus disease have occurred in the United States.[132,904] From 1980 to 1989, 80 cases of vaccine-associated paralytic poliomyelitis and 5 cases of imported disease were reported. The overall rate of vaccine-associated paralytic poliomyelitis was 1 case per 2.5 million doses of distributed vaccine; the risk for recipients was 1 case per 6.8 million doses, and for household contacts it was 1 case per 6.4 million doses. Of the 80 cases, 30 occurred in vaccinees, 32 occurred in household contacts, 4 were community acquired, and 14 occurred in immunologically abnormal persons.

Further analysis revealed that the risk associated with the first dose of vaccine was 1 case per 700,000 doses, but it was only 1 case per 6.9 million for subsequent doses; for vaccine recipients, the calculated risks were 1 case per 1.4 million initial doses and 1 case per 41.5 million subsequent doses. The calculated risks for contact cases were 1 case per 1.9 million initial doses of vaccine and 1 case per 13.8 million subsequent doses.

Immunodeficient children are at particular risk of acquiring vaccine-associated paralytic poliomyelitis.[123,904] From 1969 through 1976, 11 percent of vaccine-associated cases occurred in immunodeficient patients; 10 of 11 of these patients were children younger than 1 year of age. From 1980 to 1989, 18 percent of vaccine-associated paralytic poliomyelitis cases occurred in immunodeficient patients.[904]

Although the risks mentioned earlier were considered acceptable in view of the benefits provided, the question raised repeatedly since the 1970s was whether the United States should return to the use of inactivated poliovirus vaccine, which does not carry a risk of acquiring paralytic disease and has been highly successful in several small European countries in which more than 95 percent of the population is immunized.[305,320,422,493,508,699,755,841-844,904]

The problem was reviewed in detail by a committee of the Institute of Medicine (IOM) of the National Academy of Sciences, which reported its recommendations in April of 1977.[722] The conclusion at the time was that given the situation in the

United States, in which not more than 65 percent of susceptible children were vaccinated, oral poliovirus vaccine should continue to be the principal vaccine for routine immunization. Inactivated poliovirus vaccine, conversely, should be provided for two groups: immunodeficient persons, because of their greatly enhanced risk of acquiring vaccine-associated disease after receiving the oral vaccine; and adults receiving primary immunization, because of their greater susceptibility to paralytic disease. Also suggested was that the inactivated vaccine be available as an alternative for those who prefer it. In addition, a single dose of trivalent oral poliovirus vaccine was suggested for all entrants into the seventh grade of school as a means of added protection for later years when they became parents.

In January of 1988, a panel appointed by the IOM again reviewed policy options for vaccination against poliomyelitis in the United States.[459] The IOM panel concluded that no change in policy should be recommended at that time. However, they did recommend that a new enhanced inactivated poliovirus vaccine replace the old vaccine when inactivated vaccine was indicated. They also suggested that when a new enhanced diphtheria-tetanus-pertussis inactivated poliovirus vaccine became available, a regimen of two or more doses of it followed by the oral vaccine be considered.

In 1996, the U.S. poliovirus vaccine immunization program was evaluated extensively by both the Advisory Committee on Immunization Practices (ACIP) and the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP). The ACIP recommended that sequential administration of inactivated poliovirus vaccine followed by oral poliovirus vaccine be the schedule of choice in the United States.[746] The schedule consisted of two doses of the inactivated vaccine at 2 and 4 months of age and two doses of the oral vaccine at 12 to 18 months and 4 to 6 years of age. Both committees indicated that schedules that include all the doses of each vaccine also were acceptable.[393,746] At the present time, an all-inactivated poliovirus vaccination schedule is recommended in the United States.[17,669] It is a four-dose schedule with doses at 2 and 4 months, 6 to 18 months, and 4 to 6 years. The reader is advised to consult the recommendations of the ACIP and the AAP, as well as the manufacturers' literature, for full consideration of the contraindications and indications for poliovirus vaccines.

Routine primary poliovirus vaccination of adults older than 18 years is not conducted in the United States. However, adults at risk of exposure to wild polioviruses (laboratory workers, international travelers, health care workers) should be immunized. For the vaccination of adults, inactivated poliovirus vaccine is recommended. Patients with immunodeficiency diseases should not be given oral poliovirus vaccine; live virus also should not be used in households in which an immunodeficient person resides.

GLOBAL ERADICATION OF POLIOMYELITIS

The WHO established the Expanded Program on Immunization (EPI) in 1974.[451,979,1019] Subsequently, the use of oral poliovirus vaccine in developing countries vastly increased. In 1980 in Brazil, researchers demonstrated that mass administration with the oral vaccine on National Immunization Days (NIDs) led to a dramatic reduction in the incidence of poliomyelitis.[243] This demonstration led in 1985 to the targeted eradication of poliomyelitis from the Western Hemisphere by 1990. This campaign was successful in that the last confirmed case of paralytic poliomyelitis caused by wild poliovirus occurred in 1991 in Peru.[126] In September 1994, an international commission convened by the Pan American Health Organization certified that indigenous transmission of wild poliovirus had been interrupted in the Americas.[131]

In 1988, the World Health Assembly established the objective of global eradication of polio by 2000.[451] This program was based on four strategies recommended by the WHO: (1) maintenance of high vaccination coverage levels among children with at least three doses of oral poliovirus vaccine; (2) development of sensitive systems of epidemiologic and laboratory surveillance, including use of the standard WHO case definition (a confirmed case of poliomyelitis is defined as acute flaccid paralysis and at least one of the following: laboratory-confirmed wild poliovirus infection, residual paralysis of 60 days, death, or no follow-up investigation at 60 days); (3) administration of supplementary doses of oral poliovirus vaccine to all young children (usually those <5 years old) during NIDs to interrupt rapidly the transmission of poliovirus; and (4) "mopping up" vaccination campaigns, which are localized campaigns targeted at high-risk areas where wild poliovirus transmission was most likely to persist at low levels. NIDs are mass campaigns conducted over the course of a short period (days to weeks) during which two doses of oral poliovirus vaccine are administered to all children in the target age group regardless of previous vaccination history, with an interval of 4 to 6 weeks between doses.

From 1985 through 1990, worldwide routine vaccination coverage levels increased from 47 to 85 percent and stabilized at 80 to 81 percent from 1991 to 1994.[132] From 1985 through 1994, the number of cases reported annually decreased 84 percent, from 39,361 to 6241. The number of countries reporting polio cases decreased steadily from 1985 (99 of 196 [51%]) to 1988 (88 of 196 [45%]) and 1994 (51 of 214 [24%]). In addition, the number of countries reporting zero polio cases increased from 1985 (84 [43%]) to 1988 (104 [53%]) and 1994 (145 [68%]). The number of countries with endemic polio that conducted NIDs each year increased from 15 in 1988 to 37 in April of 1995; 24 additional countries scheduled their first NIDs for later in 1995.

At the beginning of the 21st century, NIDs had been conducted in every country in the world with endemic polio. In 1999, 7141 cases of poliomyelitis were reported worldwide. These cases occurred in 30 countries, mainly in south Asia and central Africa. By the end of 2000, fewer than 3500 cases occurred in endemic areas throughout the world, and wild-type 2 poliovirus has not been detected since October 1999.[924] At the close of 2001, the area of endemic poliomyelitis had been reduced to 10 countries, with fewer than 1000 cases reported.[711]

The global eradication program suffered a major setback in 2004 when oral poliovirus vaccine immunizations in northern Nigeria were suspended because of misinformation regarding vaccine safety.[415] Following this suspension, epidemic disease caused by type 1 virus occurred throughout Nigeria and also spread directly or indirectly to 21 previously polio-free countries.[140] This epidemic, which had extensive spread, had a major negative impact on the Global Polio Eradication Initiative. During 2005, 1856 cases were reported globally, and 1000 of these cases occurred in countries with outbreaks caused by importation.

Much attention is being paid to the end-game strategy for global polio eradication.[254,255,519] Of particular concern for the future following world eradication of wild poliovirus strains is vaccine-associated paralytic poliomyelitis.[521,522] Other concerns are the long-term excretion of highly evolved vaccine-derived polioviruses in persons with primary immunodeficiencies and polio outbreaks associated with circulating vaccine-derived polioviruses in areas with low rates of oral poliovirus vaccine coverage. Ideally, an end-game strategy would transition to the use of inactivated poliovirus vaccine, but this strategy is not realistic in much of the developing world.

Despite the substantial progress that has been made toward global eradication of polio, several challenges remain, including the following: (1) increasing vaccination levels in unvaccinated

subpopulations; (2) preventing the re-introduction of wild poliovirus into polio-free areas by eliminating reservoirs in polio-endemic countries (particularly in the Indian subcontinent); (3) increasing the awareness of donor agencies and governments in industrialized countries of the substantial financial and humanitarian benefits of global eradication of polio, thus engendering support from unaffected countries beyond that already provided by organizations such as Rotary International; (4) encouraging all countries that remain polio endemic to make eradication of polio a high priority, including the implementation of NIDs and the initiation of acute flaccid paralysis surveillance; and (5) providing support to vaccination program managers for training to develop managerial skills for implementing and maintaining effective vaccination and surveillance programs in all countries.[132] The success of the Polio Eradication Initiative will depend on finding solutions to these financial, managerial, political, and technical challenges.

The latest goal for global eradication of poliomyelitis is the year 2008. World events and new knowledge relating to reversion of poliovirus vaccine strains and recombination of poliovirus vaccine strains with nonpolio EVs led to the realization that decisions related to discontinuation of immunization after world eradication are exceedingly complex.[520,711,924,1012]

CHAPTER 179

RHINOVIRUSES

Robert L. Atmar

HISTORY

In 1954, the first recognized human rhinovirus (HRV) (type 1A) was isolated in monkey kidney cell culture by Pelon and associates[226] from a recruit at Great Lakes Naval Training Center in Chicago during an outbreak of afebrile common colds in his training company. Independently, Price and colleagues[234] reported the isolation of an antigenically identical virus from nurses and children with colds. In 1963, the HRVs were so named because of their association with illnesses of the nasal passages.[282]

Before these actual virus isolations, evidence suggested that viruses cause the common cold. Despite indications that some coldlike illnesses could be complicated by bacterial infections,[77,292] bacteria-free nasal filtrates from persons with apparent symptomatic respiratory infections clearly were able to initiate these illnesses. Kruse,[179] in 1914, first demonstrated transmission with apparently sterile filtrates, and, in the late 1920s, his results were confirmed in a series of experiments in humans and chimpanzees by Dochez and associates.[77] In the 1930s, workers from this latter laboratory reported growth of the agent in tissue culture and embryonated eggs, but their results were not confirmed.[6] In the 1940s and 1950s, Andrewes and colleagues[7] at the Common Cold Unit in Salisbury, England, and Dingle and the members of the U.S. Armed Forces Commission on Acute Respiratory Diseases were able to transmit colds from person to person with apparently sterile filtrates.[54] Jackson and colleagues[158] performed similar experiments in Chicago and also demonstrated immunity. In 1953, the Salisbury researchers reported isolation of an agent, DC, in serially passaged filtrates of tubed tissue cultures of human embryonic lungs; the virus was detected by its ability to produce colds in humans. Although these results could not be substantiated at the time, a virus *was* present; in 1968, the DC filtrates were found to contain HRV-9.[6,56]

The next major advance in growing common cold viruses took place in the late 1950s in Salisbury. Tyrrell and Parsons[283] inoculated human embryonic kidney cells with nasal filtrates and incubated the cultures under conditions simulating those of the nasal passages (e.g., 33° C, neutral pH, and in a roller drum for aeration). Six distinct types of HRVs (types 1B to 6)[61] were isolated by observing cytopathic effects.[270] Shortly thereafter, Hamparian and coworkers[61,130,173] isolated 18 HRVs (types 7 to 12 and 18 to 29) by using a semi-continuous diploid cell strain obtained by Hayflick and Moorhead[138] from human fetal lung cultures. The

use of Hayflick's cell lines greatly accelerated the isolation and characterization of "new" HRVs, and 100 serotypes (or 101 if HRV-1A and HRV-1B are counted as 2 serologic entities) officially have been identified.[129] More remain untyped, but the number of additional serotypes seems limited.[129,170,213]

Although the HRVs are associated primarily with mild upper respiratory tract disease, they also may be involved in bronchitis, sinusitis, and, on occasion, pneumonia in all age groups. These viruses seem to be precipitants of "infectious asthma" attacks. HRVs cause approximately 30 to 50 percent of all acute respiratory illnesses.[61,97]

THE ORGANISM

GENERAL DESCRIPTION

Rhinovirus is one of five genera of human pathogens in the family *Picornaviridae*.[91] *Enterovirus* includes polioviruses, coxsackieviruses, and echoviruses; *Parechovirus* includes two serotypes formerly identified as echovirus types 22 and 23; Aichi virus is the single member of *Kobuvirus*; and hepatitis A virus is the single member of *Hepatovirus*. Like the other picornaviruses, the HRVs are small (30 nm), nonenveloped (therefore resistant to lipid solvents such as ether and chloroform), and icosahedral (20-sided, hexagonal in cross section), with a genome consisting of single-stranded RNA (molecular weight, 2.5×10^6) approximately 7200 nucleotides long.[91] A picornavirus can be thought of as an RNA genome surrounded by a 12-sided protein coat (the capsid) (Fig. 179–1). The RNA alone is infectious and can serve as a messenger.

HRVs are distinguished from enteroviruses by being rendered noninfectious at an acidity lower than pH 5 and by their higher buoyant density in cesium chloride.[120] HRVs can be subdivided based on various virus characteristics, as follows: (1) into three species (HRV A, HRV B, and HRV C) based on genomic sequence analysis; (2) into three groups based on receptor usage (see later); (3) into two groups based on susceptibility to capsid-binding antiviral agents; and (4) and into 100 or more serotypes, as described earlier.[254]

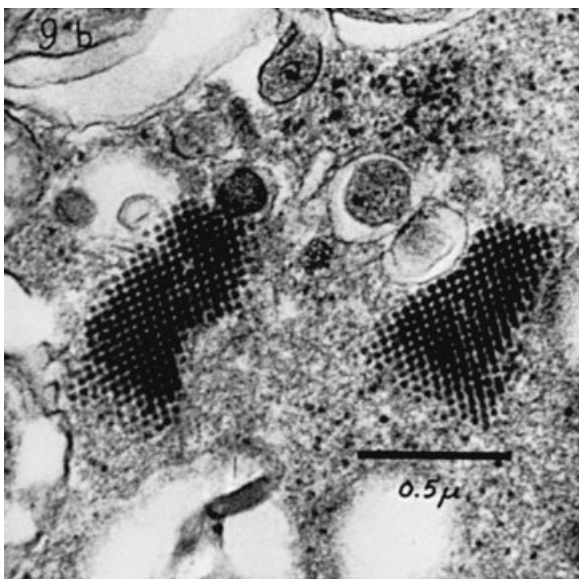

Figure 179–1 Rhinovirus type 2 in human fetal lung cells. Note the hexagonal virus crystals closely packed in a rectangular lattice (×40,000). *(From Kawana, R., and Matsumoto, I.: Electron microscopic study of rhinovirus replication in human fetal lung cells. Jpn. J. Microbiol. 15:207-217, 1971.)*

The genomes of several HRVs, including HRV-1B, HRV-2, HRV-14, HRV-16, HRV-39, and HRV-89, have been sequenced completely.[87,152,183,259,264] Partial sequences are available for the remaining recognized serotypes. Within an HRV species, a 61 to 98 percent pairwise nucleotide sequence identity of the VP1 gene exists among the different serotypes, whereas between HRV serotypes, the pairwise nucleotide sequence identity for this gene is 46 to 55 percent.[180] HRV-87 has greater sequence homology to the *Enterovirus D* species (EV-68 and EV-70) than to other HRVs, and some clinical isolates identified serologically as EV-68 lose infectivity in acid (a finding suggesting that these viruses should be classified as HRVs).[27,218] The interrelationships of viruses in these two genera will become clearer as more sequence data are obtained.

STRUCTURE OF THE VIRION

The virion is composed of 60 copies of each of 4 structural proteins: VP1, VP2, VP3 and VP4. Knowledge of the structure of the HRVs is based on the determination of the capsid structures in atomic detail for 5 serotypes, HRV-1A, HRV-2, HRV-3, HRV-14, and HRV-16.[10,175,246,247,288,303] The thin (5-nm) protein capsid has an undulating exterior marked by 12 vertices (the icosahedral fivefold axis) equally spaced over the surface. Surrounding these vertices is a steep (2.5-nm deep), narrow canyon. VP1, VP2, and VP3 are exposed on the surface of the virion, whereas VP4 is buried within the capsid.

A pocket of unknown function whose walls are lined by 17 amino acids that vary with each HRV type has been found at the base of the canyon.[8] Various organic molecules have been determined to bind in this pocket; when these molecules are bound, either the virus is prevented from uncoating (necessary to release viral RNA for its translation to viral protein) or the cell receptor is prevented from docking in the canyon.[98,229] Numerous drugs made by several different drug companies in the United States, Europe, and Japan have been developed to exploit the antipicornavirus potentialities of this pocket, and the sensitivity of the HRVs to these drugs has been used as an additional means of classifying the HRVs (into inhibitor groups A and B).[8,9] One group of these drugs, the WIN compounds synthesized by Sterling-Winthrop, has had wide scientific exposure; however, clinical trials have been discouraging.[272,275] One disadvantage of these compounds is that the various HRV serotypes vary widely in sensitivity to these organic molecules.[8] Another problem has been failure to attain effective concentrations of drug at the site of infection.

VIRUS LIFE CYCLE

The first step in the virus life cycle is binding to its cellular receptor. Only 3 different receptor binding sites exist for the 101 recognized HRV serotypes: 90 serotypes bind to intercellular adhesion molecule-1 (ICAM-1, the major receptor group), 10 other serotypes bind to members of the low-density lipoprotein receptor family (LDL-R, the minor receptor group), and 1 serotype (HRV-87) binds to a sialoprotein that may be a decay-accelerating factor (DAF, the recognized receptor for EV-70).[1,27,113,285]

ICAM-1 binds to the base of the canyon of HRVs in the major receptor group.[246,248,285] Virus-neutralizing antibody prevents virus attachment to cells by adhering to serospecific sites and blocking the cell receptor from access to its binding site at the canyon base. These antibody sites may directly overlap ICAM-1–binding sites, or they may be separate from the ICAM-1–binding sites but at a point sufficiently close to allow the binding site to be blocked by steric hindrance.[42,261] Binding of the major

receptor group HRVs to ICAM-1 leads to destabilization of the virus capsid and uncoating of the viral RNA.[114]

The LDL-R family binds to a different site for the minor receptor group of HRVs than that recognized by ICAM-1. The binding site for these HRVs is the small, star-shaped dome above the canyon on the icosahedral fivefold axis. Attachment of minor receptor group viruses to LDL-R does not lead to virus uncoating, in contrast to what is seen with binding of major receptor group HRVs to ICAM-1. Instead, internalization into acidic endosomal compartments is required for uncoating of minor receptor group HRVs.[145]

Replication of the HRVs is similar to that of the enteroviruses.[240] After attachment to the cellular receptor and endocytosis of the virus, RNA is released into the cytoplasm. Genomic viral RNA functions as messenger RNA and attaches to ribosomes, which stimulates its translation by host enzymes into a single long polyprotein. This polyprotein is cleaved by viral proteases to yield viral RNA polymerase, capsid proteins, proteases, and proteins to halt the synthesis of host proteins and other products. Under laboratory conditions, infectious virus first is formed after approximately 2 hours and reaches a maximum of approximately 1000 infectious particles per cell at approximately 7 hours. Infectious virus, however, comprises a minority of the virus-like particles formed; only approximately 1 in 200 is a complete virus capable of replicating in cell culture. All viral replication occurs in the cytoplasm, and viruses are released by cell lysis in a process involving apoptosis.[68,240]

HOST RANGE

Animals

Rhinoviruses have been isolated from natural infections in only cattle, chimpanzees, and humans.[91,192] Just two bovine rhinovirus serotypes have been reported, and they may cause infections ranging from subclinical to overt respiratory disease in epizootics; no evidence of human infection has been reported.[245] Chimpanzees and humans both are infected with HRVs; however, chimpanzee infections are subclinical.[71,258] A natural, subclinical outbreak of HRV-31 in chimpanzees was reported in a primate center.[70,71]

Many attempts have been made to infect a wide variety of animals with HRVs, but other than the chimpanzee, only the gibbon has been susceptible, and it is not reliably so.[71] An HRV-2 strain was adapted to grow in a mouse cell line (L cells), and the adapted virus was shown to grow in a mouse model.[301] Adaptation involves changes in the sequence of two nonstructural viral proteins that bind to intracellular host proteins to promote replication.[133] HRV-16, which uses ICAM-1 as its receptor, can replicate in mouse cells, but infection is blocked by the absence of ICAM-1 on the surface of mouse cells. The block can be overcome by engineering mouse cells to express ICAM-1, a finding that recently led to the development of a transgenic mouse model for HRV infection.[23,132,279] Equine "rhinoviruses" have been described, but these viruses belong to different picornavirus genera.[91,216]

Cell and Tissue Cultures

The spectrum of tissue culture cells infected by human HRVs also is narrow.[57,181] For initial isolation, human embryonic diploid cells generally are used (Fig. 179–2), although for some HRV types, an especially sensitive strain[55] of a continuous cell line, HeLa, serves as well or better.[57,181] Some HRVs grow only in human organ cultures and, perhaps, some only in living human beings.[181]

The first HRV (HRV-1A) was propagated in primary cell culture from primate kidneys (rhesus monkey cell cultures are used most commonly); surprisingly, chimpanzee kidney cell cultures do not propagate HRVs.[69] However, most HRVs propagate on original isolation only in cells of human origin, and they are called H strains; others also can be isolated in monkey kidney cell cultures and are called M strains. After laboratory propagation, all HRVs seem adaptable to the HRV-sensitive HeLa cell strain.[55] HeLa-grown HRVs attain much higher titers than those in the primary human diploid cells used for initial isolation.

ANTIGENIC PROPERTIES

An outstanding characteristic of HRV is its great antigenic diversity; at least 101 serotypes exist.[129] Evidence has shown, however, that the number of additional serotypes may be limited.[97,129,170,213] Certain serotypes cross-react, but little evidence indicates that this cross-reaction could be exploited in vaccination.[58,95,207]

HRVs often are poor antigens. Significant (fourfold or greater) increases in serum antibody may not develop in as many as 50 percent of patients from whom HRVs are isolated, and the levels attained often are low.[95-97]

HRVs may be undergoing continuous antigenic change.[207] Sufficiently marked antigenic variation has been found for HRV-22 and HRV-51 to interfere with their typing; however, this drift does not seem to predict a continuing proliferation of HRV types.[97,213,256,265]

EPIDEMIOLOGY AND GENERAL TRANSMISSION CONSIDERATIONS

SEASONAL DISTRIBUTION

During the usual September through May "cold season," HRV infections often are predominant at both ends, early fall and middle to late spring (Fig. 179–3). They also are important causes of summer colds. This seasonal pattern seems general because similar findings have been reported from families in Charlottesville, Virginia, Seattle, and elsewhere.[18,96,97,120,143,194] In the Southern Hemisphere, a similar seasonal pattern occurs, but during opposing months.[164] The general spring-summer-fall seasonal predominance of the HRVs does not mean that HRVs are absent during the remainder of the year; they are found in varying degrees year-round.[61,96,97,194,213,243]

CYCLING AND CIRCULATION OF INDIVIDUAL RHINOVIRUS TYPES

Several HRV serotypes usually circulate simultaneously within a community,[131] frequently coincident with other respiratory viruses.[72,149,209] For example, in a study of 24 neighboring families in Madison, Wisconsin (Eagle Heights Village), 14 different HRV types in addition to several nontypeable HRVs were found during the 2 academic years 1963 to 1965. Only a single type (HRV-15) was found both years. The other common respiratory viruses also were present. In virus surveillance studies performed in families in Seattle and Tecumseh, Michigan, a few "common" serotypes were found to be more prevalent in a given respiratory season and to be identified in subsequent respiratory seasons.[97,213] However, most individual HRV types do not repeat within a population from year to year.

CIRCULATION WITHIN SCHOOLROOMS

The mechanism of respiratory virus dissemination throughout the community may be the schoolroom or similar environments.

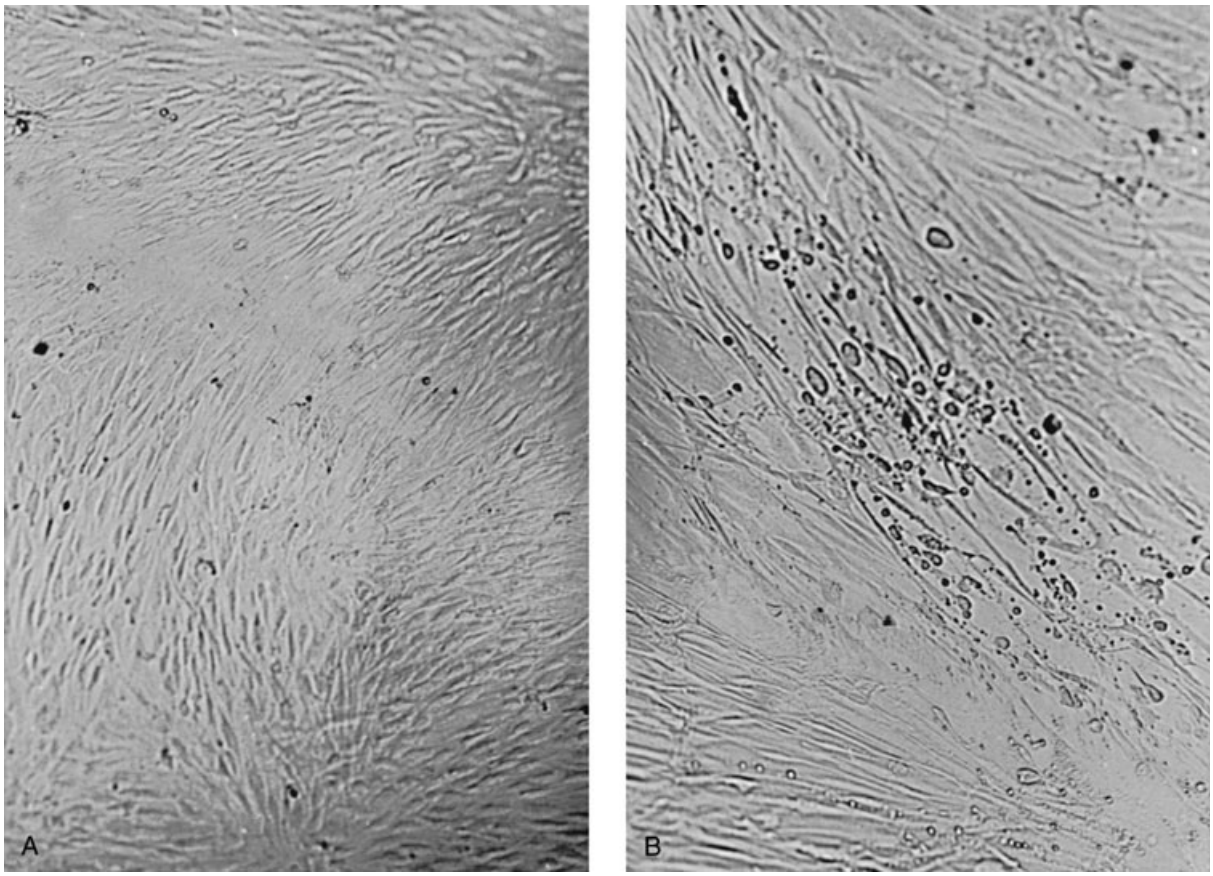

Figure 179–2 Rhinovirus type 16 infection. **A**, Normal human diploid (fetal tonsil) cell sheet. **B**, Cell sheet infected for 2 days with rhinovirus type 16. The rounded and misshapen cells are characteristic. *(Courtesy of Dr. David M. Warshauer, University of Wisconsin, Madison, WI.)*

In a Chicago nursery population, Beem[24] observed that some HRV types spread extensively and involved as many as 77 percent of the 22 children studied. He observed similar widespread infection with respiratory syncytial virus (RSV) but not with parainfluenza and influenza viruses. Similar results were observed in an upper middle-income Madison second-grade schoolroom (Fig. 179–4). The HRV types studied infected 18 to 55 percent of susceptible children; however, influenza B virus was the agent that circulated most widely.

Although several HRV types usually circulate concurrently, all types present are not equal in prevalence. In the aforementioned Chicago nursery school study,[24] 14 different serotypes were isolated during the academic year 1962 to 1963, but 10 of the serotypes did not spread at all. Only 3 types disseminated widely, and they infected more than 40 percent of the children. Similarly, in the 1963 to 1965 Madison Eagle Heights Village study, 14 HRV types were isolated, but only 3 types (HRV-43, HRV-51, and HRV-55) were "spreaders." Similar patterns of serologic prevalence were reported from laboratories in Tecumseh,[209] New York City, Seattle,[96,97] and Charlottesville.[143]

PREDOMINATING RHINOVIRUS TYPES

Although the pattern of predominating HRV types within a circumscribed population and a defined time frame seem to be well established, a predominance of serotypes over large geographic areas or over many years does not seem to occur. This phenomenon was studied exhaustively in widely separated locations and over many years: the Gulf South from 1962 to 1970, Tecumseh from 1966 to 1971 and from 1976 to 1981, and Seattle from 1965 to 1969 and from 1975 to 1979.[96,97,207,210,213] Although "common types" (usually the isolation of at least five to eight strains of a serotype during the period studied) occurred during each period and at each place, different types were "common" findings in different places and times. For example, at Tecumseh, Monto and colleagues,[210,213] during two 6-year study periods, obtained 475 HRV isolates covering 70 serotypes (out of a possible 89 at that time),[169] but only HRV-1B, HRV-10, HRV-28, and HRV-58 were isolated in both periods. However, these viruses were not particularly common because only 16, 22, 15, and 18 isolates, respectively, of these 4 types were found during the 12 years. In the neighboring state of Wisconsin from 1963 to 1965,[72] the common types were HRV-43, HRV-51, and HRV-55, completely different from those in Michigan. Finally, the late John Fox sifted data from family populations surveyed by him and others in New York City, Seattle, and Tecumseh.[96,97] He found only 4 common serotypes (HRV-1B, HRV-12, HRV-15, and HRV-38) from among 802 isolates. Dominant HRV serotypes often appear to occur locally over relatively short periods but do not extend for decades or over the nation, at least in the United States.

PERSON-TO-PERSON TRANSMISSION

EPIDEMIOLOGIC OBSERVATIONS

Individual HRV serotypes often disseminate with surprising difficulty, as noted previously in studies of Eagle Heights Village,[72]

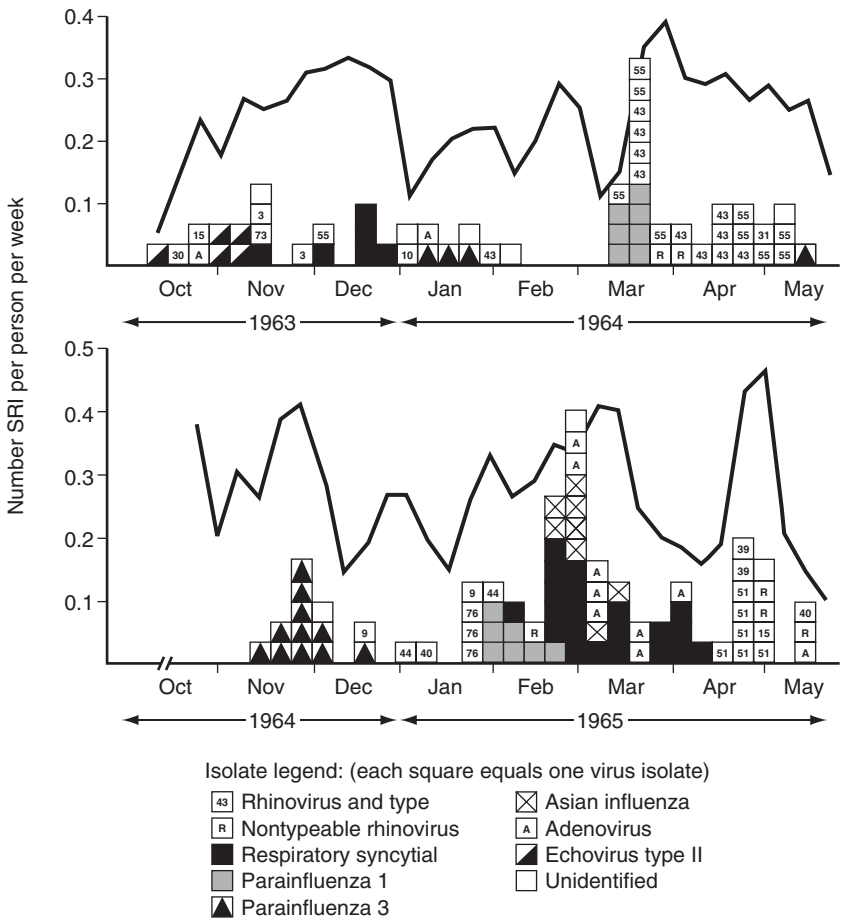

Figure 179–3 Rhinoviruses and other respiratory viruses associated with symptomatic respiratory infection. This study included three neighboring apartment buildings in Eagle Heights, a University of Wisconsin housing village in Madison, Wisconsin (24 to 26 families, ≈100 persons), from 1963 to 1965.

	Viral agent	Number of susceptible students*	Number infected (%)
1968	Nontypeable 'M' Rhinovirus	19	7 (37%)
	Rhinovirus 19	17	3 (18%)
	Rhinovirus 36	11	6 (55%)
	Parainfluenza 3	2	2 (100%)
	Respiratory syncytial	N.D.	5
1968–69	Rhinovirus 6	24	9 (37%)
	Influenza B	0	13
	Respiratory syncytial	3	8

*Number with neutralizing antibody titers ≤1:8 at the onset of study

Figure 179–4 Attack rates of several respiratory viruses within a Madison, Wisconsin, second-grade classroom of 26 students, three semesters, from 1968 to 1969.

a Madison elementary school (see Fig. 179-4), and a Chicago nursery school.[24] At least within family populations, the most common finding was that a specific HRV serotype did not spread from the index case. Hendley and associates,[143] in a study of 19 families in Charlottesville, found that HRVs from 10 of 22 index cases did not spread at all, and in only 7 families did dissemination to at least another person take place. In only 4 of the 19 families did further sequential spread occur. Fox and associates,[96,97] in a surveillance of more than 200 Seattle families, found intrafamily secondary attack rates in susceptible individuals (no homotypic antibody) to be 44 percent from 1965 to 1969 and 28 percent from 1975 to 1979. In both periods, children younger than 5 years had the highest secondary attack rate, 60 percent and 30 percent, respectively. Monto and Johnson and others[208,211] reported similar findings in 48 Panamanian families: with 5 HRV isolates used as antigens, the secondary attack rate varied from 10.5 to 56 percent.

In Madison, Wisconsin, interfamily and intrafamily dissemination of the 3 "spreading" HRV types, HRV-43, HRV-51, and HRV-55, was examined in the 24 to 26 neighboring families living in fourplex apartments in Eagle Heights Village (Fig. 179–5). These 3 serotypes were the only ones of 14 to spread beyond the index family. HRV-51 attacked 23 percent of susceptible individuals, and many family members and close neighbors remained uninfected. HRV-43 infected 34 percent of susceptible individuals; in one building, only the families in a single-end fourplex became infected. Conversely, HRV-55 caused a mini-

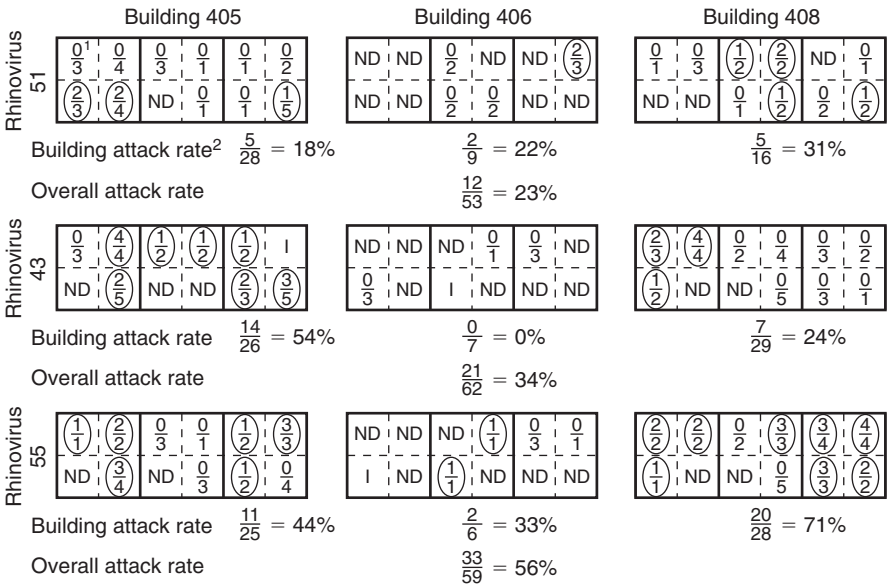

Figure 179–5 Attack rates of three "spreading" rhinoviruses in three neighboring Eagle Heights apartment buildings, Madison, Wisconsin. I, all members immune; ND, not done; O, family with one or more infected members.

[1]No. diagnosed cases/no. susceptibles (no detectable antibody)
[2]As diagnosed by either virus isolation and/or a fourfold or greater serologic response

epidemic in two buildings; several families had all members infected. HRV dissemination seemed to focus on the fourplex, probably because in the winter months the children played in the hallways and stairs connecting the fourplex apartments. Nonetheless, even the spreading HRVs left many susceptible individuals untouched among next-door fourplex neighbors and within many families.

The erratic spreading patterns of these viruses in Eagle Heights Village were perplexing. Determination of the reason for such erratic spreading patterns can be sought in well-controlled chain-of-infection experiments with human volunteers. HRV transmission experiments from several laboratories are described next.

PERSON-TO-PERSON TRANSMISSION TO HUMAN VOLUNTEERS

Experiments with Nasal Secretions from Persons with Colds of Unknown Origin

Experimentation with common colds in human volunteers began at England's Common Cold Unit in Salisbury shortly after World War II.[280,281] However, most of the transmission trials at this unit were performed with nasal secretions before discovery of most of the respiratory viruses, and the results are difficult to interpret (adenoviruses were cultivated first about 1953, followed by parainfluenza viruses, RSVs, HRVs [1956], and coronaviruses [1965]). Nonetheless, the general findings of these early experiments were correct; the usual common cold often is surprisingly difficult to transmit.[280]

Early Experiments with Rhinovirus Colds

Even in pure culture, the HRVs retained their uncertainty of transmission. Couch and colleagues,[59,63] trying to repeat a successful coxsackievirus A21 aerosol transmission experiment with HRV-15, attained no transmission after housing 15 donors (persons infected intranasally with laboratory-grown virus) with 12 recipients (persons without antibody to the donor's virus) for 26 days. At approximately the same time, the Madison laboratory performed transmission trials with HRV-55 and HRV-16 in a series of experiments ranging in duration from a 1- to 1.5-minute kiss to a 3-day weekend in a dormitory room. In 26 donors and 33 recipients, only 2 transmissions occurred, one from a 1.5-minute kiss and the other from a weekend in a dormitory.[64] Only when young married student couples were used was a substantial rate attained; among 24 couples, 9 donor spouses infected their mates, for a transmission rate of 38 percent.[65]

Median Human Infectious Dose for Rhinovirus

Judging from HRV challenge experiments with laboratory-grown virus administered by nosedrops or aerosol, less than one median tissue culture infective dose ($TCID_{50}$) can initiate infection.[64,78] Much more (2000 times) is required when placed on the tongue or dried just outside the anterior nares (10,000 times).[64] How accurately these conditions approach the natural state is not known.[141]

Characteristics of a "Good" Rhinovirus Transmitter

In the experiments with married couples, "successful" donors shed enough virus to contaminate their environment, exhibited signs and symptoms of a moderate to severe cold, and spent many hours at home with their spouses.[65] As an example of the effect of high virus shedding, intracouple transmission rates were 71 percent for donors with nasopharyngeal HRV titers of 5000 to more than 80,000 $TCID_{50}$, 33 percent for those with 1000 to 5000 $TCID_{50}$, and only 18 percent for those with less ($p = .025$). Illustrative of both shedding and production of sufficient nasal secretions was contamination of the hands with HRV: donors whose hands were assayed for virus and who transmitted infections to their spouses all had HRV on their hands, whereas none of the nontransmitters did ($p = .03$). The amount of time spent together seemed important in transmission, although many infected spouses who spent hours of direct contact with their partners did not transmit the infection.

Some Early Conclusions

The preceding findings both in epidemiologic studies and in human volunteers suggest that, in general, attending a concert or a motion picture with persons who have even obvious signs of colds is unlikely to result in infection. (Conversely, students who spend day after day in classrooms may have a higher chance of acquiring infection.) In addition, a relatively short stay (a few hours) among friends or relatives with HRV-caused colds is not likely to cause infection, even with brief embracing. Moreover, evidence from a group practice in Massachusetts showed that pediatricians' waiting rooms may *not* be places where respiratory viruses commonly are transferred.[188] These conclusions come with a caveat, however, in that direct experience is with only HRVs. Respiratory illnesses in which cough is a large component, such as influenza and measles, can result in substantial dissemination, even in a pediatric clinic.[43,112]

Route-of-Transmission Experiments

Because HRVs and perhaps other respiratory viruses often seem to spread with relative difficulty under many normal circumstances, the route of transmission becomes important because controlling the transmission of respiratory viruses in various habitats such as schoolrooms and families may be feasible by blocking transmission routes. Since the early 1970s, human volunteer experimental infection models have been used to explore HRV transmission routes. These studies have been performed primarily at the University of Virginia, England's Common Cold Unit, and the laboratory at the University of Wisconsin.

Gwaltney and Hendley[121] at the University of Virginia focused on the possibility that HRV colds were disseminated by direct or indirect hand contact. Interest in this approach had been provoked by the inadvertent transmission of HRVs from infected to non-infected persons through the vehicle of an ethanol-sterilized nasal speculum. Subsequently, the plausibility of direct hand transmission of HRVs was supported by the observation that nose picking and eye rubbing were common among Department of Medicine Grand Rounds participants and Sunday school attendees[144] (infection through conjunctival swabs had been reported previously).[33] These investigators then showed that HRV-39 retained infectivity for several hours on various surfaces and could be found on the hands of persons infected with HRV-39. The authors concluded that transmission of HRV could occur through self-inoculation by environmentally contaminated hands and demonstrated, in human volunteers, HRV-39 self-inoculation from an environmental source.[144]

The University of Virginia team in Charlottesville subsequently conducted a series of three experiments that identified direct inoculation as a route of virus transmission.[123] In two of the experiments, groups of recipients were exposed to HRV-infected donors (the HRV used was an untypeable strain, HH) in circumstances wherein they were exposed naturally in separate closed rooms to large-particle (12 recipients) or small-particle (10 recipients) aerosols produced by donors during periods of 45 minutes (large particles) or 3 days (small particles). One of the large-particle aerosol recipients was infected, whereas no one exposed to small-particle aerosols was. These essentially negative transmission rates by aerosol exposure were not surprising[121] because, as noted previously, Couch[60] had been unsuccessful in transmitting infection through the airborne route over a period of 26 days, and the Madison laboratory attained only a single HRV transmission among 11 recipients after 3 days' exposure in a dormitory.[64] The third group of Charlottesville recipients was exposed to HRV by inoculating themselves with the donor's nasal mucus. The donors blew their noses into their hands. The recipients then stroked the donors' contaminated hands for 10 seconds and then inoculated themselves by deliberately placing their fingers, two or three times, on their nasal and conjunctival mucosa. This inoculation procedure was repeated on 3 successive days. Eleven of the 15 hand-contact recipients (73%) were infected with the donors' HRV. The authors concluded that transmission by the hand-contact/self-inoculation route was much more efficient than the aerosol route was and "may be an important natural route of HRV transmission."[123]

One deficiency of this experiment was that donors and recipients shared the same air space over a measured, often brief, period during which fresh nasal mucus was transferred from the donor to the recipient. Nonetheless, Gwaltney did achieve a high rate of HRV transmission with nasal secretions, something that had not been accomplished readily in more "natural" experiments.[59,64] Also in support of hand transmission was the observation in the aforementioned married couple experiments that the ability to transmit HRV was correlated significantly with the presence of the virus on the donors' hands.[65] As a result of these various pieces of evidence and lack of compelling evidence to the contrary, hand-to-hand or fomite transmission became the accepted route for HRV contagion.[36,60] In later experiments, the Charlottesville group demonstrated approximately 50 percent transmission through fomites by using the same hand-contact/self-inoculation method described earlier, except either a coffee cup handle or a plastic tile was interposed between donors' and recipients' hands.[122]

At England's Common Cold Unit, Reed[241] investigated the likelihood of natural hand-contact transmission among residents (roommates) of several housing units, 38 of whom had been infected with HRV-2. Reed[241] found that 16 of the donors had HRV on their fingers, but none of the virus was transmitted to the fingers of their 18 roommates, even though virus could be recovered from some (6 of 40) objects recently handled by HRV-2–infected donors. Reed also found that none of 29 virus transfers from virus dried on the fingers could pass through a fomite to a recipient; the conclusion was that "spread of colds is unlikely to occur via objects contaminated by the hands of the virus shedder. . . ."

Laboratory workers at the University of Wisconsin continued their attempts to devise a natural transmission model to examine routes of transmission and, potentially, methods for interruption of transmission. Although the results of the transmission experiment with married couples were illuminating, the system itself had one great deficiency as an experimental model: the participants could not be observed during their interaction periods.[65] A model was needed in which donors and recipients could be monitored at all times. Ultimately, the scheme for such a system was suggested by two virologic-epidemiologic events in Antarctica, one from a few summer seasons (1975 to 1980) in which Dick and associates studied respiratory virus dissemination in an isolated Antarctic population and the other from a human volunteer experiment conducted in an Antarctic field party from England's Common Cold Unit.[291] Both experiences suggested that high natural transmission rates after just a few days of exposure could be achieved only in an environment with a high donor-to-recipient ratio and in a population density such as could be found in the classrooms and dormitories of a boarding school. Accordingly, a model was devised whereby donors (with the qualities of a "good" transmitter as described earlier) and recipients interacted during waking hours by playing cards and board and video games and engaging in communal studying. During the night, donors and recipients bunked together in the same or an adjoining room. With such an arrangement, graduate student monitors recorded activities and all clinical signs 24 hours a day. These artifices were successful; with 8 donors and 12 to 16 recipients, a 50 percent recipient attack rate usually was attained over a 12-hour period and a 100 percent rate over the course of a week.[76,202] Informally, this model, a fully observed monotypic HRV mini-epidemic, was named "Antarctic Hut," from its origins.[142]

Route-of-Transmission "Blocking" Experiments

Using the Antarctic Hut model, a series of 4 HRV-16 route-of-transmission blocking experiments was conducted to determine whether the virus was spread by hand contact, aerosol, or both.[76] The first 3 experiments lasted 12 hours, with 8 donors and 12 recipients; the donor-recipient interaction was through playing variants of stud and draw poker (Fig. 179–6). This interaction mode facilitated both aerosol and fomite/hand-contact transmission. Half the recipients were blocked completely from any hand contact/self-inoculation by wearing arm restraints (see Fig. 179-6). Evidently, little transmission resulted from hand or fomite contact because the HRV-16 infection rate in the restrained recipients was only slightly lower than in the unrestrained recipients, 56 versus 67 percent, an insignificant reduction ($p = .494$).

The fourth experiment, involving aerosol blocking, commenced immediately after the third. The poker game continued in the original room with eight donors alone, and all the equipment from the third experiment, including the cards (which literally were gummy from the previous 12-hour game), poker chips, pencils, and so forth, was moved to an identical room across the hall. The continuing eight-donor poker game in the room used for the third experiment was refurnished with poker implements. Subsequently, 12 new recipients entered the second room, began playing poker with the now heavily used cards and other paraphernalia, and made exaggerated hand-to-nose self-inoculation movements. Aerosol transmission was blocked effectively by the two brick walls between the rooms. Once each hour, the cards, poker chips, and other portables were exchanged between the donor and recipient rooms to maintain a freshly contaminated supply of fomites in the recipient room. The result was extremely surprising; not 1 of the 12 "fomite recipients" caught HRV-16. Judging from the results of these Antarctic Hut experiments in which fomite/hand-contact and aerosol transmission were blocked alternately, aerosol transmission clearly seemed the predominant route, at least for HRV-16 among student poker players at the University of Wisconsin. A few months after the 1987 publication of these results, an editorial appeared in *The Lancet* titled "Splints Don't Stop Colds: Surprising!"[76,263] It concluded that ". . . it looks as though coughs and sneezes *do* spread these diseases more than sticky fingers."

Subsequently, a set of experiments was conducted to determine how HRV-16 had disappeared along the five-step fomite transmission chain from nose to hand to fomite to hand to nose.[163] The experiments were a more elaborate version of Reed's previous studies,[241] and the same results were noted. The virus seemed to disappear precipitously at each step in the chain; 10^6 $TCID_{50}$ of HRV-16 in the donor's nose was reduced to 0 to 64 $TCID_{50}$ on the card-playing implements, and then the virus nearly disappeared on reaching the recipients' hands.

Additional studies examined other methods to interrupt transmission. The University of Virginia team performed a blocking experiment in the field in which mothers of families attempted to prevent hand contact/self-inoculation by dipping their fingers in iodine. The results of this 1979 to 1982 study were reported as part of a general review.[142] The illness rate during the 4 years was 40 percent lower in the mothers with iodinated fingers than in the placebo mothers, and the difference was significant ($p = .047$). However, the authors noted the difficulty of conducting and interpreting these investigations.[142] In another set of experimental human infection studies, the application of organic acids present in hand cleansers (e.g., salicylic acid, pyroglutamic acid) to the hands of volunteers decreased the likelihood of rhinovirus infection when volunteers subsequently touched their nasal or conjunctival mucosa 10 minutes after rhinovirus had been placed on their hands.[273]

The Madison group also examined transmission interruption methods to prevent spread from person to person. As part of a general investigation of the epidemiology of respiratory viruses in an isolated (≈200 persons) Antarctic population at McMurdo

Figure 179–6 A typical "Antarctic Hut" transmission experiment in progress using stud and draw poker as the interaction promoter. At each of four tables are two "donors" (infected with rhinovirus type 16) and three "recipients" (no antibody to rhinovirus type 16) (wearing surgical scrub suits). This particular experiment is one in which hand-contact/self-inoculation transmission is blocked in 6 of the 12 recipients by wearing Thatcher collars. The collars block hand-contact transmission by preventing touching of the face by the hands; therefore, virus can pass from donors to recipients only by aerosol.

TABLE 179–1 Apparent Complete Interruption by Virucidal Tissues of Rhinovirus Type 16 Transmission*

Study Group	Cotton Handkerchiefs Experiment A	Virucidal Tissues		Cotton Handkerchiefs Experiment D
		Experiment B	Experiment C	
Recipients who "caught" HRV-16 colds/total (%)†	5/12 (42)	0/12	0/12	9/12 (75)

**In each of 4 experiments, 8 volunteers with HRV-16 colds played poker for 12 hours with 12 other volunteers (without HRV-16 antibody) and for nasal sanitation used either ordinary cotton handkerchiefs (experiments A and D) or virucidal tissues (B and C). Three-ply Kleenex tissues were treated, per 100 g, with 9.1 g citric acid, 4.5 g malic acid, and 1.8 g sodium lauryl sulfate. Cotton or paper handkerchiefs were used to clear nasal passages, to smother coughs and sneezes, and to wipe surfaces. Virucidal tissues were used carefully and copiously.*

†Diagnosed by at least one isolation of HRV-16 or a fourfold rise in antibody to HRV-16 in the convalescent serum sample, or both.

HRV-16, human rhinovirus type 16.

Adapted from Dick, E. C., Hossain, S. U., Mink, K. A., et al.: Interruption of transmission of rhinovirus colds among human volunteers using virucidal handkerchiefs. J. Infect. Dis. 153:352-356, 1986.

Station in 1979, use of an iodinated facial tissue developed by the S. C. Johnson Company (Johnson's Wax) of Racine, Wisconsin, was successful in interrupting transmission.[73,291] Three days after all personnel began copious use of these tissues, the incidence of respiratory illness dropped rapidly and significantly ($p < .01$); in fact, respiratory illness nearly disappeared from the base.[75] Although this effect was striking, the trial could be controlled only historically. However, the apparent success was sufficient to interest the Kimberly-Clark Corporation, makers of Kleenex tissues, in applying virucidal facial tissue technology to interrupt HRV-16 transmission in the Antarctic Hut model. Kimberly-Clark soon made available a nontoxic, highly virucidal facial tissue. The tissues completely stopped transmission of HRV-16, in comparison to transmission rates of 42 and 75 percent in control recipients using ordinary cotton handkerchiefs ($p < .001$) (Table 179–1).[74] Kimberly-Clark test-marketed these tissues under the brand name "Avert," but their sales were lower than expected. Subsequently, two field trials of Avert in families were conducted in Charlottesville and Tecumseh, with reductions in viral transmission of 5 to 39 percent, respectively.[90,189] These results were disappointing but not unexpected. Changing established habits of personal nasal sanitation was not easy in the highly supervised, well-motivated adults in Antarctica; it may be impossible in unsupervised children.

Despite all the experimental studies to identify the principal route of virus transmission, no single route appears to be predominant. What is clear from these studies is that rhinovirus illnesses may be transmitted by both the hand-contact and aerosol routes. Certainly, the evidence presented in favor of the aerosol route as predominant should *not* discourage anyone from careful handwashing, especially around small children, in whom transmission by virus in wet mucus indeed could occur.

PATHOGENESIS AND HOST FACTORS

GENERAL COURSE OF INFECTION

Presumably, infection usually occurs through the respiratory route, although infection by the conjunctival route has been demonstrated.[33,144] To infect by the respiratory tract, a mucus blanket approximately 200 times the width of the HRV and propelled forward by continuously beating cilia must be penetrated by as yet unknown means.[141] Possibly, it is a formidable barrier and may account for the difficulty of HRV transmission. Nonetheless, when the virus is given intranasally by pipette, only one $TCID_{50}$ is needed to initiate infection.[64,78] The incubation period for a cold normally is 2 to 3 days, but a period of up to 7 days has been reported.[81,143] Ciliary dysfunction can predispose to respiratory infection.[28,35] HRVs replicate well in the upper respiratory tract (see later), and substantial evidence indicates that they replicate in the lower respiratory tract as well.[106,127,223,224]

RVs may be shed in large amounts (1000 to 1,000,000 infectious particles per milliliter of nasal washing) during the first 2 to 3 days of a cold and may be produced for 2 to 3 weeks thereafter.[76,78,81,202] However, the effect on cells of the nasopharyngeal cavity seems benign despite much local reaction to the virus, which results in the usual signs and symptoms of a cold. Systematic studies of HRV-inoculated human volunteers at the University of Virginia demonstrated that damage to the respiratory epithelium was slight, although a few sloughed ciliated epithelial cells did contain HRV antigen.[276,295] HRV was recovered only at focal sites in the nose and nasopharynx at the time of maximal symptoms, and in situ hybridization studies demonstrated evidence of HRV infection in only a minority of epithelial cells.[16,22,297] Furthermore, using primary monolayer cultures of ciliated and nonciliated epithelial cells, Winther and associates[296] demonstrated that HRV, coronavirus, influenza A virus, and adenovirus all grew well in these cell cultures; however, HRV and coronavirus produced no discernible cytopathic effect, whereas influenza virus and adenovirus nearly destroyed the cell sheet by 96 hours.

INNATE IMMUNE RESPONSE

Innate immunity is the initial host response to infection with rhinoviruses. Toll-like receptor 3 (TLR3) is activated by double-stranded RNA that is generated during virus replication, and TLR3 is up-regulated during HRV infection and is associated with decreased viral replication.[146] TLR activation leads to the production of type 1 interferons, which may be the mechanism by which viral replication is inhibited. Impaired induction of interferon-β leads to increased viral replication and is a defect that has been identified in the respiratory epithelium of asthmatic patients.[290] Numerous other components of innate immunity are also induced by rhinovirus infection, including beta-defensins, nitric oxide, and a variety of proinflammatory cytokines and chemokines (e.g., interleukin-1 [IL-1], IL-6, IL-8, RANTES [regulated on activation, normal T cell expressed and secreted]).[238,252]

Because the HRVs seem to cause only mild pathologic changes in cells of the respiratory tract, attention has turned to various immunologic or inflammatory substances as possible causes of symptomatic illness.[271] Researchers have long known that peripheral blood neutrophils increase in the first 2 to 3 days of illness in HRV-infected volunteers.[37,271] Phagocytes (neutrophils and monocytes) also have been demonstrated in large numbers in the nasal secretions of HRV-infected symptomatic human volunteers.[187] Although the microbe-killing ability of phagocytes is well known, these cells in themselves also can cause cold symptoms through the release of various toxic products, such as superoxide and hydrogen peroxide, during the respiratory burst.[31,268] In fact, increasing numbers of leukocytes in the peripheral blood

correlate with increased symptoms, and in infected human volunteers who are not ill, the white blood cell count does not increase.[271] An association has been noted between the nasal levels of two proinflammatory mediators involved in granulocyte regulation, granulocyte colony stimulating factor (G-CSF) and IL-8, and blood and nasal neutrophilia have been identified.[107,220] Nasal IL-8 levels also correlate with the severity of clinical symptoms.[115,278]

Increased nasal levels of other inflammatory mediators (e.g., IL-1β, IL-6, RANTES, kinins) have been associated with more severe clinical symptoms.[215,220,235,236,305] Furthermore, topical nasal administration of IL-6 or bradykinin leads to development of some of the symptoms of the common cold.[102,237] At least some of these inflammatory responses appear to depend on an activation pathway regulated by nuclear factor kB (NF-kB).[304,305] Resolution of clinical symptoms may be caused by the elaboration of inhibitors of inflammation, such as IL-1 receptor antagonist.[302] These inflammatory mediators may serve as a target for the development of drugs to relieve the symptoms of HRV infection, although the use of a specific kinin inhibitor did not lead to clinical improvement.[118,148]

IMMUNITY CAUSED BY SERUM ANTIBODY

Serum antibody to the various HRV types develops with age (presumably from repeated infections), and by adulthood, antibody may be detected against approximately 50 percent of HRV types tested.[119] The presence of serum antibody correlates positively with immunity, and resistance to infection and the degree of disease expression are related to the amount of antibody present.[3,4,32] As examples, in the Eagle Heights families, 21 of 75 persons (28%) without antibody were infected with either HRV-43 or HRV-55, whereas only 5 of 35 (14%) with homologous antibody to either of these agents were infected.[72] No one was infected who had homologous serum antibody levels above 16. Similar results were observed in the Charlottesville and Seattle families.[96,97,143] However, large doses can overwhelm antibody. At the clinical center of the National Institute of Allergy and Infectious Diseases, where human volunteers were used, 1000 $TCID_{50}$ was found to infect persons with serum antibody titers up to 256.[38] Judging from the paucity of reports of natural infections in persons with serum antibody titers greater than 16, virus inocula in naturally contracted cases must be low.

IMMUNITY CAUSED BY ANTIBODY IN NASAL SECRETIONS

At the National Institutes of Health, researchers found that intranasal administration of HRV vaccine produced both serum and nasal antibody, whereas two intramuscular injections of this vaccine produced little, if any, nasal antibody.[39] When the volunteers given the vaccine intranasally were challenged with approximately 100 $TCID_{50}$ of homologous HRV, they were protected significantly against both clinical illness and infection, whereas those administered the same vaccine intramuscularly remained susceptible.[227]

Conversely, other investigators who used the same vaccine preparation but gave it subcutaneously in 3 injections found nasal antibody responses in 21 of 46 (45%) volunteers.[80] These investigators discovered that when results were compared with those in unimmunized, antibody-free controls, challenge of these volunteers with 3 $TCID_{50}$ of virus produced significantly less virus shedding and reduced the duration and severity of illness. Possibly, this lower infectious dose more closely approximates a natural situation. This study also showed that protection against infection with the low virus challenge correlated with the magnitude of serum antibody and not with the presence of secretory antibody. The relative roles of serum and secretory antibody in HRV infections are still unsettled.

ANTIBODY APPEARANCE OVER THE COURSE OF INFECTION

A general pattern of the development of humoral (secretory and serum) antibody emerged from several studies.[32,83] Approximately 24 hours after infection, a sharp increase in nasal immunoglobulin A (IgA) secretion occurs. When symptoms begin approximately 48 hours after infection, rhinorrhea commences, and the transudate is composed of significant amounts of IgG. After approximately 1 week and after the actual episode of illness, virus-specific antibody, predominantly IgA, appears in the nasal passages, tears, and the parotid saliva. Serum antibody (usually IgG but occasionally IgM) also begins to be formed at 1 week and rises to peak levels at 1 month. Both serum and secretory antibodies appear sooner and rise more rapidly in persons with detectable neutralizing antibody in their pre-infection serum specimens. Antibody has been detected in nasal secretions and serum approximately 1 year after infection and, judging from the high proportion of the adult population with antibody to many HRV serotypes, probably lasts much longer.[30,119]

CELL-MEDIATED IMMUNITY

As noted previously, evidence that neutrophils increase both in the peripheral blood and in the nasopharynx during the first few days of an HRV cold is substantial.[37,294] Evidence that peripheral blood lymphocytes actually decrease in the first 2 to 3 days of an HRV cold and that migration of lymphocytes into the nasal secretions increases at this time also exists.[37,187] As noted earlier, specific humoral antibody usually is not present in the serum or nasopharynx this early in the illness, a finding suggesting that these in situ nasopharyngeal lymphocytes, through cell-mediated immunity, play an important role in controlling HRV proliferation. Hsia and colleagues[151] examined the ability of peripheral blood lymphocytes to liberate various cytokines (IL-2 and interferon-γ) and participate in other cellular immune processes (cytotoxicity and antigen-stimulated blastogenesis) during the early days of HRV colds in experimentally infected human volunteers. These investigators found that during infection, all these cell-mediated immunity activities were increased significantly when compared with pre-infection levels. Of special interest was their observation that the cellular ability to liberate higher levels of IL-2 correlated inversely and significantly ($p < .02$) with virus shedding and nasal mucus production. Cross-reactive T-cell epitopes are shared by HRVs, and T cells isolated from peripheral blood and from tonsillar tissue proliferate and secrete a variety of cytokines (interferon-γ, IL-2, IL-4, IL-5) after exposure to HRV antigens.[105,134,293] Thus, activation of T cells may contribute not only to virus clearance but also to airway inflammation.[105]

INTERFERENCE AMONG RHINOVIRUSES

Interference in infection with heterotypic HRV serotypes, which lasts between 5 and 16 weeks, has been reported in human volunteers.[92] Complete resistance to infection was observed after inoculation with as much as 2000 $TCID_{50}$ of HRV-16 (administered by nasopharyngeal spray) in a subject with an unsuspected "wild" HRV (not typed) infection present at the time of inoculation.[185] However, epidemiologic studies in a nursery school population,[24] a military population,[244] and a family population[206] showed sequential heterotypic HRV infections occurring frequently, sometimes at intervals as short as 2 days. In the family population, one subject was infected by three different HRVs

within a 30-day period. The factor or factors responsible for the interference observed in the experimental human infection model have not been identified. Simultaneous infection with an HRV and other respiratory viruses, including influenza A and B viruses, coronaviruses, parainfluenza type 1, RSV, adenoviruses, various enteroviruses, or other HRV serotypes, also has been reported.[86,97,184]

INFLUENCE OF A COLD ENVIRONMENT ON THE COURSE OF INFECTION

Exposure to cold temperatures is thought either to initiate or to exacerbate respiratory infections. In fact, chilling animals was shown to increase the severity and frequency of viral infection.[289] However, investigation of the effects of chilling on humans infected with "common cold viruses" and with HRV-15 did not demonstrate significant effects.[82] In the HRV-15 experiments, the conditions were realistic. The subjects (men) were cooled sufficiently in air to cause shivering for approximately an hour or were immersed in water long enough to cause a decline in rectal temperature.

EFFECT OF AGE AND SEX

A much higher prevalence of HRV infection is found in infants and young children than in older persons. In Seattle,[96] the HRV infection rate in children 0 to 5 years of age was nearly twice that of older children and adults (0.77 versus 0.41 infections per person per year, respectively); in Tecumseh,[210] the isolation rate in the 1- to 4-year-old group was far higher than that in any other age bracket. The high attack rates in these young children were not unexpected because fewer than 10 percent of them had antibody to any of the 56 HRV types,[121] and children ordinarily are subjected continuously to the family-like environment so conducive to transmission of HRVs. In especially crowded populations, attack rates may be high. In an Alaskan Eskimo village, 70 percent of 395 children were infected during a spring outbreak of HRV-16 infection.[299]

The frequency of infection with HRV generally declines throughout life. Beginning at the age of school attendance, the number of HRV infections declines gradually from one to two per year to 0.25 per year in the age group older than 60 years.[119,212] Results from most laboratories have found that persons 20 to 30 years of age account for an exception to the general decline in incidence with age[96,143,209,212]; HRV infections as well as infections with other respiratory pathogens increase during this period of life. Because the increase is especially marked in mothers,[96,143] it probably is the result of the transfer of respiratory illness in small children to parents.

In Tecumseh, the number of respiratory illnesses per year was consistently higher for female patients than for male patients (3 to >60 years of age).[212] If one assumes that HRVs account for a similar proportion of disease in each gender, this finding would indicate that girls and women generally have more HRV infections. As noted earlier, women with young children clearly seem to have more HRV infections than do others in their age group. In Seattle,[96] mothers had 1.5 times more HRV infections than fathers did, and in Charlottesville, women of child-bearing age had approximately 1.2 times more HRV illness than male study subjects did.[119]

EFFECT OF PSYCHOSOCIAL FACTORS

Numerous psychosocial factors have been shown to influence susceptibility to HRV infection, primarily in the experimental human infection model. Increased psychological stress, as measured by numerous stress indices, was associated with an increased susceptibility to infection and an increased likelihood of developing illness.[52,53] In contrast, having a more diverse societal network (increased number of social ties) and having a positive emotional style (i.e., sense of well-being, vigor, and calmness) were associated with resistance to infection and illness.[51,85] Antibody-negative (serum antibody levels < 1:2) subjects were equally susceptible to infection regardless of the degree of stress or number of social ties, although these factors did influence the likelihood of clinical illness.[51,52] Increased stress in working adults also was associated with an increased risk of having a natural common cold.[267]

CLINICAL MANIFESTATIONS

Consonant with their benign cytopathology in the respiratory tract, HRV infections in any age group usually cause only mild upper respiratory tract illness, that is, common colds.[60] Investigators estimate that HRVs cause 30 to 50 percent of common colds, at least in adults.[191] In healthy adults, HRV infections usually are so innocuous that human volunteers can be infected safely with these agents to study their epidemiology, pathogenesis, and control with experimental drugs.[60,142,162,202,281] However, even in adults, development of serious illness is possible: HRV-associated, radiograph-positive, atypical pneumonia has been described in military trainees[103] and in immunocompromised adults,[108,157] graft dysfunction has occurred in lung transplant recipients,[168] and exacerbation of underlying lung disease has been seen in adults with asthma and chronic obstructive pulmonary disease.[20,111,217,257] Severe respiratory disease, pneumonia, and death also have occurred in outbreaks of rhinovirus infection in geriatric patients residing in nursing homes.[147,190]

Nonetheless, children, particularly the very young, are the ones most likely to be subject to serious, sometimes fatal HRV-caused illness. As an example of a fatal outcome, a report from Los Angeles described an 11-month-old infant with mild asthma who died, totally unexpectedly, during sleep of apparent acute asthma and interstitial pneumonitis caused by HRV-47 (isolated from lung and blood specimens).[182] The authors wrote a special plea to other physicians to be alert for similar exigencies in their own patients. In this respect, two deaths of infants from possible rhinoviremia, one of which occurred during a cold, and six "cot" deaths, diagnosed as bronchiolitis/pneumonia and from which HRVs were isolated, may suggest that HRV involvement in fatal illnesses in infants is more common than realized.[243,286]

Viremia has been noted to occur in a minority of children with HRV infection and respiratory disease.[300] At least in theory, generalized illness following viremia seems possible with HRV infections; the HRVs are a division of the larger picornavirus group, which contains many viruses capable of generalized and fatal infection and whose genomes have considerable homology with the HRVs (see "Structure of the Virion," earlier).[222]

SPECTRUM OF RESPIRATORY DISEASE

Early Studies: Severe Disease in Young Children

Investigators have known since the discovery of the first HRV serotypes that these viruses cause considerably more severe illness in children than in adults. In 1959 and 1960, Hamparian, Hilleman, and their associates[131,242] conducted a clinical and virologic investigation of 15 children (<8 years old) and 20 adults from the Philadelphia area who had acute respiratory disease and from whom HRVs (then called coryzaviruses) had been isolated (Table 179–2). The 20 adults all had typical upper respiratory illness,

some with low-grade fever (peak of 37.3° C [99.2° F]). In contrast, 60 percent of the children had temperatures higher than 37.7° C (100° F), 20 percent had otitis, and 53 percent (eight children) exhibited one or more signs of lower respiratory tract involvement. One had laryngotracheitis (croup); one, bronchitis; two, asthmatic bronchitis; and one, bronchopneumonia. The last infant was 2 months old, and crepitant rales were heard over the right side of the chest anteriorly and posteriorly; the child's chest cleared in 2 days.

Shortly thereafter, in 1963, the Eagle Heights Village study of young student families began.[72] The epidemiologic aspects of this investigation were described previously (see "Epidemiology and General Transmission Considerations," earlier). Daily home clinical surveillance was performed, and, although the illnesses generally were so mild that the participants did not see a physician, the same differential severity between adults and children was noted (Table 179–3). With all viruses, including HRVs, children were much more likely to be febrile, and their symptoms were much more likely to last longer. Overall, however, HRV-caused illnesses were milder than those caused by other viruses.

A thorough investigation of infants and young children hospitalized with lower respiratory disease at Madison General Hospital was conducted at the same time (Table 179–4).[45] A virus was cultured from 38 percent of these patients, and HRVs predominated (11 of 27 isolates). These children (average age, < 1 year) with HRV infections were seriously ill: the mean temperature was 39.4° C (103° F), and eight had bronchopneumonia. Six of the virus-infected children yielded a bacterial pathogen in predominance in throat cultures. Five of these pathogens—beta-hemolytic *Streptococcus* in one, *Streptococcus pneumoniae* in two, and *Haemophilus influenzae* in two—were present coincidentally with the HRV isolates. All the patients with HRV-associated cases had antecedent milder respiratory symptoms, especially coryza.

Rhinovirus Preeminence in the Respiratory Disease of Larger Populations

Two large populations, one a general medical practice in Roehampton in England, near London,[149] and the other a group of families in Tecumseh, a small town in the United States near Detroit,[209] were assayed for the various respiratory viruses in illnesses of differing severity. Each had a pediatric population base of 900 or more. HRVs easily were the most common cause of respiratory illness in either population (Table 179–5): 26.3 percent of isolates in England and 38.1 percent in Michigan.

In both populations, HRVs frequently were associated with lower respiratory tract illness (Table 179–6); the proportion was much higher in the Roehampton clinic. The major HRV diagnosis in lower respiratory tract[149] disease was wheezy bronchitis: 42 percent of all HRV isolates in Roehampton and 15 percent in Tecumseh.[213] Otherwise, the severity of disease associated with HRV infection often was milder; in Roehampton, none of the HRV isolates were from children with bronchiolitis or pneumonia, whereas 8.4 percent of the RSV isolates were associated with one of these diagnoses. In Tecumseh, restriction of activity was

an important differential etiologic marker in that only 24.3 percent of those patients with HRV illness curtailed their normal activities, whereas the percentages often were double that for the other respiratory viruses, varying from 42 percent for RSV to 63 percent for influenza B virus.

Rhinovirus Infections in Hospitalized Children

In Bristol, England, in 1971, 377 infants hospitalized for respiratory disease yielded 199 (53%) viral diagnoses.[160] RSV was predominant and accounted for 79 percent of the diagnoses, but HRVs were second at 12 percent (23 patients). Half of the HRV diagnoses were in infants with bronchiolitis or pneumonia. HRV illnesses were comparable in severity to those caused by RSV. One 4-month-old child with HRV-associated bronchopneumonia died. Except for the absence of deaths, similar results were found in 102 hospitalized children in Colorado, where the etiologic diagnosis rate was 85 percent.[221]

Serious HRV infections in young children have been reported from several locations, and some of these outbreaks have allowed

direct comparisons between HRV and RSV infection. In the intensive care nursery of Strong Memorial Hospital in Rochester, New York, eight infants aged 2 weeks to 6 months became nosocomially infected, four with HRV and four with RSV, in early February of 1980.[287] One of the HRV isolates was from an asymptomatic baby. All seven symptomatic babies had a dramatic and sudden onset of respiratory illness that included cyanosis, apnea, labored respirations, increased nasal or tracheal secretions, tachypnea, and lethargy. Wheezing, tachycardia, irritability, and cardiac arrest each occurred in a single infant. None of the signs and symptoms differentiated between HRV and RSV illnesses.

At St. Anna Children's Hospital in Vienna from 1984 to 1986, Kellner and colleagues[172] compared the clinical features of HRV and RSV infection in 519 children aged 10 days to 3 years (median age, 6.6 months). Viral pathogens were detected in 227 (44%) of the children, and of these, 119 (23%) were RSV and 60 (12%) were HRV. The physical findings (Table 179–7) and the clinical diagnosis (Table 179–8) of the children with HRV or RSV infection were the same, except HRV infections were more likely than were RSV infections to be associated with upper respiratory tract infection.

Several retrospective reviews of clinical and laboratory records also implicated HRVs as probable causes of lower respiratory illness in infants. In 1982 and 1983, Krilov and associates[178] found 32 HRV-infected children who had significant signs of pulmonary disease in Boston hospitals; half of these children had radiologic evidence of new focal infiltrates. From 1984 to 1988, Abzug and associates[2] examined all virus-positive cultures from pneumonias in neonates younger than 30 days in Denver hospitals. The definition of pneumonia was strict and included new infiltrates on chest radiographs in addition to several typical physical signs. Forty patients were found; RSV was isolated from slightly more than half the cases, and HRVs and enteroviruses, at 6 isolates each, were the second most frequent. McMillan and colleagues[199] identified 48 pediatric patients who had HRV infections and were admitted ($n = 40$) or treated in the emergency center ($n = 8$) at their institution in Syracuse, New York, between 1985 and 1989. Most of these patients ($n = 41$) were younger than 1 year old and almost half ($n = 20$) had a clinical picture of bronchiolitis. Suspected sepsis ($n = 9$) was the next most common diagnosis. Jacques and colleagues evaluated 193 French children younger than 3 years of age hospitalized with bronchiolitis. HRV was the second most common cause of bronchiolitis (23% of cases), after RSV (30%).[161]

Kim and Hodinka[174] identified 93 pediatric patients with HRV infection who were evaluated in the emergency center ($n = 5$) or admitted ($n = 88$) to their hospital in Philadelphia between 1990 and 1996. Most of these children ($n = 67$) were younger than 1 year old. An acute respiratory illness was the most common clinical finding ($n = 78$, 84%), with fever and suspected sepsis the next most common ($n = 13$, 14%). A second viral or bacterial pathogen was identified in 8 (9%) of the subjects. Many of the subjects ($n = 62$, 67%) had an underlying condition such as prematurity or reactive airway disease. These investigators concluded that HRV infection was associated with severe lower respiratory illness and the need for hospitalization and could be a complicating factor in patients with underlying conditions.[174] Chidekel and colleagues[46] examined 40 patients with bronchopulmonary dysplasia and noted 8 episodes of worsening lung disease in 6 infants associated with HRV infection. The findings and clinical course of these infants were similar to those noted in other infants infected with RSV, although the need for mechanical ventilation was greater in association with RSV infection.

Glezen and colleagues[109] performed a prospective study to evaluate the occurrence of respiratory virus infection in subjects with respiratory or cardiac disorders admitted to three hospitals in Houston, Texas, between 1991 and 1995. HRV infections were identified in 51 subjects from a total of 1198 evaluated ill-

nesses; 6 of them were associated with a second respiratory virus infection.[89] In children younger than 5 years of age, exacerbation of asthma, bronchiolitis, and suspected sepsis were the most common clinical findings, whereas in older children and young adults, almost all subjects had an exacerbation of asthma. In older adults, a complication of an underlying disease (asthma, chronic obstructive lung disease, congestive heart failure) or pneumonia was diagnosed. In this prospective study, HRV infections were an important cause of lower respiratory tract illness in all age groups.[89]

Despite the foregoing evidence that HRVs can be an important cause of severe lower respiratory tract disease, large studies in Chapel Hill, North Carolina,[67] Huntington, West Virginia,[25] and Tucson, Arizona[298] by experienced investigators yielded the usual respiratory viruses in appropriate numbers. However, only 1 to 3 percent of these viruses were HRVs. These studies probably underrepresent the importance of HRV-caused disease in these populations because negative cultures do not necessarily mean the absence of HRVs (see "Diagnosis of Infection," later). These viruses are difficult to grow, even in supposedly sensitive cell cultures, and often only a few organisms are present in the specimen (Table 179–9).

In summary, evidence is accumulating that HRVs can cause serious lower respiratory illness, especially in young children. In some populations, HRVs may be second to RSV in importance and may cause comparably severe signs and symptoms.

Asthma

A specific lower respiratory illness in which the HRVs clearly appear important, perhaps most important, is "wheezy bronchitis" or "infectious asthma." The association between HRVs and these illnesses first was noted by Horn, Gregg, and their associates[149,150] as part of their previously described 1967 to 1972 Roehampton study of ill children (see Table 179-5). Forty-two percent of the 162 HRV isolates at Roehampton were from children with attacks of wheezy bronchitis, approximately twice the percentage of other viruses causing this syndrome. Many of these children were known to be subject to recurrent episodes.

During the later years (1971 to 1972) of this period, the Madison laboratory performed a longitudinal clinical and microbial study (children were sampled at least twice weekly for viral and once monthly for bacterial culture) of 16 nonatopic children with "infectious asthma" and 15 of their unaffected siblings. A clear temporal relationship was found between (1) the onset of symptomatic respiratory infection, (2) an asthmatic episode, and (3) the presence of viruses, predominantly HRVs, in the pharynx (Fig. 179–7).[204,205] Precipitation of an asthmatic episode occurred much more frequently during severe symptomatic respiratory infections than during mild ones. HRVs caused an asthma attack in 14 of 15 severe symptomatic respiratory infections but in only 1 of 6 mild ones. Subclinical infections never precipitated an attack. Except for one instance in which *H. influenzae* may have caused asthma, bacterial infections were not associated with asthma attacks, even when they were accompanied by severe symptomatic respiratory infection. As shown in Figure 179-7, the severe group A streptococcal infections in subjects CC and P did not precipitate asthma, whereas severe HRV-49 infections in these two children caused more than three asthma attacks that were sufficiently incapacitating for the child to stay home from school.[205] The asthmatic siblings seemed especially susceptible to symptomatic infection; total infections of probable viral origin ($p < .02$), known viral infections ($p < .01$), and HRV-caused symptomatic respiratory infections ($p < .01$) all were significantly greater in the asthmatic than in the nonasthmatic siblings.[203]

A somewhat similar year-long prospective investigation was conducted in England[156] in 30 preschool children with histories of recurrent respiratory infection often accompanied by wheezing, as well as in their unaffected siblings. The children with recurring infections had approximately twice the number of illnesses and viruses isolated than the controls did. Their illnesses also were much more severe, and they often involved the lower respiratory tract. HRVs were heavily preponderant, at 57 percent of the isolates, and were associated with wheezy bronchitis four times more often than were RSVs. Atopic children, as measured by positive skin testing and raised serum IgE levels, did not seem especially subject to development of recurrent infection.

At the University of Colorado, McIntosh and associates[197,198] demonstrated in 1973 the importance of other respiratory viruses in asthma; later, these investigators suggested that RSV is the major agent associated with asthma in children younger than 4 years and that HRVs are preeminent in older children and adults.[197,198] Subsequent reports demonstrated the importance of HRVs in older children, as well as in many younger children. As examples of HRVs in younger children, in patients with recurrent asthma who were seen at the pediatric allergy unit in Oslo from 1981 to 1983, most cases of acute bronchial asthma were HRV associated (45%), with RSV being second (19%).[34] Twenty-nine percent of those patients in the virus-infected group were between 2 and 3 years of age, and the incidence gradually decreased to 1 percent in adolescents 15 years of age. Also illustrative of HRV in very young children is the prospective study of the 30 English preschool children with recurrent wheezing infections described earlier, in which HRVs were most important in children whose mean age was 2.2 years.[156] Mertsola and colleagues[201] in Turku, Finland, examined children with wheezy bronchitis (mean age, 3.2 years) and found HRVs and coronaviruses to be most important. The comparative importance of RSV and HRV in asthma in infants (median age, 6.6 months) with probable wheezy bronchitis (see "Obstructive bronchitis" in Table 179-8) was examined from 1984 to 1986 by Viennese investigators; 28 isolates yielded RSV, and only 8 yielded HRV.[171] In a later article from this group covering the period from 1986 to 1990, 179 RSV isolates and 49 HRVs were recovered from these hospitalized infants; most of the HRVs were recovered from infants with some wheezing.[170] Only 3 patients had pneumonia without wheezing.

A cohort of 9- to 11-year-old children with asthma was evaluated from April of 1989 to May of 1990.[165,167] Nucleic acid detection methods (reverse transcriptase–polymerase chain reaction [RT-PCR]) were used in addition to traditional culture methods to identify HRV infections. Respiratory viruses were detected in 80 to 85 percent of illness episodes (the rate depended on the definition of illness), and HRVs were present in approximately half the illnesses. The occurrence of respiratory viral infections in this cohort correlated strongly with hospital admissions for both children and adults in the same geographic area.[166] HRVs also have been associated with exacerbations of asthma in adults, although at a somewhat lower frequency (as many as 33% of episodes).[20,217]

Viral infection is an important risk factor for wheezing in children of all ages who are receiving emergency care.[88,186] Having either an RSV or an HRV infection that results in a wheezing

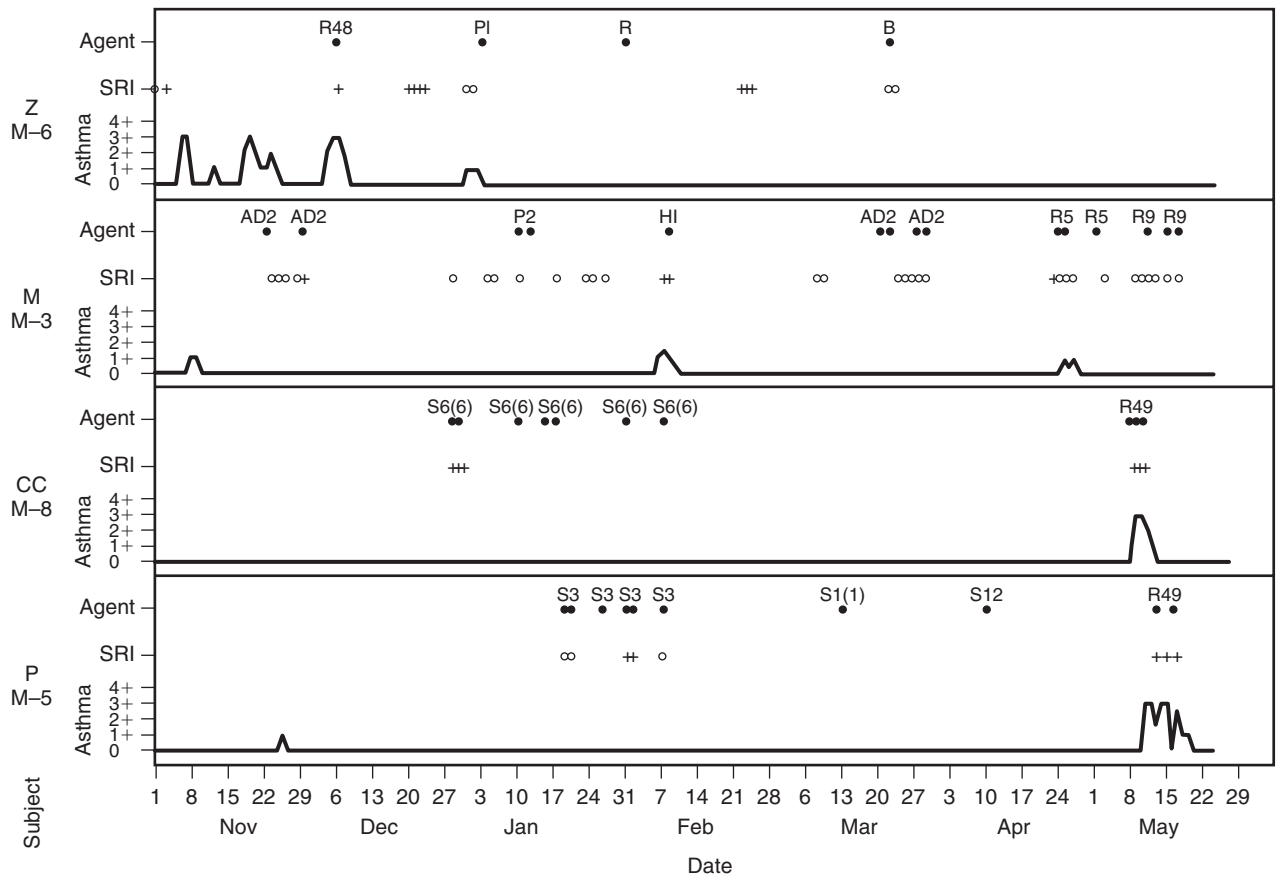

Figure 179–7 Temporal relationship among asthma, symptomatic respiratory infection (SRI), and infectious agent in four children with "infectious" asthma. N., et al.: Viruses as precipitants of asthmatic attacks in children. J. A. M. A. 227:292-298, 1974.)*

illness during the first year of life is an independent risk factor for wheezing during the third year of life.[186] RSV infection and passive exposure to tobacco smoke were associated most frequently with wheezing illness in young children (<2 years).[88] Thirty-one percent of children older than 2 years had an accompanying viral infection, usually an HRV infection, and were more likely to have IgE antibody to inhalant allergens than were the younger children. This study illustrates the dichotomy of causes for wheezing illness in the pediatric age group: RSV infection is the predominant cause in infants, and atopy combined with viral infection, usually HRV infection, is the main cause in older children.

Two investigative groups serotyped the HRVs isolated from children with wheezy bronchitis and found no types to be particularly "asthmagenic"; the Viennese group identified 12 serotypes, and the Madison group reported 21.[170,203-205] Only 3 serotypes overlapped: HRV-1B, HRV-20, and HRV-32. Therefore, a total of 30 different HRV serotypes precipitated asthmatic attacks.

The mechanism of bronchospasm in virus-infected patients with wheezy bronchitis has generated much speculation and research. HRVs can replicate in the lower respiratory tract and have been found in the lower airways.[106,127,154,223,224] Whether the virus-associated bronchospasm is caused by viral replication in the lower airways or by induction of inflammatory mediators resulting from their growth in the upper respiratory tract has been a subject of debate, although accumulating evidence favors the former possibility.[104] HRV infection clearly induces the production of numerous proinflammatory cytokines, and an increased number of inflammatory cells has been demonstrated in the lower respiratory tract in association with HRV infection.[100,104] The presence of activated cytotoxic T cells in the lower airways has been suggested to contribute to asthma-associated mortality.[219] Host factors also play a role, in that bronchial epithelial cells from asthmatic individuals produce less interferon-β and have less apoptosis and greater viral replication following infection with HRV than do cells from nonasthmatic subjects.[290] Animal models also suggest the possibility that reflex neurogenic pathways may be activated in association with respiratory viral infection and may lead to bronchoconstriction. The pathogenesis of respiratory virus-induced bronchospasm is an area of active research, with the hope that preventive or therapeutic intervention strategies can be developed.

Otitis Media

Although acute otitis media is chiefly a bacterial disease, with approximately two thirds of middle ear fluid specimens yielding *S. pneumoniae*, *H. influenzae*, or both, and *Moraxella catarrhalis* and other bacteria playing lesser roles, otitic involvement often is preceded or accompanied by a putative viral upper respiratory tract illness.[11,13,176,250] Most bacterial pathogens found in middle ear fluid are colonizers of the nasopharynx, and bacterial infection of the middle ear is considered to be a direct extension from that area.[176] Clear and comprehensive evidence of viral extension from the nasopharynx to the middle ear has been established.

Sarkkinen and coworkers,[253] using antigen-detection techniques on middle ear fluid and nasopharyngeal secretions, found RSV, adenovirus, and parainfluenza viruses in either the middle ear fluid or the nasopharyngeal secretions of 58 of 131 children (44%) with acute otitis media. Twenty-four of these children had viruses in middle ear fluid, and only 1 of the 24 did not have the same viral antigen in both the middle ear fluid and nasopharyngeal secretions. Most of the sampling was conducted during a local epidemic of RSV infection, and the curve of RSV detection in the middle ear fluid and nasopharyngeal secretions followed the pattern of the RSV epidemic curve. Other investigators have found similar relationships between the viruses in middle ear fluid and nasopharyngeal secretions.[47,177]

Gwaltney[117] isolated one HRV from culture of 16 middle ear fluid specimens in 1971. In 1986, Chonmaitree and colleagues[47] reported 3 HRV isolates in 84 middle ear fluid specimens; then Arola performed a thorough investigation of the role of HRVs in this illness.[11-14,250] In 1987 to 1988, nasopharyngeal secretions were taken from 363 patients (mean age, 2.5 years) with acute otitis media, and viruses were detected in 154 (42%); surprisingly, HRV predominated over RSV, 24 versus 13 percent.[11] HRVs were isolated all through the year, but the usual fall and spring peaks were observed. Patients with RSV infection generally were sicker, with higher fever ($p < .05$) and more severe cough ($p < .01$), but the appearance of the tympanic membrane was similar in both patients with HRV and RSV infections.

Arola and collaborators[13] attempted to detect virus in both the nasopharyngeal secretions (116 cases) and middle ear fluid (143 cases) of patients with acute otitis media (mean age, 1.5 years) and were successful in 33 (28%) and 16 (11%), respectively. HRVs were the predominant isolate, with 21 (18%) in nasopharyngeal secretions and 11 (8%) in middle ear fluid. Fifty-three percent of the patients harbored a bacterial pathogen in middle ear fluid. In the HRV-positive group in whom both viral and bacterial cultures were performed, 6 of 9 middle ear fluid specimens yielded no bacterial pathogens; that is, HRV was the only pathogen found. Unfortunately, these investigators were not able to serotype the HRVs to determine whether the same serotype was present in both the nasopharyngeal secretions and the middle ear fluid.

More recent studies have found evidence of HRVs in middle ear effusion with RT-PCR methods. Pitkaranta and colleagues[231] isolated respiratory viruses from the middle ear effusions of 30 percent of 100 children who had otitis media with effusion. HRVs constituted approximately two thirds of the respiratory viruses identified. Bacterial pathogens were identified in 35 percent of the samples, and both bacteria and viruses were found in 11 percent. A criterion for selection was the absence of an upper respiratory tract illness within the preceding week, so whether the presence of HRV RNA represented evidence of ongoing or past infection is unclear. Blomqvist and colleagues[26] found HRV RNA in middle ear effusions from 41 percent of children with otitis media in the first 2 years of life, and Chantzi and colleagues[41] found a similar prevalence of HRV RNA in otitis media effusions.

Although in general, the presence of both bacterial and viral pathogens in middle ear fluid does not interfere with the effectiveness of antibacterial therapy, in those specific patients whose acute otitis media is refractory to treatment, it may.[14] When measured against a comparison group of 66 "normal" acute otitis media cases (controls), 22 patients with refractory cases harbored significantly more viral pathogens than did controls (68% versus 41%, respectively; $p < .05$). In addition, when only the middle ear fluid of these groups was examined for the presence of viruses, the patients with refractory cases had virus in 32 percent of samples versus 15 percent in controls. HRVs were the dominant viruses in both groups. Bacterial pathogens were grown from the middle ear fluid of 4 of the 22 in the poor-responder group, and all harbored concomitant respiratory viruses, 2 of which were HRVs; only 1 of the 4 bacteria was resistant to the antibacterial agent used in therapy. These investigators also examined patients in the 66-patient control group who were refractory to treatment and found significantly more ($p < .05$) viruses in the middle ear fluid of this group than in those with a good response to therapy. These authors concluded that the presence of viruses in the middle ear fluid of children with acute otitis media can delay response to antibacterial therapy.

Chonmaitree and associates[48] in Galveston, Texas, also investigated the role of viruses in middle ear fluid as agents that may interfere with antibacterial therapy. In the initial report by these investigators, viruses were cultured from the middle ear fluid of 11 of 58 children (19%); RSV and HRV were the most frequent viruses isolated, at 3 each. Of the patients in whom therapy failed, significantly more ($p < .05$) harbored viruses as well, and of those whose bacteria were susceptible to the treatment antibiotic, significantly more had combined viral-bacterial infections.

In two subsequent reports, the highest rate of poor bacteriologic outcome occurred when HRV was isolated from middle ear fluid. Seven of nine instances of HRV infection resulted in bacteriologic treatment failure.[266]

These studies from Finland and Texas suggest that viruses, including HRVs, may play a role in acute otitis media, especially in prolonging the response to antimicrobial treatment. Perhaps pertinently, McBride and associates[196] at the University of Pittsburgh and the University of Virginia used HRV-infected human volunteers and found that the eustachian tube became occluded in 50 percent of the volunteers and that abnormal middle ear pressure was present for as long as 10 days. These studies were extended by Buchman and colleagues,[29] who inoculated 60 volunteers with HRV-39. Middle ear pressures of less than –100 mm H_2O were noted in 22 subjects (37%). In 2 of the 3 patients who had pressures less than –100 mm H_2O, upper respiratory illness with middle ear effusion developed. In this study, the otologic manifestations of experimental HRV infection were extended to include otitis media.

Arola and colleagues[12] examined the role of viruses in 61 children (mean age, 3.2 years) with subacute or chronic asymptomatic otitis media with effusion. Five HRVs and one adenovirus were found in the middle ear fluid. In addition, bacterial pathogens were isolated from the patient with adenovirus infection and from two of the patients with HRV infection. None of these patients with otitis media and effusion were ill with an upper respiratory tract infection at the time the specimen was obtained, and the effusion had endured 30 to 60 days before myringotomy was performed.

Sinusitis

RVs can cause a clinical syndrome of rhinosinusitis that appears similar to that caused by bacterial infection. Gwaltney and colleagues[124] performed computed tomography of the sinuses on adults with acute common colds (<4 days' duration). HRV infection was documented by culture in 27 percent. Radiographic abnormalities included mucosal thickening and air-fluid levels. The signs and symptoms resolved without antibiotic therapy, a finding thus suggesting that the radiographic signs were caused by an acute viral infection. Few attempts have been made to recover viruses directly from the sinuses. Two reports from Virginia noted that 140 aspirates obtained by direct puncture of the maxillary sinuses yielded 86 positive specimens, only 12 of which contained viruses. Seven of these viruses were HRVs, and the remainder were influenza A or parainfluenza viruses.[125,128] Five of the viruses were isolated in conjunction with bacterial pathogens. In a more recent study, Pitkaranta and associates[230,232] used RT-PCR and in situ hybridization to identify HRVs in 50 percent of adults with acute community-acquired sinusitis. Because the

signs and symptoms of viral rhinosinusitis and bacterial sinusitis can be difficult to distinguish, the American Academy of Pediatrics developed clinical practice guidelines for the diagnosis and treatment of bacterial sinusitis.[50]

Rhinovirus Infections in Nonindustrialized Populations

Not many HRV surveillance studies have been conducted in nonindustrialized populations, but those that have reveal some unique findings. In the spring of 1967, Wulff and associates[299] observed an outbreak of HRV-16 and HRV-29 infection in a 93-family (429 children) Eskimo population in Bethel, Alaska. The larger, HRV-16 outbreak was analyzed thoroughly. The investigators found 37 HRV-16 isolates, but only 19 of them were from ill children; therefore, nearly half, 18 children, had subclinical infections. The ill children often were only mildly so; 12 had common colds, and only 1 child had bronchitis and 1 child had pneumonia. HRV-16 spread widely in the population under study; 70 percent of antibody-free children demonstrated a fourfold or greater serologic response. Eighty-five of the 93 families were infected with HRV-16, and the 8 families that escaped infection had only 1 to 3 children each. The amount of HRV dissemination was not especially surprising because it was not much higher than that of HRV-55 in Eagle Heights Village, but, unexpectedly, half the HRV infections were subclinical.

Much subclinical HRV infection also was reported in a surveillance of 136 preschool children in 2 small villages (combined population of 1750 in 1982) on an island in the Melanesian nation of Vanuatu, a group of 80 islands located in the South Pacific approximately midway between Australia and Fiji.[269] HRVs by far were the predominant viruses (21 isolates), all were type 16, and all caused subclinical infection. In addition, pneumococci often were found in conjunction with these symptomless HRV-16 cases and rarely otherwise.

These two examples of a high rate of subclinical HRV infection are unusual judging by experience in more industrialized societies. Surveillance of a year-long (1971 to 1972), twice-weekly sampling of 33 children aged 3 to 11 years in Madison produced much different results. As depicted in Figure 179-7 and Table 179–10, only 11 (0.8%) cases of asymptomatic shedding occurred all year. Conversely, all these children were members of at least middle-income families, and some continental U.S. populations may be analogous to those in underdeveloped nations. Gwaltney[119*] noted that the rate of overall inapparent HRV infection in the continental United States may approach 25 percent.

However, as emphatically described in reviews by Chretien and associates[49] and by Graham,[110] asymptomatic infection with respiratory viruses is not the major problem of families in communities and nations struggling to raise their children in healthy environments. Graham[110] estimated that worldwide, 98 to 99 percent of deaths from acute respiratory disease occur in developing nations. A study of children aged 5 years or younger was conducted in such a nation, Kenya.[139] Eight hundred twenty-two children with severe acute respiratory disease were examined etiologically by modern cell culture techniques. Fifty-four percent of the children yielded viruses (444 isolates), with enterovirus by far being the most common (162 isolates), followed by RSV (98 isolates) and the HRVs (54 isolates). Half the HRV isolates also were culture-positive for possible bacterial pathogens, and 11 HRV isolates were from infants younger than 3 months. The authors concluded that HRVs may be significant respiratory pathogens in Kenya.

HRVs were found to be prevalent in a 29-month household-based study in an impoverished urban population in Fortaleza, Brazil; 175 children younger than 5 weeks in 63 families were surveyed for clinical illness and respiratory viruses.[66] The study yielded two major findings: (1) the burden of respiratory illness in these children was so continuous that assigning beginning and ending dates was impossible, and (2) HRVs, by far the most common virus isolated, accounted for 46 percent of all viruses obtained. HRV was dominant in all age groups, but overwhelmingly so in children 0 to 6 months of age. In this age group, only HRV and parainfluenza virus were isolated, in a ratio of approximately seven HRVs to one parainfluenza virus. The role of HRVs in nonindustrialized nations must be assessed carefully. For example, what proportion of HRVs in this study in Brazil were just "innocent bystanders," as found in the subclinical infections in Bethel and Vanuatu (see previous discussion)?

TABLE 179–10 Rhinoviruses and Other Viral and Bacterial Pathogens Isolated during Periods of Respiratory Illness and When Free of Illness from 33 Middle-Income Children Aged 3 to 11 Years (Average Age, 6 Years): Madison, Wisconsin, from 1971 to 1972*

Pathogens	1971-1972 (Nov-Feb)	1972 (Mar-May)	Total
Illness-Free	753	566	1319
Agents isolated			
Rhinoviruses	4 (0.5)†	7 (1.2)	11 (0.8)
Other viruses‡	10 (1.3)	6 (1.1)	16 (1.2)
Bacterial pathogens§	14 (1.9)	4 (0.7)	18 (1.4)
Total	28 (3.7)	17 (3.0)	45 (3.4)
Respiratory Illness	305	195	500
Agents isolated			
Rhinoviruses	13 (4.3)	57 (29.2)	70 (14)
Other viruses	44 (14.4)	14 (7.2)	58 (11.6)
Bacterial pathogens	35 (11.5)	10 (5.1)	45 (9.0)
Total	92 (30.2)	81 (41.5)	173 (34.6)

**Throat swabs were taken twice weekly and inoculated into three cell lines and a sheep blood agar plate.[203,205]*

†Percent isolation rate (i.e., 4/753, 0.5%).

‡Adenoviruses, influenza viruses A and B, parainfluenza virus, herpes simplex virus, and enteroviruses. Coronaviruses would not have been isolated; the fact that they often are midwinter viruses may account for the relatively low isolation rate for 1971 to 1972.

§Chiefly group A streptococci in more than 100 colonies per pour plate.

DIAGNOSIS OF INFECTION

HRV infections cannot be diagnosed solely on the basis of clinical grounds because they cause such a wide spectrum of respiratory illness, particularly in infants and children. However, because of the characteristic spring-summer-fall seasonal pattern of the HRVs, tentatively assigning an HRV origin in patients with mild to moderate respiratory illness during these months is not unreasonable.

Obtaining a culture of the etiologic agent and interpreting the meaning of a positive specimen can be difficult with HRVs. These viruses often propagate unpredictably, even in relatively sensitive diploid cell cultures such as WI-38 and FT cells or in Ohio strain HeLa cells,[17,55,57,61] and often these cells are highly variable in their susceptibility.[119] Isolation of HRV from children is hampered by the common practice of relying on a throat swab. Inocula from many throat swabs contain one tissue culture infectious virus particle or less and seldom contain infectious particles by the hundreds (see Table 179-9). Hendley and colleagues[143] found nasal specimens to be superior for HRV studies, and diagnostic rhinovirologists from many nations successfully use nasal aspirates.[150,171,201] Specimens should be placed in cell culture as soon as possible and without previous freezing and thawing (however, refrigeration [4° C] overnight results in little loss). If freezing is necessary and dry ice is used, great care must be taken to avoid contamination of the specimen with sublimed carbon

dioxide because the resultant carbonic acid rapidly kills the virus. Cell cultures should be incubated at 33° C and slowly rolled. Evidence of virus growth usually is seen between 2 days and 2 weeks. Once a cytopathic effect is evident, standard techniques for identification are used.[62] Because of the technical difficulties in isolating HRVs, before initiating etiologic studies of viral respiratory illness, specimen collection and culture procedures should be developed carefully in collaboration with an experienced respiratory virologist.

HRVs are known to be found in the absence of symptoms, but infrequently, at least in industrialized nations. Cherry[44] compiled shedding data from well children who were part of nine independent studies (1798 specimens) and found the total subclinical shedding rate to be 3 percent. HRV shedding from well children was 5 percent or less in 8 of these studies but was 11 percent in the remaining survey of a Chicago nursery school population.[24] Only 11 (0.8%) of 1319 specimens from healthy Madison children aged 3 to 11 years yielded an HRV by culture (see Table 179-10). However, the rate of subclinical HRV shedding is known to be high, up to 50 percent, in some populations in developing countries, so healthy control specimens should be obtained when possible to measure background HRV carriage rates.[269,299]

As described early in this chapter, HRVs have many base sequences in common among the RNA genomes of the various serotypes, especially in the noncoding region at the 5′ end. Several laboratories have taken advantage of this observation by designing RT-PCR assays for the detection of HRVs. Some assays do not distinguish HRVs from enteroviruses, whereas others are HRV-specific.[101,126,155] The superiority of RT-PCR techniques compared with cell culture methods first became evident in a clinical study of children with acute respiratory illnesses. Johnston and colleagues[167] detected HRV by PCR in 146 of 292 samples (50%) that yielded HRV in only 47 (16%) by standard culture. PCR was thus three times more sensitive than was culture for detecting HRV infection. Many subsequent studies confirmed the superiority of RT-PCR assays over culture methods for the detection of HRVs.[5,18,20,153] The development of sensitive real-time RT-PCR assays raised the possibility that clinical virology laboratories would become able to identify HRV infection rapidly.[255] RT-PCR assays also can be used to classify picornavirus isolates as enteroviruses or HRVs; Atmar and Georghiou[19] found 100 percent concordance between PCR results and acid lability testing.

PREVENTION AND TREATMENT

Prevention and treatment are addressed thoroughly in Chapter 8 and elsewhere, and only measures specific to the HRVs are added here. Although some protection after the use of inactivated vaccines has been demonstrated,[80,228] the existence of at least 101 serotypes limits the prospect of vaccine development. However, based on the observation that cross-reacting antigenic groupings exist among the HRVs, developing a vaccine that targets these epitopes may be possible.[58]

The most effective HRV cold-preventive agent described to date that has been demonstrated to be effective for natural HRV colds in Australia and the United States is interferon-α, a protein produced as part of the host's natural antiviral defense and now produced for experimentation by genetic recombinant methods.[84,135] Investigators administered this agent by nasal spray to other members of a family after symptoms appeared in the index case; 80 percent of the secondary HRV colds were prevented. However, interferon given in this fashion does not seem to be effective against other respiratory viruses; for example, in a follow-up study in Seattle, interferon-α did not reduce the incidence of colds when administered in a protocol identical to that used in the previous family studies, chiefly because HRV infections were in the minority.[79,84,99,135] HRVs often have a decided seasonality, so rapid diagnosis of the index case by PCR would be helpful to determine when interferon-α could be used effectively to stop intrafamily spread. A combination of rapid diagnosis and family prophylaxis with interferon-α could be most helpful in families such as those with asthmatic children, in whom HRV infection may be serious (see "Clinical Manifestations"). The disadvantage of interferon prophylaxis is that prolonged intranasal administration (>7 days) or repeated treatment produces an inflammatory response consisting of nasal stuffiness, ulceration, and blood-tinged discharge.[251]

Numerous antiviral agents that have in vitro activity against HRVs have been developed. The earlier section in this chapter on structure of the virion describes the development of some of these agents, development made possible by taking advantage of current detailed knowledge of HRV structure and specific cell receptors. Several of these preparations, including capsid-binding agents, soluble receptor (soluble ICAM-1), and antibody to the receptor (ICAM-1), have been tested in clinical trials, but development of most of these agents has not been pursued for a variety of reasons,[21,277] as reviewed by Arruda and Hayden.[15] Another capsid-binding agent, pleconaril, has in vitro antiviral activity against many enteroviruses and HRVs, and phase III clinical trials on naturally acquired colds demonstrated some reduction in the severity and duration of several respiratory symptoms.[136] However, pleconaril induces the cyp3A4 enzyme that can lead to menstrual irregularities in women taking oral contraceptives.[93] This concern, along with the drug's modest efficacy, prevented its use from being approved by the U.S. Food and Drug Administration; an intranasal form is still under development.[225] Another anti-RV drug, rupintrivir (formerly AG7088), is a potent, irreversible inhibitor of viral 3C protease that has reached clinical trial.[137,195] Further studies of both these agents, especially in children, will be needed to determine their potential benefits.

Colds usually are treated symptomatically with mild nonsteroidal anti-inflammatory drugs, sympathomimetics (e.g., phenylpropanolamine), and antihistamines; these agents are discussed in Chapter 8.[262] Anticholinergic agents (e.g., topical ipratropium bromide) and first-generation antihistamines reduce severity of rhinorrhea, whereas second-generation ("nonsedating") antihistamines have no effect. The efficacy of the first-generation antihistamines may result from the ability of these agents to block muscarinic as well as histaminic receptors and to cross the blood-brain barrier.[214] Sympathomimetics decrease nasal obstruction, although topical administration may lead to rebound nasal obstruction. Nonsteroidal anti-inflammatory agents decrease the severity of some of the systemic symptoms associated with colds (e.g., malaise, headache).[272] A combination of antiviral and antimediator preparations may provide effective therapy.[120] Various other treatments, including vitamin C,[40,140] *Echinacea*[200,274] intranasal humidified air,[94,284] and zinc lozenges,[159,193,233] have been evaluated, and some studies have reported a clinical benefit, although other studies have failed to confirm such findings.[272] Almost all clinical evaluations of symptomatic and alternative therapies have been performed in adults; very few data exist on the utility of such therapy in children.[193,260]

The use of oral or inhaled corticosteroids appears to enhance the shedding of viable virus.[116,239] One potential consequence of corticosteroid use, seen in a study of pediatric patients with a common cold syndrome, is a significant increase in the risk of developing acute otitis media in HRV-infected subjects.[249] Thus, steroids do not have a role in the treatment of HRV infections. Similarly, no role exists for the use of antibiotic therapy in uncomplicated HRV infection.

Acknowledgment

The author would like to acknowledge the contributions of Elliot C. Dick, Stanley L. Inhorn, and W. Paul Glezen, who contributed to this chapter in previous editions of the text.

CHAPTER 180

HEPATITIS A VIRUS

Anthony E. Fiore ❂ Beth P. Bell

HISTORY

Hepatitis A has been recognized as a clinical entity for centuries, and large epidemics of jaundice occurred during military campaigns in ancient and modern times. During the past several decades, epidemiologic and clinical studies defined the infectious nature of the disease, which led to the differentiation of "infectious hepatitis," now designated hepatitis A.[177] Before 1970, attempts to isolate a virus associated with hepatitis A were uniformly unsuccessful, and information concerning the clinical course of infection, the fecal-oral route of transmission, and the efficacy of immunoglobulin in preventing disease was obtained from studies conducted in humans.[177,179,363] In 1973, hepatitis A virus (HAV) was identified by immune electron microscopy in stool samples of patients with hepatitis A.[113] This discovery led to the development of serologic tests that differentiate acute and resolved infections, characterization of the virus, definition of pathogenetic events during infection, and further definition of the epidemiology of HAV infection. HAV has been propagated in cell culture,[74,261,349] which has led to the development and licensure of vaccines shown to be highly efficacious in preventing infection and disease in immunized individuals.[46,156,347]

PROPERTIES

CLASSIFICATION

HAV is a 27-nm, nonenveloped, positive-sense RNA virus belonging to the family *Picornaviridae*. Although HAV initially was classified in the genus *Enterovirus*, nucleotide analysis indicates that HAV is distinct from all other picornaviruses.[193,358] Compared with other enteroviruses, HAV has essentially no nucleotide or amino acid homology, does not have an intestinal replication phase, replicates slowly in cell culture and rarely produces a cytopathic effect, and is relatively resistant to inactivation by heating.[71] For these reasons, HAV has been reclassified in a separate genus designated *Hepatovirus*.[223,358]

GENOMIC ORGANIZATION AND GENETIC VARIATION

The HAV genome is composed of single-stranded, positive-sense RNA containing approximately 7500 nucleotides. HAV genomic organization and replication are similar to those of poliovirus and other picornaviruses: (1) the 5′ end is not translated, contains an internal ribosomal entry site, and has a covalently linked protein (VPg); (2) sequences for structural proteins are located toward the 5′ end, followed by sequences encoding nonstructural proteins, including proteases and RNA polymerases; and (3) the viral RNA encodes a single polyprotein from which functional structural and nonstructural proteins are cleaved proteolytically.[193,350,358] Each capsid structural motif is composed of three major polypeptides (VP1, VP2, and VP3) of 22,000 to 33,000 d that form an outer shell with icosahedral symmetry. On the basis of nucleotide sequence, a fourth polypeptide, VP4 (2500 d), should be encoded but has not been identified in mature virions.[358]

HAV exists as a single serotype. The neutralization site appears to be conformational and derived from epitopes located on VP1 and VP3 as identified by neutralizing monoclonal antibodies.[232,255] A high degree of nucleotide conservation exists among geographically diverse human HAV isolates. However, nucleotide variation in VP1 and VP3 has been used to define four human HAV genotypes and several subgenotypes,[230,270] and this genetic variation has proved useful in identifying clusters and linking apparently sporadic cases.[6,84,151,231,268] Genotype does not appear to influence the clinical presentation or outcome of infection.[124] In addition, HAVs that appear to be restricted in their primary replication to Old World monkeys have been isolated.[233,320]

HAV replicates more slowly in cell culture than do other picornaviruses; wild-type virus requires many weeks of adaptation before infectious foci or HAV antigen is detected.[29,197,290] HAV produces a high ratio of defective to complete (infectious) virus both in cell culture and during infection.[37,358] Cell culture adaptation is associated with mutations in nonstructural proteins and the 5′ nontranslated region.[102,103] Mutations in the VP1/2A and 2C genes are associated with attenuation, and virulence can be restored if genes from the wild-type virus are re-introduced.[101] Cell culture–adapted HAV rarely produces a cytopathic effect, although cytopathic strains have been isolated and serve as a useful model for laboratory studies.[72,235] Adaptation also results in loss of virulence (attenuation) when it is evaluated in the chimpanzee model of infectivity.[164] Cell culture systems that are more permissive to replication of virulent wild-type virus have been reported.[111,174]

The HAV virion appears to be extremely stable, although the molecular determinants of this characteristic are not known. HAV is stable in the environment, with only a 100-fold decline in infectivity when it is stored for longer than 4 weeks at room temperature.[71,213,214,253] The virus retains infectivity when it is treated with nonionic detergents, organic solvents, and low pH at 38° C for 90 minutes.[71] HAV is more resistant than is poliovirus to heat in that it is inactivated only partially at 60° C for 1 hour.[71] Temperatures of 85° C to 95° C for 1 minute are required for complete inactivation of HAV in foods such as shellfish.[71,222] HAV is inactivated completely by formalin (0.02% at 37° C for 72 hours) but appears to be relatively resistant to free chlorine, especially when the virus is associated with organic matter.[205,288] For general-purpose disinfection, a 1:100 dilution of 5 percent sodium hypochlorite (i.e., household bleach) in tap water inactivates HAV in most situations.[46,109]

EPIDEMIOLOGY

ROUTES OF TRANSMISSION

Routes of HAV transmission are determined by the timing and location of virus replication, circulation, and excretion during infection. HAV replicates in the liver, is excreted in bile, and is found in highest concentration in stool (up to 10^8 infectious particles per milliliter).[311] The highest concentration in stool occurs during the 2-week period before jaundice develops or liver enzymes become elevated, followed by a rapid decline after jaundice appears (Fig. 180–1).[113,294,311] Children and infants may shed HAV for longer periods than adults do. Through the use of

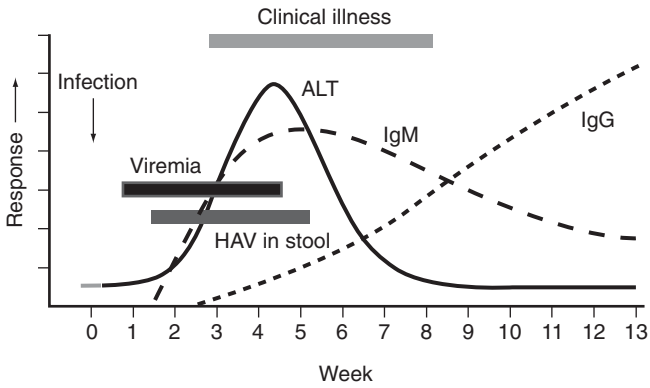

Figure 180–1 Immunologic, virologic, and biochemical events during the course of a typical hepatitis A virus (HAV) infection. ALT, alanine aminotransferase.

polymerase chain reaction (PCR) to amplify viral nucleic acid, HAV RNA has been detected in the stool of infected neonates for as long as 6 months after infection, and some studies have shown excretion in older children and adults 1 to 3 months after the onset of clinical illness.[156,268,271,361] Chronic shedding of HAV does not occur; however, virus may be present in stool during relapsing illness (see the section on relapsing hepatitis A).[293] Viremia occurs during the prodromal stage of infection and extends through the period of liver enzyme elevation (see Fig. 180–1), with virus concentrations several orders of magnitude lower than those in stool.[36,64,178,191] In experimentally infected animals, HAV can be detected in saliva during periods of peak excretion in stool,[64] but transmission by saliva has not been demonstrated.

Detection of HAV antigen in stool by enzyme immunoassay or detection of HAV RNA in serum or stool by PCR does not demonstrate that an infected person is infectious because these assays may detect defective as well as infectious viral particles. Nucleic acid amplification by immunocapture PCR requires the presence of intact virus,[39,164] and HAV RNA may be detected in stool for months with immunocapture PCR. However, the period of infectivity appears to be shorter than the period when HAV RNA can be detected in stool. Data from epidemiologic studies suggest that peak infectivity occurs during the 2 weeks before the onset of symptoms. For practical purposes, both children and adults with hepatitis A can be assumed to be non-infectious 1 week after jaundice appears.

Because of the high concentration of virus in the stool of infected persons, HAV transmission occurs primarily by the fecal-oral route, usually by person-to-person transmission in households and extended-family settings and between sexual contacts.[299] Person-to-person transmission results in high rates of infection in young children in developing countries and has been the predominant mode of transmission in the United States, particularly during community-wide outbreaks, as well as in outbreaks in childcare centers.[22,32] HAV can remain infectious in the environment,[214] and fecal contamination of food or water can result in common-source outbreaks. HAV has been transmitted by transfusion, but such transmission occurs rarely because the blood donation must occur during the early prodromal stage of the disease or from an asymptomatic person who is viremic.[191] In the United States, nucleic acid amplification tests such as PCR now are applied to screening of source plasma used for the manufacture of plasma-derived products. These assays are sufficiently sensitive to remove most units that have HAV, and serosurveillance for HAV infections among clotting factor recipients in the United States indicates that HAV infections are now rare in this risk group.[49]

Two published case reports have described intrauterine transmission of HAV during the first trimester that resulted in fetal meconium peritonitis.[190,215] After delivery, both infants were found to have a perforated ileum. The risk of transmission to newborns by pregnant women in whom hepatitis A develops in the third trimester of pregnancy appears to be low.[317] However, newborns who acquire HAV infection in this manner or from a transfusion usually are asymptomatic, and the infection is detected by the development of hepatitis A in hospital staff or other persons having contact with the infant.[271,342]

PATTERNS OF DISEASE WORLDWIDE

Worldwide, the endemicity of HAV infection differs markedly among and within countries (Fig. 180–2). Patterns of HAV infection can be differentiated, each being characterized by distinct age-specific profiles of prevalence of antibody to HAV (anti-HAV), incidence of hepatitis A, and prevailing environmental (hygienic and sanitary) and socioeconomic conditions (Fig. 180–3).[18,22,140,160]

In areas with a high endemic pattern of infection, represented by the least developed countries (i.e., parts of Africa, Asia, and Central and South America), poor socioeconomic conditions allow HAV to spread readily (see Fig. 180–2). Most persons are infected as young children, and essentially the entire population is infected before reaching adolescence, as demonstrated by the age-specific prevalence of anti-HAV (see Fig. 180–3).[16,73,160,321] Because virtually all HAV infections occur in age groups in which asymptomatic infection predominates, reported disease rates may be low and outbreaks rare.

In areas of intermediate endemicity, HAV is not transmitted as readily because of better sanitary and living conditions, and the predominant age at infection is older than that in highly endemic areas (see Figs. 180–2 and 180–3).[60,160] Paradoxically, the overall incidence and average age of reported cases often increase because high levels of virus circulate in a population that includes many susceptible older children, adolescents, and young adults, in whom symptoms are likely to develop with HAV infection.[137] Large common-source outbreaks also can occur because of the relatively high rate of virus transmission and the large number of susceptible persons, especially among those of higher socioeconomic levels. Such an outbreak occurred in Shanghai in 1988, with more than 300,000 cases associated with the consumption of contaminated clams.[143] Nonetheless, person-to-person transmission in community-wide epidemics continues to account for much of the disease in these countries.[334]

Shifts in age-specific prevalence patterns indicating a transition from high to intermediate endemicity are occurring in many parts of the world (see Fig. 180–3). As this transition occurs, marked variations in hepatitis A epidemiology are seen among countries and within countries and cities, with some areas displaying a pattern typical of high endemicity and others of intermediate endemicity (see Fig. 180–2).* Considerable hepatitis A–related morbidity and associated costs can occur, even in developing countries. Hepatitis A is reported to account for 50 to 60 percent of all acute viral hepatitis cases among children in Pakistan, and 232 children with fulminant hepatic failure secondary to hepatitis A were admitted to one tertiary care referral hospital in Karachi during a 9-year period.[280] Hepatitis A was the etiology of the fulminant hepatitis of two thirds of the children treated at two hospitals in Argentina during a 15-year period; and in one of these hospitals performing liver transplantation, a third of the liver transplantations in children were required because of

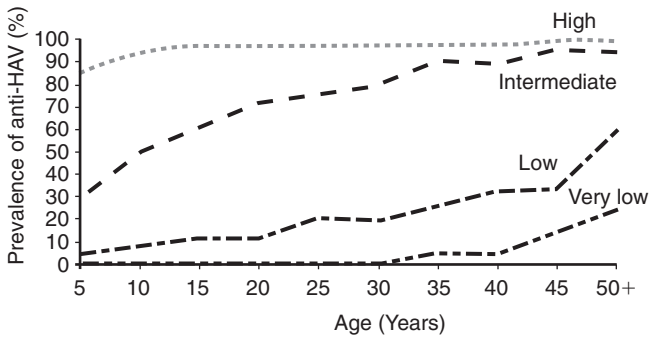

Figure 180–3 Patterns of hepatitis A virus (HAV) infection worldwide.

fulminant hepatitis A.[61] Another small series from Turkey indicated that HAV was the most common identifiable cause of acute liver failure among children, accounting for 26 percent of cases.[13]

In most areas of North America and western Europe, sanitary and hygienic conditions are such that the endemicity of HAV infection is low (see Figs. 180–2 and 180–3). Relatively fewer children are infected, and disease often occurs in the context of community-wide and childcare center outbreaks and occasionally as common-source outbreaks.[24,129,259,281,313] In some regions (e.g., Scandinavia), the endemicity of HAV infection is very low and disease occurs almost exclusively in defined risk groups, such as travelers returning from areas where HAV infection is endemic or illicit drug users.[34]

PATTERNS OF DISEASE IN THE UNITED STATES

Although the epidemiology of hepatitis A in the United States has been altered profoundly by the introduction of hepatitis A vaccines, hepatitis A remains a frequently reported vaccine-preventable infectious disease (Fig. 180–4). Rates have declined sharply since the mid-1990s. In 2004, 5683 cases were reported to the Centers for Disease Control and Prevention (CDC), representing an 82 percent decline compared with rates from 1990 to 1997 and significantly lower than previous incidence nadirs.[45,341] However, national surveillance systems collect data on symptomatic cases, and incidence models indicate that most infections are not symptomatic. One such analysis estimated that an average of 271,000 infections occurred per year during 1980 to 1999, 10.4 times the reported number of symptomatic cases.[8] With use of similar modeling methodology, an estimated 56,000 infections occurred in 2004.[45]

Variation by Age and Race or Ethnicity

Historically, the highest hepatitis A rates were reported among children 5 to 14 years of age, with approximately one third of cases occurring among children younger than 15 years.[51] Because many young children have unrecognized or asymptomatic infection, they also are likely to represent a major reservoir for HAV transmission. Incidence models indicated that during the 1980s and 1990s, more than half of HAV infections occurred among children younger than 10 years, most of whom were younger than 4 years.[8] Since the mid-1990s, decreases in rates among children have been greater than among adults, and the proportion of cases among children dropped from 35 percent in the pre-vaccine era to 19 percent in 2003.[341]

Among racial and ethnic groups, before the use of hepatitis A vaccine, rates among Native Americans and Alaska Natives were more than 10 times the rate in other racial and ethnic groups, and rates among Hispanics were approximately three times higher than among non-Hispanics. These disparities have lessened or disappeared in the era of routine childhood vaccination, with rates among Hispanics in 2003 approximately twice those among non-Hispanics (86% decline compared with 1990-1997); rates among Native Americans and Alaska Natives are now the same as or lower than those among other ethnic groups (Fig. 180–5).[341]

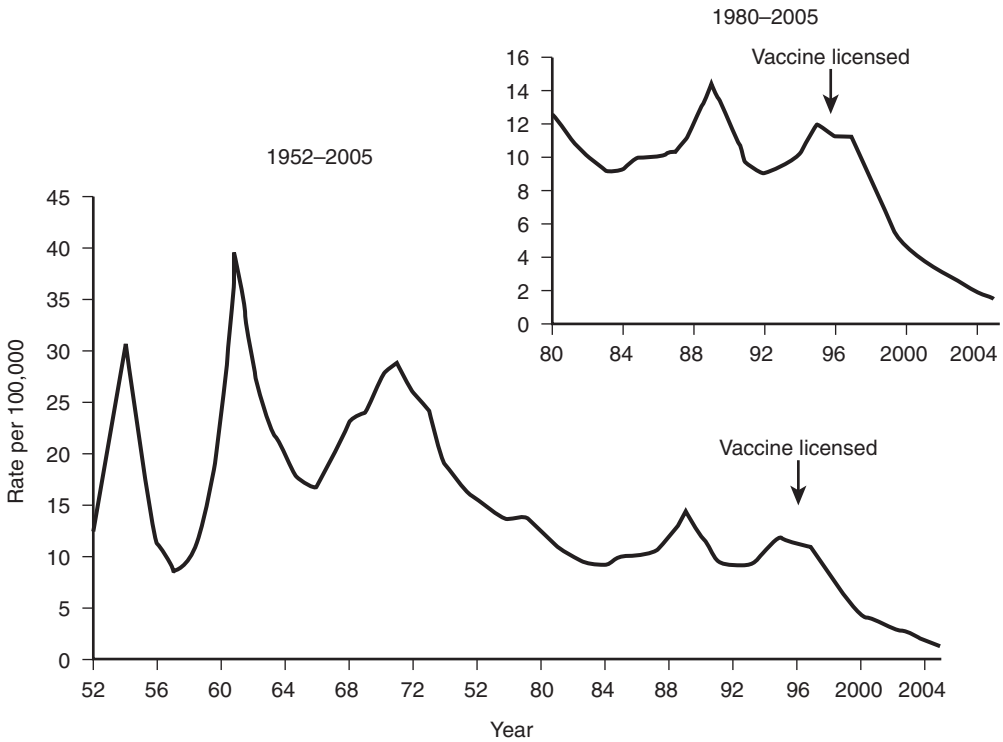

Figure 180–4 Hepatitis A incidence rates (per 100,000 population) based on cases reported to the Centers for Disease Control and Prevention (1966-2005).

The black dotted line represents the rate among Native Americans and Alaska Natives; the dark gray line, the rate among Hispanics; the gray dashed line, the rate among blacks; the black line, the rate among whites; and the light gray line, the rate among Asian/Pacific Islanders. The inset depicts the much higher rates among American Indians/Alaska Natives separately, allowing an appropriate y-axis scale to be used. *(Data from the Centers for Disease Control and Prevention, National Notifiable Diseases Surveillance System, Atlanta, GA.)*

As determined by the Third National Health and Nutrition Examination Survey conducted during 1988 to 1994, approximately one third of the U.S. population had serologic evidence of previous HAV infection.[21] Anti-HAV prevalence was related directly to age (ranging from 9 percent in children 6 to 11 years of age to 75 percent in persons older than 70 years), and it was related inversely to income. The age-adjusted prevalence of anti-HAV was higher among foreign-born (68%) than U.S.-born (25%) participants and higher among Mexican Americans (70%) than non-Hispanic blacks (39%) and whites (23%).[21]

Geographic Variation

Analyses of national surveillance data collected during the 1980s and 1990s showed striking regional variation in the incidence of hepatitis A. The national average incidence was approximately 10 cases per 100,000 persons per year during 1987 to 1997, with the highest rates and most cases consistently occurring in a limited number of states and counties concentrated in the western and southwestern United States.[304] Approximately two thirds of cases were reported from the 17 states with the highest rates, even though only one third of U.S. residents lived in these states. With the implementation of routine vaccination of children in these states in 1999, rates equalized across the country,[341] with significantly greater reductions in incidence in areas where vaccination was recommended (Fig. 180–6).[275,341]

Potential Sources of Infection

The distribution of potential HAV exposures that are identified among reported cases also has changed in the vaccination era. The proportion of cases attributable to household or sexual contact with a person who has hepatitis A, the most commonly reported potential source of infection, has declined as routine hepatitis A vaccination of children has increased, from 15 to 25 percent to 12 percent of reported cases in 2005.[45,47] The number of international travel–associated cases has remained approximately the same; but as overall incidence declined, the proportion of cases attributable to this exposure rose to an average of 13 percent during 2002 to 2004. Almost 40 percent of cases among children report recent international travel.[45] Recognized foodborne outbreaks account for a small proportion of cases in most years (3% to 5%), but large outbreaks such as those associated with contaminated green onions in 2003 have increased the proportion of cases associated with food in some years to as high as 16 percent.[6,45,47,348] Cyclic outbreaks occur among men who have sex with men and users of injecting and non-injecting drugs; during outbreak years, this exposure can account for 10 to 15 percent of nationally reported cases.[45,47,67,123,144,150,276] Nearly 50 percent of patients with hepatitis A do not have a recognized source of infection[45,47] but might be contacts of persons, especially children, with asymptomatic infection.

Community-Wide Epidemics

Historically, most cases of hepatitis A in the United States occurred in the context of community-wide epidemics, during which infection is transmitted from person to person in households and extended-family settings.[24] Once initiated, these epidemics often persisted for several years and proved difficult to control,[249,286] even when attempts were made to vaccinate some portion of the population rapidly.[11,69] Children played an important role in HAV transmission during these epidemics. In communities with historically the highest hepatitis A rates, as exemplified by Native American and Alaska Native communities, the pattern of transmission was similar to that found in countries with an intermediate endemicity of HAV infection (see the section on patterns of disease worldwide).[42,83,186,285,355] The best explanation for these observations is that asymptomatic transmission was occurring in susceptible young children at low levels during interepidemic periods until a cohort of susceptible children became large enough to sustain a community-wide outbreak.[285,295] Asymptomatic transmission among children also has been important in sustaining outbreaks in areas with consistently elevated rates. During community-wide outbreaks, serologic studies of members of households with an adult case and no identified source have found that 25 to 40 percent of contacts younger than 6 years had serologic evidence of having had recent HAV infection (CDC, unpublished data).[268,299] In one of these studies, 52 percent of households of adults without an identified source of infection included a child younger than 6 years, and the presence of a young child was associated with household trans-

mission of HAV.[299] In this study, transmission chains were identified involving as many as six generations and more than 20 cases. With the advent of routine vaccination of children, community-wide outbreaks have largely ceased. Community-wide outbreaks that have been sustained by transmission among adults in high-risk groups continue to be identified, and novel strategies to provide vaccination in settings such as jails have had some success.[47,231,241,314,338]

EPIDEMIOLOGY OF HEPATITIS A IN SPECIFIC SETTINGS

CHILDCARE CENTERS

The role of children with asymptomatic infection has been recognized in outbreaks in childcare centers since the 1970s.[282,283] Because infection in children usually is mild or asymptomatic, these outbreaks often are not recognized until adult contacts (usually parents) become ill.[142] Outbreaks rarely occur in centers that do not have children in diapers and occur more commonly in larger centers.[142] Both poor hygiene in these children and the need for staff to handle and change diapers contribute to spread. Despite the occurrence of outbreaks when HAV is introduced into a childcare center, studies of childcare center employees do not show a significantly increased prevalence of HAV infection in comparison to control populations.[120,159] On occasion, outbreaks in childcare centers can be the source of more extensive transmission within a community.[86,141,330] However, most disease within childcare centers probably reflects transmission from the community. Hepatitis A outbreaks within childcare centers have become unusual events in recent years and are likely to be eliminated as routine vaccination of all young children is implemented.

OTHER GROUPS AND SETTINGS

Hepatitis A cases in schoolchildren usually reflect disease that has been acquired in the community. However, multiple cases among children within a school may indicate a common-source outbreak.[151] Historically, HAV infection was endemic in institutions for the developmentally disabled; but with smaller facilities and improved conditions, the incidence and prevalence of infection have decreased, and outbreaks rarely are reported in the United States.[305]

During the past two decades, outbreaks have been reported with increasing frequency in illicit drug users in North America, Australia, and Europe.[56,144,150,152,241,276,284,314,338] In the United States, these outbreaks often have occurred in the context of a large community-wide outbreak; and in the past decade, they frequently have involved users of injected and non-injected methamphetamine, who may account for as many as 30 percent of reported cases in these communities during outbreaks.[24,150,152,231,338] Cross-sectional serologic surveys have demonstrated that injecting drug users have a higher prevalence of anti-HAV than the general U.S. population does.[157,336] Transmission among injecting drug users probably occurs through both percutaneous and fecal-oral routes.[152]

Hepatitis A outbreaks in men who have sex with men have been reported frequently, most recently in urban areas in the United States, Canada, England, and Australia.[54,67,123,303] These outbreaks may occur in the context of an outbreak in the larger community.[24] Some studies conducted during outbreaks and seroprevalence surveys among men who have sex with men have identified specific sex practices associated with illness, whereas others have not demonstrated such associations.[67,68,146,165,336]

Transfusion-related hepatitis A rarely occurs because HAV does not result in chronic infection and blood donors are screened for elevated aminotransferase levels. Currently, nucleic acid amplification tests also are used to screen source plasma used in the manufacture of plasma-derived products. However, during the mid-1990s, outbreaks were reported in Europe and the United States in patients who received factor VIII and factor IX concentrates prepared by solvent-detergent treatment to inactivate lipid-containing viruses.[207,297] HAV is resistant to solvent-detergent treatment, and contamination presumably occurred from plasma donors with hepatitis A who donated during the incubation period. The risk of acquiring infection in patients with hemophilia is not known, although data from one serologic survey of hemophiliac patients suggested that they might be at increased risk for acquisition of HAV infection.[204] However, no HAV infections attributed to blood products were identified in an analysis of serosurveillance data collected from 140 hemophilia treatment centers in the United States between 1998 and 2002, suggesting that improved viral inactivation procedures, donor screening, and increased hepatitis A vaccine coverage among clotting factor recipients can reduce the risk of transmission of HAV to recipients of clotting factors.[49] Transmission related to blood transfusions also has resulted in nosocomial outbreaks in neonatal intensive care units.[170,240,271] Hepatitis A has been reported in adult cancer patients treated with lymphocytes that apparently were incubated in serum from a donor with HAV infection, although the patient source was not identified.[345]

Nosocomial transmission from adult patients to health care workers usually has been associated with fecal incontinence of the patient.[135,247] Such transmission is a rare event, however, because most patients with hepatitis A are hospitalized after the onset of jaundice, when infectivity is low.[110,294] Health care workers have not been found to have an increased prevalence of anti-HAV in comparison to control populations in serologic surveys conducted in the United States.[128]

Persons from developed countries who travel to developing countries with a high, transitional, or intermediate endemicity of HAV infection are at substantial risk of acquiring hepatitis A (see Fig. 180–2).[301] A more recent study of Swiss travelers estimated the risk to be 6 to 30 cases per 100,000 months of stay in developing countries among persons who did not receive immune globulin or vaccine before departure.[228] The risk is higher among travelers staying in areas with poor hygienic conditions,[183] it varies according to the region and the length of stay, and it appears to be increased even among travelers who reported staying in urban areas or luxury hotels.[301] In some European countries, returning international travelers with hepatitis A account for a substantial proportion of reported cases (16% to 40%).[59,351] In the United States, the proportion of cases attributed to recent international travel increased from 5 to 7 percent in the 1990s to 18 percent in 2004; children accounted for nearly 50 percent of cases attributed to international travel in 2004.[45] Children from immigrant communities who are visiting friends and relatives in their parents' countries of origin have been identified as an important source of cases. In one large study among San Diego children during 1998-2000, the number of cases increased 1 to 2 months after times when travel was most often reported (Fig. 180–7).[344]

Food-borne hepatitis A outbreaks are recognized relatively infrequently in the United States and are associated most commonly with contamination of food during preparation by a food handler with HAV infection. Implicated foods include those not cooked after handling, such as sandwiches and salads, glazed pastries, ice, and cold drinks, as well as partially cooked foods.* Control of these outbreaks usually requires intensive public

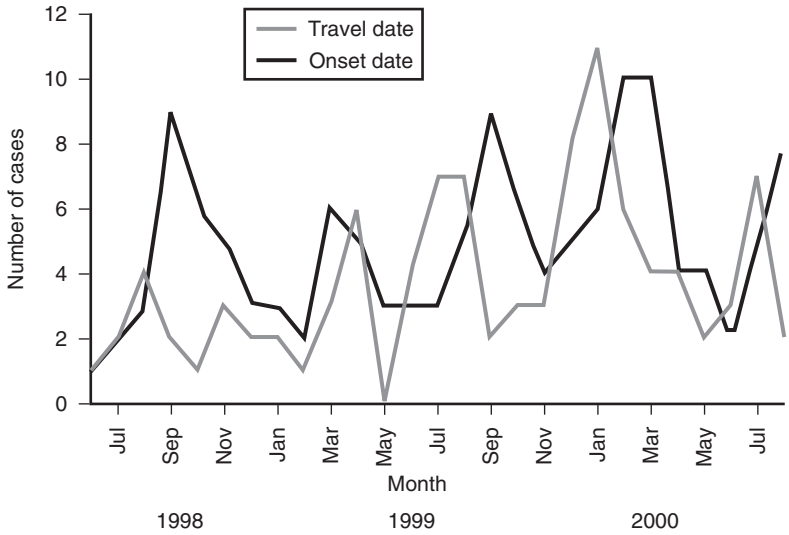

Figure 180–7 Number of hepatitis A cases among children, San Diego County, June 1998–August 2000, by date of onset and date of international travel.[344]

health effort.[77] However, persons who work as food handlers are not at increased risk for acquiring hepatitis A because of their occupation. Food contaminated before retail distribution, such as lettuce or fruits contaminated at the growing or processing stage, has been recognized increasingly as the source of hepatitis A outbreaks.[6,84,151,239,265,272,348] Outbreaks related to contaminated shellfish, commonly noted in the past,[85,90,244,258] have become increasingly uncommon but occasionally are identified.[27] No water-borne hepatitis A outbreaks in the United States have been reported since the 1980s; earlier outbreaks were linked to sewage contamination or inadequate treatment of water.[26,31,35,40,87,122,205]

PATHOGENESIS AND PATHOLOGY

PATHOLOGY

The light microscopic findings in acute hepatitis A, which include inflammatory cell infiltration, hepatocellular necrosis, and liver cell regeneration, are common to all forms of acute viral hepatitis. These histologic findings vary with the stage and severity of hepatitis. Early biopsy specimens generally show portal infiltration by lymphocytes, plasma cells, and periodic acid–Schiff positive macrophages.[91,312] Spotty or focal necrosis, as evidenced by balloon degeneration, shrinkage, and fragmentation of hepatocytes, is seen commonly.[91] HAV antigen is found primarily in the cytoplasm of hepatocytes, but it also can be found in liver macrophages. However, because HAV infection is self-limited and does not result in chronic liver disease, liver biopsy rarely is indicated (see the section on treatment).

Differences have been noted in the light microscopic findings of hepatitis A and other forms of viral hepatitis, particularly hepatitis B. In addition to degeneration of hepatocytes in the perivenular area, periportal inflammation and destruction of hepatocytes adjacent to the portal area may be more pronounced than in hepatitis B.[1,245,312] Findings in some patients, including extension of the inflammatory infiltration from the periportal area into the hepatic parenchyma and disruption of the limiting plate, may be difficult to distinguish from chronic hepatitis.[1,91] Cholestasis may be more prominent than in hepatitis B.[277]

The histologic findings in fulminant hepatitis A are indistinguishable from those in other forms of fulminant viral hepatitis. Examination of pathologic specimens shows massive hepatic necrosis, abnormal architecture of surviving hepatocytes, and a diffuse inflammatory response.[172] Viral antigen can be found in pathologic specimens.

PATHOGENESIS

The mechanism by which HAV crosses gastrointestinal epithelium and infects liver cells has not been established. HAV is able to bind to human cells through a specific cellular receptor inserted into the plasma membrane, and DNA that encodes this receptor (huhavcr-1) has been identified in many human tissues.[112] This cellular receptor, also known as TIM-1, appears to regulate the size and effector functions of T cells and also might play a role in the development of atopy.[216] Other researchers have shown that HAV-IgA complex can translocate across epithelial cells and that HAV-IgA complexes are taken up by hepatocytes through the asialoglycoprotein receptor.[95,96] In this model of HAV infection, virus would first infect gastrointestinal cells and then be transported into the enterohepatic circulation as part of an HAV-IgA complex with subsequent selective uptake by hepatocytes.

CELLULAR IMMUNE RESPONSE

Unlike other picornaviruses, infection of cultured cells with wild-type HAV has no cytopathic effect. The general assumption is that HAV infection also is noncytopathic in vivo and therefore the cytopathic changes in the liver associated with hepatitis A are immune mediated. HAV is able to suppress interferon-β gene expression in the initial stages of infection, which might facilitate prolonged viral production and infection of neighboring cells.[114] Symptoms and biochemical evidence of liver injury do not occur at the time of maximum virus replication and fecal shedding (during the late incubation period). Rather, liver injury is associated closely with viral clearance. $CD8^+$, class 1–dependent, cytotoxic, and virus-specific T cells that are capable of producing interferon-γ are present in the circulation and the liver.[119,324,325] Additional inflammatory cells, recruited to the site of infection by interferon-γ and other cytokines secreted by $CD8^+$ cells, may be responsible for much of the liver injury. Complement has been shown to bind to HAV capsid proteins, and serum complement levels drop during infection, but whether complement-mediated cellular injury occurs is unclear.[210] The mechanism by which infection is resolved remains uncertain.

HUMORAL IMMUNE RESPONSE

Antibodies directed against conformational epitopes displayed on intact virions as well as empty viral capsids are produced during the later stages of infection (see the section on genomic organization and genetic variation). Virus-specific IgM and IgG and IgA antibodies are present in serum; IgM anti-HAV generally can be detected at the onset of symptoms (see Fig. 180–1).

CLINICAL MANIFESTATIONS

Similar to other forms of viral hepatitis, the clinical manifestations of HAV infection are variable and range from asymptomatic anicteric infection to symptoms of acute hepatitis, including fever, malaise, anorexia, nausea, vomiting, right upper quadrant pain, and jaundice. The likelihood of having symptomatic HAV infection and the severity of the illness are related to the age of the patient. In early childhood, infection usually is asymptomatic, whereas infection in adulthood generally is accompanied by symptoms. The diagnosis of hepatitis A must be confirmed by serologic testing because no constellation of symptoms is pathognomonic of the disease.

INCUBATION PERIOD

The average incubation period is 28 to 30 days but can range from 15 to 50 days.[176] The average incubation period has been reported to be shorter in patients who acquired HAV infection by parenteral transmission from contaminated blood products and in chimpanzees infected parenterally than in those infected orogastrically.[210,287]

SPECTRUM OF ILLNESS

HAV infection, confirmed by the detection of IgM anti-HAV in serum, can be inapparent (asymptomatic, with no elevation in serum aminotransferase levels), subclinical (asymptomatic, with elevation of serum aminotransferase levels), or clinically evident (with symptoms). Specific symptoms of liver dysfunction include jaundice and dark urine caused by hyperbilirubinemia. However, symptomatic hepatitis A without jaundice (anicteric) does occur. Nonspecific symptoms of acute hepatitis A can include fever, myalgia, anorexia, nausea, right upper quadrant pain or discomfort, diarrhea, and pruritus.

Many acute HAV infections, particularly inapparent and subclinical infection and anicteric hepatitis A, are not recognized as cases of viral hepatitis.[299,360] The frequency of symptoms with acute infection is influenced strongly by age. Children are less likely to have symptomatic infection than adults are, and jaundice rarely occurs in children younger than 6 years.[131] In one report describing outbreaks in several daycare centers, the proportion of infected children without symptoms was 84 percent in children younger than 3 years, 50 percent in children 3 to 4 years of age, and 20 percent in children 5 years or older.[142] Symptoms develop in most adults with acute infection. In a study of two outbreaks among young adult U.S. military personnel, symptoms developed in 76 to 97 percent of infected persons, and approximately 55 percent were icteric.[187]

CLINICAL SIGNS AND SYMPTOMS

In an individual patient, the clinical symptoms of acute hepatitis A are indistinguishable from those caused by other forms of viral hepatitis. Particularly in older children and adults, the onset of illness often is quite abrupt and may consist of fever, myalgia, anorexia, malaise, nausea, intermittent dull abdominal pain, and vomiting. Fever (temperature rarely higher than 102° F) and headache occur more frequently than in other forms of acute viral hepatitis.[306] Pediatric patients may have diarrhea or, less commonly, upper respiratory symptoms such as cough, sore throat, and runny nose, and the diagnosis of hepatitis A might not be considered in children with predominantly respiratory or gastrointestinal symptoms and transient fever without the typical malaise, fatigue, and anorexia.[117,195] Dark urine followed by jaundice and light-colored stool, if present, will appear within a few days to a week after onset of the prodromal symptoms.[25,138,187,195] When this icteric phase begins, symptoms often resolve and appetite returns in young children, but older children and adult patients may experience a transient worsening in the prodromal symptoms of anorexia, malaise, and weakness.[172,227]

In addition to jaundice and scleral icterus, physical findings may include mild hepatomegaly and tenderness, but severe tenderness suggests other diagnoses. The spleen may be palpable in 10 to 20 percent of patients, and posterior cervical adenopathy may be present.[63,187,318] Pleural effusions have been reported to occur, do not appear to be associated with more severe disease, and resolve spontaneously.[3] Ascites, peripheral edema, and findings indicative of hepatic encephalopathy suggest the presence of a more severe form of hepatitis (see the section on atypical clinical manifestations and complications of hepatitis A). Ultrasonographic findings in children with uncomplicated hepatitis A have included edema or thickening of the gallbladder wall, abdominal lymphadenopathy, and, less commonly, transient ascites and pancreatic abnormalities.[63,169]

The symptoms of hepatitis A last for several weeks on average and usually not longer than 2 months.[173] Prolonged or relapsing hepatitis A can occur (see the section on relapsing hepatitis A) and, in the case of prolonged hepatitis A, may be associated with genetic markers for autoimmune hepatitis.[107]

LABORATORY ABNORMALITIES

As in other forms of viral hepatitis, during HAV infection, inflammation of the liver is accompanied by abnormalities in serum hepatic enzymes, with increases in serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, and gamma-glutamyltranspeptidase (GGTP) levels. Elevations of serum ALT and AST occur most consistently and may precede the appearance of symptoms by a week or more (see Fig. 180–1). Peak levels generally occur 3 to 10 days after the onset of symptoms and are between 200 and 5000 IU but can reach as high as 20,000 IU. The level of ALT usually is higher than that of AST because the inflammatory response is destructive, particularly to the plasma membrane, in acute viral hepatitis. ALT is found in the cytosol of the plasma membrane, whereas AST is located mainly in cell mitochondria.[138]

Serum bilirubin levels, although frequently elevated, usually remain below 10 mg/dL and peak 1 to 2 weeks after illness begins. Higher levels can be seen in some patients, especially when HAV infection is complicated by cholestasis (see the section on cholestatic hepatitis A) or hemolysis secondary to an underlying glucose-6-phosphate dehydrogenase (G6PD) deficiency state.[58] In patients with G6PD deficiency, indirect bilirubin may account for more than 50 percent of the total bilirubin. Alkaline phosphatase concentration and 5′-nucleotidase activity usually are elevated only mildly, rarely reaching more than 2 or 3 times the normal level. GGTP levels generally are 3 to 10 times the upper limit of normal.

Serum immunoglobulin levels often are elevated, and IgM levels frequently are higher than those in acute hepatitis B and

non-A, non-B hepatitis.[362] In patients without underlying liver disease, the prothrombin time usually is normal. A prolonged prothrombin time, generally associated with severe liver damage, is a prognostic indicator for the development of fulminant hepatitis.[356]

Patients with acute HAV infection usually have a mild lymphocytosis with occasional atypical mononuclear cells.[227] Except for patients who have hemolysis associated with G6PD deficiency, the hematocrit generally is normal.[58,227]

Apart from patients who have relapsing or cholestatic hepatitis A (see the section on atypical clinical manifestations and complications of hepatitis A), serum bilirubin and aminotransferase levels usually return to normal by 2 to 3 months after the onset of illness in most patients.[173]

DIAGNOSTIC TESTS

Because the pattern and magnitude of symptoms and the hepatic enzyme abnormalities of hepatitis A are not distinctive for hepatitis A, the diagnosis requires serologic detection of IgM anti-HAV along with demonstration of an acute onset of signs and symptoms of hepatitis and jaundice or elevated aminotransferase levels. Persons with signs and symptoms of hepatitis and an epidemiologic link to other confirmed cases are likely to have hepatitis A, even if no laboratory confirmation is available. Sensitive and specific radioimmunoassays or enzyme immunoassays show that virtually all patients have detectable IgM anti-HAV during the acute or early convalescent phase of HAV infection (see Fig. 180–1).[200] A small proportion (3%) of patients tested within 3 days of the onset of symptoms may be IgM anti-HAV negative but become IgM anti-HAV positive within the initial 2 weeks of illness.[200] During the first 4 to 8 weeks after the onset of symptoms, the titer of IgM anti-HAV in serum is high.[145] Antibody generally disappears within 6 months, although rarely it can be detected for 2 years or longer.[93,145,171,200] False-positive IgM anti-HAV test results among persons who have no other evidence of recent infection have been reported, suggesting a low positive predictive value when it is used to test asymptomatic persons with no known recent HAV exposures.[44,48] IgM anti-HAV may be detectable for a longer time in patients with symptomatic illness than in those with asymptomatic infection.[145,163,296]

IgG anti-HAV is present in low titer at or shortly after the onset of acute HAV infection, and the titer rises during the course of several weeks as the IgM anti-HAV titer falls (see Fig. 180–1). IgG anti-HAV remains detectable in serum for the lifetime of the individual and confers lasting protection against disease. Secretory IgA antibodies are detected in a minority of humans or primates with acute HAV infection but are unlikely to provide any significant protection against HAV infection.[300] IgG anti-HAV is transferred passively across the placenta and declines to undetectable levels in most infants by the time they reach 12 to 15 months of age.[20,201,202]

Commercially available enzyme immunoassays either detect total (IgG and IgM) antibody against HAV capsid proteins by using a competitive inhibition (blocking) format or detect IgM antibody to capsid proteins by using an IgM capture format.[194] These assays do not measure the neutralizing antibodies responsible for biologic activity against HAV, but detection of total anti-HAV by conventional assays is correlated with the appearance of neutralizing antibodies.[175,194] Neutralizing antibody can be detected by assays that measure inhibition of HAV in cell culture (i.e., radioimmunofocus inhibition test or plaque assay).[7,72,194,196] Neutralizing antibodies elicited against one strain of HAV have been shown to have biologic activity against other HAV strains.[196]

When tested in parallel with a World Health Organization anti-HAV reference reagent, the lower limit of detection of most commercially available assays is approximately 100 mIU/mL of anti-HAV.[127,194] Administration of immune globulin provides a high level of protection against hepatitis A, although the antibody concentrations achieved by passive immunization with immune globulin or active immunization with vaccine are 10- to 100-fold lower than those produced after natural infection.[194] Antibody concentrations achieved by passive or active immunization and known to provide protection against HAV infection both in vivo and in vitro may be below the level of detection of most commercial immunoassays.

The lower limit of antibody necessary to provide protection against HAV infection is unknown. In vitro studies with cell culture–derived virus suggest that low levels of antibody (e.g., <20 mIU/mL) are neutralizing.[196] Clinical trials that evaluated vaccine efficacy have not provided an estimate of the minimum protective antibody level because vaccine-induced levels of antibody have been very high and few infections have occurred in vaccinees. Experimental studies in chimpanzees indicate that very low levels of passively transferred antibody (<10 mIU/mL) obtained from immunized individuals do not protect against infection but prevent clinical hepatitis and shedding of virus.[262]

PCR assays can be used to detect HAV RNA in stools and sera of persons with HAV infection, although these tests are available only in a few research laboratories. PCR techniques using serum specimens have been useful in some clinical, epidemiologic, or environmental studies. Although HAV concentrations in stool decline quickly after illness onset, HAV RNA can be detected in most serum specimens that are collected within 4 to 6 weeks after onset of illness.[36]

ATYPICAL CLINICAL MANIFESTATIONS AND COMPLICATIONS OF HEPATITIS A (Table 180–1)

RELAPSING HEPATITIS A

Relapsing hepatitis is a relatively common manifestation of hepatitis A that occurs in approximately 10 percent of patients.[278] One to 4 months after having the initial episode of acute hepatitis, these patients have a second episode; more than one relapse rarely occurs.[133,278,316] Patients with relapsing hepatitis A have no distinctive clinical features of their first disease episode. After the first episode, most patients experience a significant improvement in symptoms and biochemical abnormalities. However, the frequency with which serum aminotransferase levels completely normalize during this period has been variable; in one report, normalization occurred in only one of seven patients with relaps-

Renal syndromes (acute renal failure, nephritic syndrome, acute glomerulonephritis)[12,82,161]
Pancreatitis[224]
Aplastic anemia and thrombocytopenia[104,206]

ing hepatitis A.[316] The relapse episode of hepatitis rarely is more severe than the initial episode and is accompanied by elevated serum aminotransferase levels (typically to > 1000 U/L) and persistence of IgM anti-HAV. Molecular studies have demonstrated the presence of HAV in stool and HAV RNA in serum during relapse, but whether patients are infectious is unknown.[133] The illness usually lasts a total of 16 to 40 weeks and results in full recovery.[133,278] Although the pathogenesis of relapsing hepatitis is unknown, it probably is immunologically mediated.[278] Persistent HAV infection with a relapsing clinical course has been reported in patients after they have undergone liver transplantation for fulminant hepatitis A; HAV-specific genomic sequences have been identified in the grafts of these patients.[106,356]

FULMINANT HEPATITIS A

In the United States, a relatively small proportion of all fulminant hepatitis is caused by hepatitis A.[212,246,264,279,315] A prospective multicenter study conducted among 348 children with acute liver failure in the United States, Canada, and the United Kingdom found that only three cases (1%) could be attributed to hepatitis A.[298] However, 26 to 60 percent of children with acute liver failure had hepatitis A in tertiary care center–based studies conducted in Turkey, India, Argentina, and Pakistan.[10,13,280] Among patients hospitalized with hepatitis A, the case-fatality rate has been estimated to be 0.14 percent.[219] In the 1988 Shanghai epidemic that involved primarily adolescents and young adults, 47 deaths (0.015%) were recorded among the 310,746 diagnosed cases.[66] The case-fatality rate among cases reported through national surveillance in the United States from 2001 to 2005 was 0.5 percent but varied by age, from 0 percent among those younger than 5 years to 1.4 percent of cases older than 60 years.[45-47] However, based on all cases of hepatitis A reported in the United States, the case-fatality rate from fulminant hepatitis A is approximately 0.4 percent.[45] Host factors reported to be associated with an increased risk for development of fulminant hepatitis include older age[38,180,219,337,359] and underlying chronic liver disease.[2,80,167,192,331,337,357,359] Reported findings among persons with fulminant disease include lower viral load and nucleotide or amino acid substitutions in the 5′ untranslated region,[125] P2 region, and P3 region of the HAV genome.[230]

Fulminant hepatitis A has no distinctive clinical features that distinguish it from fulminant hepatic failure of other causes. Within approximately 8 weeks of the onset of illness, symptoms of hepatic encephalopathy and marked prolongation of the prothrombin time are noted in patients with no history of previous liver disease.[243] Complications can include cerebral edema, sepsis, gastrointestinal bleeding, and hypoglycemia. The prognosis of fulminant hepatitis A without transplantation is better than that of fulminant disease related to other viral causes, and 40 to 70 percent of patients can be expected to recover.[130,242,279,315] In one hospital series, more rapid onset to liver failure after onset of jaundice was associated with improved outcome, and higher bilirubin concentration and more prolonged prothrombin time were associated with poor outcomes.[81]

EXTRAHEPATIC MANIFESTATIONS

During acute hepatitis A, transient rash and arthralgias occur in as many as 14 and 19 percent of patients, respectively, particularly during the prodromal period.[130,316] Urticaria has been reported but occurs less frequently than in acute hepatitis B.[92] Papular acrodermatitis of childhood, the Gianotti-Crosti syndrome, rarely occurs in the United States but has been reported elsewhere in association with HAV infection.[273] The cutaneous lesions, which consist of nonpruritic, symmetric flat papules on the face, extremities, and buttocks, may persist for several weeks before spontaneously resolving.[97]

Other extrahepatic manifestations that occur chiefly in association with cholestatic or relapsing hepatitis A include cutaneous vasculitis and cryoglobulinemia.[78,153,154] The vasculitis, manifested as erythematous maculopapular lesions often affecting the lower extremities and buttocks and typically associated with purpura, appears as leukocytoclastic vasculitis and granular deposits of IgM anti-HAV and complement in blood vessel walls in skin biopsy specimens. Cryoglobulinemia includes cryoglobulins composed of IgG and IgM and IgM anti-HAV antibodies.[78,153,154,278] These manifestations resolve spontaneously with resolution of the hepatitis.

In the absence of fulminant disease, neurologic syndromes have been observed only rarely in association with hepatitis A. Guillain-Barré syndrome has been reported to occur 3 days to 2 weeks after the onset of hepatitis A, as have myeloradiculopathy, vertigo, mononeuritis (cranial or peripheral nerve), meningoencephalitis, and exacerbation of multiple sclerosis.[14,33,251,307] Renal complications, including acute renal failure, nephrotic syndrome, and acute glomerulonephritis, also rarely have been reported in children who did not have fulminant disease.[12,82,161] Self-limited, mild pancreatitis likewise appears to occur.[224] Reported hematologic complications include aplastic anemia and severe thrombocytopenia.[104,206] Gestational complications, including premature rupture of membranes and placental separation, have been reported among pregnant women with acute hepatitis A, but infants born to these women were healthy otherwise.[99]

CHOLESTATIC HEPATITIS A

Cholestatic hepatitis occurs in a small percentage of patients with hepatitis A. These patients are deeply icteric and may have pruritus, fatigue, fever, loose stools, anorexia, dark urine, and weight loss. In two reports of 10 patients with cholestatic hepatitis A, peak serum bilirubin levels generally were higher than 10 mg/dL, with some as high as 38 mg/dL, and remained elevated for 12 to 16 weeks.[136,316] Serum aminotransferase levels declined but remained elevated during the period of cholestasis. In one of these reports, five patients had prolonged prothrombin times that normalized with the administration of vitamin K.[136]

Cholestatic hepatitis A can be distinguished from obstructive jaundice by normal abdominal ultrasound findings. Conducting further invasive diagnostic procedures, such as liver biopsy or direct forms of cholangiography, is not necessary in most cases.[278] Although patients will recover completely without therapy, a course of corticosteroids with a gradual taper during a span of at least 4 weeks has been reported to hasten relief of symptoms and resolution of cholestasis.[278]

HEPATITIS A TRIGGERING AUTOIMMUNE HEPATITIS

Several reports have described patients in whom hepatitis A is followed by type 1 autoimmune chronic hepatitis.[263,316,332] Laboratory studies demonstrated a T-cell defect in these patients, thus suggesting a genetic predisposition to the development of autoimmune hepatitis that is "triggered" by HAV infection. These patients have required corticosteroid therapy, sometimes for long periods.

TREATMENT

Hepatitis A has no specific therapy, and because HAV infection is self-limited and does not result in chronic infection or chronic liver disease, treatment generally is supportive. Hospitalization

may be necessary for patients who are dehydrated from nausea and vomiting or who have fulminant hepatic failure. Because no conclusive data indicate that bed rest or inactivity influences the course of illness, no restriction of activity is necessary. Similarly, no specific diet is indicated, although many patients may have an intolerance to fatty foods during their illness. Medications, particularly those that have the potential to cause hepatic damage and those that are metabolized by the liver, including acetaminophen, should be used with caution. The half-life of these medications may be prolonged.

A specific therapy for fulminant hepatic failure caused by hepatitis A has not been established. Small uncontrolled trials conducted among adults in the 1980s suggested that some patients benefited from prostaglandin E or interferon, but no additional data to indicate that these therapies are efficacious have been published. No evidence exists that exchange transfusions, plasmapheresis, or corticosteroids are effective.[105,138] Adults with fulminant hepatitis A who received prostaglandin E or interferon have been reported to show improvement in small, uncontrolled trials.[199,291] Amantadine and ribavirin have shown activity in vitro against HAV.[70] Liver transplantation is successful in some patients.[315,356] Persistent HAV infection has been demonstrated in some transplant recipients, but whether it affects survival is unknown.[98,106] Because survival rates of adult and pediatric patients are relatively high without transplantation and no single factor is predictive of a poor outcome, establishment of criteria for choosing candidates for transplantation has been difficult.[130,243,315,329] Reported survival rates after transplantation in patients with fulminant hepatitis from all viral causes range from 40 to 89 percent, depending on the severity of liver failure and other factors.[188,315,356]

PREVENTION

In addition to general measures of good personal hygiene, particularly handwashing, provision of safe drinking water, and proper disposal of sanitary waste, pre-exposure or postexposure immunization primarily with hepatitis A vaccine or with immune globulin can prevent the acquisition of hepatitis A.

IMMUNE GLOBULIN

Immune globulin is a sterile solution of antibodies prepared by a serial cold ethanol precipitation procedure from pooled human plasma that has tested negative for hepatitis B surface antigen, antibody to human immunodeficiency virus (HIV), and antibody to hepatitis C virus.[65] This precipitation procedure has been shown to inactivate hepatitis B virus and HIV.[57] Since 1995, immune globulin prepared in the United States has been required to be negative for hepatitis C virus RNA by PCR amplification or to be produced by a method that ensures additional virus inactivation. When it is administered before exposure or within 2 weeks after exposure, immune globulin is more than 85 percent effective in preventing hepatitis A by passive transfer of anti-HAV.[171,226,302] Whether immune globulin completely prevents infection or leads to asymptomatic infection and the development of persistent anti-HAV (passive-active immunity) probably is related to the amount of time that has elapsed between exposure and administration of immune globulin.[195,302] Although in recent years immune globulin lots have had slightly lower titers of anti-HAV, probably because of a decreasing prevalence of previous HAV infection in plasma donors, no clinical or epidemiologic evidence of decreased efficacy has been reported.[309]

Previously unvaccinated household and sexual contacts of patients with hepatitis A should receive hepatitis A vaccine or immune globulin as soon as possible but no later than 2 weeks after exposure.[44a] Aggressive use of immune globulin or vaccine is indicated to control hepatitis A outbreaks in childcare centers in which hepatitis A is diagnosed in a child or employee[44a,46,283] and in other settings (e.g., hospitals, facilities for developmentally disabled persons) when outbreaks occur.[449] When a food handler is identified with hepatitis A, postexposure prophylaxis should be administered to other food handlers at the establishment and under limited circumstances to patrons.[43,44a,115] Once cases are identified that are associated with a food service establishment, it generally is too late to administer postexposure prophylaxis to patrons because the 2-week postexposure period during which prophylaxis is effective will have passed.

Immune globulin also may be given to persons who are traveling to countries with high, transitional, or intermediate endemicity of HAV infection (see Fig. 180–2) instead of or in addition to hepatitis A vaccine.[44a] Immune globulin should be given to children younger than 12 months who are traveling to such countries because hepatitis A vaccine is not licensed in the United States for children in this age group (see the section on vaccines).[44a] Although hepatitis A often is asymptomatic in infants and young children, pre-exposure prophylaxis is indicated to prevent the rare severe cases and transmission to others after return from abroad.

For postexposure prophylaxis, 0.02 mL/kg body weight of immune globulin is administered intramuscularly. For infants and young children, the injection can be administered in the anterolateral aspect of the thigh or the deltoid muscles; for older children and adolescents, the injection should be administered in the deltoid or gluteus muscles, into which a large volume of immune globulin can be injected.[50] If the immune globulin is administered in the gluteus, the injection should be given in the superior-lateral aspect to avoid injury to the sciatic nerve.[50]

For pre-exposure prophylaxis of travelers, the dose of immune globulin is 0.02 mL/kg body weight if travel will be for less than 3 months. Because of the decay of passive immunity during the course of time, a dose of 0.06 mL/kg is necessary for persons who will be abroad for 3 to 5 months, and re-administration every 5 months is necessary for extended trips. Hepatitis A vaccine, if it is not contraindicated, is a better choice for such persons.

Serious adverse events from immune globulin rarely occur. Because anaphylaxis has been reported after repeated administration to persons with IgA deficiency, these persons should not receive immune globulin.[100] Pregnancy or lactation is not a contraindication to the administration of immune globulin. For infants and pregnant women, a preparation that does not include thimerosal is preferable.

Immune globulin does not interfere with the immune response to oral poliovirus vaccine, to yellow fever vaccine, or, in general, to inactivated vaccines. However, immune globulin can interfere with the immune response to some live attenuated vaccines (e.g., measles-mumps-rubella vaccine [MMR], varicella vaccine). Administration of MMR and varicella vaccines should be delayed for at least 3 months and at least 5 months, respectively, after the administration of immune globulin. Immune globulin should not be given within 2 weeks after the administration of MMR or within 3 weeks of the administration of varicella vaccine, unless the benefits of immune globulin administration are greater than the benefits of vaccination.[50] For travelers younger than 1 year in whom the use of immune globulin may interfere with the administration of other needed vaccines (e.g., MMR, varicella), the use of inactivated hepatitis A vaccine could be considered (see the section on inactivated vaccines).

HEPATITIS A VACCINE

The ability to propagate HAV in cell culture allowed the development of hepatitis A vaccines. Both inactivated and live attenu-

ated hepatitis A vaccines have been developed by use of defined isolates from infected cell lines.[88,208,209,221,260,292] However, only inactivated vaccines have been evaluated for efficacy in controlled clinical trials and licensed in the United States, and the live attenuated vaccines evaluated to date do not appear to offer any distinct advantage over inactivated vaccines.[156,347]

Vaccine Preparation and Performance

Inactivated hepatitis A vaccines are prepared by a method similar to that used to prepare inactivated poliovirus vaccine, by propagation of cell culture–adapted virus in human fibroblasts, purification by ultrafiltration or other methods, formalin inactivation, and adsorption to an aluminum hydroxide adjuvant.[9,62] Inactivated vaccines using the HM175 strain and the CR326F′ strain have been licensed in pediatric and adult formulations for intramuscular administration and are available in the United States for persons 12 months of age and older (Table 180–2). One of these vaccines (HM175 strain) is formulated with 2-phenoxyethanol as a preservative, whereas the other is formulated without a preservative (see Table 180–2).[250] The antigen content of one vaccine (CR326F′ strain) is expressed as units of HAV antigen as defined by a standard; the antigen content of the other vaccine (HM175 strain) is determined by reactivity in a quantitative immunoassay for HAV antigen and is expressed as enzyme-linked immunosorbent assay units (ELU; see Table 180–2).

Two other inactivated hepatitis A vaccines are manufactured and available in Europe and other parts of the world.[154,185,252,335] In addition, a combination inactivated hepatitis A and recombinant hepatitis B vaccine is available in the United States for persons 18 years and older[46]; a pediatric formulation is available in Europe, Canada, and other parts of the world.[89]

In extensive studies in children and adults, the inactivated hepatitis A vaccines available in the United States have been found to be highly immunogenic. In general, after one dose of vaccine, 95 to 100 percent of children 1 year or older and adults respond with concentrations of antibody considered to be protective; a second dose given 6 to 18 months later results in a boost in antibody concentration and probably is important for long-term protection.[15,20,62,148,218,234] Persons whose second dose is delayed as long as 3 to 8 years after the first dose have responses to vaccination similar to the responses of those who receive the vaccine on licensed schedules.[19,158,354] Studies conducted among infants and children younger than 18 months have demonstrated that simultaneous administration of hepatitis A vaccine with diphtheria–tetanus–acellular pertussis (DTaP), *Haemophilus influenzae* type b (Hib), hepatitis B, MMR, and inactivated poliovirus vaccines does not affect the immunogenicity and reactogenicity of these vaccines.[20,76,132,220,323] IgM anti-HAV occasionally can be detected by standard assays, primarily if it is measured soon (i.e., 2 to 3 weeks) after vaccination (CDC, unpublished data).[289,333]

Conditions that may result in reduced immunogenicity include HIV infection, chronic liver disease, and older age. Among adults with HIV infection, 61 to 87 percent had protective antibody concentrations after completing the vaccination series.[147,168,237,339] Higher $CD4^+$ T-lymphocyte count at baseline was associated with response to vaccination.[147,168,267,339] However, HIV-infected persons with normal or near-normal $CD4^+$ T-lymphocyte counts have response rates that exceed 95 percent.[343] Among persons with chronic liver disease, seroprotection rates were similar to those observed among healthy adults, but the final antibody concentrations were substantially lower.[166,189]

Studies in children younger than 1 year indicate that the vaccine is safe and immunogenic for those who do not have passively transferred antibody from previous maternal HAV infection.[20,198,254,319] In studies of infants who received hepatitis A vaccine according to several different schedules, those with passively transferred maternal antibody at the time of vaccination responded, but final antibody concentrations were approximately one third to one tenth those of infants who did not have passively transferred antibody and were vaccinated according to the same schedule.[20,76,198,201,254,319] The clinical significance, if any, of these lower antibody concentrations is unknown. One study found that all infants vaccinated in the presence of passively transferred maternal antibody responded to a booster dose given 6 months later with an anamnestic response, suggesting that they had been primed by the primary series.[76] However, in another small study, two of six children who had lost detectable antibody did not have an anamnestic response to a booster dose administered approximately 6 years after they had received the primary vaccine series in infancy in the presence of passively transferred antibody.[116] Most infants born to anti-HAV–positive mothers have lost detectable antibody by the time they reach 12 to 15 months of age, and both pediatric hepatitis A vaccines are now licensed for use in children as young as 12 months.[121,202]

Inactivated hepatitis A vaccine has been shown to be highly efficacious in preventing clinically apparent disease. In a study of approximately 40,000 Thai children 1 to 16 years of age, the efficacy of inactivated vaccine (HM175 strain) was 94 percent (95% confidence interval, 79% to 99%) after two doses (360 ELU per dose) administered 1 month apart.[156] In a study of another inactivated vaccine (CR326F strain) involving approximately 1000 children aged 2 to 16 years in a New York community with high hepatitis A rates, efficacy was 100 percent (lower bound of the 95% confidence interval, 87%) starting 17 days after the administration of one dose (25 U).[347]

Since hepatitis A vaccines became available in the United States in 1995, studies, demonstration projects, and surveillance data have evaluated their effectiveness in controlling and preventing the development of hepatitis A in communities. In areas with the highest hepatitis A rates, such as Native American and Alaska Native communities, vaccination of the majority of children—and in some cases adolescents and young adults—resulted in a rapid decline in the incidence of disease, and with ongoing routine vaccination of children, the reduction in incidence of disease has been sustained.[28,52,217] In larger, more heterogeneous

TABLE 180–2 Recommended Doses and Schedules for Inactivated Hepatitis A Vaccines Available in the United States[46]

Age (yr)	Vaccine*	Dose†	Volume (mL)	No. of Doses	Schedule‡ (mo)
1-18	HAVRIX	720 ELU	0.5	2	0, 6-12
	VAQTA	25 U	0.5	2	0, 6-18
≥19	HAVRIX	1440 ELU	1.0	2	0, 6-12
	VAQTA	50 U	1.0	2	0, 6-18
>18	TWINRIX	720 ELU	1.0	3	0, 1, 6§

**HAVRIX is manufactured from HAV strain HM175 by GlaxoSmithKline; VAQTA is manufactured from HAV strain CR326F′ by Merck & Co, Inc.; TWINRIX is a combined hepatitis A and hepatitis B vaccine that also contains 20 μg per dose recombinant hepatitis B surface antigen protein.*

†ELU, enzyme-linked immunosorbent assay units.

‡Zero months indicates initial dose; subsequent numbers represent months after the initial dose.

§An alternative 4-dose schedule, given on days 0, 7, 21-30, followed by a dose at month 12, also is licensed in the United States.

communities with lower but consistently elevated hepatitis A rates, interruption of ongoing community-wide epidemics by vaccination of children proved more difficult.[69] In contrast, sustained routine vaccination of children can reduce hepatitis A incidence markedly during the course of time (see vaccine recommendations and use).[11,75,94,341]

Hepatitis A vaccine also is effective when it is used to prevent infection after exposure. Hepatitis A vaccine administered soon after exposure prevented infection in a chimpanzee model.[269] Hepatitis A vaccine was found to be 79 percent efficacious in preventing infection compared with no treatment in a small randomized trial conducted in Italy.[274] However, the confidence interval was wide (7% to 95%), and the study did not include a comparison group that received passive postexposure prophylaxis with immune globulin.[23] In a randomized controlled trial conducted in Kazakhstan, among persons aged 2 to 40 years who were contacts of hepatitis A cases, the efficacy of hepatitis A vaccine administered within 14 days after exposure to HAV was shown to be similar to that of immune globulin in healthy children and adults less than 40 years of age.[333] Based on their results and because the vaccine offers a number of advantages over immune globulin, the Advisory Committee on Immunization Practices (ACIP) of the U.S. Public Health Service currently recommends the hepatitis A vaccine in preference to immune globulin for postexposure prophylaxis of healthy persons from the ages of 12 months to 40 years.[44a] Advisory groups or expert panels in some other countries also have recommended that hepatitis A vaccine be used as the primary means of preventing hepatitis A after exposure.[236,308]

Experience to date indicates that the incidence of adverse events after vaccination is comparable to that after the administration of other widely used vaccines. In prelicensure clinical studies in children, the side effects reported most frequently included soreness, tenderness, warmth, or induration at the injection site (4% to 19%); feeding problems (8%); and headache (4%).[46,132,220] Through 2005, more than 188 million doses have been sold worldwide, including more than 50 million doses in the United States.[46] No serious adverse events in children or adults have been identified that could be definitively ascribed to hepatitis A vaccine.[30,46] The Vaccine Adverse Events Reporting System (maintained by the U.S. Food and Drug Administration and the CDC) has received approximately 6000 reports of adverse events occurring after receipt of hepatitis A vaccine. The most common events were minor and of brief duration, such as fever, injection-site reactions, rash, and headache. The 871 serious adverse events included Guillain-Barré syndrome, transaminitis, idiopathic thrombocytopenic purpura, and seizures among children.[46,238] Rare adverse events reported postmarketing include syncope, jaundice, erythema multiforme, anaphylaxis, brachial plexus neuropathy, transverse myelitis, encephalopathy, and others. For events for which incidence rates are available, such as Guillain-Barré syndrome, reported rates were not higher than reported background rates.[46]

Anti-HAV persists at protective levels in vaccinated adults for at least 10 to 12 years after vaccination[327,328] and in children for at least 5 to 6 years after vaccination.[108,326] In one follow-up study, two thirds of infants who did not have passively transferred maternal antibody at the time of vaccination had detectable anti-HAV 6 years later, and all who had lost antibody had an anamnestic response to a booster dose.[116] Estimates based on kinetic models of decline in antibody suggest that the duration of protection could be 15 to 25 years or longer.[326,352,353]

In some settings, performing pre-vaccination serologic testing may be considered in an attempt to reduce cost by not vaccinating persons with previous immunity.[41] Testing of children is not indicated because of their expected low prevalence of infection and the lower cost of vaccine for this age group. Testing may be considered for older adolescents in certain population groups with a high prevalence of infection (e.g., Native Americans, Alaska Natives), but the cost of testing, the vaccine cost, and the likelihood that the person will return for vaccination should be taken into account. Post-vaccination testing is not indicated because of the high rate of response to the vaccine. Furthermore, most anti-HAV testing methods licensed for use in the United States cannot reliably detect the low anti-HAV concentrations generated by immunization.

Vaccine Recommendations and Use

Recommendations for the use of hepatitis A vaccine were issued first by the ACIP (Table 180–3), the American Academy of Pediatrics, and other groups in 1996 and updated in 1999 and 2006.[4,46,51,53] As part of an incremental strategy aimed at achieving widespread routine vaccination, the 1999 recommendations called for routine vaccination of children living in areas where rates of hepatitis A consistently had been elevated (see Table 180–3). Various vaccination strategies that were suggested included vaccinating one or more single-age cohorts of children or adolescents, vaccinating children in selected settings (e.g., daycare), and vaccinating children and adolescents over a wide range of ages in a variety of settings, such as when they seek health care for other purposes. The final step in this incremental strategy, routine vaccination of children nationwide, was recommended by the ACIP in 2006.[46]

The impact of routine vaccination of children initially was shown in areas that historically have had the highest hepatitis A rates (e.g., Native American communities), where this strategy had been recommended since 1996. Surveys conducted in 1999 to 2000 indicated vaccination coverage of 50 to 80 percent of preschool- and school-age Native American and Alaska Native children, thus suggesting that the recommendation for routine vaccination was being implemented.[28] By 2000, the incidence of

TABLE 180–3 ACIP Recommendations for Routine Preexposure Use of Hepatitis A Vaccine

Group	Comments
All children at age 12-23 months*	Integrate into routine childhood vaccination schedule; children who are not vaccinated by age 2 years can be vaccinated at subsequent visits
Children aged 2-18 years	Maintain existing program†; can be considered in areas without existing programs
International travelers	Except persons traveling to Canada, western Europe, Japan, Australia, or New Zealand, who are at no greater risk than in the United States
Men who have sex with men	Includes adolescents
Illicit drug users	Includes adolescents
Persons with chronic liver disease	Increased risk of fulminant hepatitis A with HAV infection
Persons receiving clotting factor concentrates	
Persons who work with HAV in research settings	
Anyone wishing to obtain immunity	

**Hepatitis A vaccine is not licensed for children younger than 12 months.*

†States covered by 1999 ACIP recommendations (Alabama, Alaska, Arizona, California, Colorado, Idaho, Minnesota, Missouri, Nevada, New Mexico, Oklahoma, Oregon, South Dakota, Texas, Utah, Washington, Wyoming, and selected areas in other states).[51]

From Centers for Disease Control and Prevention: Prevention of hepatitis A through active or passive immunization. Recommendations of the Advisory Committee on Immunization Practices (ACIP). M. M. W. R. Recomm. Rep. 55(RR-7):1-23, 2006.

hepatitis A in Native Americans and Alaska Natives had declined by 97 percent compared with the beginning of the preceding decade and was the same as the overall U.S. rate.[28]

National surveillance data indicate that routine vaccination of children living in areas with consistently elevated rates, which was recommended in 1999, has had an impact on the overall incidence of hepatitis A in the United States. Since 2001, incidence rates in each successive year have been historic lows, with the 2004 rate of 1.9 cases per 100,000 population demonstrating a 79 percent decline compared with previous lows observed in the early 1990s (see Fig. 180–4). Rates declined most dramatically among children in parts of the country where routine vaccination of children was recommended and where the estimated coverage was highest.[341]

Vaccine coverage data are limited but indicate that declines in incidence have occurred with modest levels of coverage, suggesting a strong herd immunity effect.[5,75,275] Modeling studies suggested that 39 percent of potential cases were averted in 2001 because of the direct effects of immunization and herd immunity.[275] Similar observations have been made in Israel and Spain. The incidence of hepatitis A declined by 95 percent in Israel within 3 years after initiation of an immunization program among children 18 to 24 months old, even though no catch-up vaccination of other age groups was attempted.[75] Routine vaccination of 12-year-old children in Catalonia, Spain, was followed by a 58 percent reduction in overall incidence.[94] Hepatitis A incidence is cyclic, and data from additional years are needed to verify that low rates are sustained and attributable to vaccination and to provide a definitive determination of the overall impact of this strategy of routine childhood vaccination. However, the consistency and strength of these data render alternative explanations unlikely.

The data indicating that vaccination of children could have a powerful impact on incidence rates in all ages and the demonstration of vaccine safety and immunogenicity for children as young as 1 year were key factors supporting the decision to expand routine vaccination to all children aged 12 to 23 months in the United States. Economic analyses also were considered. One study estimated that routine vaccination given when children reached age 1 year in the United States would result in 183,806 fewer infections and 32 fewer deaths in a single U.S. birth cohort, with a cost-effectiveness ratio of $173,000 per life year gained and $24,000 per quality-adjusted life year gained.[266]

Vaccination of persons at increased risk of acquiring hepatitis A, including travelers to countries where hepatitis A is endemic, adolescent and adult men who have sex with men, persons who use illegal drugs, those who work with HAV in research settings, and persons who have clotting factor disorders, also is recommended.[46] Persons with chronic liver disease who acquire hepatitis A have been reported to have a high case-fatality rate and are recommended for vaccination also.[46]

Vaccination of successive cohorts of children eventually should result in a sustained reduction in the incidence of disease nationwide and thus provide the opportunity to eliminate HAV transmission. To achieve this goal, implementation of recent ACIP recommendations for vaccination of young children nationwide will be needed. Pediatric combination vaccines that include hepatitis A vaccine would facilitate this effort.

SUBSECTION 2

Caliciviridae

CHAPTER 181

Caliciviruses

David O. Matson

Caliciviruses currently include four genera that differ in genomic organization and phylogenetic comparisons of genomic sequence identity. Recent studies have blurred distinctions among the genera in the host of origin and ecologic relationships.

Caliciviruses were recognized to be distinct pathogens in 1932, when outbreaks of a vesicular exanthem restricted to domestic pigs occurred in California (vesicular exanthem of swine virus [VESV] infection, prototype of the *Vesivirus* genus of *Caliciviridae*).[12] The illness initially was thought to be foot-and-mouth disease of cattle, and the potential for confusion between foot-and-mouth disease and VESV in an era when rapid and definitive diagnostic assays were unavailable led to the designation of VESV as a foreign animal disease and to extensive programs to eradicate the agent. These programs continued for decades and had a major impact on the agricultural industry of the West Coast of the United States. VESV strains, when later visualized by electron microscopy, had distinctive and unique features that led to the name *calicivirus* (from "chalice," for the virion's surface cups). A program of sterilization of feed and restriction of feed types finally stopped the outbreaks in the 1950s. In the 1970s, the source of the outbreaks was suggested to be marine animals fed to pigs, especially fish meal.[243] The hypothesized existence of a close relationship between caliciviruses isolated from marine mammals and VESVs was proved by genome sequencing, which established that these caliciviruses have marine and terrestrial reservoirs.[203]

Caliciviruses in humans were recognized first in 1972, when viral particles were linked to an outbreak of gastroenteritis in schoolchildren, teachers, and their household contacts in Norwalk, Ohio.[4,137] The Norwalk agent (prototype of the *Norovirus* genus) was round and had a rough particle surface when visualized by electron microscopy, but these features did not permit any definitive classification to be made. Many similar small, round-structured viruses (SRSVs) were described subsequently from outbreaks of gastroenteritis around the world. A few experiments with these outbreak agents suggested that at least some of them had physical properties similar to those of the known animal caliciviruses.[136]

In the 1970s, investigators using electron microscopy to survey diarrhea stool specimens from children visualized particles that did not have the appearance of SRSVs but instead were similar to the animal caliciviruses previously identified.[6,165,185] These "typical" caliciviruses occurred in a small percentage of sporadic diarrhea stool specimens and in a few outbreaks of gastroenteritis, including an outbreak in an orphanage in Sapporo, Japan (prototype of the *Sapovirus* genus). Genomic sequencing has confirmed that the SRSVs and human viruses with typical calicivirus morphologic features are caliciviruses.[131,160,181]

In 1984, a highly fatal, highly contagious hepatitis was observed in European rabbits bred in China.[275] This syndrome spread some 7000 miles across Asia into Europe and reached Spain

within 4 years, a dispersal rate of approximately 5 miles (8 kilometers) per day in a sedentary host. European rabbit populations experienced mortality rates exceeding 90 percent within 3 days of exposure. Typical calicivirus particles were visualized in infected rabbit livers, and this calicivirus, the rabbit hemorrhagic disease virus (RHDV; prototype of the *Lagovirus* genus), eventually was linked to the syndrome.[209,215]

These summaries illustrate the diversity of the ecologic relationships of the caliciviruses, highlight the broad spectrum of illness (from mild gastroenteritis to fatal hepatitis) associated with members of the family, and indicate how recently many of these widespread caliciviruses have been discovered.

PROPERTIES OF CALICIVIRUSES

Evidence of human infection has been detected for each of the four calicivirus genera. Each genus is discussed, with special emphasis on human infection.

STRUCTURAL FEATURES OF THE VIRION

The *Caliciviridae* is a family of nonenveloped RNA viruses classified until 1978 within the *Picornaviridae*.[40] The caliciviral genome is a positive-sense, single-stranded RNA molecule of approximately 8000 nucleotides. Caliciviruses have a single structural polypeptide with a molecular weight of approximately 60,000 d. Typical calicivirus virion particles are 40.5 nm in diameter and have an icosahedral symmetry with 32 cup-shaped surface depressions (Fig. 181–1).[221] Distinguishing the identifying features of a calicivirus in a stool specimen is not always easy (see Fig. 181–1B). Staining of particles, particle integrity, and component debris vary among clinical samples. In one orientation, the surface cups combine to generate a Star of David image under the electron microscope (see Fig. 181–1C). In another orientation, the depressions are responsible for spikelike projections from the surface (see Fig. 181–1D).

Cryoelectron microscopy and x-ray crystallography have resolved the three-dimensional structure of typical and SRSV morphologic types.[35,219-222] Typical virion particles have 90 true arches protruding from the surface of a shell that has a diameter of 27 nm. When such particles are visualized by negative-stain electron microscopy, as in a clinical laboratory, the particles are smaller (30 to 35 nm) than the true 40.5 nm, presumably from desiccation. The arches form surface spikes in some particle orientations, and when the particles are rotated, the compressed two-dimensional image of the three-dimensional particle transforms the walls of the cup-shaped depressions into the distinctive Star of David appearance. SRSVs differ from typical caliciviruses in that they have shorter arches; otherwise, the structures of the two forms are similar.

TAXONOMIC RELATIONSHIPS AMONG THE CALICIVIRUSES

Recent decisions made by the International Committee on Taxonomy of Viruses include the separation of caliciviruses from picornaviruses in 1978,[40] inclusion of hepatitis E virus in the family in 1995,[46] recognition and naming of distinct calicivirus genera, separation of hepatitis E virus from the family in 1999,[15,83,85] and renaming of the Norwalk-like virus (now *Norovirus*) and Sapporo-like virus (now *Sapovirus*) genera in 2002.[182]

Phylogenetic evaluation of sequence identity among calicivirus strains sorts them according to the same four groups as does sorting by genomic organization (see later).[15] The most informative genomic region for classification of a strain within the family and within a genus is the capsid region, whereas the RNA polymerase gene is conserved sufficiently among the genera to blur distinctions. The strains fall into four genera; each genus also includes multiple clades of uncertain biologic significance (Fig. 181–2).

PROTOTYPE STRAINS AND HOSTS OF ORIGIN

The four calicivirus genera differ in genomic organization and degree of shared sequence identity (Table 181–1).[15,173] Strains commonly recovered from natural human gastroenteritis illness fall into two genera: *Norovirus*, a virtual synonym for SRSVs,

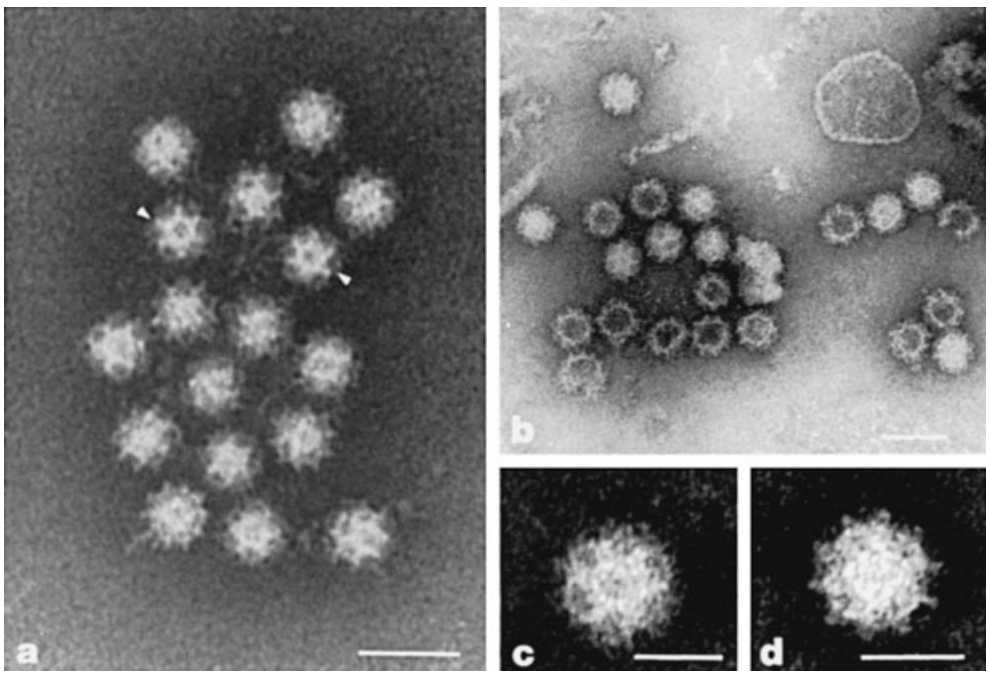

Figure 181–1 Human calicivirus particles visualized by electron microscopy. Particles in a preparation of a purified Sapporo/1982/Japan prototype strain show distinct surface cups, and the Star of David pattern is visible on some particles (**a,** *arrowheads).* Particle staining, particle type, and debris in clinical specimens are variable, which frustrates the recognition of distinct structural features. **b,** Specimen from a child from Houston, Texas, infected with an antigenically distinct *Sapovirus.* Two particles at high magnification show the Star of David pattern (**c**) and the 10 surface projections (**d**) characteristic of calicivirus (specimen from a symptomatic child attending a daycare center in Phoenix, Arizona). Bar in **a** and **b** = 50 nm; bar in **c** and **d** = 25 nm.

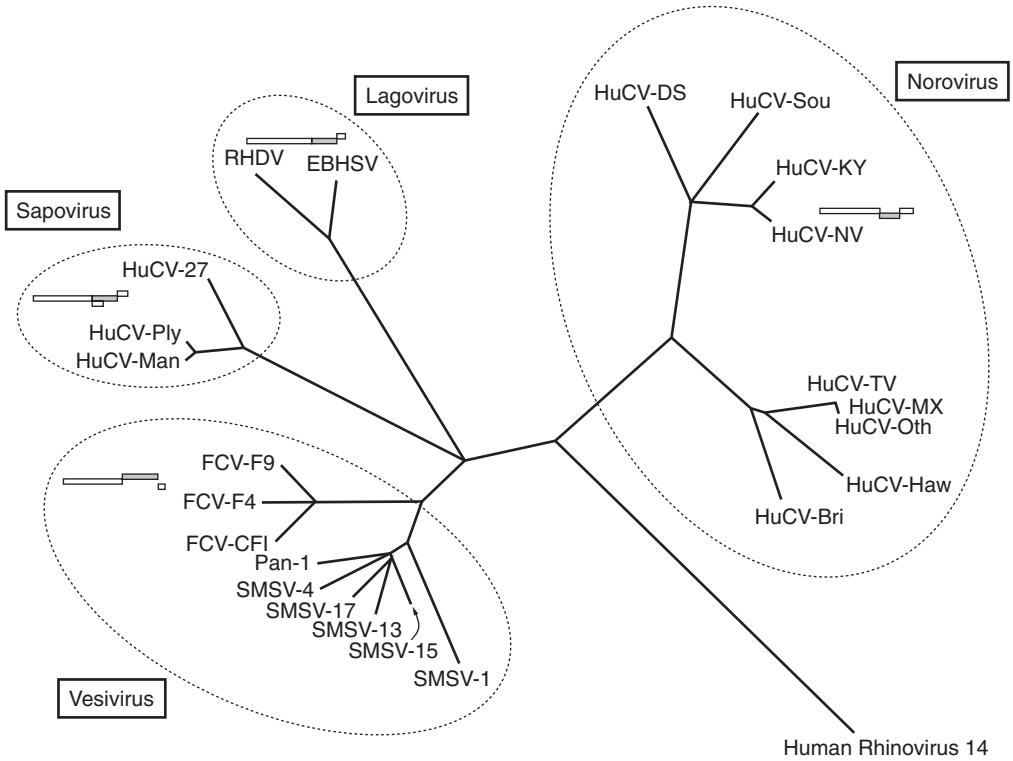

Figure 181–2 Distance tree (Fitch-Margoliash method) constructed from the capsid-region nucleic acid sequences of selected caliciviruses by use of 1000 bootstrapped dataset replications and the computer program FITCH of PHYLIP 3.5c. The branch points indicated are those appearing in more than 95 percent of the bootstrapped trees. Ovals indicate strains with a common genomic organization. Rhinovirus 14 is included as an outgroup. *(From Berke, T., Golding, B., Jiang, X., et al.: Phylogenetic analysis of the Caliciviruses. J. Med. Virol. 52:419-424, 1997.)*

TABLE 181–1 Genera of Human and Animal Caliciviruses

Genus	Known Hosts	Examples
*Norovirus**	Human, cow, pig	Norwalk and Snow Mountain viruses; Jena virus (bovine)
*Sapovirus**	Human, pig	Sapporo caliciviruses 82/Japan, 86/Houston, 90/Houston; Manchester and Plymouth viruses; porcine enteric calicivirus
Lagovirus	Rabbit, hare? pig? dog? human? fox? mouse? bird?	Rabbit hemorrhagic disease virus of Europe, Asia, Australia, New Zealand; European brown hare syndrome virus
Vesivirus	Pig, cat, chimpanzee, sea lion, dolphin, mussel, sea otter, raccoon, Aruba Island rattlesnake, human	A48; feline caliciviruses F4, CFl, F65, F9; Pan-1, Tur-1; San Miguel sea lion virus types 1 to 17; SMSV-5 Hom-1

**Previous names of these genera were Norwalk-like and Sapporo-like viruses; synonyms for* Norovirus *and* Sapovirus *were small, round-structured viruses and typical caliciviruses, respectively.*
Data from references 15, 83, 242, 244.

which include the Norwalk virus and Snow Mountain virus prototypes, and *Sapovirus*, a virtual synonym for typical human caliciviruses. The genera of common animal caliciviruses include *Lagovirus* and *Vesivirus*. *Lagovirus* prototypes include RHDV and European brown hare syndrome virus. *Vesivirus* prototypes include VESV; feline calicivirus, a cause of hemorrhagic pneumonia in cats; and other strains of marine and terrestrial animal origin. Additional genera may exist because many clinical specimens contain virus particles with structural features of caliciviruses that have been resistant to genomic characterization.

The perceived restriction of *Norovirus* and *Sapovirus* infections to humans has been broken by the finding of Newbury agent and Jena virus, noroviruses of cows, and porcine enteric calicivirus (a *Sapovirus* of pigs).[53,57,68,95,161] In addition, evidence of *Vesivirus* infections in humans is conclusive, although the spectrum of illness remains uncertain. The *Vesivirus* San Miguel sea lion virus serotype 5 (SMSV-5) produced blisters on the extremities of a laboratory worker, an illness similar to that observed in the original sea lion host.[244] Similar, less conclusive cases of *Vesivirus* illness also have occurred in field biologists working with marine mammals, anti-*Vesivirus* antibody has been detected in association with non-A-G hepatitis in humans, and *Vesivirus* genome has been detected in the blood of asymptomatic donors.[245] Other *Vesivirus* strains have caused illness in several primate species.[251] Evidence of *Lagovirus* infection in humans is suggestive. Antibody developed in one person exposed to the *Lagovirus* RHDV in a Mexican outbreak.[87] A case-control study of exposure and prevalence of antibody to RHDV in Australia after continent-wide escape of the virus from Australian Animal Health Laboratory facilities suggested that subclinical human infection was a common occurrence in persons with certain rabbit exposure,[173] although this conclusion is controversial.[23,24,186,249]

GENOMIC ORGANIZATION

The genomic organizations among calicivirus genera differ in the number and size of open-reading frames (ORFs), the presence of certain genes, and the need for post-translational cleavage for gene product function (Fig. 181–3).[25,59,131,160,188,226] The genome

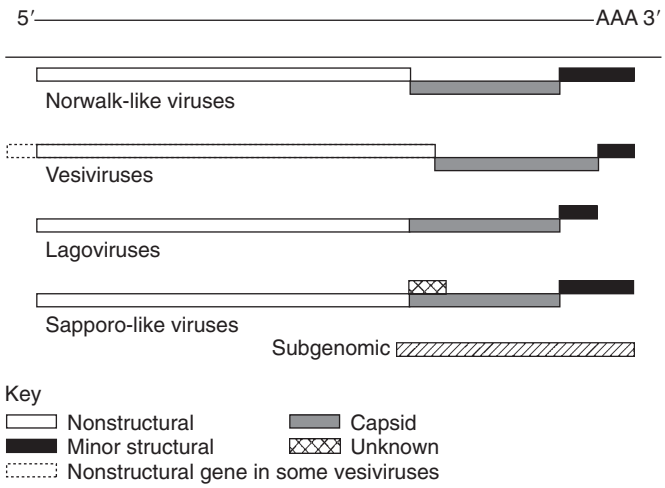

Figure 181–3 Genomic organization of calicivirus genera. The genome of *Norovirus* has three open-reading frames (ORFs) that in the 5′ to 3′ direction include a nonstructural polypeptide, the virion capsid gene, and a minor structural protein. The genomes of the other three genera differ from that of noroviruses in the length of the ORFs, including a unique gene at the 5′ end of ORF1 in some vesiviruses and a post-translationally cleaved N terminus of the capsid protein in vesiviruses and sapoviruses. A subgenomic RNA beginning just 5′ of ORF2 and continuing to the poly-A tail is synthesized during replication. Some sequence comparisons suggest that the longer ORF3 of *Norovirus* (and the comparable gene of *Sapovirus*) arose by intragenic recombination.

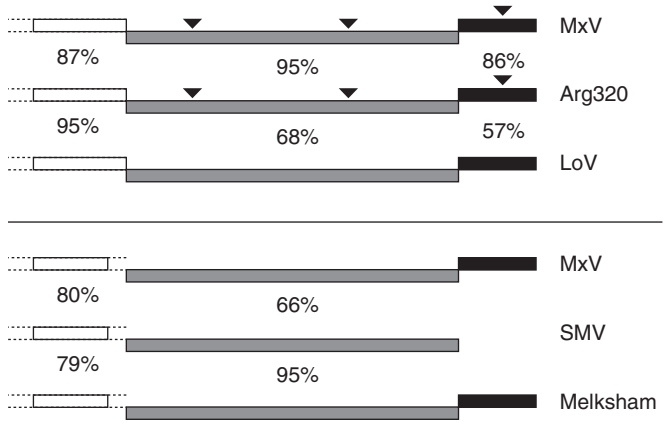

Figure 181–4 Sequence comparisons of Argentine calicivirus strain 320 (Arg320; *top*) and Snow Mountain virus (SMV; *bottom*), each with two other noroviruses. Arg320 is significantly closer to Lordsdale virus (LoV) than to Mexico virus (MxV) in the RNA polymerase genome region and significantly closer to MxV than LoV in the capsid and ORF3 genes. Deletions or insertions in the capsid and ORF3 genes of Arg320 are shared with MxV but not with LoV. SMSV is equally close to MxV and Melksham virus in the known polymerase region but much closer to Melksham than MxV in the capsid region. The ORF3 sequence is not available for SMV. Box shadings are as in Figure 181–3. *(Data from references 104 and 125.)*

of noroviruses has three ORFs. ORF1 encodes a polyprotein cleaved during replication into a set of nonstructural proteins, ORF2 encodes the capsid protein, and ORF3 encodes a protein that appears to be a minor structural protein.[253] Vesiviruses differ from noroviruses in that a longer genome is present in some vesiviruses (e.g., Pan-1)[226] but not in others (e.g., feline calicivirus)[25] and a longer ORF1 with an additional predicted protein is found at the N terminus. The ORF2 of vesiviruses is longer than that of noroviruses, with the extra nucleotides at the 5′ end of ORF2.[226] This extra sequence encodes a protein fragment that must be post-translationally cleaved to agree with experimental data of *Vesivirus* virion structure.[221] The ORF3 of vesiviruses (~120 amino acids) is approximately half the size of that of noroviruses (250 to 275 amino acids). In lagoviruses and sapoviruses, the genes found in the ORF1 and ORF2 of noroviruses and vesiviruses are fused into one longer ORF1. A gene comparable to that of ORF3 of noroviruses also is present. An ORF in another frame at the 5′ end of the capsid gene occurs in sapoviruses but not in all *Sapovirus* strains. ORF2 and ORF3 genes are included in a subgenomic RNA that is conterminal with the genomic RNA. Consensus amino acid motifs encoded within the proteins are markers for enzymatic and structural functions (2C, 3C, 3D, and PPG) shared with picornaviruses and other viruses with a single-stranded RNA genome.

Each completely sequenced *Norovirus* genome exhibits conservation of the 5′ end nucleotide sequence of the genome and the 5′ end of the capsid gene. This sequence conservation is high within the same strain and among strains in the same genus.[149,174] The conserved sequence also probably favors recombination of RNA among calicivirus strains. The conserved sequence surrounding the consensus amino acid motifs is a target for primers to initiate reverse transcriptase in reverse transcription–polymerase chain reaction (RT-PCR) detection assays that rely on amplification of the viral RNA.[130]

RECOMBINANTS

EVIDENCE FOR RECOMBINATION WITHIN CALICIVIRUSES. With the description of statistically distinct phylogenetic clades within calicivirus genera, data were available to recognize strains that might be natural recombinants within caliciviruses. Two examples are the well-characterized Argentine strain 320 (Arg320) and the prototype Snow Mountain virus, recognized to be recombinants when the RNA polymerase and capsid regions of these strains were characterized (Fig. 181–4).[104,125] In both strains, the change in relative sequence identity took place at the ORF1/ORF2 junction, where sequence conservation at the 5′ end of the genome also occurs (see earlier), thus indicating that the recombination site occurred there. This site also was suggested (see later) to be the break-and-rejoin site for recombination between caliciviruses and picornaviruses. For Arg320, the ORF1 sequence was closest to the Lordsdale virus, a contemporaneously circulating strain, and the capsid and ORF3 sequences were closest to Mexico virus, also prevalent when Arg320 was collected. A similar change in relative sequence identity also occurred with Snow Mountain virus, which was detected when partial polymerase and capsid sequences were compared with reference Mexico and Melksham viruses, again strains circulating at the same time.

Except for the recombinant genomic structure, the recombinants otherwise are unremarkable, and the strains were recognized only because they initially were characterized in two genomic regions. Recombination may be a mechanism by which caliciviruses quickly escape host immunity, analogous to antigenic shifts in influenza viruses but by a different molecular mechanism. The recombination event could have occurred recently or remotely in the past.

POTENTIAL ORIGINS OF RECOMBINANTS WITHIN CALICIVIRUSES. Generation of recombinants within caliciviruses requires certain biologic and molecular attributes. Infection of single cells simultaneously by two caliciviruses implies an absence of immune or molecular interference. Outbreaks caused by multiple *Norovirus* strains and co-infection with different

Norovirus strains do occur.[70,74,80,103,179,256] Calicivirus RNA also must have attributes that permit or favor recombination, such as a site where errors in procession of RNA polymerase can occur. The subgenomic RNA is the molecule most likely to participate in recombination because of its relatively high copy number in infected cells and because it would have an accessible end. The highly conserved 5′ end sequence of the genome and the 5′ end of the capsid gene in noroviruses is an obvious common target for calicivirus RNA polymerase to switch from one RNA molecule to another. The recognized recombinants may be a subset, those viable, among a larger set of recombinant molecules produced during replication.

EVIDENCE FOR RECOMBINATION OF CALICIVIRUSES WITH OTHER VIRUS FAMILIES. After sequencing a portion of feline calicivirus strain F9, Neill[202] observed that ORF1 contained significant sequence identity with picornaviruses. This significant identity was concentrated around certain amino acid motifs within ORF1 that are homologous to those within the nonstructural region of picornaviruses and encode, in order, the 2C, 3C, and 3D genes. The order of these motifs and the approximate number of nucleotides between them were the same in both virus families (Fig. 181–5). The capsid gene of caliciviruses also is homologous to the VP1 to VP4 capsid proteins of picornaviruses to the extent of a shared PPG amino acid motif in a relatively conserved 5′ portion of the capsid gene or genes, formation of capsomeres having polypeptide β-pleated sheets as a core structural element, and formation of a spherical virion capsid by the protein or proteins.[219] The reversal of order of these major domains in the genomes of the two virus families led to the hypothesis that at some point in time, the caliciviruses and picornaviruses were "recombination partners."[60]

ANTIGENIC PROPERTIES OF THE VIRION

The presence of a single calicivirus capsid protein ought to limit the antigenic complexity of the virion. Despite this limitation, circulating caliciviruses are highly diverse (e.g., see Hohdatsu and colleagues[108]). Assays to detect viral antigen and antiviral antibody have been developed for prototype strains of the genera and for distinct genetic clades within them.[97,123,132,197] Within the limits of testing, analysis of convalescent and hyperimmune antisera does not detect strains across generic boundaries, thus suggesting that different genera represent distinct antigenic groups. Furthermore, epitopes not shared across phylogenetic clades within a genus have been identified.[100,129,276,277]

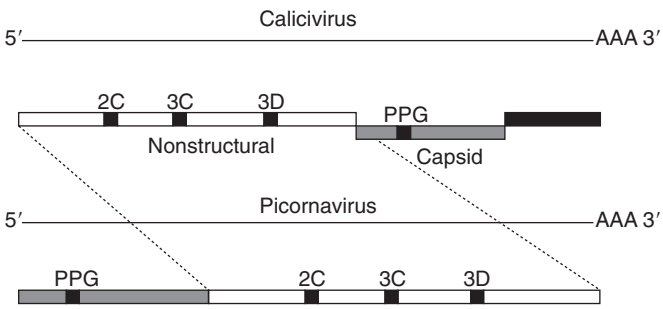

Figure 181–5 Genomic organization of caliciviruses and picornaviruses showing the switch in order of nonstructural and structural genes. In caliciviruses, the nonstructural genes are encoded in ORF1; several of the genes were recognized because of the presence of significant sequence identity and consensus motifs like those known for picornaviruses (2C, 3C, and 3D). The capsid gene of caliciviruses is encoded in ORF2 (noroviruses and vesiviruses; see Fig. 181–3), which lies 3′ to the nonstructural genes, and is marked by a PPG motif that signals a relatively conserved region between the families. In picornaviruses, this order of nonstructural-structural "gene cassettes" is reversed, with the order and approximate distance of motifs within the nonstructural peptide the same. Box shadings are as in Figure 181–3.

Many vesiviruses can be cultivated readily in cell culture, whereas cultivation of viruses in the other genera has been successful for only a few strains.[68,242,247,251] The vesiviruses include a large number (>40) of serotypes (neutralization types).[242] Similarly, characterization of lagoviruses suggests the existence of serotypes.[205,272] Determination of whether the other genera have similar diversity has not been possible because of the lack of ability to test strains for their neutralization characteristics. Antigenic characterization of caliciviruses is at a primitive level of development.

NOROVIRUS AND *SAPOVIRUS* HUMAN CALICIVIRUSES

Noroviruses and sapoviruses share a number of properties. To avoid repetition, I discuss features common to the genera under each of the following headings and then those distinct to each genus.

EPIDEMIOLOGY

General Prevalence

Serologic studies indicate that *Norovirus* and *Sapovirus* infections occur commonly, with virtually all individuals having antibody by the time they reach the second decade of life, wherever studied. Noroviruses and sapoviruses have been found everywhere that they have been sought and probably have a worldwide distribution. Strains from multiple genetic clades and antigenically distinct strains within each genus co-circulate wherever it has been studied.[124,279] In the same way, regional differences exist in the prevalence of antibody to specific types and in the number and distribution of the genogroups and sub-genogroup clades.[71,72,81,110,166,206,208,260]

Noroviruses are known best for causing outbreaks of gastroenteritis in adults, commonly associated with contaminated water and food, particularly shellfish. Noroviruses account for approximately 60 percent of such outbreaks in North America and Europe for which no bacterial or parasitic cause can be found.[63,86,107,120,147,148,191] Studies suggest that large changes in the relative prevalence of *Norovirus* clades have occurred during the past 30 years. For example, prototype Norwalk virus and closely related strains appear to have been the predominant noroviruses in the 1970s in several regions studied.[86] Thereafter, Snow Mountain virus and related strains (in a separate genetic clade within *Norovirus*) have been predominant, and strains within the clade that contains the prototype Norwalk virus are found infrequently (<5%).[82,128,129,172,260,268] In addition, some *Norovirus* strains appear to prevail within a community for as short a time as 1 year.[121,166] The causes of such temporal variation are uncertain, but they at least are related to widespread distribution of contaminated foodstuffs or water (or both) in a pattern like that observed for *Salmonella*.[102,180] This epidemiologic pattern also suggests the existence of type-common neutralizing epitopes; for individual antigenic types, each causes only a small percentage of illness episodes in a region at any time. Contamination events, in which a single type is delivered across a large geographic region in a short period with an inoculum large enough to overcome (mild) host resistance, would thus be needed for any one antigenic type to be predominant. Such predominance would be of short duration.

Recombinant norovirus Arg320 and Snow Mountain virus first were recovered from persons with gastroenteritis in Argen-

tina and the United States, respectively.[125,136] Arg320 also was recovered from outbreaks of gastroenteritis in the United States[132] and the Netherlands.[146] Snow Mountain–like strains occur worldwide. The widespread occurrence of these recombinants in symptomatic persons suggests their ready infectivity, easy transmissibility, sustained virulence after multiple passages in humans, and genetic and ecologic stability.

Unlike the noroviruses, sapoviruses are known primarily from sporadic cases of diarrhea in children, although outbreaks in closed populations do occur.[36,37,45,124,132,200] The proportion of outbreaks traced to sapoviruses probably will increase as improved methods for detection of them are applied. Typical caliciviruses visualized in stool specimens by electron microscopy but not yet further characterized probably fall into this genus.[43-45,50,185,210]

Morbidity and Mortality

Cross-sectional surveys of diarrhea stool specimens from children or adults yield *Norovirus* in 0.5 to 16 percent of samples, with the higher values reported by recent studies and achieved by applying more sensitive detection methods.[55,56,143,167,207,212-214,224,279] Attack rates in outbreaks frequently are high: 20 to 90 percent. These observed attack rates for outbreaks are similar to those from volunteer studies involving a single (low) inoculum of the Norwalk virus 8FIIa prototype, in which 82 percent of volunteers were infected and 56 percent were ill.[79] Secondary attack rates in common-source outbreaks range from 5 to 30 percent.[78] A general tendency is that noroviruses are detected more frequently in cross-sectional studies of subclinical or moderately severe illness than in episodes resulting in hospitalization; this trend is the reverse of that observed for rotaviruses, which are detected more frequently in more severe illness.[213,279] Death from *Norovirus* illness rarely occurs. Cross-sectional studies in adults show noroviruses to be comparably prevalent, although studies from severely ill adults are conspicuously absent.[56,144,169,229] In adults, the severity of *Norovirus* infections often is greater, and this trend is in part a consequence of an unusual pattern of protective immunity observed for these strains (see later).

Like noroviruses, sapoviruses are identified more frequently in less severe gastroenteritis episodes than in cases resulting in hospitalization. Cross-sectional surveys of gastroenteritis in nonhospitalized children have found sapoviruses in as many as 20 percent of cases.[172,201,207,228,267] Similar studies of hospitalized children have found sapoviruses in as many as 5 percent of acute gastroenteritis episodes.[279] Death from *Sapovirus* infection is rare but does occur.[67]

Age Incidence and Prevalence

Norovirus infections in developed countries generally have been thought to occur in individuals aged 4 years or older. This conclusion was derived from comparative serologic studies that revealed large differences in patterns of acquisition of age-specific antibody between developing and developed countries. For example, in Bangladesh, the prevalence of antibody in 4-year-old children was 100 percent, as opposed to a prevalence of 19 percent in children of the same age in the United States.[16,138] In addition, studies of outbreaks suggested that young children in developed countries were spared.

More recent studies using more sensitive assays have changed these conclusions. For example, among 154 infants aged 23 months who participated in a vaccine trial in Finland from 1987 to 1989, 73 percent had anti–Norwalk virus antibody.[157] In England, the prevalence of antibody to Norwalk virus in 1991 and 1992 was 48 percent in 1-year-old toddlers overall, with the prevalence in that age group ranging from 12 to 60 percent in different regions.[81] In South Africa, antibody prevalence in 1992 was 57 percent in 1-year-old children.[260] These results contrast with those from Hokkaido, Japan, where the prevalence of antibody to Norwalk virus in children aged 1 to 3 years was approximately 6 percent.[206] In England and Japan, but not in South Africa, a significant increase in the prevalence of antibody to Norwalk virus was noted in school-age children, in whom it reached 80 percent in England and 70 percent in Japan by the time they reached the third decade of life.

Children are likely to be infected with multiple *Norovirus* types.[47,179] Testing of a large population-based collection of sera from two cities in Chile for antibody to prototype Norwalk virus and Mexico virus (a Snow Mountain–like *Norovirus*) suggested that these two viruses had different modes of transmission and that exposure to the two types differed in that population.[208] For example, the overall prevalence of antibody to Norwalk virus was 83 percent and that to Mexico virus was 91 percent in this age-stratified sample of persons living in Santiago, whereas it was 67 percent and 90 percent, respectively, in Punta Arenas ($p < .001$ for antibody to Norwalk virus). Consumption of uncooked vegetables was an independent risk factor for the acquisition of antibody to both viruses in Santiago but only for Mexico virus in Punta Arenas. Consumption of seafood and attendance at childcare centers were independent risk factors for the acquisition of antibody to both viruses in Punta Arenas but not in Santiago. Results of this kind, to which attributes of the person providing serum, other than just age and location, are matched to the results of antibody testing, are needed for a more complete understanding of the modes of transmission and ecologic differences among calicivirus genera. The large differences in the prevalence of age-specific antibody among and within countries suggest that "herd immunity" to neutralizing epitopes specific to such clades can develop in populations. Such differences also suggest that the acquisition of antibody is the result of selected, variable, and cumulative exposure, such as from multistate and multicontinent movement of strains in contaminated food.[5,133,153,231]

Serologic studies confirm that children acquire *Sapovirus* infection soon after birth and that virtually all are infected by the time they reach 4 years of age.[48,198,233] Children are infected with multiple *Sapovirus* types during this period.[48,177,178] Outbreaks have been described in infants, young children, and adults.[107] The prevalence of antibody to sapoviruses exceeds 70 percent in adults studied in Asia, Australia, Africa, Europe, and North America.[48,198,214]

Norovirus and *Sapovirus* outbreaks tend to be recognized in closed populations where common exposure occurs, such as nurseries, childcare centers, schools, hospitals, camps, hotels, and ships.* Outbreaks in young adults in military camps and on deployment, especially navy ships, are a special example because of the often increased severity of *Norovirus* illness in young adults.† Vehicles of infection in outbreaks include water from regulated and unregulated delivery systems and foods commonly washed, such as salad and fruit.‡ Shellfish are a frequent source of infection. Person-to-person spread also occurs. New infections can occur during the course of several weeks, with the longest outbreak lasting 3 months. Such prolonged or repeated outbreaks have been associated with persistent asymptomatic excretion in food handlers, continual surface contamination at the site, and re-exposure to the same strain from contaminated foods.[33,36,49,52,76,258,273]

Seasonal Patterns

Both sporadic and outbreak-associated *Norovirus* infections have a winter seasonality (Fig. 181–6).[84,195,279] This trend

*See references 33, 36, 83, 170, 178, 179, 199, 224, 240, 266.
†See references 1, 2, 8, 9, 17, 32, 38, 41, 89, 119, 167, 175, 184, 211, 234, 240, 241, 262.
‡See references 3, 6, 19, 20, 42, 43, 65, 88, 92, 154, 164, 196, 227, 270.

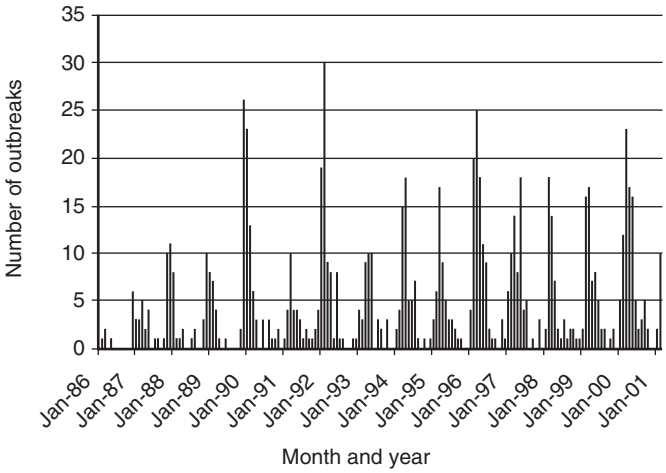

Figure 181–6 Seasonality of 840 presumed viral outbreaks in nursing homes for the elderly in Maryland, 1986 to 2000. Detailed analyses of 20 outbreaks found noroviruses in 18. *(Data extracted from Figure 1 in Green, K. Y., Belliot, G., Taylor, J. L., et al.: A predominant role for Norwalk-like viruses as agents of epidemic gastroenteritis in Maryland nursing homes for the elderly. J. Infect. Dis.* 185*:133-146, 2002.)*

has exceptions, however. Infections related to certain foodstuffs will occur when such foodstuffs are harvested and eaten fresh (fruit, salads, shellfish) or processed, shipped, and consumed later (frozen fruits, ice). Infection from exposure related to certain types of recreation, such as swimming, should have a seasonal predominance. In addition, contamination of water supplies should occur more frequently when flooding results in mixing of water and sewage and when shellfish are harvested.[98,183,187,217,236]

A distinct seasonal prevalence of *Sapovirus*-associated illness is not as apparent, but a winter predominance is suggested from several studies.[177,214,279]

PATHOGENESIS AND PATHOLOGY

Viral Infection

The incubation period after exposure to *Norovirus* ranges from 10 to 51 hours, with a mean of 24 hours.[37,79,139,178,261,274] Illness usually lasts 2 to 3 days.[79] Excretion begins as early as 15 hours after the development of infection, peaks at 25 to 72 hours after infection occurs, and persists at least 7 days. Transmission of infection occurs by fecal-oral spread. Noroviruses also have been detected in vomitus, thus suggesting the possibility of spread by aerosol or dispersion of vomitus particles.[27,28,141,235]

Some volunteers administered Norwalk virus 8FIIa prototype had no response, neither illness nor evidence of infection, to the inoculum. These nonresponders have B blood type.* Results from binding assays support the role of complex sugar structures that determine blood-type specificity in *Norovirus* virion attachment. The absence of these cell surface structures prevents illness because the cell is not infected. In at least one instance, this resistance has been traced to a single amino acid change in a vital protein.[263] These findings complement those suggesting that certain ethnic groups are inherently resistant to infection.[62]

Similar information about sapoviruses is lacking.

*See references 66, 105, 106, 111, 112, 114, 115, 117, 118, 126, 127, 155, 159, 168, 192, 194, 230, 259.

Pathology

The pathogenic features of *Norovirus* infection have not been determined. The following information is based on studies of porcine and calf enteric caliciviruses.[30,34,69,96,101,230] Enteric animal caliciviruses cause lesions in the proximal portion of the small bowel. The first day after inoculation, enterocytes swell along the sides of the microvilli at the base. Damaged enterocytes subsequently slough, with stunted villi left behind. The adjacent villi fuse, which helps maintain the integrity of the intestinal mucosa. Neutrophils and mononuclear cells infiltrate the epithelium. The peak of pathologic abnormalities is 3 to 7 days after inoculation occurs, at which time gradual healing begins, with normal villus architecture being restored approximately 10 days after inoculation. Mucosal injury is accompanied by deficiencies of β-galactosidase activity and D-xylose absorption. The capacity for D-xylose absorption recovers by the time the normal histologic appearance of the villi is restored, but the β-galactosidase deficiency is delayed for an unknown period thereafter. Individual responses to inoculation vary in both the distribution and severity of lesions.

Prototype Norwalk virus causes similar histologic abnormalities, also located in the proximal part of the small bowel.[237,238,271] However, the abrupt onset of illness in adults and the consistent finding that individuals with antibody are more likely to be ill than are individuals lacking antibody suggest that an immune mechanism plays a role in illness.[145,158]

The pathogenic features of *Sapovirus* calicivirus infection in humans have not been determined and are presumed to be the same as those for *Norovirus* caliciviruses.

Immunologic Events

The humoral immune responses to *Norovirus* and *Sapovirus* infection are like those for infection with other virus. Individuals lacking antibodies show a rapid rise in the titer of serum and fecal antibody that persists for months, and individuals with high serum antibody levels are unlikely to mount an antibody response when they are re-exposed to the virus. Children with anti-*Norovirus* or anti-*Sapovirus* antibody appear to be protected against subsequent infection, at least in the short term.[49,64,157,158,200] A striking and consistent observation is that adult volunteers inoculated with noroviruses who have higher levels of preexisting serum or fecal antibody are more likely to excrete virus or to be ill than are individuals who have low or no preexisting antibody.[79,216] The mechanism for this apparent conflict is unknown, but the usual observation is that serum or fecal antibody is a marker for protection against infection. Likely, the assays used to assess protective status measure predominantly cross-reacting, non-neutralizing antibody induced by multiple exposures, rather than the specific, neutralizing antibody needed for protection.

When the symptom profile of 50 Norwalk virus volunteers was assessed, the increased risk of being symptomatic with higher preexisting antibody titers was statistically significant for ill subjects who had vomiting as the predominant clinical feature.[79] Because vomiting in the gastroenteritis syndrome may result from a process different from that causing diarrhea, this observation suggests an alternative pathogenic mechanism peculiar to the noroviruses. The existence of such an alternative pathogenic mechanism would explain the unusual observation that age-specific morbidity tends to be greatest in adults. One issue unresolved from these studies is whether the antibody assays used in these volunteer studies measured neutralizing or non-neutralizing anti–Norwalk virus antibody. Moreover, asymptomatic infection apparently can occur independent of the absence of attachment structures related to blood type.[79,116]

CLINICAL MANIFESTATIONS

The clinical manifestations of *Norovirus* and *Sapovirus* are those of acute gastroenteritis.[79,136,232,264] In 50 adult volunteers inoculated with Norwalk virus, diarrhea was noted in 59 percent, nausea in 66 percent, cramps in 66 percent, headache or body ache in 66 percent, vomiting in 39 percent, chills in 24 percent, and fever in 22 percent.[79] This constellation of common symptoms is indistinguishable from those associated with other gastroenteritis pathogens. As is the case for most other viral pathogens, most *Norovirus* and *Sapovirus* infections are likely to be asymptomatic. Extraintestinal infection caused by noroviruses and sapoviruses is unknown. Protracted illness can occur in individuals with immune compromise.[73]

In 154 hospitalized children with calicivirus infection, vomiting was present in 120 (78%) patients, diarrhea in 102 (66%), and fever in 82 (53%).[279] The prevalence of these symptoms was similar in *Norovirus*- and *Sapovirus*-associated illness. Fever was noted more commonly (76%) in patients younger than 3 months than in older children (45%, $p < .001$). Similarly, vomiting occurred more commonly (86%) in older patients than in patients younger than 3 months (56%, $p < .001$). The median duration of symptoms was 1 day for vomiting (median number of episodes, 6 per day; range, 1 to 35 per day), 2 days for diarrhea (median of 6 stools per day; range, 1 to 50), and 1 day for fever. Conditions associated with hospitalization in these 154 children included dehydration ($n = 42$, 27%), respiratory symptoms ($n = 15$, 10%), and seizures ($n = 6$, 4%). Metabolic acidosis ($n = 2$), hypoglycemia ($n = 1$), and hypocalcemia ($n = 1$) were rare findings. The median cost for an episode of calicivirus-associated illness in these children was $3574 (1999 dollars), more than 90 percent of which was for the cost of hospitalization. These 154 hospitalized children had 191 visits to a physician's office and 45 visits to an emergency department, in addition to the hospital stay.

In direct comparison to rotavirus infection, *Norovirus*- and *Sapovirus*-associated illness was a mean of 2 points, of a 20-point score, less severe than rotavirus-associated illness.[214,279] Younger children (<3 months) had less severe illness than older children did ($p = .006$). The combination of vomiting, diarrhea, and fever occurred more frequently (58% of cases) in rotavirus-associated illness than in calicivirus-associated illness (23%, $p < .001$). Coinfections with rotavirus increased the severity of calicivirus-associated illness. Children hospitalized for rotavirus illness were older (median age, 408 days) than those hospitalized for calicivirus illness (median age, 257 days; $p < .001$).

Sapovirus illnesses also usually are indistinguishable from those caused by other gastroenteritis pathogens. A few children who were studied intensively after they were hospitalized for *Sapovirus* illness had prolonged malabsorption, frank rectal bleeding, severe dehydration and acidosis, and transient leukopenia. Three children with combined immunodeficiency and *Sapovirus* infection early in life that resulted in chronic diarrhea and death have been described.[18,43,73] Sapoviruses have been the only identified pathogen in the stool specimens of a few children who died of gastroenteritis, but little information describing the illness or the pathologic findings in these children has been reported.[43,67]

DIAGNOSIS

Differential Diagnosis

Recognized outbreaks of calicivirus infection have tended to be associated with a rapid onset of symptoms and a broad age range of affected persons, especially if they are associated with common exposure to water or food. The pattern of symptoms is a fairly good marker for calicivirus-associated outbreaks: a brief duration of illness, 2 to 3 days; vomiting as a prominent symptom in more than 50 percent of the outbreak cases; an incubation period of 24 to 48 hours; a high (30%, usually > 50%) secondary attack rate; and cultures of freshly processed stool specimens negative for bacterial, parasitic, or fungal pathogens.[99,140,162] When outbreaks have such characteristics, noroviruses will be detected in more than 80 percent of them. Sapoviruses have been detected with current diagnostic techniques in approximately 3 to 5 percent of such outbreaks. Stool samples should be submitted to a facility skilled in using individual assays for these pathogens. Caliciviruses are destroyed by repeated freezing and thawing.[45,113] Therefore, bulk stool samples stored at 4° C and not frozen should be collected early after the development of infection and referred promptly. Consultation with the reference laboratory should precede sample referral.[156]

Specific Diagnosis

Detection methods relying on target nucleic acid amplification are needed for noroviruses and sapoviruses because virus is excreted in stool in low concentration, rarely exceeding 10^6 particles per gram of stool. In addition, assays for antigen detection are relatively specific; they apparently do not detect group-specific epitopes on the viruses, and the sensitivity of commercial assays is approximately a third that of RT-PCR for noroviruses in outbreak or cross-sectional collections.[26,54,58,77] Only a few laboratories routinely perform calicivirus detection assays, and some strains are not detected by the best designed consensus primer oligonucleotides because of genomic sequence diversity among strains.* RT-PCR amplicons from the viral RNA polymerase genomic region are produced most reliably, but conservation among strains within and between genera in this region is sufficiently strong to warrant caution in assigning causality of an outbreak of illness to a particular strain based on the sequence of the (frequently small) amplicons from this region.[14,15] Paired serum samples may be required to detect and to confirm the presence of an etiologic agent.

VESIVIRUS CALICIVIRUSES

EPIDEMIOLOGY

General Prevalence

Vesiviruses include a large number of serotypes isolated from many different animal hosts, including pigs, cows, cats, dogs, sea lions, sea otters, walruses, whales, several snakes, pygmy chimpanzees, and gorillas, as well as a few isolates from humans.[13,61,75,171,242-244,252] These viruses probably have a worldwide distribution in terrestrial and marine environments, although studies of San Miguel calicivirus–like strains are lacking outside North America. Vesiviruses include at least 40 neutralization types (serotypes). The prevalence of these serotypes in different regions has had little study.

Morbidity and Mortality

Vesiviruses cause a variety of severe illnesses in animals. The morbidity and mortality rates of individual strains differ from species to species in experimental infections. One laboratory worker was infected with SMSV-5 and experienced an influenza-like illness, followed during the next several days by viremia and vesicular exanthem similar to that observed in the original pin-

*See references 29, 93, 94, 109, 123, 129, 130, 135, 163, 190, 223, 225, 269, 278, 279.

niped host.[244] SMSV-5 was visualized in vesicular fluid by electron microscopy and was cultured from the lesions; the genome was amplified and sequenced. The worker also mounted a greater than fourfold serum neutralizing antibody response to SMSV-5. Biologists working with marine mammals had similar illnesses but were studied less intensively than was the laboratory worker.[12,244,248] Anti-vesivirus antibodies have been detected in 12 percent of normal blood donors, at higher prevalence (21%) among otherwise normal donors with elevated serum levels of liver transaminases, and at highest prevalence (47%) among patients with hepatitis associated with blood exposures.[245] Some persons in the groups with normal and elevated transaminase levels also had *Vesivirus* RNA circulating in the blood.

Host and Social Factors

Although vesiviruses cause a variety of diseases, only a few cause gastroenteritis, a feature common to *Norovirus* and *Sapovirus* caliciviruses.[51] Among the vesiviruses are a number that exhibit a broad range of hosts. For example, SMSV-5 has been found to infect sea lions, seals, opaleye fish, pigs, cattle, and laboratory workers.[242,250]

PATHOGENESIS AND PATHOLOGY

Viral Infection

Vesiviruses cause infection on mucosal surfaces (pneumonia, aphthous ulcers) and disease after viremia (generalized vesicular eruption, encephalitis, hepatitis, spontaneous abortion). The incubation period after exposure is short: 1 to 4 days.[255] Excretion varies among species. For three cultivatable vesiviruses, asymptomatic and persistent excretion of virus was detected for months after primary infection.[134,247,251]

Pathology

The pathogenic features of *Vesivirus* infection vary and depend on the syndrome of the affected host.

CLINICAL MANIFESTATIONS

The proven clinical manifestations of *Vesivirus* calicivirus infection in humans are limited to a few cases. Because vesiviruses cause a variety of illnesses in animals and these viruses occur naturally in primates, the potential spectrum of illness in humans is broad. Groups at greatest risk of acquiring infection probably would be zoo workers, indigenous populations handling marine mammals, veterinarians, and laboratory workers, but studies of these groups have been limited.[249] The clinical implications of the finding of anti-*Vesivirus* antibody and RNA in serum are uncertain. The RNA in serum was found in persons judged well enough to donate blood.[245]

DIAGNOSIS

Many vesiviruses can be cultivated in cell culture, and many are found in sufficiently high concentration in clinical samples to permit the use of electron microscopy and classic virologic methods for detection of infecting viruses. Other strains have resisted cultivation, and molecular techniques have been developed for them.[176,204,239] Vesiviruses are heat labile, and clinical samples should be submitted promptly and unfrozen.

LAGOVIRUS CALICIVIRUSES

EPIDEMIOLOGY

General Prevalence

The prototype *Lagovirus* is RHDV. Lagoviruses include the genetically distinct European brown hare syndrome virus and multiple genetically distinct strains recovered from asymptomatic rabbits.[22,23,150-152,272] Rabbits also are infected with *Vesivirus* strains, which may lead to confusion.[171] Antigenic diversity occurs in the *Lagovirus* genus, but the number of serotypes in the genus is unknown, for like noroviruses and sapoviruses, lagoviruses cannot be cultivated in the laboratory.[272] RHDV has been epidemic in Asia and Europe since it was first recognized in China in 1984. Rabbits in more than 40 countries have been affected. Disease spreads rapidly and appears to "leap" large distances in a short time. The ability of the virus to spread rapidly across large bodies of water (e.g., the English Channel) suggests that arthropods or other flying vectors have a role in transmission.[31] One outbreak in Mexico was traced to a shipment of rabbit meat from Asia; extensive slaughter of rabbits in Mexico was required to eradicate the agent.[87] Three outbreaks have occurred in North America and Cuba.[21] The source of these outbreaks is unknown, although deliberate importation and release has been suspected in one instance.

RHDV was released in 1995 in controlled field studies off the coast of mainland Australia but escaped from the study site the same year and spread onto the continent.[122] Subsequently, the virus was introduced illegally into the South Island of New Zealand. Clandestine, deliberate spread in both countries to control exotic European rabbits led to wide dispersal of the agent. These releases occurred despite conflicting evidence of RHDV infection in other animal species and, subsequently, in humans.[24,173]

Morbidity and Mortality

RHDV infections are highly fatal (>80%) in wild and domesticated European rabbits. Subclinical infections occur in young rabbits, and immunity from early infection appears to attenuate later exposure. In the food-associated outbreak in Mexico, antibody developed in one human. Zoo workers, rabbit breeders, and foresters would have the largest occupational risk of RHDV exposure. The human infection in the Mexican outbreak apparently was subclinical.[87] Ostensibly subclinical infection also occurred in some persons exposed to rabbits in Australia after escape of the virus there.[173]

Host and Social Factors

The range of hosts of lagoviruses and the host of RHDV before it was recognized in rabbits in China are unknown. In Australian studies, numerous Australian animal species challenged with a subimmunogenic dose of RHDV had no antibody response. On the other hand, antibodies did develop in kiwis, mice, dogs, and foxes; in the case of foxes, the serum antibody response was attributable to oral feeding.[39] Natural spread in rabbits is enhanced by their colony breeding behavior.

CLINICAL MANIFESTATIONS AND PATHOGENESIS

The incubation period after exposure is 1 to 3 days.[265] Lagoviruses cause a fatal hepatitis in rabbits and hares that results in disseminated intravascular coagulation and diffuse hemorrhage. Death is rapid: 6 to 12 hours after the onset of illness. RHDV and European brown hare syndrome virus appear to be sufficiently distinct to preclude cross-protection.

DIAGNOSIS

Because the infections in the Mexican worker exposed during the RHDV outbreak and in the workers in Australia who tested antibody positive apparently were subclinical, the spectrum of potential infection in humans is unknown. Samples from persons with suspected infection should be submitted to reference laboratories after consultation. Diagnosis can be established with immunologic and molecular techniques.

TREATMENT AND PREVENTION

SPECIFIC MEASURES

No specific treatment of calicivirus infection has been reported. The existence of at least partially effective vaccines for feline calicivirus and RHDV indicates that this prevention method would work for other caliciviruses. A norovirus vaccine incorporating an immunogen-expressed capsid protein that self-assembles into virion-like particles is being developed.[10,11,90,257] Feline interferon and ribavirin inhibit the replication of feline calicivirus (a *Vesivirus*) in feline cell lines.[189,218] Morpholino antisense oligomers blocked production of virion by three *Vesivirus* strains in multiple cell lines[17a,254] These antisense compounds have potential for prophylaxis and treatment of illness.[246]

NONSPECIFIC MEASURES

Children with diarrhea are more likely than are children without diarrhea to be excreting enteric viruses, which reflects an association between the incidence of diarrhea and the cleanliness of the environment. This principle is likely to hold for caliciviruses as well. For children in care settings with other children, a few infection control measures are likely to reduce the spread of infection. Such measures include trained personnel, cleanliness of surfaces and food preparation, exclusion of ill or carrier care providers, adequate handwashing, and exclusion or cohorting of ill children.[51,91] Laboratory workers exposed to caliciviruses should be aware of the risk of acquiring infection. Infection with noroviruses requires a very small inoculum, on the order of 100 particles.[261,274]

PROGNOSIS

Understanding of the features of calicivirus infection has increased rapidly since 1990, when molecular tools for studying the viruses became available. The availability of refined diagnostic reagents will permit an accurate assessment of the extent and variety of calicivirus-associated illness and of the food and water sources of infection to be made. Rapid progress is occurring in improvement of detection methods for noroviruses in various types of food contamination[164] as well as of methods to kill them on the food before consumption.[142] Specific preventive measures are being developed, but their potential is clouded by uncertainty about the antigenic and genetic diversity of strains and the strength of cross-protection induced by exposure to one or more strains.

CHAPTER 182

Hepatitis E Virus

Ravi Jhaveri

Hepatitis E virus (HEV) is a virus that was characterized only recently but probably has been infecting humans for hundreds of years. New information about the animal reservoirs, epidemiology, and molecular biology is constantly becoming available. Recent natural disasters and regional warfare have highlighted HEV as an agent that causes epidemics in areas where sanitation and public health systems have broken down. This chapter is a summary of the discoveries so far with emphasis on the impact of children infected with HEV.

HISTORY AND DISCOVERY OF VIRUS

As methods to detect hepatitis A and B viruses as the major causes of fecal-oral and blood-borne hepatitis, respectively, became more reliable in the 1970s, more cases were being classified as non-A, non-B hepatitis. Investigations in regions of south Asia looked at epidemic and endemic cases of acute hepatitis.[40,67,147] Case patients all had a clinical course that was very similar to hepatitis A virus (HAV) infection, despite having a remote history of HAV infection, and the result of testing for other causes of viral hepatitis was negative. Many researchers considered that a distinct enteric viral agent was the cause of these cases.

The first evidence of this came when Balayan and colleagues[18] used stool extracts from infected humans orally administered to a human volunteer known to be HAV immune. Classic hepatitis symptoms ensued, and stool from the infected volunteer was used to re-infect cynomolgus macaques. Electron microscopy of stool samples from the asymptomatic and early symptomatic phases showed virus-like particles (VLP) approximately 30 nm in diameter that banded at 1.35 g/cm^3 on a cesium chloride gradient.[24,25] VLPs showed no cytopathic effect when passaged in tissue culture, and mice inoculated with the VLPs showed no signs of disease.[18]

The field experienced a major advance after reverse transcription–polymerase chain reaction (RT-PCR) was used to identify hepatitis C virus in 1989.[30] Similar methods were used to determine the nature of the non-A, non-B enteric virus.[111] Reyes and colleagues[111] constructed cDNA clones from infected bile that subsequently hybridized with RNA from infected animal and human liver as well as isolates from five distinct geographic outbreaks. Sequence analysis revealed the presence of an RNA-dependent RNA polymerase, a common feature of plus-stranded RNA viruses. Northern blot hybridization identified a 7.4-kb molecule present only in homogenates from infected liver samples. The agent was pronounced *hepatitis E virus*, and the same group cloned and sequenced HEV during the subsequent year.[127]

MICROBIOLOGY AND GENOME ORGANIZATION

HEV is a plus-sense RNA virus with a genome size of approximately 7200 base pairs.[127,148] Initial cloning of the Burma strain revealed the presence of three overlapping open-reading frames (ORFs).[127,137] ORF1 is approximately 5000 base pairs in length and encodes the nonstructural proteins.[73,127] ORF2 begins 37 base pairs downstream from the ORF1 stop codon and codes for the viral capsid.[127] ORF3 is only 369 base pairs and overlaps both ORF1 and ORF2. The viral RNA contains a short 5′ untranslated region of approximately 27 base pairs and a 3′ untranslated region of approximately 65 base pairs.[127] The genome has a 7-methyl cap at the 5′ untranslated region and a poly-A tail of approximately 150 to 200 bases.[62] The organization of the genome is represented in Figure 182–1.

Initial comparative genomic analysis deduced the likely functions of the ORF1 nonstructural regions.[73] They include the methyltransferase "capping" motif (~amino acids 56-240), the papain-like cysteine protease (~amino acids 433-592), the RNA helicase (~amino acids 960-1204), and the RNA-dependent RNA polymerase (~amino acids 1207-1693). Details of ORF1 processing are limited, but recent data examining ORF1 with use of a baculovirus system showed extensive cysteine protease processing.[9,103,116] The enzymatic activities of the methyltransferase and RNA-dependent RNA polymerase have been demonstrated in independent studies.[7,83]

ORF2 codes for the viral capsid protein.[127] Specific studies of the ORF2 have shown a membrane export signal sequence (amino acids 1-36) at its extreme N terminal, several glycosylation sites, and multiple smaller processed forms.[58,112,127,151] ORF2 has dimerization sites and can assemble into VLPs when the first 110 amino acids are deleted.[78,79,149]

The specific role of the ORF3 has yet to be determined, although many studies have revealed varied effects, which include interaction with the MAPK/ERK pathway, ORF2 binding, and self association.[66,74,142,143]

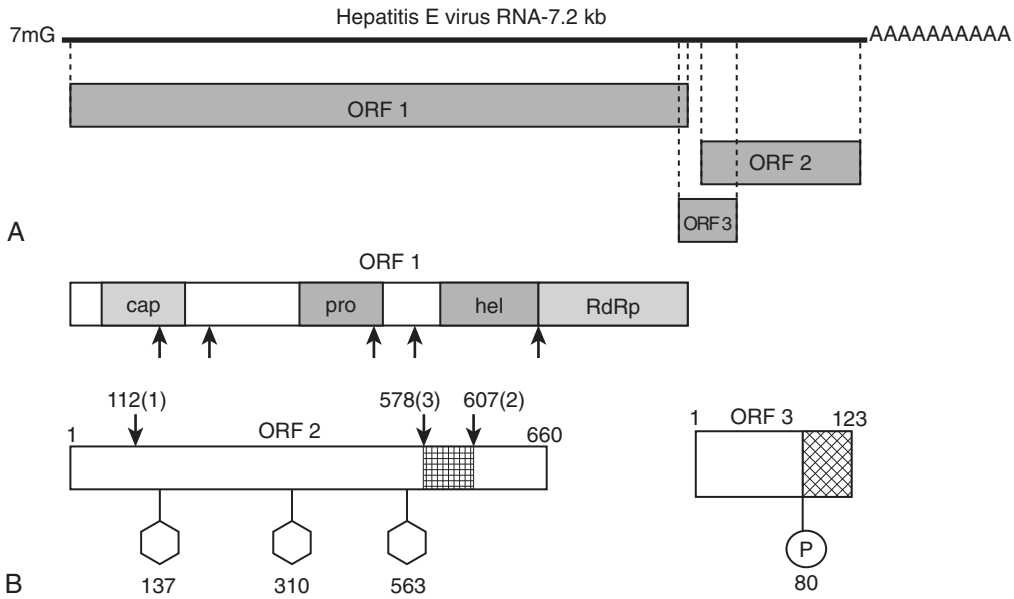

Figure 182–1 Representation of HEV genome and open-reading frames. **A,** HEV genome overview. The HEV RNA is single stranded and features three overlapping reading frames: ORF1, ORF2, and ORF3. **B,** Individual features of the HEV ORFs. ORF1 contains the nonstructural protein domains *(shaded)*, which include the methyltransferase (cap), cysteine protease (pro), helicase (hel), and RNA-dependent RNA polymerase (RdRp). Proposed cleavage sites are illustrated with the bold arrows at their approximate locations. ORF2 is the structural capsid protein, which is 660 amino acids in length. Cleavage sites are indicated by the bold arrows at their determined amino acid positions. Glycosylation sites are represented with polygons at their determined amino acid positions. The domain of ORF2 that has been determined to be the neutralization epitope is represented by the crosshatched box. ORF3 is the smallest protein, and its phosphorylation site is represented by the circle labeled P. The domain responsible for dimerization is represented by the diagonal hatched box.

VIRAL STRUCTURE AND STABILITY

Electron micrographs from fecal samples of patients and animals infected with HEV show the virus to be approximately 27 to 30 nm in diameter.[18,24,25]

Ultrastructural studies of HEV have involved ORF2 expression, and the empty VLPs produced are slightly smaller than the infectious HEV.[79,149] The VLPs assemble from 30 dimers to form a spiky hollow sphere.[149] Although the empty VLP shares much similarity with the native virion in appearance, further confirmation is lacking until a tissue culture system is available.

Several strains of HEV are almost completely heat inactivated by 60° C, compared with 66° C for HAV[39] with some interstrain variability. Virus-containing stocks have been stable at extreme cold temperatures with several freeze-thaw cycles.[39] Based on persistent HEV infections during an outbreak from water containing chlorine concentrations of 0.3 to 0.6 mg/L, HEV may be resistant to chlorine inactivation.[50]

VIRAL LIFE CYCLE

An important note is that HEV does not grow in tissue culture conditions, so detailed information about viral structure and life cycle is limited.[40] Limited studies have shown evidence of HEV replication in primary macaque hepatocyte cultures.[128,129] When in vitro–transcribed RNA from a full-length cDNA clone was transfected into liver cell lines, viral proteins could be detected and the culture supernatant could be used to infect a rhesus monkey.[103]

Currently, no information is available about the viral receptor for HEV. After the virus gains access to the cell, it uncoats and translates its RNA to produce a sufficient number of nonstructural proteins to begin the transcription-replication process.[103] A genomic and 2-kb subgenomic RNA are produced, as is a negative-stranded replication template.[46,129] With the accumulation of transcripts, structural proteins as well as more plus-sense daughter RNA begin to accumulate. ORF2 gets cleaved, dimerizes, and associates with the HEV RNA to form new virions.[124] These accumulated virions subsequently are released by an unknown mechanism.

VIRAL GENETICS

Four main genotypes of HEV have been identified.[148] Genotype 1 is distributed throughout the world from south Asia to northern Africa. Genotype 2 is seen most commonly in Mexico but has been isolated in certain countries in Africa. Genotypes 3 and 4 are the zoonotic strains of HEV that are found in swine and humans from developed Western countries and China, respectively. Genotypes 1 and 2 are approximately 70 to 80 percent homologous, whereas genotype 3 strains are more removed from genotype 2 strains (25-50% homology).[93] In general, genotypes 1 and 2 are closer to each other[82] and are responsible for endemic and epidemic diseases, whereas genotypes 3 and 4 are more closely related[82] and are responsible for zoonotic disease and sporadic human cases.

Only one serotype of HEV has been identified.[90,91,115,148] Some evidence indicates that HEV develops quasispecies during epidemics that allow adaptation within individual hosts.[47]

TAXONOMY AND CLASSIFICATION

Before its characterization, HEV was thought to be closely aligned with the calicivirus family on the basis of physical characteristics.[18,127] After the full cloning of the virus and the identification of the three ORFs were achieved, the virus was classified formally with the caliciviruses.

Subsequent work showed that HEV shared several characteristics with rubella virus and other "alpha-like" viruses.[73] An analy-

sis performed comparing the helicase and polymerase regions of HEV with members from the *Caliciviridae*, *Picornaviridae*, and *Togaviridae* families showed significant divergence.[20] The International Committee on Taxonomy of Viruses decided to separate HEV from the *Caliciviridae* family on the basis of these findings and leave it unclassified, where it still remains.[48]

EPIDEMIOLOGY

ENDEMIC HEPATITIS E

Hepatitis E is endemic in areas of the developing world where sanitation and clean water are not readily available. South and Southeast Asia and north Africa experience endemic disease, as do regions of Mexico and South America. Large epidemics of hepatitis E occur in these endemic countries and are related to widespread contamination of water after natural disasters. Cases of hepatitis E occurring outside these areas inevitably were traced back to travel to one of these areas.

Unlike with HAV, most of the seroprevalence studies performed in endemic countries have shown that children are not universally infected with HEV early in life. Children in the first decade have anti-HEV–positive rates of approximately 3 to 4 percent,[10,15] and the peak of HEV seropositivity occurs in the second and third decades of life. However, studies from regions of Egypt and northern regions of India demonstrate a pattern that is similar to HAV, with 60 to 70 percent of children younger than 10 years being anti-HEV positive.[6,42,89] Egypt has much higher prevalence rates than does neighboring Israel, whereas southern and central India have anti-HEV rates much lower than those of the northern regions previously described.[10,65,96] A study of children from Moscow showed HEV seroprevalence rates that fell between those of most other studies.[1] Explanations for these regional differences are lacking. Table 182–1 is a summary of HEV seroprevalence studies performed in children from different parts of the world.*

One of the Egypt seroprevalence studies performed follow-up to examine seroconversion and estimated the incidence of HEV infection.[123] Of the 919 villagers who were anti-HEV at the beginning of the study, 34 seroconverted in 10 months' time for an incidence of 41.6/1000 person-years for this group.

Studies of sporadic acute hepatitis in endemic areas indicate the burden of HEV disease in those countries. Studies examining children presenting with acute hepatitis symptoms in Egypt and Sudan show that HEV is either the leading or second leading cause in children.[38,55,56] A similar study from India showed that, although HEV was the second leading cause after HAV of acute hepatitis requiring admission to a children's hospital, it caused a slightly higher percentage of acute liver failure.[106] One study found that HAV and HEV infections led to worse outcomes in acute liver failure, but other studies have not substantiated those findings.[16,85]

Several studies also from endemic areas have been designed specifically to examine the differences in HAV and HEV infections.[27,114] The results of these studies have shown that HAV disease peaks earlier in life than does HEV disease and that although the clinical symptoms of acute hepatitis are very similar, the hepatic dysfunction from HEV tends to peak earlier in the illness and may take longer to resolve. Because the peaks of HAV and HEV seroprevalence and disease in endemic countries do not overlap, some researchers have suggested that HAV disease either somehow protects against or interferes with HEV infection.[125] No specific proof of this hypothesis is available currently.

*See references 1, 6, 8, 10, 19, 21, 32, 35, 42, 57, 65, 80, 88, 89, 107, 109, 118, 133.

Although the reservoir for HEV is not known, the detection of HEV from various sewage samples combined with results of studies of patients with prolonged viremia indicates that the virus probably can exist in these environments to sustain its transmission cycle.[100,104,144]

EPIDEMIC HEPATITIS E

Hepatitis E epidemics often are related to events that cause disruption of sanitary conditions (war, earthquakes, flooding). Recent war-associated epidemics among the refugees from the Darfur region of Sudan and Iraq in 2004 illustrate the nature of HEV epidemic circulation.[22,44,50,145]

In a refugee camp in western Sudan, more than 2600 cases of HEV infection were reported among the estimated 78,000 residents in the second half of 2004.[22,50] Of the total cases, almost 10 percent required hospitalization, and of the hospitalized cases, 45 (17.8%) died.[22] Most of the deaths involved pregnant women, 19 of 45 (42.2%), and in fact the sentinel cases for the hepatitis E epidemic were two pregnant women who died in July 2004. The overall mortality rate for the epidemic was 1.7 percent. A total of 1133 pregnant women were in the refugee camp; 220 reported jaundice (19.4% attack rate), and the mortality rate was 8.2 percent.

The main source of water for the camp was unchlorinated groundwater pumped in through pipelines or surface water with chlorine added that refugees could access.[50] In the analysis of those patients with symptomatic HEV infection and those with asymptomatic infection, patients aged 15 to 45 years had a higher attack rate and more symptomatic infections (4.3% and 71%, respectively) compared with the group aged younger than 15 years (2.4% and 22%, respectively). Intrafamilial spread of HEV does not appear to play a significant role during epidemic conditions.[5,12]

ZOONOTIC HEPATITIS E

As more widespread serologic studies were performed to assess rates of anti-HEV seropositivity, cases with no identifiable travel risks were discovered in developed countries with no known endemic HEV activity.[43,88,134] Many of the cases had heavy animal exposures, most commonly to swine. This finding led researchers to investigate the possibility that HEV was, in fact, a zoonosis and that either direct animal contact or ingestion of raw or undercooked meat could produce HEV infection. Meng and colleagues[94] conducted a multiphase study to determine if swine were infected with HEV and to isolate the virus. They performed enzyme-linked immunosorbent assays (ELISAs) on multiple swine herds and found that the majority were anti-HEV positive and that the seroprevalence increased with age. They observed newborn piglets, monitored for seroconversion, and demonstrated concurrent histologic hepatitis and viremia by RT-PCR. In a follow-up study, serum from the infected piglets was used to infect pathogen-free experimental pigs.[92] Pigs could not be infected with human strains of HEV. Rhesus monkeys and chimpanzees, a human surrogate, were successfully infected with the swine HEV.[93] An isolate of HEV from the United States that was genetically similar to the swine HEV successfully infected pathogen-free pigs, thus proving that swine HEV could infect both pigs and humans and was the likely cause of sporadic cases of hepatitis E in the United States and other developed countries. HEV genotypes 3 and 4 now have been established as being the strains most frequently isolated from animals that are nonendemic HEV cases from industrialized countries.[33]

Many animal species likely are infected with HEV. Among those described are swine, deer, chickens, rodents, and cats.[51-53,61,101] Of

note, avian HEV, which has been demonstrated as the cause of hepatosplenomegaly syndrome in chickens, shares only 50 to 60 percent homology with human and swine HEV and has not been shown to be able to infect nonhuman primates.[52,54]

VERTICAL AND BREAST MILK TRANSMISSION

Studies of pregnant women with HEV infection also have shown that vertical transmission does occur. The small studies performed show that HEV is likely to be transmitted at high rates, that fetal demise can occur before birth, and that infants can be severely affected.[70,119]

Limited studies of breast milk transmission have been performed. HEV RNA and anti-HEV antibody have been detected in colostrum components, but at significantly lower titers compared with serum.[29] No cases of HEV transmission in the infants were linked definitively to breast milk; however, the mothers with advanced liver disease were not allowed or able to breast-feed in this study. In short, no recommendations exist to contraindicate breast-feeding in this population aside from those mothers with severe disease.

OTHER MODES OF HEPATITIS E VIRUS TRANSMISSION

Cases have been reported of HEV linked with transfusion of contaminated blood. Donors were in the presymptomatic viremic phase, and recipients of those blood products developed symptoms of acute hepatitis with a shorter incubation period than that of patients infected through the usual fecal-oral route.[13,14,23,71]

Consumption of undercooked wild game meat has been implicated in HEV infections. Several cases have been reported of acute HEV infection occurring after consumption of uncooked or undercooked deer and wild boar meat.[76,131,132]

PATHOGENESIS AND IMMUNITY

PATHOGENESIS

The details of pathogenesis in HEV infection are largely unknown. How the virus infects enterocytes and spreads from the intestine to the liver after ingestion of HEV-contaminated water or food remains unknown. Studies in swine show replicative HEV RNA present in colon, small intestine, lymph nodes, tonsils, and liver as early as 3 days after infection.[146]

Evidence of HEV replication within the liver as detected by HEV antigen is apparent by 7 days after infection. At the peak, HEV antigens can be detected in 70 to 90 percent of hepatocytes before the onset of symptoms, and then the prevalence drops off rapidly.[4] Viremia is detectable in serum, stool, and bile before the onset of symptoms.[28,81,136] Anti-HEV appears at the same time as do the histologic signs of inflammation.[31] Similar to HAV infection, disease likely is caused by the immune response to the virus and not by the virus itself.[4]

Most of the information about progression and pathogenesis comes from studies of inoculation of HEV into animals.[18,81,136,138] These studies usually involved intravenous administration, with an incubation period from administration to development of viremia of approximately 3 weeks, approximately 1 week less on average than occurs in humans. HEV RNA can be detected in serum, stool, and bile 1 week before clinical symptoms become apparent.

In the HEV volunteer studies, the patients developed constitutional symptoms at approximately 4 weeks after administration.[18,28] Specific symptoms and the biochemical abnormalities of hepatitis developed 1 week later. Early studies showed that viral particles appeared in stool with the onset of symptoms and continued through the peak period of hepatitis symptoms; antibody was present at the only time they tested, 1 week after the peak hepatitis symptoms occurred.[18] Subsequent studies using RT-PCR showed that HEV RNA was present in serum before stool samples and was present from 1 week before to 2 weeks after symptoms had begun.[28] Peak alanine aminotransferase elevations corresponded with peak symptoms, and symptoms lasted between 30 and 80 days. HEV IgG persisted well beyond the study end-point.[28]

The presence of HEV RNA in stool and serum can vary significantly from patient to patient.[3] In 20 patients diagnosed with sporadic HEV, HEV RNA appeared in serum at days 4 to 7 after the onset of symptoms in 89 percent of patients tested and persisted beyond day 22 in 21 percent. HEV RNA in stool samples was present in 73 percent of patients at days 8 to 14 after symptoms, peaking slightly later than did serum HEV RNA, and it persisted beyond day 22 in 13 percent. A subset of patients will have HEV RNA in serum and stool for up to 120 days.[100] Patients with prolonged shedding possibly serve as a reservoir for spread of HEV to the environment.

A summary of the clinical progression of HEV infection is graphically represented in Figure 182–2.

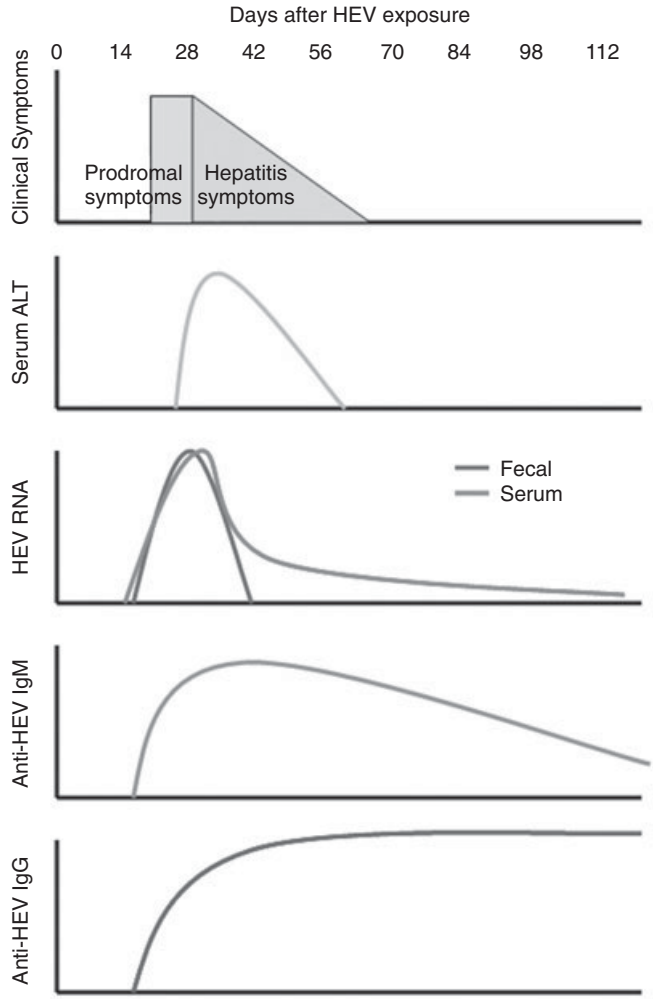

Figure 182–2 Representation of the course of HEV infection with approximate times after HEV exposure. In volunteer and animal experiments, prodromal symptoms will appear approximately 3 weeks after infection, which precedes the symptoms of hepatitis by about 1 week. The hepatitis symptoms can last 4 to 6 weeks on average, with significant variation. Serum alanine aminotransferase peaks with the onset of hepatitis symptoms. HEV RNA can be detected in either stool or serum approximately 3 weeks after infection with the onset of the prodrome and be detected for 1 to 3 weeks in duration, with some patients experiencing prolonged viremia. HEV IgM and IgG appear in concert with the onset of symptoms and after the peak of HEV RNA. IgM peaks slightly earlier than IgG and can taper quickly, with some disappearing by 3 months. IgG peaks later and lasts several months after infection. (See companion Expert Consult web site for color version.)

IMMUNITY

HEV antibody appears with the onset of symptoms and after the peak of viremia. IgM appears just ahead of IgG. HEV IgA appears at the same time as does IgM and appears to persist slightly (about 1 month) longer after infection than IgM does.[126,135] ORF2 is the dominant immunogen across all types of HEV, although antibodies to ORF3 can be detected in patients.[49,55,56,87,150] A more detailed discussion of neutralizing antibodies can be found in the vaccine subsection.

Some studies have shown that HEV IgG responses wane quickly after infection, whereas others show a more durable antibody response.[45] The waning of IgG levels is the basis for the theory that accumulation of susceptible adults forms the vulnerable population during HEV outbreaks.

Although evidence of cellular immunity to HEV exists, its role in eradication of infection and persistence of viral immunity is unknown.[99]

CLINICAL MANIFESTATIONS

The signs and symptoms of acute HEV infection are indistinguishable from those seen with HAV infection.[4,27,56,114] A prodromal illness consisting of malaise, anorexia, nausea, abdominal pain, fever, myalgia, and headache precedes the findings of jaundice, hepatomegaly, and serum transaminase elevations. No cases of chronic infection with HEV have been reported.

One study examining children after a common-source exposure provides insight into the manifestations of HEV in this group. Twenty students from a private school in urban north India were exposed to HEV while on a camping trip.[17] The exact source was never identified, but investigators were able to monitor the children for signs and symptoms of HEV infection as well as for serologic and virologic confirmation of infection. The clinical symptoms are summarized in Figure 182–3. Of the 20 children, 17 developed clinical illness (85%) but only 10 developed symptoms of acute hepatitis. The other seven children remained anicteric, with symptoms of malaise, nausea, abdominal pain, and headache. The children with jaundice had a different incubation period (25-38 days; median, 33 days) compared with the children without jaundice (22-95 days; median, 27 days). HEV IgM was found in all patients. HEV RNA was found in 11 children, including one of the children who never developed any symptoms. Because this study is one of the few to have a point source of exposure, determination of whether the very high rate of infection is due to the younger age of the patients, the strain of the virus, or the nature of the exposure is difficult.

Rates of fulminant hepatic failure and mortality from HEV disease are estimated to be approximately 1 to 4 percent. Studies from endemic areas suggest that the rate may be higher in children, but those data have not been widely substantiated.[105] The rate is closer to 15 to 50 percent in patients with preexisting liver diseases and compensated cirrhosis, whether caused by chronic hepatitis B or C or by other metabolic liver disease.[110]

Pregnant women are highly vulnerable to HEV infection.[34,69] Before HEV infection was fully characterized, infected pregnant women were recognized as having high rates of fulminant liver failure and mortality rates of 20 percent or higher.[72] This feature of HEV infection is not restricted to a particular region or genotype, as illustrated by the Darfur outbreaks. The mechanism for severe disease in these women is unknown, although one study showed an increased T_H2 cytokine bias in peripheral blood mononuclear cells from pregnant HEV-infected patients that could allow a dysregulated inflammatory response.[22,102]

Extrahepatic manifestations of HEV infection have been reported, but they are uncommon findings. Pancreatitis can occur shortly after the onset of acute hepatitis symptoms.[59,84,95] Several reports have described patients with significant hemolysis with glucose-6-phosphate dehydrogenase deficiency associated with acute HEV infection.[2,152] Neurologic manifestations described include transverse myelitis, Bell palsy, and Guillain-Barré syndrome.[36,37,63,86,120] All of these manifestations resolve spontaneously in conjunction with the hepatitis. Whether they are a result of direct viral effects or are an immune-mediated phenomenon remains unclear. An interesting note is that most of the extrahepatic manifestations have been reported in children.

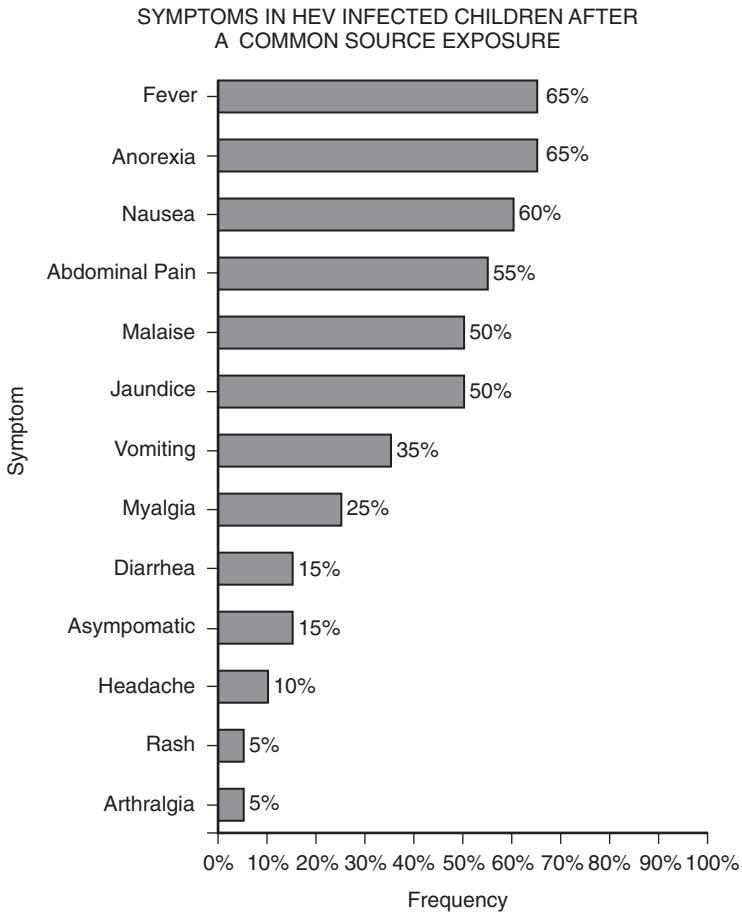

Figure 182–3 Symptoms observed in children after a common-source exposure to HEV. Jaundice was seen in only 50 percent of patients overall, and 15 percent were completely asymptomatic. *(From Arora, N. K., Panda, S. K., Nanda, S. K., et al.: Hepatitis E infection in children: Study of an outbreak. J. Gastroenterol. Hepatol.* 14*:572-577, 1999.)*

DIAGNOSTIC TESTING

SEROLOGY

Antibody confirmation is the most widely available method used to diagnose HEV infection. ELISA for both IgG and IgM can be obtained at many reference laboratories. The ORF2 capsid protein is the most common antigen used to detect antibody.[141] Some studies have shown that inclusion of the other ORFs can increase the specificity and positive predictive value of the test. A few studies have shown that HEV IgA may perform better than IgM-based testing does.[126,135] This finding needs to be confirmed in larger studies.

A comparison of different HEV ELISA kits during an epidemic in Indonesia found that the sensitivity of the tests was much better in symptomatic patients compared with asymptomatic ones (72-91% versus 39-51%, respectively).[97] Also, the Walter Reed kits for IgG and IgM performed better than did the GeneLabs and Abbott IgG tests. Testing of normal healthy controls who were HEV negative by PCR showed that the serologic testing had high specificity, again with the Walter Reed tests performing best. The caveat of the study is that the GeneLabs IgM kit was an older version of the test, and the limitations of the assay may not apply to the newer kit.

A new rapid immunochromatographic assay showed promising results when it was evaluated for use in resource-poor countries to diagnose acute HEV infection.[98] With use of 25 μL of serum or 35 μL of whole blood applied to the test strip and a 15-minute incubation period, the kit had a sensitivity of 93 percent and a specificity of 99.7 percent.

POLYMERASE CHAIN REACTION ANALYSIS

RT-PCR for HEV RNA can be performed within the first month of illness on either serum or stool.[3] The testing is less available commercially and likely to be conducted in research or select public health laboratories. Studies have shown that real-time PCR testing may allow more rapid and sensitive detection of HEV RNA, with the additional benefits of detecting multiple HEV genotypes and the ability to test environmental samples in addition to clinical samples.[41,60]

ELECTRON MICROSCOPY

HEV in stool samples from patients also has been visualized by electron microscopy.[18,121] In general, these methods incorporate HEV antibody to adsorb intact virus to increase the likelihood of detection. Again, this testing is not generally available.

DISEASE PREVENTION AND VACCINE CANDIDATES

AVOIDANCE OF DISEASE

Practical measures can be taken to reduce the risk of acquiring HEV infection when traveling to endemic regions.[26] Consuming only boiled or bottled water, avoiding ice, eating fruits that can be peeled, and eating only well-cooked foods are recommended measures.

Pregnant women and patients with chronic liver disease should avoid travel to areas endemic for HEV or regions experiencing HEV disease outbreaks.

ANTIBODY PREPARATIONS

There are no available antibody preparations that can be used as preexposure or postexposure prophylaxis for HEV infection. Small studies have shown successful passive immunization in animals.[139] Studies with immune serum globulin in endemic areas have shown mixed effects.[11,68] All the studies were small, and the antibody preparations were of varying amounts given at varying times, so definitive conclusions about the role of antibody cannot be made.

THERAPIES

Few studies of therapeutic options for acute HEV infection have been performed. One uncontrolled study used glycyrrhizin in patients with significant acute hepatitis from HEV, but no meaningful conclusions can be drawn from its results.[130] A hammerhead ribozyme targeted to the 3′ untranslated region revealed decreases in the in vitro activity of an HEV reporter.[122] Development of therapies for HEV infection is not likely to be effective for the simple reason that the peak of viral activity usually is before and along with the onset of symptoms. The patients with prolonged viremia are not necessarily the sickest patients; indeed, they often are asymptomatic.

VACCINE CANDIDATES AND FUTURE THERAPIES

Early vaccine studies used cynomolgus monkeys actively immunized with a recombinant ORF2 protein. Subjects were protected after challenge with homologous virus compared with passively immunized or control animals.[139]

Work to identify neutralizing antibody showed that the epitopes recognized were in the terminal region of ORF2, amino acids 578 to 607.[116] These antibodies were protective of HEV infection when incubated with HEV before administration to monkeys. This epitope is present within the 56-kd form of the capsid protein.

A recombinant 56-kd ORF2 vaccine protected rhesus monkeys challenged with HEV 1 month after a two-dose series was completed.[108,140] Repeated challenge at 6 months and 1 year showed a rate of protection against hepatitis of 75 percent, which increased to 100 percent in animals given a third dose of vaccine 1 month before challenge.[153] Postexposure vaccination did not prevent development of HEV infection.

Subsequent phase I testing in humans induced anti-HEV titers of 40 U/mL or greater in 88 percent of vaccinees after receipt of three doses.[113] Only a few minor local reactions and no significant adverse events occurred. On the basis of these early trials, a large human field trial was completed in Nepal in 2001. Two thousand seronegative soldiers were randomized to receive three doses during 6 months of the recombinant HEV vaccine or placebo.[117] The subjects were observed for signs and symptoms of acute hepatitis for 2½ years. There were 69 total cases of acute HEV, 66 in the placebo group and 3 in the vaccine group, an efficacy of 95.5 percent in subjects receiving three doses of vaccine. The intent-to-treat analysis showed an efficacy of 88.5 percent. The vaccine was well tolerated, with local pain at the injection site being the most frequent complaint.

In an alternative vaccine strategy that is being investigated, VLPs are given orally to induce local and systemic immunity. As described previously, the HEV ORF2 forms dimers in vitro that assemble into VLPs.[79] These VLPs are very immunogenic when administered to guinea pigs directly and also were used to detect anti-HEV antibody from infected macaques. Mice immunized with HEV VLPs in increasing amounts developed serum IgG

and IgM responses at 2 to 4 weeks after immunization.[75] Mice given the higher inoculums (50 and 100 μg) also developed fecal IgA responses. Subsequent challenge experiments in cynomolgus macaques showed that oral immunization with VLPs not only produced serum and fecal antibody but protected the animals from intravenous challenge with native HEV strains.[77] These studies provide promise that an oral vaccine for HEV is a possibility.

DNA vaccines have shown encouraging initial results as well. Macaques given a DNA plasmid encoding the HEV ORF2 by the gene gun technique developed significant anti-HEV IgG within 4 months of vaccination.[64] The macaques then were challenged with intravenous HEV, and the vaccinated macaques were negative for HEV RNA in serum and stool and showed no increase in the titers of anti-HEV throughout the test period, whereas the unvaccinated group had detectable HEV RNA, one had alanine aminotransferase elevations, and all had a significant increase in their anti-HEV titers.

SUMMARY

Despite the lack of a tissue culture system for HEV, much progress has been made toward development of a vaccine that is effective. Fundamental questions of virus entry and pathogenesis still linger, as well as why certain patients are highly susceptible to severe HEV disease, whereas others are not. The nature of the differences in the epidemiology and clinical manifestations of HEV infection in children also needs to be studied further. When a vaccine is available, studies on the most effective use in endemic and epidemic settings will also need to be undertaken.

SUBSECTION 3

Reoviridae

CHAPTER 183

Reoviruses

James D. Cherry

Reoviruses are ubiquitous in nature, but their role in human disease is vague. After reoviruses were classified in 1959, numerous reports noted their association with human disease.[36,64,76] Since that time, these viruses have been evaluated extensively in laboratory animal studies, but few cases of human disease have been reported during the last 4 decades.

HISTORY

On the basis of its cytopathic effect in monkey kidney tissue culture and its recovery from stool specimens at a time of enterovirus surveillance, the first recovered reovirus was designated ECHO virus type 10.[9,10] This virus and four similar strains were recovered in 1954 from the stools of healthy children in Cincinnati and Mexico.[59,60] By 1959, researchers were aware that ECHO 10 viral strains appeared to have many characteristics that were different from those of enteroviruses, such as large size and unique cytopathic effect, and they were withdrawn from this grouping. The term *reovirus* was chosen to stress the association of these agents with both the respiratory *(r)* and enteric *(e)* tracts. The *o* for orphan was retained in the designation. In the early 1960s, reoviral infections were noted in association with human illness.[15,26,30,36,68,69,102]

PROPERTIES[8,51,52,63,64,93-95]

Reoviruses are members of the family *Reoviridae*.[17,52] This family has numerous double-stranded RNA viruses that infect mammals, birds, reptiles, fish, mollusks, insects, plants, and arthropods.[52] There are nine genera in the family, and they can be subdivided by the presence or absence of a turret-like protein that projects from the innermost capsid layer. Of the turreted *Reoviridae*, only orthoreoviruses infect humans and are addressed in this chapter. Orthoreoviruses commonly are called simply reoviruses. Nonturreted *Reoviridae* include the following viruses that cause disease in humans: rotaviruses (Chapter 185) and orbiviruses and coltiviruses (Chapter 184). Three serotypes of orthoreoviruses cause infection in humans. All mammalian reoviruses are related by a common group-specific, complement-fixing antigen.[72,94] Three distinct human serotypes can be identified by neutralization or hemagglutination inhibition.[70]

Reovirus particles are composed of an inner protein shell (core) with a diameter of 60 nm that is surrounded by an outer protein shell (outer capsid) measuring 81 nm in diameter.[52] The outer capsid has icosahedral symmetry and is composed of between 92 and 180 hexagonal and pentagonal subunits (capsomers). The genome of orthoreoviruses has a total size of approximately 23,500 base pairs with 10 gene segments: three large (L1, L2, L3), three medium (M1, M2, M3), and four small (S1, S2, S3, S4). These genes encode 12 proteins. The outer capsid is composed of four proteins: sigma-1, sigma-3, lambda-2, and mu-1. Sigma-1 is the reovirus cell-attachment protein against which serotype-specific neutralizing antibodies are developed. This protein also is the hemagglutinin. The reovirus receptor is the junctional adhesion molecule 1 (JAM1).[18,87] Sigma-3 protein binds double-stranded RNA and is sensitive to protease degradation. It is a zinc metalloprotein that has effects on translation. Lambda-2 protein is important in particle assembly and mu-1 in cell penetration.

The inner capsid is composed of four proteins: lambda-3, lambda-1, mu-2, and sigma-2. Lambda-3 is an RNA-dependent RNA polymerase. Lambda-1 is a zinc metalloprotein that binds RNA. Mu-2 binds RNA, and sigma-2 binds double-stranded RNA.

The four nonstructural proteins are mu-NS, mu-NSC, sigma-1s, and sigma-NS. Mu-NS is a core-binding protein, and sigma-NS binds single-stranded RNA. The roles of mu-NSC and sigma-1s are unknown.

Reoviruses are moderately heat-stable. The half-life at 56° C of a type 3 strain is 1.6 minutes; at 37° C, it is approximately 2.5 hours. Reoviruses are inactivated by visible light in the presence of heterocyclic dyes. They are inactivated by ultraviolet light but are more resistant to this treatment than are RNA viruses with single-stranded nucleic acid. Reoviruses are stable through a wide pH range and also are stable as aerosols, particularly when the relative humidity is high. They are relatively resistant to 3 percent formaldehyde solution, 1 percent hydrogen peroxide, and 1 percent phenol but are inactivated completely by 70 percent ethyl alcohol at room temperature for 1 hour. Brief exposure to 70 percent ethanol is ineffective in disinfecting reoviruses, but brief exposure to 95 percent ethanol or sodium hypochlorite is effective.

Reoviruses replicate with a cytopathic effect in a large number of tissue culture systems of both primate and other animal origins. For recovery from clinical material, monkey kidney tissue culture is satisfactory. Cytopathic effect is enhanced in rolled compared with stationary cultures.[37] Infected cells develop characteristic cytoplasmic inclusions that contain double-stranded RNA, virus-specific proteins, and complete and incomplete viral particles. All three serotypes agglutinate human erythrocytes, and this virus-cell interaction is stable in a wide temperature and pH range.

Of all viruses that naturally infect humans, reoviruses have the broadest host range. They have been recovered from natural infections in cattle, chimpanzees, monkeys, mice, dogs, turkeys, sheep, pigs, chickens, and cats.[11,22,24,42,44,45,65,73,98,99] In addition, hemagglutination-inhibiting and neutralizing antibodies to one or more of the three reoviral serotypes have been found in the serum of rabbits, horses, trout, guinea pigs, antelopes, zebras, warthogs, bats, wallabies, quokkas, kangaroos, and several genera of New World monkeys.[50,67,70,72,82,83]

Because of their widespread prevalence in nature and the ease of causing infection in laboratory animals, reoviruses have been used widely in pathogenicity studies. The following unique illnesses have been observed: diabetes mellitus in mice; hydrocephalus in hamsters, ferrets, rats, and mice; encephalitis in mice; chronic infection with runting in mice; myocarditis in mice;

TABLE 183–1 Hemagglutination-Inhibiting (H1) Antibodies to Reovirus Type 2 in 253 Serum Specimens Collected in Boston, Massachusetts, from 1959 to 1962

Age Group	Percentage with H1 Titer ≥1:20
Premature newborn	68
0-6 months	25
7-12 months	9

chronic obstructive jaundice associated with choledochal obliteration in mice; and lymphomas in mice with chronic infection.*

EPIDEMIOLOGY

The serologic data presented in the preceding section of this chapter demonstrate that reoviruses are prevalent infectious agents in the animal world. Similarly, surveys of sera collected from humans indicate worldwide human infection.† The occurrence in nature of identical viruses in many different animals and humans leads to consideration of possible transmission from species to species. At present, this transmission has not been demonstrated.

Reoviruses are recovered frequently from sewage.[16,29,33,39,43,53] In San Diego, reoviruses have been recovered more consistently than has any other virus throughout the year from sewage.[16] This finding suggests that reoviral infection is endemic in humans in the San Diego area.

The type 2 hemagglutination-inhibiting antibody prevalence pattern by age in sera collected in Boston from 1959 to 1962 is presented in Table 183–1. Antibody is transmitted transplacentally to the newborn. During the first year of life, this acquired antibody wanes, after which antibody prevalence increases with increasing age. Approximately 50 percent of school-aged children have hemagglutination-inhibiting antibody titers to type 2 reovirus greater than or equal to 1:20; approximately 80 percent of adults have similar titers. Two more recent studies have shown a similar prevalence of antibody to reovirus type 3.[77,88]

The method of transmission of reoviruses is unknown. However, because they are recovered most frequently from the feces, the primary spread probably is by the fecal-oral route, similar to that of enteroviruses. Because the reoviruses are stable in aerosols and because respiratory illness has been associated with reovirus infections, the respiratory route is an additional possibility.

CLINICAL MANIFESTATIONS

The role of reoviral infections in human disease is far from clear. In most instances, virologic or serologic evidence of reoviral infection has been a sporadic finding in human illness, so that cause and effect are difficult to establish. However, in volunteer studies in young adults, infection resulted in clinical illness.[26,66]

The prevalence of antibody to all three reoviral types in humans and the frequency of reovirus isolation from human sewage indicate that human infection is a common occurrence, but the relative paucity of virus recovered during studies of community disease suggests that most infections are inapparent or associated with trivial illness.

UPPER RESPIRATORY ILLNESS

In the winter of 1957, Rosen and colleagues[68] noted an outbreak of infection with reovirus type 1 in nursery children in a welfare institution. Illness was noted in 16 of 22 infected children and was characterized by low-grade fever (rectal temperatures from 38.1° C to 38.6° C [100.6° F to 101.5° F]), rhinorrhea, and pharyngitis. The average duration of fever was 2.2 days; in nine children, the duration was only 1 day. Three children had diarrhea, and three had mild otitis media. In another study conducted at the same institution during the winter of 1955 to 1956, four children with reovirus type 3 infection and illness were noted.[69] One child had a temperature of 38.9° C (102° F), coryza, and tonsillitis; another child had fever (temperature of 38.2° C [100.8° F]), cough, and diarrhea; and two children had only coryza. During another reovirus type 3 outbreak in the fall of 1957, all six infected infants had symptoms. Five children had mild fever, five had coryza, and four had diarrhea. Pharyngitis was not observed in any of the infected children.

Other sporadic instances of similar mild upper respiratory illnesses have been described.[12,23,26,80,84] In volunteer trials in young adults, reovirus type 1 infection was associated with malaise, rhinorrhea, cough, sneezing, pharyngitis, and headache in some subjects in one study,[66] and coldlike illness was observed in 37 percent of subjects in another trial.[26] In both volunteer studies and natural infection, mild diarrhea occurred with the upper respiratory illness.

PNEUMONIA

Tillotson and Lerner[91] described a 5-year-old girl who had extensive pneumonia and died after 15 days of illness. This child initially had fever, cough, rhinorrhea, and a generalized maculopapular rash. When admitted to the hospital on the 10th day of illness, the child was cyanotic and in marked respiratory distress; rash was present no longer, but mild pharyngitis and conjunctivitis were. A chest radiograph revealed a diffuse confluent pneumonia, and reovirus type 3 was recovered from the lungs, adrenals, liver, spleen, kidney, a lymph node, heart, brain, and blood.

Joske and associates[30] described a 10-month-old girl who died after having a respiratory illness of 4 days' duration. A reovirus type 1 was recovered from the stool and brain of this child, and postmortem study revealed interstitial pneumonia, myocarditis, hepatitis, and encephalitis. El-Rai and Evans[15] reported the case of an 18-year-old man who had fever (temperature of 39.4° C [103° F]), nausea, vomiting, cough, and patchy pneumonia. He had serologic evidence of infection with reovirus type 1. Pneumonia has been noted in another child with reovirus type 3 infection.[84]

GASTROINTESTINAL MANIFESTATIONS

Mild diarrhea has been noted both in association with upper respiratory illness and as an isolated event.[58,66,68,69,73] Because reovirus type 3 consistently produces steatorrhea in mice, this clinical manifestation has been sought in illnesses of children and noted in six.[72,84] Three patients with hepatitis and encephalitis

*See references 27, 32, 40, 41, 54, 55, 57, 78, 81, 85, 94.
†See references 4-6, 19, 31, 35, 36, 38, 56, 71, 75, 89, 92.

have been described.[30] Zalan and associates[102] have noted two patients in whom abdominal pain and cramps were prominent.

In 1980, Bangaru and associates[1] reported the similarity of induced hepatobiliary injury caused by reovirus type 3 infection in mice and biliary atresia in human infants. Subsequent to this observation, Morecki and colleagues[20,48,49] looked for an association between reovirus type 3 infection and biliary atresia in humans. In their first report, they found that 17 of 25 patients (68%) with biliary atresia had antibodies (indirect immunofluorescent antibody technique) to reovirus type 3, whereas similar antibodies were recovered in only 3 of 37 control sera.[48] In a second study, they found that 62 percent of babies with extrahepatic biliary atresia and 52 percent of infants with idiopathic neonatal hepatitis had antibodies to reovirus type 3; only 12 percent of control children had similar antibodies.[20] In an ultrastructural and immunocytochemical study, they found evidence of reovirus type 3 in the porta hepatis of an infant with extrahepatic biliary atresia.[49]

Using similar serologic techniques, Dussaix and associates[13] were unable to find any relationship between reovirus type 3 antibody and either biliary atresia or neonatal hepatitis. They found reovirus type 3 antibody in sera from 45 percent of infants with biliary atresia, 50 percent of infants with neonatal hepatitis, and 50 percent of control infants. Minuk and colleagues[47] found no association between reovirus type 3 infection and idiopathic cholestatic liver disease in adults. Brown and colleagues[7] reported a relatively large study of reovirus type 3 infection and extrahepatic biliary atresia and neonatal hepatitis. They interpreted their data as demonstrating no correlation between the virus and the illnesses studied. However, the geometric mean antibody value in the combined biliary atresia and neonatal hepatitis groups was significantly higher than that of the control group. Richardson and associates[62] reported a study in which they examined the percentage of IgG, IgA, and IgM serum antibodies to reovirus type 3 in 40 infants with extrahepatic biliary atresia, 59 infants with neonatal hepatitis, 61 infants with cholestatic liver disease with causes other than extrahepatic biliary atresia or neonatal hepatitis, and 138 control infants with no liver disease. They found no difference in the prevalence of IgG and IgA antibodies between the groups with liver disease and the control subjects. They did, however, note a greater prevalence of IgM antibody in each of the groups with liver disease compared with the rate in the control group. However, this increased prevalence of IgM antibody could be the result of false-positive titers due to the liver disease rather than evidence of recent or ongoing infection. Steele and associates,[86] using a reverse transcriptase–mediated polymerase chain reaction (RT-PCR), found no evidence of reovirus type 3 in preserved tissues from infants with cholestatic liver disease. Recently, Saito and associates,[74] using RT-PCR, could find no amplification product in tissue or stool specimens from patients with biliary atresia, infantile obstructive cholangiopathy, or congenital dilation of the bile duct.

EXANTHEM

Exanthem has been a common manifestation of clinically apparent reoviral infections.[15,30,36,91] Lerner and associates[36] noted exanthem in six of seven children infected with reovirus type 2. Predominant symptoms in these patients included fever, malaise, anorexia, and pharyngitis. Two children had adenopathy, and one child had diarrhea. The rash was maculopapular in five patients and vesicular in one child. One child had a measles-like illness with photophobia, conjunctivitis, cervical lymphadenopathy, and a confluent maculopapular rash that lasted approximately 1 week.

Exanthem has been noted in a 5-year-old girl with pneumonia and type 3 reovirus infection, a 28-month-old girl with encephalitis and type 2 infection, and an 18-year-old adolescent male with pharyngitis and cervical and posterior occipital lymph node enlargement and type 2 infection.[15,30,91]

NEUROLOGIC DISEASE

Joske and colleagues[30] described three cases of hepatitis-encephalitis syndrome with reoviral infections. All these cases had abnormal liver function test results and clinical and laboratory evidence of meningeal and cerebral involvement. One child died, one had mild neurologic residua at the 6-week follow-up, and one recovered without difficulty. Two patients were infected with reovirus type 2 and one with reovirus type 3.

El-Rai and Evans[15] found serologic evidence of reovirus type 2 infection in two children with aseptic meningitis, and Zalan and colleagues[102] described two children with reovirus type 2 infections associated with leg weakness and pain. Johansson and colleagues[28] described a 3-month-old girl with meningitis, diarrhea, vomiting, and fever. Reovirus type 1 was isolated from this child's cerebrospinal fluid, and the child had a fourfold rise in neutralizing antibody to the isolated virus. Krainer and Aronson[34] described a 29-year-old woman who died of disseminated demyelinating encephalomyelitis in which a reovirus was recovered from the cerebrospinal fluid and brain. Recently, Tyler and associates[96] isolated a type 3 reovirus from the cerebrospinal fluid of a 6.5-week-old child with meningitis. This child recovered without obvious neurologic sequelae.

OTHER MANIFESTATIONS

A 25-year-old man with Hodgkin disease had persistent reovirus type 1 viruria for a 5-week period, but no associated clinical illness was demonstrated.[14] Reoviruses have been recovered from biopsy material from patients with Burkitt lymphoma.[2,3] One child with hemorrhagic bullous myringitis was infected with reovirus type 2.[102] Terheggen and colleagues[90] noted a 28-year-old man with mild myocarditis from whom a reovirus was isolated from the stool sample.

REOVIRUSES AS POTENTIAL ANTI-CANCER AGENTS

Studies during the present decade indicate the potential of reoviruses to selectively destroy many different types of neoplastic cells.[21,25,46,79,97,100,101] Many malignant cells have an activated Ras pathway that results in a deficient ability to mount an anti-reovirus response that is mediated by the cellular protein PKR. Organ culture and animal model systems have shown promising results with reovirus type 3 in numerous different malignant neoplasms. At present, many phase I and phase II trials are in progress.[61,97]

DIAGNOSIS

Because no specific clinical features suggest reoviral infection, virologic and serologic studies are necessary for establishing the diagnosis. Reoviruses can be recovered from clinical material in primary monkey kidney tissue culture.[63] Care must be taken in interpreting results, however, because reoviruses can be contaminants of monkey tissue cultures. Cytopathic effect in tissue culture is enhanced by rolling during incubation.[37] Identification of virus is made by neutralization; the distinctive cytopathic effect should be helpful in selecting strains for study with reovirus antisera. In research laboratories, reoviruses also can be detected

by molecular techniques such as in situ and dot-blot hybridization and PCR.[94] Paired serum specimens can be examined for antibody titer rise to reoviruses by neutralization, indirect immunofluorescent antibody technique, enzyme-linked immunosorbent assay, or hemagglutination inhibition. Recent infection can also be identified by the demonstration of specific IgM antibody by enzyme-linked immunosorbent assay.

CHAPTER 184

Orbiviruses, Coltiviruses, and Seadornaviruses

Theodore F. Tsai

Viruses in the genera *Orbivirus*, *Coltivirus*, and *Seadornavirus* differ from others in the family *Reoviridae* structurally, in physicochemical properties, and by their arthropod mode of transmission.[2,4,44] More than 100 orbiviruses are classified into 14 serogroups defined by relationships in complement fixation, agar gel precipitation, and immunofluorescent assays. Additional serocomplex relationships are recognized, whereas individual viruses are differentiated by neutralization tests. Orbiviruses are principally animal pathogens (e.g., the bluetongue viruses); only viruses in the Kemerovo, Orungo, Lebombo, and Changuinola serogroups have been shown to cause human illness. Coltiviruses recognized to be human pathogens include Colorado tick fever (CTF) virus and Eyach virus; Banna virus is the only seadornavirus recognized to cause human illness.[2,4]

The orbiviruses are spherical nonenveloped viruses with two protein shells: an outer shell (capsid) approximately 86 nm in diameter and an inner shell (core) 69 nm in diameter. The inner core VP7 protein, arranged in trimers, contains group-reactive antigens, and the outer capsid VP2 or VP5 proteins bear serotype-specific antigens. The viruses are acid labile, and some exhibit sensitivity to lipid solvents. The double-stranded RNA viral genome is composed of 10 segments associated with viral structural and nonstructural proteins. Their complete nucleotide sequences and coding assignments have been determined for a bluetongue virus, and partial information is available for others. In general, reassortments of genomic segments among viruses within serogroups are viable, but not between groups, thus validating the broad serogroup classification. The genetic relation-

ships (e.g., RNA hybridization) among viruses within serogroups diverge from the antigenic relationships in some instances, which provides an additional basis for taxonomic classification.

The coltiviruses and seadornaviruses resemble the orbiviruses in size and in having two capsids but possess genomes organized into 12 RNA segments.[2,44] Seadornaviruses' morphologic features and structural protein similarities with rotaviruses suggest an evolutionary relationship.

COLORADO TICK FEVER VIRUS

CTF is an acute tick-borne febrile illness caused by the eponymous coltivirus.[5,12,17,18]

Eyach virus isolated from *Ixodes* ticks in France and Germany, S6-1403 isolated in California from a gray squirrel, and mosquito strains from Indonesia are related to but distinct from CTF virus and have not been associated with human disease.[4,27] RNA hybridization studies of CTF viral strains from a 33-year interval found minor heterogeneity, thus suggesting that a single gene pool has been maintained by mixing of viral strains and by constraints on viral replication within tick vectors and vertebrate hosts. A wide variety of small and large mammals are infected naturally with the virus, but clinical illness develops only in humans. Experimental infection of rhesus monkeys, hamsters, and mice produces hematologic changes similar to those occurring in human infections.[20]

EPIDEMIOLOGY

Cases occur principally in association with the habitats and activity patterns of the wood tick *Dermacentor andersoni*. Most cases occur in May and June, when adult ticks are most active, but infections from March to November have been reported. Infections are acquired principally in the western part of the United States and Canada in the known geographic distribution of the vector (Fig. 184–1).[7,10-12] CTF viral antibodies have been found in serosurveys in South Korea, but no viral isolates have been recovered (unpublished observations, C. H. Calisher).

In rare cases, CTF has occurred in persons who had not traveled to areas of known risk, such as those exposed to ticks brought home on the clothing of family members and, in one case, by transfusion.[33,38,42,43]

CTF virus is maintained in a 2- to 3-year cycle among small mammals, principally rodents, and *D. andersoni* ticks (Fig. 184–2).[5,12,18] Once infected in the larval stage, ticks remain infected through the nymphal and adult stages (trans-stadial transmission). Larvae are infected by viremic rodents. After molting, they carry the virus through the winter, and as nymphs, they infect other rodents and renew the cycle of transmission the following spring. Humans become infected incidentally by the bite of infected adult ticks.

The least chipmunk *(Eutamias minimus)*, the golden-mantled ground squirrel *(Spermophilus lateralis)*, and the porcupine *(Erethizon dorsatum)* appear to be the primary hosts for larval, nymphal, and adult *D. andersoni;* secondary hosts include rock mice *(Peromyscus maniculatus)*, meadow voles *(Microtus pennsylvanicus)*, and pine squirrels *(Tamiasciurus hudsonicus)*.[6]

D. andersoni is found exclusively in the high plains and in mountainous terrain between 4000 and 10,000 feet in altitude in the geographic distribution previously mentioned. The specific microhabitats where infected ticks are most prevalent are south-facing slopes with open stands of ponderosa pine, moderate shrubs, and rocky surfaces that provide favorable habitats for the intermediate rodent hosts.[6,32] Both male and female adult ticks can transmit infection to humans, and the period of attachment required for transmission of the virus may be very brief.

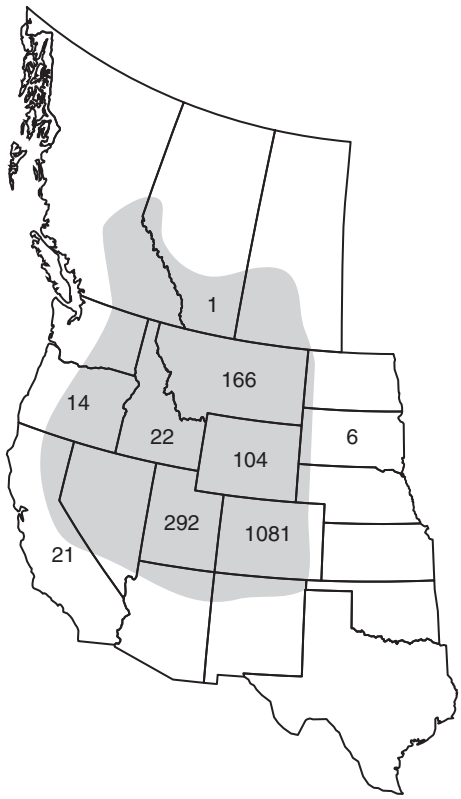

Figure 184–1 Geographic distribution of *Dermacentor andersoni* ticks and reported cases of Colorado tick fever, 1980 to 1991.

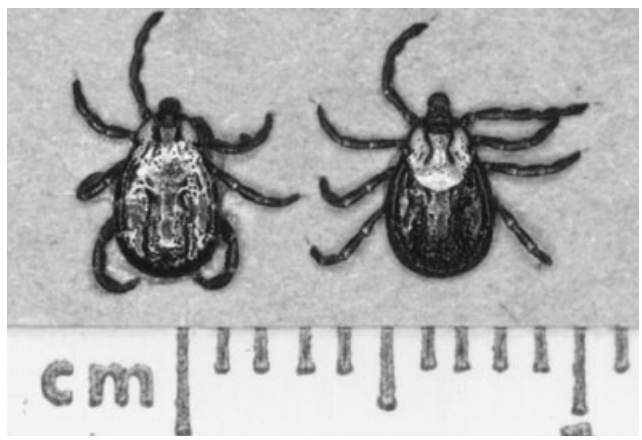

Figure 184–2 Adult male *(left)* and female *(right) Dermacentor andersoni* ticks. Both can transmit Colorado tick fever virus.

CLINICAL MANIFESTATIONS

A history of a tick bite or tick exposure is given by more than 90 percent of patients.[21] The incubation period usually is 3 to 4 days, with a range of 0 to 14 days after known exposure to a tick.[21] The onset typically is abrupt, with fever, chills, malaise, headache, retro-orbital pain, myalgia, lumbar pain, and hyperesthesia. Nausea, vomiting, and abdominal pain occur less frequently. Upper respiratory symptoms usually are absent, although conjunctival injection may develop. Lymphadenopathy and hepatosplenomegaly are found in some patients. Maculopapular and petechial eruptions have been observed in 5 to 12 percent of cases.[41]

The disease classically is diphasic; an initial attack lasting 2 to 3 days is followed by an equal interval of defervescence and a second and rarely a third recurrence. However, this saddleback pattern is absent in more than 50 percent of cases. Symptoms resolve several days after the second bout of fever, but prolonged asthenia lasting for several weeks is a typical finding, especially in adults.[21]

Leukopenia is a hallmark of the illness. The mean initial leukocyte count is 3900/mm^3, which diminishes to a nadir 5 to 6 days after the onset of illness, often during the period of remission. A left shift with an absolute neutropenia and relative lymphocytosis is a usual finding. Examination of bone marrow aspirates shows maturational arrest in the granulocytic series, with absent mature forms and numerous metamyelocytes and myelocytes. Megakaryocytes are depleted, and a reduced peripheral platelet count (<150,000/m^3) is found in most patients; however, thrombocytopenia rarely reaches a level of clinical significance.[25,31]

Uncomplicated recovery is the rule. Epididymo-orchitis, pneumonitis, hepatitis, and pericarditis have been reported as complications, but the most serious complications are encephalitis and hemorrhage,[15,19,21,23,30] which have been reported nearly exclusively in children younger than 10 years.[10,21,39,41] Three deaths have been reported, all in children who exhibited signs of generalized bleeding accompanied by a reduced platelet count.[9,21] Examination of the bone marrow in one child disclosed a generalized depression of myeloid and erythroid elements and a marked reduction in megakaryocytes. Central nervous system signs consistent with meningitis and encephalitis have been reported in both children and adults. Examination of cerebrospinal fluid disclosed elevated protein and mononuclear cell pleocytosis in the few cases that have been described.

D. andersoni is a vector for both CTF and Rocky Mountain spotted fever (RMSF).[4] Although dual isolation of CTF virus and *Rickettsia rickettsii* from the same tick has not been reported, a concurrent rickettsial infection could not be discounted in all of the previously mentioned fatal cases attributed to CTF. Furthermore, a dual infection could develop in an individual exposed to more than one tick.

CTF virus is teratogenic in experimentally infected mice, but few clinical data are available on the teratogenic potential of the virus in humans.[22] One pregnant woman aborted 2 weeks after having an illness; and in an infant delivered 6 days after the onset of CTF in the mother, a febrile illness with leukopenia developed at 3 days of age, thus indicating a possible vertically acquired infection. In a single reported instance, a second attack of CTF has been documented, which indicates that immunity may not be permanent.[21]

The combined historical elements of tick exposure and outdoor activity in an enzootic area should suggest the diagnosis in patients with a spring-summer grippe-like illness. In a controlled study, abdominal pain, pharyngitis, and rash were less common symptoms in patients with CTF than in patients with other acute illnesses in the same season. Although RMSF occurs rarely in the states in which CTF is prevalent, the possibility of this potentially fatal disease should be considered in the differential diagnosis. Helpful differentiating features include the rarity of a petechial rash in CTF and its biphasic course. Tick-borne relapsing fever also follows a remitting course, but it has a more acute and toxic onset; splenomegaly occurs commonly, and remission is by crisis. The geographic distribution of the diseases overlaps; however, human encounters with the argasid (soft) tick vectors of relapsing fever (*Ornithodoros* ticks) are likely to occur in cabins and other protected areas.

Eyach virus has been implicated in central nervous system infections and polyradiculitis in Europe. However, its tick-borne transmission from *Ixodes ricinus* that also transmits *Borrelia*, *Anaplasma*, and Kemerovo group viruses has prevented establishment of a clear interpretation.

PATHOPHYSIOLOGY

Experimental infection of rhesus monkeys, rodents, and human marrow cells in vitro has shown that CTF virus infects the erythropoietic elements (erythroblasts to reticulocytes) at an early stage of infection.[13,14,20,26,36,38] After the infected cells mature and are released into the peripheral circulation, the virus persists intracellularly, where it has been identified by electron microscopy.[14,36] CTF virus has been cultured from circulating erythrocytes for up to 120 days after the onset of illness.[24] Red cell survival evidently is not shortened, and infected cells circulate in the presence of neutralizing antibody. Prolonged viremia has not been associated with either a protracted or a more severe course of illness. Infected CD34$^+$ progenitor cells and impaired mononuclear cell production of colony-stimulating factors may contribute to the acute aregenerative cytopenia.[37] High levels of serum interferon-γ correlate with fever during the acute phase of illness.[1]

LABORATORY DIAGNOSIS

Direct immunofluorescent examination of blood smears for intraerythrocytic viral antigen is an accessible and rapid approach to laboratory diagnosis.[13] However, polymerase chain reaction analysis and viral culture of blood samples are more sensitive.[3,26] Ninety-six percent of all cases diagnosed by seroconversion are identified by isolation of virus from acute or convalescent blood samples in baby mice or Vero or BHK cells.[8,13] Freezing and thawing of the clot should be avoided. Virus has been isolated from a blood clot that had been refrigerated for 14 months. Serologic diagnosis by demonstration of fourfold rises in neutralizing, complement-fixation, immunofluorescent, or enzyme-linked immunosorbent assay antibody is confirmatory.[3] Enzyme-linked immunosorbent assays that distinguish between CTF and Eyach virus antibodies are available.[34] Neutralizing antibody rises slowly; only a third of patients had detectable neutralizing antibody 10 days after onset, but fourfold rises appeared within 30 days of onset in 92 percent.

TREATMENT

No specific therapy is available. Because thrombocytopenia may occur and hemorrhage is a reported complication in children, antipyretics that interfere with coagulation should not be used.

PREVENTION

Repellents containing permethrin should be sprayed on clothing, and repellents containing diethyltoluamide (DEET) or picaridin should be applied to exposed skin (see Table 187–2 in the chapter on western equine encephalitis). Long pants should be tucked into socks, and shirts should be worn tucked into slacks. Clothing, gear, and skin should be inspected frequently for attached ticks. Light-colored clothing facilitates such inspections. One case of human-to-human transmission by transfusion of infected blood has been reported.[42] Persons with documented CTF should be prohibited from donating blood until the often prolonged viremia has cleared.[38]

BANNA AND WX-3 VIRUSES

Banna and WX-3 viruses have been associated with febrile illness and encephalitis in China. Both have 12 RNA segments and are antigenically distinct from the CTF, S6-1403, and Eyach viruses (coltiviruses from the Rocky Mountain region, California, and Germany). Banna virus has been classified taxonomically as a seadornavirus (Southeast Asian dodeca RNA viruses).[2,4] Banna virus was isolated from encephalitis patients in Yunnan Province in southern China and later from 98 patients with fever, headache, and arthralgias from Xinjiang Province in western China.[28] WX-3 and nine related strains that segregate into four distinct RNA electropherotypes were isolated from *Culex tritaeniorhychnus* mosquitoes in Gansu Province and the suburbs of Beijing in 1991.[40] Serologic evidence of recent infection with the strains was found in 50 percent of patients with encephalitis in Henan Province and in 17 percent of patients in Jiangsu Province, suggesting that these coltiviruses may be a leading cause of summer viral encephalitis after Japanese encephalitis. Details of the clinical illness and epidemiology of infection have not been reported. A real-time polymerase chain reaction assay for Banna virus nucleic acid has been developed.[45] Related seadornaviruses from China and Southeast Asia are orphan viruses not yet associated with human illness.

KEMEROVO AND RELATED VIRUSES

The Kemerovo serogroup contains more than 50 chiefly tick-borne viruses divided into four serocomplexes. Only Kemerovo, Tribec, and Lipovnik viruses have been associated with human illness. Kemerovo virus was isolated from the cerebrospinal fluid of two patients with encephalitis and from ticks in the Kemerovo region of Russia; seroconversion was demonstrated in 10 other patients with meningoencephalitis with tick bites and in whom Russian spring-summer encephalitis was excluded.[7,29] The virus is transmitted in an *Ixodes persulcatus*–rodent cycle. Lipovnik virus has been reported in neurologic infections in the former Czechoslovakia, where flaviviral tick-borne encephalitis is endemic; one study showed seroconversion to Lipovnik virus in half the patients with encephalitis who were studied, including some with suspected dual infection with tick-borne encephalitis virus.[29] This finding seems plausible because both viruses are transmitted by *I. ricinus* ticks, and multiple exposure to singly infected ticks or infection with a dually infected tick may be possible. In addition, serologic evidence of Lipovnik or Tribec infection was reported in patients with chronic polyradiculoneuritis; however, spirochetal infection was not ruled out in these cases. The increasing geographic range of *I. ricinus* ticks in Europe to more northerly latitudes and to higher elevations, attributed to global warming, could lead to increased transmission of these orbiviruses, as has been observed with tick-borne encephalitis virus.

On the basis of serologic rises in patients with acute febrile illness diagnosed clinically as RMSF, a Kemerovo-related virus is suspected to occur in the southwestern region of the United States. Patients with a history of a tick bite or tick exposure, whose sera were negative for *R. rickettsii*, demonstrated fourfold or greater changes in immunofluorescent titers to Lipovnik and Six Gun City viruses (Kemerovo group). Rises in immunofluorescent antibody titers to 128 to 512 suggested recent infection with a Kemerovo-related virus, possibly a novel agent or related to rabbit syncytium virus, which is enzootic in the United States. The patients had acute febrile illnesses with myalgia, vomiting, and severe abdominal pain, along with leukopenia, thrombocytopenia, and anemia, similar to RMSF. No agent has been isolated, but neither was the possibility of *Ehrlichia* infection excluded. Serologic evidence of infection was found in a cotton rat in the vicinity of one case. The syndrome tentatively is called Oklahoma tick fever.

ORUNGO VIRUS

Orungo virus is unrelated antigenically to the other orbiviruses. Infection is prevalent in western, central, and eastern Africa and apparently is transmitted in a sylvatic monkey–*Aedes* mosquito cycle similar to that of yellow fever. Human-to-human transmission by *Anopheles* mosquitoes is speculated to occur. The virus has been isolated from patients with fever and headache, and serologic evidence of infection has been reported in outbreaks of illness characterized by fever, headache, myalgia, nausea, and vomiting. Seroconversion has been observed in patients studied during yellow fever outbreaks, presumably because of concurrent transmission of the viruses. The virus also was isolated from the blood of a child with convulsions and flaccid paralysis.[16,35]

LEBOMBO VIRUS

Lebombo virus is not grouped antigenically. The virus was isolated first from *Aedes circumluteolus* mosquitoes in South Africa. Subsequently, the virus was recovered from a Nigerian child with nonspecific febrile illness; the virus also was isolated from rodents and mosquitoes in Nigeria.[35]

CHANGUINOLA VIRUS

Changuinola virus belongs to an antigenic complex of 12 principally phlebotomine-borne orbiviruses. The virus is transmitted in Panama among forest mammals and *Phlebotomus* flies. Only one human case has been reported—a nonspecific febrile illness in a mosquito catcher.

CHAPTER 185

Rotaviruses

Richard L. Ward ✪ David I. Bernstein ✪ Mary Allen Staat

Rotaviruses are recognized as the single most important cause of severe infantile gastroenteritis worldwide.[124,183,212,262,412] In the United States, these viruses are estimated to cause between 24,000 and 110,000 hospitalizations in young children annually[182,183,226,227,323,331,466] and 20 to 60 deaths.[182,183,226,227] Direct medical costs associated with rotavirus disease in the United States have been estimated to be between $100 and $400 million annually.[10,331,545] Indirect costs are significant, accounting for an additional $500 million each year,[296,545] leaving the total rotavirus costs at $1 billion per year in the United States.[545] On a world scale, rotaviruses are estimated to be responsible for more than 600,000 deaths annually.[183,244,262,410] For these reasons, rotaviruses have received a high priority as a target for vaccine development.[244,455]

Transmission of rotaviruses occurs by the fecal-oral route, providing a highly efficient mechanism for universal exposure that has circumvented differences in regional and national cultural practices and public health standards. The symptoms associated with rotavirus disease typically are diarrhea and vomiting accompanied by fever, nausea, anorexia, cramping, and malaise that can be mild and of short duration or produce severe dehydration.[261,265,282,435,465,477,511,515,549] Severe disease occurs primarily in young children, most commonly between 6 and 24 months of age. Approximately 90 percent of children in both developed and developing countries experience a rotavirus infection by the time they reach 3 years of age.[261,262] Rotavirus infection normally provides short-term protection and immunity against subsequent severe illnesses but does not provide lifelong immunity; furthermore, numerous cases of sequential illnesses have been reported.* Neonates also can experience rotavirus infections, and they occur endemically in some settings but typically are asymptomatic.[29,32,203,213,364,424] These neonatal infections have been reported to reduce the morbidity associated with a subsequent rotavirus infection.[29,32] Rotavirus illnesses also occur in adults[125,136,161,237,275,468,473,599] and the elderly,[111,326,327,514] but as with other sequential rotavirus infections, the symptoms usually are mild. Recently, however, a series of reports have described a unique association between severe gastrointestinal disease in adults and serotype G2P[4] rotaviruses, the properties of which are described later in this chapter.[65,202,242,373,537,608]

Because of the frequent occurrence of rotavirus infections and the reduced severity of illness typically associated with sequential infections, a realistic goal for a rotavirus vaccine may be to protect against severe disease. Several vaccine candidates have been developed and evaluated in infants, with promising results.†

*See references 32, 35, 76, 95, 123, 166, 300, 330, 388, 456, 564, 607.

Incorporation of an effective rotavirus vaccine into the infant immunization schedule in developed countries could reduce the number of hospitalizations due to dehydrating diarrhea in young children by 40 to 60 percent.[455] More important, worldwide use of such a vaccine could decrease by approximately 10 to 20 percent the total number of deaths caused by diarrhea.[124,244,455] Once effective rotavirus vaccines become universally available, control of rotavirus disease no longer will be limited to the nonspecific methods, such as rehydration therapy for replacement of body fluids and electrolytes, presently being used.

HISTORY

Viruses with morphologic features later associated with rotaviruses were observed first by electron microscopy in 1963 in intestinal tissues and rectal swab specimens from mice and monkeys.[4,324] These agents, called epizootic diarrhea of infant mice virus and simian agent 11, respectively, were described as 70-nm particles that had a wheel-like appearance. Hence, they were later designated "rota" viruses from the Latin word for wheel.[153,606] In 1969, Mebus and colleagues[350] demonstrated the presence of these particles in stools of calves with diarrhea, thus associating these viruses with a diarrheal disease in cattle. The correlation between these viruses and human diarrheal disease was reported first in 1973 by Bishop and colleagues,[34] who used electron microscopy to examine biopsy specimens of duodenal mucosa from children with acute gastroenteritis. Within a short time, these and other investigators confirmed the association between the presence of rotavirus in feces and acute gastroenteritis.[33,59,119,152,266] In addition to their distinctive morphologic features, these human viruses along with their animal rotavirus counterparts were later shown to share a group antigen[263,602] and have been classified as members of the *Rotavirus* genus within the *Reoviridae* family.[336] In 1980, particles that were indistinguishable morphologically from established rotavirus strains but lacked the common group antigen were discovered in pigs.[43,481] This finding subsequently led to the identification of rotaviruses belonging to six additional groups (B to G) based on common group antigens, with the original rotavirus strains classified as group A.[482] Only groups A to C have been associated with human diseases, and most known cases of rotavirus gastroenteritis have been caused by group A strains. However, non–group A rotaviruses have been associated with large outbreaks in China, particularly among adults,[241] and Japan,[288,334] which suggests that they could become major pathogens in the future. This suggestion is supported by seroepidemiology data showing high prevalence of group C rotavirus antibody in different countries.[249,381,462,544]

PROPERTIES

Visualization of the rotavirus particle by conventional electron microscopy revealed a double-shelled structure with icosahedral symmetry.[139,228,328] The outer shell is composed of two structural proteins, VP4 and VP7, which form capsomers that radiate from the inner capsid composed of the major structural protein VP6.[142,262] This inner shell surrounds a core containing the segmented, double-stranded RNA viral genome and three additional structural proteins, VP1, VP2, and VP3.

Much greater structural definition was obtained by cryoelectron microscopy (Fig. 185–1). This technique showed that the rotavirus core is surrounded by a third protein shell composed of VP2,[440,500] which can self-assemble into corelike particles when it is expressed in insect cells by a baculovirus recombinant.[108,621] Thus, the mature rotavirus particle contains three protein layers with radii of 21 to 26.5 nm (inner layer), 26.5 to 35 nm (intermediate layer), and 35 to 38 nm (outer layer). Detailed analysis of the outer layer suggests that it is composed primarily of the VP7 glycoprotein (780 molecules/virus), which contains 132 aqueous channels that are positioned over 132 channels within the perforated VP6 intermediate shell, also composed of 780 molecules/virus.[442,610] Sixty dimers or trimers of the VP4 protein, 20 nm in length, are anchored to the VP6 layer and form spike-like projections as they extend through and 11 to 12 nm beyond the VP7 layer.[439,440,500,609,611] Thus, the full diameter of the mature rotavirus particle, including the VP4 spikes, is approximately 100 nm.

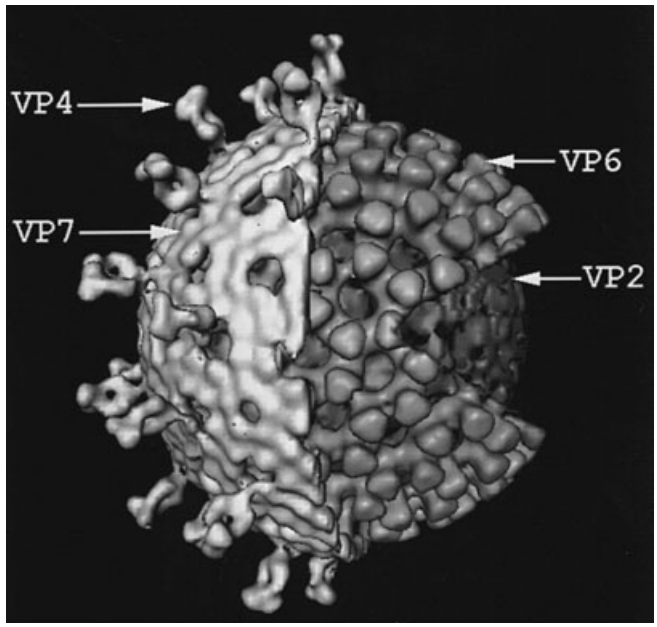

Figure 185–1 Computer-generated image of the triple-shelled rotavirus particle obtained by cryoelectron microscopy. The cutaway diagram shows the outer capsid composed of VP4 spikes and VP7 shell, intermediate VP6 shell, and inner VP2 shell surrounding the core containing the 11 double-stranded RNA segments and VP1 and VP3 proteins. *(Courtesy of Dr. B. V. V. Prasad, Baylor College of Medicine, Houston, TX.)*

Further examination of the rotavirus structure by cryoelectron microscopy has indicated that the inner layer composed of VP2 molecules not only encloses the viral genome but interacts with it as well.[441] This interaction has been found to cause significant conformational changes in the VP2 structure. Furthermore, VP1 and VP3 have been proposed to form a complex below the VP2 layer that interacts with ordered portions of the genome.[441] This interaction appears to be a prerequisite for transcription and capping of new mRNAs by VP1 and VP3, respectively, on initiation of the rotavirus replication cycle in an infected cell.[291] Finally, the amino terminus of VP2 has been reported to be necessary for the encapsidation of VP1 and VP3.[293,621] The genome of rotavirus is composed of 11 segments of double-stranded RNA that encode the six structural proteins—VP1 to VP4, VP6, and VP7—and six nonstructural proteins designated NSP1 to NSP6.[142] Each segment encodes one known rotavirus protein, except segment 11, which encodes both NSP5 and NSP6 using alternative open-reading frames.[338] The function of each of these proteins is now at least partially understood.* The genome segments range in size from approximately 660 to 3300 base pairs, and their encoded proteins, the known functions of which are briefly described in Table 185–1, have molecular weights of approximately 12,000 to 125,000.

10	750	NSP4	2.0	Nonstructural glycoprotein Transmembrane protein Enterotoxin
11	660	NSP5	2.2	Nonstructural protein Phosphorylated NSP2 and NSP6 binding
		NSP6	1.2	Nonstructural protein NSP5 binding

The double-stranded RNA genome segments of rotavirus can be extracted from viral particles and separated by polyacrylamide gel electrophoresis into 11 distinct bands visualized by ethidium bromide or silver staining (Fig. 185–2). Each rotavirus strain has a characteristic RNA profile or electropherotype, a property that has been used extensively in epidemiologic studies of these viruses.* The characteristic RNA electrophoretic pattern of group A rotaviruses consists of four size classes containing segments 1 to 4, 5 and 6, 7 to 9, and 10 and 11. RNA segments of strains belonging to less well characterized rotavirus groups (i.e., groups B to G) also can be separated into four size classes, but the distribution of segments within these classes differs from group to group.[44,421,480,482]

REPLICATION

Rotaviruses are activated by cleavage of the outer capsid VP4 protein by trypsin-like proteases into proteins VP5* and VP8,† which remain virus associated.[9,91,140,143,306] After attachment to receptors on the cytoplasmic membrane‡ through association with protein VP8,§ the activated virion either passes directly through this membrane or is taken within a vesicle into the cytoplasm.[141,168,258,303,523,524] Either during membrane penetration[110,524] or soon thereafter, the outer capsid proteins are removed, thus stimulating the RNA-dependent RNA polymerase (i.e., the VP1 transcriptase) associated with the inner shell to synthesize the 11 viral mRNAs that are capped by VP3, extruded from the virus cores through channels in the VP2 and VP6 protein layers at the 12 vertices of the viral particles, and subsequently translated into viral proteins.[138,157,221,292,329,414,417,436,565] Once viral proteins accumulate within the cytoplasm, large inclusions or viroplasms are formed in which the assembly of virion precursors is initiated.[5,8,145] Particle assembly may be initiated by the formation of complexes within the viroplasm that contain plus-stranded RNAs from the 11 genome segments along with VP1 and VP3 and RNA-binding nonstructural proteins NSP2, NSP5, and NSP6.[413,529] Although the mechanism is unknown, the virus faithfully assembles and packages one of each of the plus-stranded RNAs within individual precursor viral complexes. These complexes eventually lose their nonstructural proteins, evolve into double-layered viral particles with the sequential addition of VP2 and VP6, and convert their single-stranded RNAs into double-stranded genome segments.[73,169,325,414-416,418,600] The double-layered particles then bud into the rough endoplasmic reticulum after their transient association with the NSP4 transmembrane glycoprotein.[70,318,354,385,437,531] VP4 is added either before entry into the endoplasmic reticulum or sometime thereafter. The other rotavirus glycoprotein VP7, which becomes sequestered within the rough endoplasmic reticulum, then is added to complete the formation of mature viral particles.[93,317,318,438,520] These mature viruses accumulate within the lumen of the rough endoplasmic

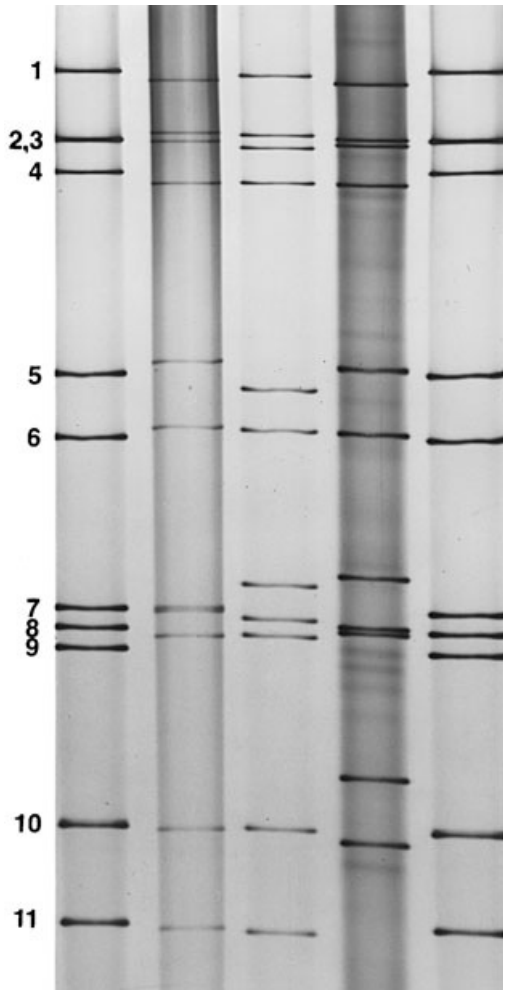

Figure 185–2 Polyacrylamide gel electrophoretic patterns of genomic RNAs obtained from group A human rotaviruses and visualized by silver staining. The patterns demonstrate the characteristic four size classes of RNA separated into groups of 4, 2, 3, and 2 segments each. Human rotavirus strains included (from left to right) are as follows: lane 1, Wa; lane 2, 248 strain; lane 3, 456 strain; lane 4, DS-1; lane 5, Wa.

reticulum until cell lysis occurs, as a result of either accidental cell death (oncosis)[428] or programmed cell death (apoptosis).[521] In cell culture, maximum production of infectious rotaviruses is found at approximately 12 hours after infection is initiated.[90]

CLASSIFICATION OF ROTAVIRUS

ELECTROPHEROTYPES AND GENOGROUPS

A variety of classification schemes have been used to characterize rotaviruses for epidemiologic purposes. Each scheme, however, is intertwined with a unique property of viruses with segmented genomes (i.e., the ability to form reassortants). During the rotavirus replication cycle, newly formed plus-sense viral mRNAs are free within the viroplasm before incorporation into replication intermediates in the first stages of virion assembly.[447] From these genomic precursors, the appropriate number and combination of segments are selected for assembly of progeny virions. Co-infection of cells with more than one virion permits reassortment of the mRNAs from both parents. If co-infection is with different strains of virus, reassortment of mRNAs results in progeny that are genetic mosaics of the co-infecting strains (Fig. 185–3). These new strains, or reassortants, are identified by their specific array of genome segments, usually through their electrophoretic mobilities during polyacrylamide gel electrophoresis (i.e., electropherotypes). The properties of the new virus strains depend on which segments are inherited from which parent and the functional behavior of each particular combination of segments and their protein products.

Rotavirus reassortants form readily in cell culture[170,192,447,554,586,587,589] in co-infected experimental animals[53,184] and in humans,[246,339,598] which is responsible, at least partially, for the variety of rotavirus strains found in nature.[188,298,541,594,617] Reassortant formation between rotavirus strains is not a universal phenomenon, however. For example, no evidence that reassortants form between strains belonging to different rotavirus groups has been found.[612] Even within group A rotaviruses, severe limitations exist within strain combinations that are capable of forming stable reassortants, limitations that appear to be related directly to the degree of genetic variation between strains.[447,586]

One outcome of restricted reassortant formation between rotavirus strains is the concept of genetic families[160] or genogroups.[371] A genogroup is composed of rotavirus strains with gene segments that form interstrain RNA-RNA hybrids of sufficient stability to migrate as defined bands during polyacrylamide gel electrophoresis.[371] Thus, members of a genogroup share a high degree of genetic relatedness and have significantly less genetic homology with members of other genogroups. Because rotavirus genogroups appear to be species specific,[154,370,371] interspecies transmission of rotaviruses should be detectable readily by genogroup analyses. Almost all human rotaviruses belong to the Wa or DS-1 genogroup,[160,372,597] a designation developed from these prototype strains. The concept of genogroup has been used extensively to determine the origin of rotaviruses causing human infections and disease, particularly to detect viruses or reassortants with gene segments of animal origin.[55,113,117,118,134,361,368,369,553]

SEROTYPES

Both outer capsid proteins of rotavirus, VP4 and VP7, contain neutralization epitopes, and thereby both are involved in determination of serotype.[198,200,235,257,391] Serotyping originally was based solely on differences in the VP7 protein because animals hyperimmunized with rotaviruses develop most neutralizing antibody to this protein. Cross-neutralization studies conducted with these hyperimmune sera readily separated the strains into VP7 serotypes.[236,604] When researchers later found that VP4 could, in some cases, be the dominant neutralization protein,[86,423,591,594] a dual serotyping scheme was required. Rotavirus classification based on VP4 and VP7 designates P type and G type to describe the protease sensitivity and glycosylated structure of these two proteins, respectively.[142] Although VP7 serotypes could be determined readily by cross-neutralization studies, serotype determination was more difficult to make for VP4.[186,319,407,507,527] Therefore, two numeric systems were devised to classify the VP4 protein in rotavirus strains. One is based on comparative nucleic hybridization and sequence analyses (genotypes),[142,171,190] and the second is based on neutralization (serotypes) with use of antisera against baculovirus-expressed VP4 proteins[186] or reassortants with specific VP4 genes.[507] The P serotype usually is indicated by an open number, whereas the P genotype is noted with a bracketed number. For example, the most common P type worldwide belongs to serotype P1A and genotype 8, thus designated P1A[8].

Until recently, 15 G types[142,232] and 20 P types[173] had been identified. However, several new P types have been identified on the basis of sequence analyses within the past few years, bringing

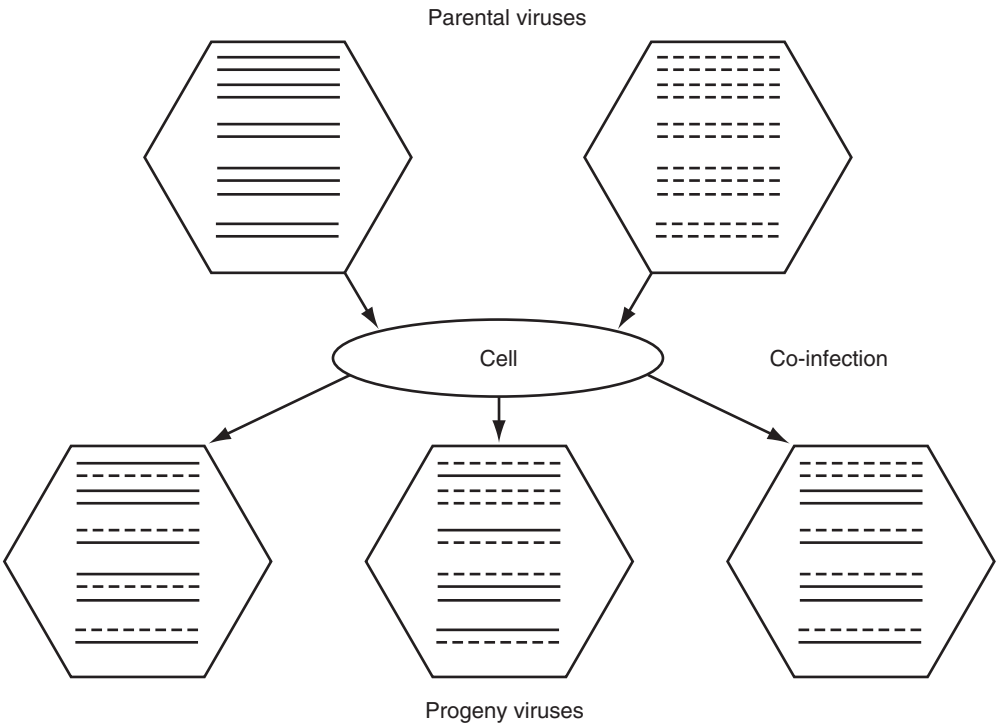

Figure 185–3 Diagram of the formation of reassortant progeny rotaviruses after co-infection of a cell with two different (parental) strains of rotavirus.

the total to 25.[232,302,344,444,448] Human rotaviruses belonging to 11 G serotypes have been isolated,[176] but most have been identified as G1, G2, G3, or G4, and strains belonging to these G types commonly have been designated serotype 1, 2, 3, or 4, respectively.[262] The severity of illness caused by viruses belonging to these four serotypes has varied little if at all.[15,20,450] Likewise, 7 P genotypes have been found in humans, but almost all illnesses have been associated with P genotypes 4, 6, and 8.[172,262] However, other G and P types commonly have been isolated in some settings; particularly, serotype G9 strains have been found worldwide, sometimes representing a large fraction of the isolates.[112,113,173,362,445,489,518,538] A Latin American study also suggested that the severity of illness may be greater with G9 strains.[301]

GENETIC LINKAGE

If the G and P types of rotaviruses found in humans could associate freely because of reassortant formation, the combinations of types for these proteins should be generated randomly; however, this clearly is not the case. For example, G1P[8] and G2P[4] rotaviruses, similar to the prototype Wa and DS-1 strains, respectively, frequently are isolated but belong to two distinct genogroups of human rotaviruses.[371] Therefore, they rarely should form stable reassortants, an assumption that has been substantiated through analyses of numerous rotavirus strains.

Other associations among gene segments also have been found. The VP6 protein or group antigen can be divided into two subgroups (I and II) on the basis of antigenic differences within this protein.[199,528] Almost all G2 and G8 human rotaviruses belong to subgroup I, whereas G1, G3, G4, and G9 human rotaviruses belong almost solely to subgroup II.[87,174,236,463,526] G3 also is a common serotype in animal strains; but in contrast to results found with G3 human strains, almost all G3 animal rotaviruses belong to subgroup I. In addition, subgroup I human but not animal strains have been found to have a characteristic "short" electropherotype associated with an inversion in the migration order of segments 10 and 11.[256,286] Thus, distinct genetic linkages have been found by serotype, genotype, subtype, and electropherotype analysis as well as by genogroup determination.

CROSS-SPECIES ROTAVIRUS INFECTIONS

Rotaviruses have an extremely wide host range, but natural cross-species infections, particularly those between animals and humans, may be rare occurrences. However, numerous human isolates appear to be animal strains or animal-human rotavirus reassortants, as determined by genogroup and sequence analyses.[55,113,117,118,134,337,361,368,369,553] The importance of these strains in human disease may be limited. Researchers have suggested, however, that once they are adapted to replication in humans, such strains may become important human pathogens.[370]

The property of host restriction has been used extensively to develop rotavirus vaccines for humans from naturally attenuated bovine, ovine, and simian rotaviruses. Oral immunization of infants with these experimental live virus vaccines has resulted in low to moderate levels of intestinal replication and partial protection against human rotavirus illnesses.[22,82,85,159,289,356,566,567] Thus, the barrier of host restriction can be bypassed sufficiently under these controlled conditions to permit the development of protective immune responses in a heterologous host. Experimental studies in animals have shown that intestinal replication of rotaviruses in heterologous species generally is limited, and if shedding of progeny viruses is detectable, it often occurs only when animals are inoculated with high doses of the heterologous viruses.[53,61,100,148,342,396,595,596]

The basis for host-range restriction is unknown and probably involves the collective properties of at least several genes. When reassortants between a murine and a simian rotavirus were used in a mouse model, however, a significant linkage to host-range restriction was associated with gene 5 encoding NSP1,[53] the primary function of which may be to block development of innate immune responses to the virus by its interaction with interferon regulatory factor 3.[16,191] Other studies also report nonrandom selection of gene 5 in progeny after co-infection of cells in

culture[192] and in mice,[184] suggesting a possible growth advantage associated with this gene. The gene encoding NSP1 also shows a high amount of sequence divergence among rotaviruses of different species,[143] which supports its possible role in host restriction. Of note, however, is that in a study in which the NSP1 gene from a bovine rotavirus that produces an abortive infection in pigs was substituted in a porcine rotavirus that replicates productively in pigs, the new reassortant still demonstrated productive replication in piglets.[47] Thus, NSP1 is not the only determinant of host range.

EPIDEMIOLOGY OF ROTAVIRUS

AGE-DEPENDENT SUSCEPTIBILITY TO ROTAVIRUS DISEASE

In addition to restrictions in interspecies transmission of rotaviruses, age restrictions are associated with rotavirus disease. In animals, rotavirus illness appears to be limited to the first days or weeks of life. Mice are susceptible to rotavirus disease only for their first 15 days of life but can experience a rotavirus infection for their entire lifetime.[347] Similarly, piglets and calves are most susceptible to rotavirus diarrhea during their first days of life.[45,276] In contrast, severe human rotavirus disease occurs most commonly in infants between 6 and 24 months of age (Fig. 185–4),[262,467,585] but milder rotavirus illnesses occur throughout our lifetimes.

Causes for the reduced severity of rotavirus disease before 6 months and after the first years of life continue to be subjects of intense investigation. Possibly, nonimmunologic, age-dependent changes that occur within the intestine, including an observed decrease in virus-specific receptors on enterocytes between suckling and adult mice, could account for this reduced severity.[461] A similar suggestion has been made for calves.[561] This suggestion also may help explain why human infants are more susceptible to rotavirus illnesses than are older children or adults. Decreased concentrations of proteases needed to cleave the VP4 protein in intestinal secretions of newborns relative to older infants also could help explain the resistance of neonates to rotavirus disease.[295]

Neonatal rotavirus infections are common occurrences and appear to be endemic in some newborn nurseries.[32,424,463] On the basis of sequence analyses, researchers proposed that neonatal strains possess unique VP4 genes, which have been classified as genotype P[6].[142,156,185] Because neonatal rotavirus infections also typically are asymptomatic, rotaviruses containing P[6] VP4 genes were designated neonatal or asymptomatic strains. Further epidemiologic studies have shown that these descriptions are not accurate; that is, asymptomatic neonatal infections sometimes are caused by non-P[6] strains,[116,118] and many symptomatic infections of older infants are caused by P[6] strains.[112-114,173,362,445,517,538] In fact, P[6] rotaviruses are probably the third most common P genotype associated with rotavirus illnesses worldwide today. Therefore, why most neonatal rotavirus infections are caused by P[6] strains and whether the P[6] genotype is in any way responsible for the asymptomatic phenotype of these infections remain unclear. However, the virulence of P[6] strains found in African neonates was associated with genetic differences in the genes encoding not only VP4 but also VP7 and NSP4, suggesting a possible linkage between multiple rotavirus genes and the virulence of neonatal strains.[408]

The onset of rotavirus disease in infants has been reported to coincide with the decline of maternal IgG antibody titers to low concentrations.[624] Furthermore, excellent correlations have been observed between responsiveness to the live rotavirus vaccine Rotarix and transplacental neutralizing antibody titers to the vaccine strains (unpublished results). Therefore, the commonly asymptomatic nature of neonatal rotavirus infections may be due, at least partially, to protection from transplacental antibody that may persist for the first months of life.[27] Mechanisms by which transplacental maternal antibody might protect against intestinal infection are unclear. Passive transfer of neutralizing antibody to the intestine of both humans and animals is associated with protection,[45,122,135,224,483,495,506,509] but circulating anti-rotavirus IgG

appears to confer little if any protection in animals.[394,508,509] Possibly, maternal IgG in humans is taken into the intestine, where it neutralizes rotaviruses before infection. Regardless of why rotavirus infection of neonates typically is asymptomatic, these infections have been found to reduce the severity of rotavirus illnesses in older infants.[29,32] For these reasons, two rotavirus strains obtained from neonates were developed initially as vaccine candidates,[14,356] and two others obtained from India[117,118] have been evaluated recently in a safety and immunogenicity study.[30]

The reduced severity of rotavirus disease in older children and adults probably is due primarily to immune responses stimulated by previous rotavirus infections. In developed as well as in developing countries, almost all humans experience at least one rotavirus infection by the time they reach 3 years of age, and circulating rotavirus antibody remains detectable indefinitely.[261,262] Protection against rotavirus infection and disease in children and adults has been correlated with titers of both circulating and intestinal rotavirus antibody.* Although these antibodies have not been established as the effectors of protection, their presence indicates a natural infection that has elicited a protective immune response.

ROTAVIRUS SEASONALITY AND SOURCES OF EPIDEMIC STRAINS

As with other respiratory and enteric viruses, distinct seasonality is associated with rotavirus disease.[104,212,266,281,546] It is particularly evident in temperate climates, where rotaviruses probably are responsible for the large increase in diarrheal deaths that occur during the winter season.[182,226,227,294] The seasonality of rotavirus disease is less apparent in tropical climates but is still more prevalent in the drier, cooler months.[213] The cause for the seasonality of rotavirus disease is a topic of considerable interest but remains unknown.

The transmission of rotavirus infections is thought to be fecal-oral, with little evidence of airborne transmission. Yet a unique pattern of rotavirus infections that follows the general direction of the prevailing winds is observed annually in North America.[294] These infections begin in Mexico and the southwestern United States in mid to late fall and travel systematically across the continent, ending in the northeastern United States and Maritime Provinces of Canada in the spring (Fig. 185–5). Until recently, this was the only description of a repetitive geographic sequence for the seasonal epidemic activity of a viral agent. However, a similar pattern of rotavirus spread was reported for western Europe, where the seasonal peak started in Spain in January and ended in the more northern countries in March.[281] These annual events, including wind movements, have no satisfactory explanations. The phenomenon appears to be independent of latitude, which argues against temperature-dependent associations and humidity. Furthermore, the electropherotypes and serotypes of isolates found in different geographic locations can vary,[581] a counterindication for a gradual, physical transmission of rotavirus infections as a wave to the north and east.

Because rotavirus illnesses occur with seasonal regularity and decrease to almost undetectable levels during the off-season, the virus must be retained in a less active state during most of each year. Retention of human rotavirus in animal reservoirs between seasons is unlikely because of the low interspecies transmissibility associated with this virus, as already discussed. Therefore, the virus may continue to replicate at low levels in humans until conditions are favorable for the annual epidemic. The occasional

*See references 35, 76, 95, 105, 195, 268, 332, 389, 563, 564, 582, 583.

rotavirus illnesses that occur in the off-season support the suggestion that humans are a reservoir. It is also possible that the virus survives in the environment, which provides continuous exposure throughout the year but results in sustained rotavirus illnesses only during seasonal epidemics. Rotaviruses are shed in extremely high concentrations (i.e., approximately 10^{11} particles/g of human feces),[590] retain their infectivity for many months at ambient temperatures,[144,272,358] and are detectable readily on environmental surfaces.[63] Therefore, the environment could be a reservoir for human rotavirus and a possible source for the initiation of seasonal epidemics.

To provide clues about the origin of rotavirus strains responsible for epidemics, many extensive studies have been performed to characterize the circulating viruses, primarily using electropherotypes, genotypes, and serotypes. From these studies, investigators have determined that rotavirus strains in a specific locale can vary little over sequential seasons or change dramatically, even within a single season.[434,463,496,526,585] Furthermore, multiple strains often are present within a region at any period during an epidemic. Because gene reassortment can be extensive after coinfection with rotavirus,[114,188,298,301,339,416,447,598] identification of the source of new strains within a defined geographic area is difficult. They could be derived from outside sources, they could be obtained from local reservoirs, or they could arise by gene reassortment of circulating strains. Clearly, if the source of virus responsible for initiating annual rotavirus epidemics could be identified, much would be learned about the epidemiology of rotavirus.

PATHOLOGY AND PATHOGENESIS

HISTOLOGIC AND STRUCTURAL CHANGES IN INTESTINAL VILLI

After fecal-oral transmission of rotavirus, infection is initiated in the upper intestine and typically leads to a series of histologic and physiologic changes. These changes have been examined extensively, particularly through experimental infections of animals (Fig. 185–6). Studies in calves revealed that rotavirus infection caused the villus epithelium to change from columnar to cuboidal, which resulted in shortening and stunting of the villi.[348,349,420] The cells at the villus tips became denuded; in the underlying lamina propria, the numbers of reticulum-like cells increased and mononuclear cell infiltration was observed. The infection started at the proximal end of the small intestine and advanced distally. The most pronounced changes usually, but not always,[539] were associated with the proximal small intestine. When bovine rotaviruses of different virulence were compared, a low-virulence strain infected the proximal small intestine poorly but infected more villus enterocytes in the mid and distal intestine than did the high-virulence strain.[48,216] Although the low-virulence strain replicated in these cells and caused cytopathic effects, it did not damage the intestinal structure or affect function. Similar observations were made after piglets were infected with rotavirus.[98,197,419,532]

The pathology of murine rotavirus infection also has been examined in several studies, and the results are similar to those found in larger animals.[3,13,19,96,285,304,405,513] Many of these studies have been conducted with heterologous rotavirus strains that require infection with much greater quantities of virus because of the restricted replication of these viruses in mice.[19,53,148,201,396,596] The histologic changes induced by these heterologous strains are similar to those found after murine rotavirus infection, even though viral replication is limited after oral inoculation with these viruses. Mice are susceptible to rotavirus diarrhea during their first 2 weeks of life, and recently a series of strikingly clear results on murine rotavirus infection in neonatal mice were reported.[39] They included time-dependent histologic changes in the intestine, kinetics of rotavirus replication, shortening of intestinal villi, induction of apoptosis, and alterations in cell migration kinetics.

Ward, Ohio Agricultural Research and Development Center, The Ohio State University, Wooster.)*

Studies with the mouse model also have revealed a potential hazard associated with the possible use of heterologous viruses as vaccine candidates. Although replication of the homologous strains appeared to be restricted to the intestine, oral inoculation of either mice with severe combined immune deficiency (SCID) or normal mice with a simian rotavirus resulted in its spread to the liver and induction of hepatitis.[550,551] Because of evidence that shows abnormal liver function occurs during natural rotavirus infection in humans,[204,206,283] this observation caused concern about the use of animal strains as vaccine candidates. However, no significant alteration of liver function has been associated with any rotavirus vaccine candidate after extensive investigations, even though most candidates have been derived from animal rotavirus strains. As discussed in detail in a later section, however, use of the same simian rotavirus strain in combination with three monoreassortants of this virus as a vaccine in infants was found to increase the incidence of intussusception in the week after administration of the first dose of vaccine.[404] This occurrence caused the removal of the vaccine from the market.

A few studies have examined the pathologic changes in the intestines of humans, but the results appeared to be similar to

those found in animals.[228,525] Tissue tropism for rotavirus infection in humans also appeared to be restricted normally to villi of the small intestine. Sporadic instances of nongastrointestinal rotavirus-associated disease, including the association with abnormal liver function mentioned before, as well as respiratory and nervous system involvement have been reported.* However, because no consistent evidence of extraintestinal replication of rotavirus had been forthcoming, the general assumption was that rotavirus disease is strictly intestinal. This assumption, however, changed dramatically in 2003 when both antigenemia (presence of rotavirus protein in the blood) and viremia (presence of live rotavirus in the blood) were found during rotavirus infection in several strains of animals and in humans.[38] Since that time, this observation has been confirmed with a number of studies that included several in humans.[11,37,75,109,147,151,373] On the basis of these observations, the possibility that rotaviruses are a common cause of a variety of nonintestinal diseases has gained impetus and will be a subject of intense investigation in coming years.

As with host-range restriction, the molecular basis for pathogenicity has not been established. Offit and coworkers[392] reported that the virulence of reassortants generated between heterologous rotaviruses and tested in a mouse model correlated with the presence of the VP4 protein from the more virulent virus. Neither rotavirus strain used in this study (a simian and a bovine strain) replicated efficiently in mice, however, suggesting that the observation may have limited applicability. A later study with murine-simian rotavirus reassortants revealed no association between the VP4 protein and virulence.[53] In that study, the strongest association between virulence and a gene product was with NSP1, a nonstructural protein.

Associations between virulence and specific gene segments also were examined in piglets. Virulence variants that appeared to differ only in their VP4 genes were isolated from the feces of an infected pig.[46,60] To eliminate the possibility that virulence was determined by other gene products, the VP4 gene of the virulent strain was transferred into the avirulent strain by reassortment.[530] This transfer caused the avirulent strain to become virulent.[51] In another study with reassortants between a virulent porcine virus and a human strain attenuated for piglets, investigators found that the porcine rotavirus genes encoding VP3, VP4, VP7, and NSP4 were required for virulence in piglets.[233] Whether either of these observations has general applicability or pertains only to a limited combination of rotavirus strains because of specific interactions among their proteins remains to be determined. Passage of a porcine rotavirus in piglets was reported to increase its virulence dramatically,[46] whereas passage of a virulent porcine rotavirus in cell culture attenuated this virus.[548] Thus, the associations between specific rotavirus genes and virulence can be altered readily by natural selection through mutation. Until very recently, one could not make specific nucleotide changes within rotavirus genes and re-incorporate the modified gene into new infectious rotavirus particles. However, a system of reverse genetics for rotavirus has now been reported, at least for the rotavirus gene segment encoding VP4.[279] Expansion of this system of reverse genetics to the other rotavirus genes should permit investigators to identify specific amino acid and protein structural changes that are responsible for rotavirus virulence and attenuation.

MECHANISMS OF DIARRHEA

Although rotaviruses cause severe diarrhea in numerous species, including humans, the mechanisms responsible have not been determined and may be due to multiple factors. An early study in piglets indicated that net sodium and calcium fluxes were not different between control and infected animals, but glucose-mediated sodium absorption was diminished by rotavirus infection.[120] On the basis of this and other physiologic changes, the authors concluded that retarded differentiation of uninfected enterocytes that migrated at an accelerated rate from the crypts after the virus had invaded villus cells was responsible for absorptive abnormalities. Another study with piglets led to the conclusion that destruction of the villus tip cells causes carbohydrate malabsorption and osmotic diarrhea.[193] In mice, researchers reported that carbohydrate malabsorption did not occur as in piglets and, therefore, crypt cell secretions may be the cause of fluid loss.[97] Intestinal prostaglandin E_2 concentrations were reported to be elevated after rotavirus infection of piglets, leading to the suggestion that prostaglandin E may be a secretory component of diarrhea in this animal model.[625] Additional studies in animals and humans concerning changes in the absorption of macromolecules across the intestinal surface after an episode of rotavirus infection have revealed no general pattern.[197,223,243,384] Uptake of some molecules, such as horseradish peroxidase and 2-rhamnose, is increased; uptake of other molecules, such as lactulose and D-xylose, is decreased. Therefore, the relationship between the absorptive properties of intestinal mucosa induced by rotavirus infection and development of diarrhea remains unclear.

The importance of virus replication for induction of rotavirus diarrhea also has been challenged. Inoculation of mice with heterologous rotaviruses had been observed to produce diarrhea only when mice were inoculated with large quantities of these viruses, and in these cases, diarrhea occurred despite a lack of efficient viral replication.[53,396,596] Subsequently, inoculation with a large number of inactivated particles from a heterologous rotavirus was reported also to result in diarrhea.[502] The authors suggested that rotavirus attachment or entry into cells was sufficient to induce diarrhea in this model and that the mechanism of rotavirus-induced diarrhea was consistent with a viral toxin-like effect exerted during virus-cell contact.

Diarrhea also has been induced in infant mice and rats by intraperitoneal inoculation with the rotavirus NSP4 protein as well as with a 22–amino acid peptide derived from this protein.[12,360] Investigators observed that this protein and its peptide caused an increase in calcium concentration in insect cells when added exogenously.[535] In subsequent experiments, NSP4 and its peptide were found to increase the levels of intracellular calcium[536] by activating a calcium-dependent signal transduction pathway that mobilizes transport of this ion from the endoplasmic reticulum.[133,535] Further reports suggest that NSP4 possesses membrane destabilization activity[54,534] that may result from increased intracellular calcium concentrations, resulting in cytoskeleton disorganization and cell death.[56,57,428,429] Thus, binding of NSP4 to intestinal epithelium after its release from infected cells may contribute to altered ion transport and diarrhea. Another possible target for secreted NSP4 is the enteric nervous system, which lies under the villus epithelium. Rotavirus infection has been shown to activate this system in mice, and drugs that block nerve activity attenuate rotavirus-induced fluid secretion in vitro and attenuate diarrhea in vivo.[314] Whether this is a major mechanism of diarrhea occurring after rotavirus infection remains to be determined. Some additional studies in mice support a role for NSP4 as a cause of diarrhea,[231,622] whereas others indicate that mutations in NSP4 are not responsible for attenuation of rotavirus in either mice or humans,[7,297,593] thus questioning its importance as a cause of diarrhea in nature.

IMMUNITY

Much has been learned about the immune response to rotavirus, but the key question of what provides protection from infection

*See references 220, 229, 230, 254, 270, 280, 299, 322, 335, 363, 378, 380, 383, 409, 486, 550, 551, 555, 557, 601, 613, 615, 623.

or disease remains unanswered. Rotavirus infections clearly induce a humoral immune response beginning with production of IgM antibodies and later including IgA and IgG antibody.[121,205,340,458] Infection also induces local, intestinal antibodies that are predominantly IgA but also include IgG and IgM initially.[24,106,121,205,332,340,458] After infection develops in mice, as many as 50 percent of all IgA-producing B cells in the lamina propria of the intestine can be, for at least a brief time, rotavirus-specific.[503] Cell-mediated immunity, including lymphoproliferative responses, also can be detected transiently after infection develops in adult humans,[247,321,400,401,469,540] and a brisk cytolytic T-cell response ($CD8^+$) has been found in the intestines and spleens of infected mice.[397,398]

The most immunogenic protein appears to be VP6. Thus, antibodies measured by enzyme-linked immunosorbent assay (ELISA) are directed mainly at this protein, but they are not neutralizing antibodies.[501] Some evidence suggests, however, that IgA antibodies directed at VP6 can be protective by mechanisms that are not completely understood but may involve intracellular inhibition of rotavirus replication within infected enterocytes during polymeric antibody transport to the intestinal lumen.[62,149,498] Antibodies directed at either the VP4 or the VP7 proteins can neutralize virus and provide protection when they are given passively to animals.[333,402] Although numerous problems are associated with measurement of the VP4- and VP7-specific responses in humans,[390] the preponderance of information suggests that after infection occurs, the predominant response appears to be to the VP4 protein[58,591,594]; VP7 antibodies were noted more commonly after vaccination with a poorly replicating vaccine, WC3.[23,588] Both VP4 and VP7 proteins can induce type-specific and cross-reactive serotype responses, although most of the VP7 responses are type specific, whereas those directed at VP4, especially the VP5 region,* are more likely to be cross-reactive.[186,196,319,359,527] These findings have important implications for vaccine development, as will be discussed.

Rotavirus-specific cytotoxic T lymphocytes recognize epitopes on several rotavirus proteins that generally are not serotype specific, including at least VP7, VP4, VP6, and VP2.[164,393,398] Adoptive transfer of splenic lymphocytes from mice infected with homologous or heterologous rotavirus strains can protect suckling mice.[399] Protection was major histocompatibility complex restricted and appeared to depend on the presence of $CD8^+$ lymphocytes. Similarly, $CD8^+$ splenic or intraepithelial lymphocytes obtained from the intestine of rotavirus-infected mice can eliminate the chronic rotavirus shedding seen in SCID mice.[132] Adoptive transfer of $CD8^+$ cells from mice immunized with baculovirus recombinants expressing VP1, VP4, VP6, or VP7 also can terminate the chronic shedding in SCID mice.[131] Studies revealed that adoptive transfer of splenic $CD4^+$ cells from either naive or rotavirus (VP6)–immunized mice resolved shedding in chronically infected, immunodeficient Rag-2 mice.[346] Therefore, either $CD8^+$ or $CD4^+$ T cells are capable of resolving rotavirus infections. Possible roles of these cells in resolution or prevention of human rotavirus infections remain to be determined.

An obvious place to begin to understand rotavirus immunity is to determine the effectiveness of previous rotavirus infections in prevention of subsequent infections and disease. The important questions relate not only to the degree of protection but also to whether protection is serotype specific. As discussed earlier in this chapter, multiple serotypes of human rotavirus are based on neutralization epitopes on the VP4 (P serotypes) and VP7 (G serotypes) outer capsid proteins. Thus, protection may be limited to those strains that share neutralization epitopes, or it may be associated with the development of other B- or T-cell immune responses to shared epitopes.

Many investigators have reported that natural rotavirus infections produce incomplete protection, but little doubt exists that previous infections protect against severe disease associated with re-infection.* In a large study, protection from both rotavirus re-infection and rotavirus diarrhea increased with each new infection.[563] Sequential infections even with the same serotype have been reported, however. In the initial study reporting rotavirus disease with re-infection by the same serotype, the investigators noted that protection of young children in a Japanese orphanage lasted 6 months then declined after 1 year.[76] This study noted a close correlation between titers of serotype-specific antibody and protection. Some animal studies also support a role for serotype-specific infection. Thus, in a study with piglets, immunization with reassortant viruses containing either the VP4 or the VP7 protein of the same serotype was protective, whereas immunization with reassortants containing heterotypic genes for these proteins was not protective.[234] In other studies using mice, this association was not as clear,[596] and protection was better correlated to serum and intestinal levels of IgA.[148,342,347]

Although, as discussed earlier, re-infections with rotavirus appear to be common occurrences, other studies have shown protection that lasts at least 1 year.[26,32,581] Neonates infected within the first 2 weeks of life were protected against severe disease but not against re-infection in one study.[32] In another, infants who developed a symptomatic or an asymptomatic rotavirus infection during the first year of study were protected against contraction of a subsequent rotavirus illness or even an asymptomatic re-infection during the following year.[26] Similarly, when the placebo recipients of a large vaccine trial were observed, a natural rotavirus infection in the first year was found to be 93 percent protective against a symptomatic re-infection in the second year.[581] This protection occurred even though the G1 strains that circulated during the first year were responsible for only 66 percent of rotavirus disease in the second year. Other studies conducted in less developed countries and in daycare centers have not shown the same degree of protection.[35,95,330,456,563] Differences in these studies may be due to the variation in circulating strains, the dose of exposure, or the duration of protection.

Protection has been correlated to both serum and stool antibody titers produced after natural rotavirus infection.[35,76,95,105,106,332,389,433,563,564,583] In one study, serum antibody levels, especially IgA, were found to be a marker for protection.[564] Reports of a correlation with serotype-specific neutralizing antibody and protection[76,389] have not been supported in other larger studies.[225,584,624] In the largest study, which was conducted in Bangladesh during a 2-year period when four major G serotypes circulated, the titers of both homologous and heterologous neutralizing antibody were significantly lower in patients with acute rotavirus disease than in matched control subjects.[584] However, further analysis could not find a correlation with serotype-specific neutralizing antibody. Thus, protection seemed to be correlated better with the magnitude of the response rather than with specific neutralizing responses. Similarly, animal studies in both calves and mice have shown that protection can occur in the absence of serotype-specific neutralizing antibodies in the serum, feces, or intestinal washes.[49,50,342,345,596,603]

Some results from rotavirus vaccine trials also fail to support a role for serum neutralizing antibody and protection. Thus, immunization with heterologous animal rotavirus vaccines has provided protection in some studies without inducing serum neutralizing antibody to human serotypes.[84,569] In other studies that failed to demonstrate overall efficacy, protection was seen in those who developed the highest antibody titers to the heterologous vaccine,[27,592] again implicating the magnitude of the response

*See references 26, 32, 35, 76, 95, 123, 166, 330, 388, 456, 476, 563, 564, 581, 607.

*See references 26, 32, 35, 76, 95, 123, 166, 330, 388, 456, 476, 563, 564, 581, 607.

rather than specific neutralizing antibody titers. It is possible, however, that serum antibodies are merely markers for the true protective responses in the intestine.

Studies evaluating the protective role of previous infections and the mechanism of protection have used adults in challenge studies. Although essentially all adults have been infected previously with rotavirus, they are susceptible to re-infection and mild disease on natural exposure.[237,599] Initial challenge studies revealed an association between the pre-inoculation titer of serotype-specific neutralizing serum antibody and protection.[268] These studies later were extended to show a correlation between VP7 antibody and protection but failed to establish a relationship between intestinal antibodies and protection.[195] When similar studies were conducted with a larger group of adults, the correlation between both serum and intestinal antibody became clearer.[582,583] The most significant correlations were found to be between serum rotavirus IgG and shedding and between intestinal neutralizing antibody and illness. However, some subjects with high titers of antibody became infected and ill, whereas some subjects with low titers appeared to be protected.

As already noted, animal models also have proved useful for examining protective immune responses. Initially, large animals, such as piglets and calves, were used, whereas mouse models were limited to the study of passive protection because mice are susceptible to rotavirus diarrhea only for the first 15 days of life. Use of mice was extended to studies on protection with the advent of the adult infection model in which protection against fecal shedding of rotavirus antigen, rather than protection against diarrhea, was used as the indicator of active immunity.[596]

Initial studies of passive immunization, including cross-fostering studies in mice, found that gastrointestinal but not circulating antibodies were protective and that secretory IgA was more effective than was IgG at providing protection.[45,311,394,483,495,506] Animals can be protected with antibodies directed at either VP4 or VP7.[395,402] Similarly, active immunization against both homotypic and heterotypic challenge has been demonstrated in mice, calves, pigs, and rabbits.[50,99,101,234,345,596,602] Protection has been seen after both oral and parenteral immunization, although what provides protection is not clear. In studies of mice, although no correlation could be found between protection and either serum or intestinal neutralizing antibody, levels of serum or fecal rotavirus IgA did correlate with protection.[148,342]

The use of these models has been extended to gene knockout mice to distinguish the role of $CD8^+$ cells and antibody in protection and have particular relevance to vaccines. These studies indicated that $CD8^+$ cytolytic cells are important for resolution of an infection, but only antibody could provide protection from a subsequent challenge.[162,163,165,341] Other reports have indicated that antibody may be important for complete resolution of a rotavirus infection as well as for protection against subsequent infection.[343,559] A study in mice revealed that oral immunization of mice with a rotavirus that was fully heterotypic to the challenge strain provided nearly complete protection against fecal rotavirus shedding, but this protection was dependent on the ability of antibody to be transported through intestinal epithelial cells.[560] This result supports the earlier suggestion that heterotypic protection after live virus immunization may be due to intracellular inhibition of virus replication, at least in mice.[149,498,560] Taken together, these results indicate that the levels, location, and targets of protective antibody as well as the proteins against which it is directed are of immediate importance, provided the results found in mice are relevant to larger animals and humans.

Information on protective immune responses continues to become available and should prove useful in the development of rotavirus vaccines. The absence, to date, of a reliable immunologic marker of protection, however, continues to render vaccine trials more difficult.

VACCINES

The development of rotavirus vaccines has been a high priority for public health institutions.[244,455] Cost-effectiveness analyses have shown that a rotavirus immunization program would be cost-effective from the perspective of society and the health care system.[545] Because natural rotavirus infections induce excellent protection, at least against severe rotavirus disease, vaccine efforts have been directed mostly at the development of live attenuated rotavirus vaccines.[102,155,180] Most of these efforts have concentrated on the use of animal rotavirus strains, labeled the Jennerian approach[264,389] because it relies on the natural attenuation of animal viruses in humans for safety and largely heterotypic immune responses for protection. The initial efforts with animal rotavirus vaccines yielded inconsistent results. Therefore, in an attempt to make the vaccines more closely related to human strains, human rotavirus genes coding for the proteins that induce neutralizing antibody were introduced into these animal strains by creating reassortant viruses as described earlier. This approach has been labeled the modified Jennerian approach.[155] Table 185–2 lists some of the major efficacy trials conducted to date.

Just 10 years after the identification of rotavirus as an agent of severe diarrhea, the first vaccine trials were performed.[569] The initial study used RIT 4237, a bovine rotavirus. It was soon followed by evaluations of other animal rotavirus vaccines, including a rhesus monkey rotavirus (RRV or MMU 18006) and another bovine rotavirus (WC3). Next, animal-human reassortants using RRV and WC3 and a human strain (89-12) attenuated by multiple tissue culture passages were evaluated. These three vaccines went on to become licensed products (discussed later). Less extensive studies also have been performed with neonatal human viruses M37 and RV3[14,158,578] that are thought to be naturally attenuated as well as cold-adapted vaccines.[88,155] Most recently, two other promising vaccines have entered clinical trials: a bovine human (UK) reassortant[267,574] and naturally reassorted human neonatal strains isolated in India.[30,179]

Jennerian Vaccines

The initial studies of RIT (bovine) vaccine produced variable results. The vaccine was safe and effective in Finland, providing a protective efficacy of approximately 50 percent against all disease and a greater than 80 percent protection against severe disease.[566-568] However, later studies in developing countries were disappointing,[126,218,289] showing little or no efficacy. Similarly, the vaccines failed to provide protection in a study performed on the Navajo reservation in Arizona.[492]

The WC3 rotavirus vaccine similarly is of bovine origin and also appears to be free of side effects. It replicates poorly in humans, but infants develop a neutralizing antibody response to WC3 and both rotavirus IgA and IgG antibody.[27] The initial studies conducted in Philadelphia appeared promising,[84] but later trials in Cincinnati[27] and in less developed countries[175] did not show significant protection. WC3 was, therefore, used to make reassortants containing rotavirus genes encoding the VP7 and VP4 proteins of human serotypes, which became the vaccine approved in the United States (RotaTeq) and discussed later.[88]

RRV replicates better in humans than do the bovine vaccine strains, perhaps because it is a G3 strain and shares serotype specificity with human G3 strains, but it also produces mild side effects, including low-grade fever and mild diarrhea, especially when it is given to older children who have lost maternal antibodies.[310,426,570] RRV induces serum rotavirus IgG and IgA, intestinal rotavirus IgA, and RRV-neutralizing antibody but no neutralizing antibody against non-G3 human rotavirus.[79,311,426] Protection with this vaccine was inconsistent, ranging from greater than 50 percent, even in developing countries,[159,320,425,452] to moderate (20-50%),[453,576] to nonexistent.[79,492] Some evidence suggests that pro-

tection is more effective in G3 than in G1 outbreaks,[102,155] but the evidence is not conclusive.

Reassortant (Modified Jennerian) Vaccines

Because of the consensus that homotypic immunity might increase the protection seen with rotavirus vaccines and because of a lack of consistent protection with the animal strains, the next efforts were directed toward creating reassortant vaccines that contain the VP7 or the VP7 and VP4 encoding genes of human rotavirus strains, with the remainder of the genes from an animal strain. As discussed earlier, these proteins were chosen because they induce neutralizing antibody. The segmented genome of rotavirus renders production of these reassortant rotaviruses relatively easy. One goal of this strategy is to create a multivalent vaccine containing viruses with human rotavirus genes representing the main human serotypes. Reassortant vaccines were developed with RRV[355,357] and WC3[25,85,542] and later UK[267,574] as the animal strain.

The RRV-human VP7 rotavirus reassortants were developed into Rotashield. This vaccine contains RRV and reassortants with the VP7 genes of G1, G2, or G4 serotype and the 10 other genes from RRV (Fig. 185–7). The G3 serotype virus of this vaccine is RRV. Thus, four of the common VP7 serotypes were incorporated into the vaccine. Vaccination produced a rotavirus IgG and IgA serum antibody response, but neutralizing antibodies are produced predominantly to RRV rather than to the human serotypes.[22,423,451] This finding appears to be consistent with the experiments showing that VP4, rather than VP7, is more immunogenic after natural infection.[591,594]

Extensive evaluations of the tetravalent RRV reassortant were completed before licensure.[21,252,427,451] In two large trials conducted at centers across the United States,[21,451] the tetravalent vaccine was found to be safe, with the subjects having a slight increase in temperature after the first dose. The efficacy of the vaccine against rotavirus disease for the first year was 49 to 64 percent, whereas during a 2-year follow-up, it was 57 percent. Protection increased with severity scores to a level of about 80 percent for severe disease. Vaccination also significantly decreased the number of medical office visits for rotavirus gastroenteritis or dehydration. Vaccination appeared to provide protection against both G1 and G3 serotypes. Similar results were reported from Finnish studies, except that fever occurred somewhat more commonly and efficacy was somewhat enhanced.[252] Protection similar to that seen in the U.S. studies also was provided by the vaccine when it was used in a less developed country, Venezuela.[430]

For these reasons, the vaccine Rotashield was licensed in the United States in 1998 and recommended for general use in all infants.[6] However, less than 1 year after licensing, 15 cases of intussusception that occurred shortly after vaccination was administered were reported to the Vaccine Adverse Events Reporting System.[67] Subsequent analysis led the American Academy of Pediatrics Advisory Committee on Immunization Practices to conclude that an association existed between receipt of the vaccine and development of intussusception and to withdraw the recommendation for use.[1,68] The vaccine was, therefore, withdrawn by the manufacturer.

The initial publication describing the association reported an increased risk for development of intussusception 3 to 14 days after receipt of the first dose of vaccine (adjusted odds ratio, 21.7).[366] A smaller risk also existed after receipt of the second dose of vaccine. Researchers estimated that one case of intussusception attributable to vaccination with RRV would occur for every 4670 to 9474 infants vaccinated. Ecologic studies that followed reported a lower vaccine-attributable risk.[365,504] The exact excess burden of intussusception during the life of the child has yet to be defined, but the best estimates are 1 per 10,000 to 12,000.[278,284,430,504] Further analysis also has revealed that the risk is age related and substantially increased in those older than 90 days.[472,505] The

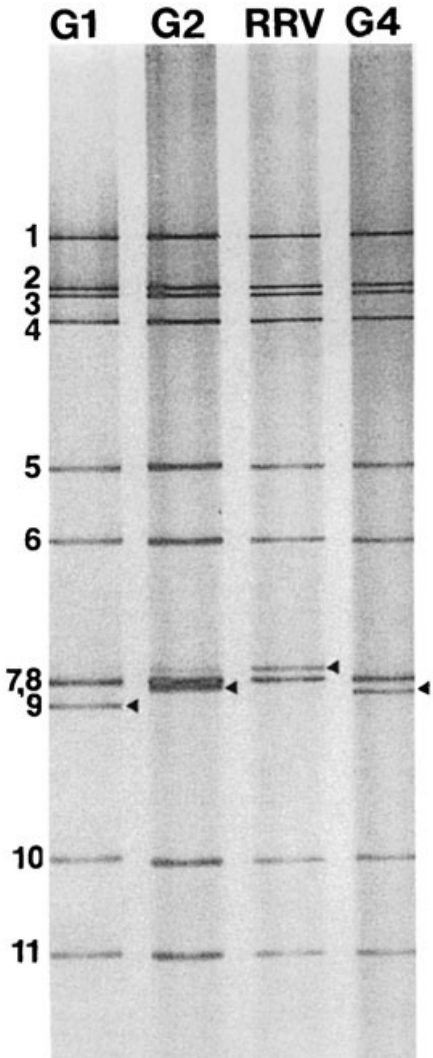

Figure 185–7 Polyacrylamide gel electrophoretic patterns of the genome segments from RRV and the G1, G2, and G4 reassortant strains that compose the tetravalent RRV-based vaccine. The strains all contain 10 RRV genes and differ only in the gene segment encoding the VP7 protein, which migrates in the seventh (RRV) or ninth (reassortants) position, as designated by arrowheads.

pathogenic mechanism for this association has yet to be defined.[316] The relationship, if any, between wild-type rotavirus infection and intussusception is discussed in the clinical section.

Further evidence for the effectiveness of this approach can be found in a large post-licensure vaccine effectiveness study. In this study, Rotashield was 100 percent (95% confidence interval: 75%, 100%) effective in preventing hospitalization due to rotavirus[512] in children receiving three doses of vaccine. When two doses of vaccine were given, the vaccine also was 100 percent effective (95% confidence interval: 62%, 100%), and one dose was 89 percent (49%, 97%) effective.

In 2006, a pentavalent WC3-based reassortant vaccine, RotaTeq, was licensed, first in the United States and subsequently in the European Union, Canada, and Mexico. After the WC3 vaccine was shown to be safe but not consistently effective,[27,84,175] a monovalent vaccine containing the VP7 protein of a human G1 rotavirus was developed. This vaccine was reported to be effective, especially against more severe disease, during a predominantly serotype G1 outbreak in Rochester.[564] Next, a WC3-based reassortant quadrivalent vaccine including both VP7 and VP4 human rotavirus gene substitutions with G1, G2, G3, or P[8] substitutions and most other segments from WC3 was evaluated. In studies conducted at multiple centers in the United States, it was shown to be safe and effective against all cases of rotavirus gastroenteritis (75%) and especially against severe cases (100%).[83] An important note is that in the multiple trials of WC3 and WC3 reassortant vaccines, the viruses replicate less well than does RRV and do not induce fever as was noted with RRV and RRV reassortants.

The pentavalent RotaTeq vaccine contains the VP7 and VP4 reassortants plus a VP7 G4 reassortant.[89] The vaccine is suspended in a liquid sodium citrate and phosphate buffer at a minimum titer of approximately 1.2×10^7 infectious units per dose. The vaccine is given in a three-dose schedule in infants between 6 and 32 weeks of age, with a first dose administered between 6 and 12 weeks of age.

Because of the association of Rotashield with intussusception, the next rotavirus vaccines were required to undergo very large safety trials. The large pivotal trial of RotaTeq of more than 70,000 infants showed that the vaccine was safe and, unlike Rotashield, did not induce fever.[575] Most important, no association with intussusception was found. Intussusception occurred in 12 vaccine recipients and 15 placebo recipients within 1 year after the first dose of vaccine was administered; these figures include six vaccine recipients and five placebo recipients who developed intussusception within 42 days after receiving any dose (relative risk, 1.6; 95% confidence interval, 0.4 to 6.4). The vaccine also was highly effective, reducing all G1-G4 rotavirus gastroenteritis by 74.0 percent, severe gastroenteritis by 98.0 percent, and hospitalizations and emergency department visits by 94.5 percent.

Attenuated Human Vaccine

The other new vaccine, available first in Mexico in 2005 and then in the European Union and throughout much of the world including developed, less developed, and developing nations, is Rotarix. It is a live oral vaccine, based on the attenuated human strain 89-12. Strain 89-12 is a G1P[8] strain, the most common strain worldwide, initially obtained from an infant with rotavirus gastroenteritis in Cincinnati, Ohio.[28] The isolate was attenuated by multiple passages in tissue culture and then evaluated as a vaccine. Studies using 89-12 showed that it was safe, although similar to Rotashield, the 89-12 vaccine induced a low-grade fever in 19 percent of recipients. Results of a multicenter efficacy trial showed that two doses of this vaccine provided 89 percent protection against any rotavirus disease and 100 percent protection from more serious disease.[25]

The 89-12 strain was then purified by limiting dilution and further passaged in tissue culture. The final product, initially called RIX 4414 and later marketed as Rotarix, was evaluated in several studies. Initial safety testing[572] revealed that the vaccine was safe and did not induce the fever that followed the parent 89-12 vaccine. Subsequent reports from Singapore,[432] Finland,[573] Latin America,[475,485] and the United States[129] confirmed the safety, verified that the vaccine was not associated with fever, and reported that the vaccine remained highly immunogenic. Thus, the additional passages or limiting dilution purification resulted in a vaccine strain that was not reactogenic. The vaccine also did not interfere with the immune responses to the other concomitantly used vaccines.[129,485] In the initial efficacy trial of RIX 4414 conducted in Finland during the course of two rotavirus seasons, the vaccine was found to be 73 percent protective against all rotavirus gastroenteritis and 90 percent protective against severe gastroenteritis, despite the relatively low dose of vaccine used.[573]

As with RotaTeq, this vaccine was then evaluated in a very large safety trial.[475] In a study of more than 63,000 infants conducted primarily in several countries in Latin America, the

vaccine proved to be safe and did not induce fever and, most important, was not associated with intussusception. Thus, during the 31-day window after each dose, six vaccine recipients and seven placebo recipients had definite intussusception with no evidence of clustering (difference in risk, –0.32 per 10,000 infants; 95% confidence interval, –2.91 to 2.18; $p = .78$). For the duration of the study, 16 cases of intussusception occurred in the placebo group compared with nine in the vaccine group.

In this large study, efficacy was 85 percent against severe rotavirus diarrhea and hospitalizations and reached 100 percent against more severe gastroenteritis. Of note, efficacy was high (>86%) against severe rotavirus diarrhea caused not only by G1P[8] strains but also by the VP4-related G3P[8], G4P[8], and G9P[8] strains. Efficacy against G2P[4] strains in the few subjects infected with these viruses was less, 41.0 percent. However, in several meta-analyses, the efficacy was 67 to 71 percent, indicating that the vaccine will be efficacious against strains that do share VP4 or VP7 proteins.[475,571] An important note is that direct comparison of the two new vaccines is difficult to make because each used different scoring systems and the studies were conducted in populations with different risks for developing severe gastroenteritis. In the most recent trial of more than 4000 infants conducted in six European countries, a population more similar to that used for evaluation of RotaTeq, protection was 87 percent against any rotavirus gastroenteritis, 96 percent against severe disease, and 100 percent against hospitalization due to rotavirus.[571] In this study, efficacies against G3, G4, and G9 rotaviruses were similar to the efficacy against G1 and exceeded 95 percent, and efficacy against G2 strains was 75 percent. Of importance, efficacy against hospitalization due to gastroenteritis of any cause was 75 percent. The vaccine is reconstituted in a calcium carbonate buffer and given in a two-dose schedule at approximately 2 and 4 months of age.

Non-Live Vaccines

Preclinical studies have included the use of virus-like particles[103,387] that appeared to be protective in mice but not in pigs[616]; DNA vaccines[74,78]; and subunit vaccines, including VP7, VP4, and VP6.[77,580] The excellent protection in mice, particularly with VLPs or VP6 protein, remains to be verified in human studies.

CLINICAL MANIFESTATIONS

Rotavirus is the most common cause of dehydrating diarrhea in children in the United States and worldwide and infects nearly every child in the first few years of life.[42,115,124,213,259,261,262,412] In the United States, more than 600,000 cases of severe diarrhea are caused annually by rotavirus, resulting in 20 to 60 deaths.[181-183,226,227,274] An estimated 1 in 80 children younger than 5 years is hospitalized, and 1 in 7 requires an outpatient or emergency department visit because of rotavirus diarrhea.[183] A worldwide estimated 610,000 deaths are associated with rotavirus infection.[124,244,262,410] The incidence of rotavirus infections is highest in children between the ages of 6 and 24 months,[467] but the age may be lower in less developed countries.[215,450] Adults, including elderly patients, also are susceptible to re-infection, which can cause mild and sometimes severe disease.[111,136,237,275,326,468,599]

Initial and subsequent rotavirus infections often are asymptomatic. In cohort studies in which infants were observed from birth, as many as 50 percent of initial rotavirus infections were asymptomatic.[211,450,467,563,624] In one report, a carrier state was described.[69] Reports of neonatal infections that are asymptomatic in selected settings are common.[29,32,203,213,364,424]

The incubation period for rotavirus is approximately 1 to 3 days.[268] In children with symptoms, the onset often is abrupt, with fever and vomiting followed by explosive, watery diarrhea. Vomiting may precede the diarrhea in approximately half the cases.[214] Stools are non-bloody and generally lack fecal leukocytes, but mucus may be found in 20 percent.[240,433] Fever occurs commonly during rotavirus illness, with estimates of between 45 and 84 percent of patients.[282,465,519,549] The disease usually is self-limited, lasting 4 to 8 days, although the duration of symptoms ranged between 2 and 22 days in a Guatemalan study.[607] In one cohort study in children with symptomatic disease, 62 percent had mild disease, 35 percent had moderate disease, and 3 percent had severe disease; 7 percent of children required hospitalization.[450] In another study, 64 percent of children with rotavirus diarrhea had vomiting, 64 percent had fever, 14 percent were dehydrated, and 18 percent were hospitalized.[427] In children hospitalized with rotavirus infection, 63 percent had fever, vomiting, and diarrhea at presentation; children also presented with any two or only one of these symptoms.[511] When hospitalization is required, the stay usually is brief, with an average of 4 days and a range of 2 to 14 days.[465] Recovery generally is complete, but persistent diarrhea associated with lactose intolerance has been described.[18,273]

In general, rotavirus infections are more severe than are those caused by other viral gastrointestinal agents.[36,465] In developing countries, 20 to 40 percent of hospitalizations for diarrhea in children younger than 5 years are due to rotavirus infections,[124] whereas in the United States, rotavirus is estimated to account for between one third and two thirds of admissions for diarrhea in children.[41,466] Vomiting, dehydration, and hospitalization occur significantly more often in patients infected with rotavirus than in those with other causes of diarrhea.[465,549] In one study,[465] vomiting and diarrhea also lasted longer in patients infected with rotavirus (2.6 versus 0.9 days and 5.0 versus 2.6 days, respectively). In another study, the severity score for rotavirus diarrhea was almost twice that of disease having other causes.[476]

In children with dehydration caused by rotavirus, dehydration was more likely to be isotonic than was dehydration caused by other agents.[465] However, in another study, one fourth of the patients infected with rotavirus presented with hypernatremic dehydration.[282] Other reported findings in children with rotavirus include irritability and pharyngeal or tympanic membrane erythema. Numerous reports associate respiratory symptoms (e.g., cough, pharyngitis, otitis media, and pneumonia) with rotavirus infections, but the relationship of these symptoms to rotavirus is unclear, and the ability to isolate rotavirus from respiratory secretions has varied among studies.[214,299,465,493,623] Laboratory findings are related mostly to the extent of dehydration and can include elevated blood urea nitrogen and evidence of mild metabolic acidosis.

The peak viral shedding in stools occurs on approximately day 3 of illness.[119,579] When it was evaluated by polymerase chain reaction (PCR), the duration of rotavirus shedding ranged from 4 to 57 days in hospitalized patients.[457] Approximately half of the children shed for fewer than 10 days and 70 percent for fewer than 20 days. In Guatemala, prolonged viral shedding also has been reported for as long as 5 weeks and was associated with immunodeficiency.[330,494]

Other clinical manifestations associated either etiologically or incidentally with rotavirus infection have been described and include encephalitis and meningitis*; various upper and lower respiratory infections, including otitis media, laryngitis, pharyngitis, and pneumonia[299,379,465,493,623]; Kawasaki syndrome[335]; sudden infant death syndrome[613]; hepatic abscess[206]; and pancreatitis.[378] Elevated liver function test results also have been reported during rotavirus infection.[204,206,283] Neonatal necrotizing enterocolitis also has been linked with rotavirus.[271,471] However, the difficulty of false-positive reactions obtained with some ELISA tests in neonates must be considered.[80,449,543] Rotavirus infections can be

*See references 230, 254, 270, 315, 322, 380, 486, 557, 601, 615.

more severe in immunosuppressed persons, including bone marrow transplant recipients, patients infected with human immunodeficiency virus, and those who are malnourished,[137,178,250,260,614] and they may spread to the liver and kidney.[178] Of interest, rotavirus antigen recently has been reported to be found also in the blood of immunocompetent children with confirmed rotavirus gastroenteritis.[38,75,151] The role that circulating rotavirus may have in these extraintestinal manifestations is intriguing but unknown.[446]

In the past, central nervous system involvement associated with rotavirus infections,[486] including aseptic meningitis[555,601] and encephalopathy,[270] was determined by electron microscopy and antigen detection through immunologic methods. However, more recently, cases have been reported by identification of rotavirus RNA in the cerebrospinal fluid with use of reverse transcription–polymerase chain reaction (RT-PCR) analysis. Rotavirus RNA has been found in the cerebrospinal fluid in rotavirus-infected children with seizures,[315,383,409] encephalitis,[230,315,380,615] and encephalopathy.[322] Of the 20 reported cases, 15 were reported to have full recovery, but three had significant neurologic complications and two children died. Each of these reports suggests that rotavirus may have a spectrum of organ involvement and disease that extends beyond the gastrointestinal tract.

The relationship between intussusception and natural rotavirus infection is of great interest because of the reported link between the tetravalent RRV vaccine and intussusception (discussed in the section on vaccines). Several studies have investigated the possible infectious etiology of intussusception.[31,92,238,280,363,377] Given the rarity of intussusception, these studies have had a small sample size, and several different pathogens have been identified in these case series. Adenoviruses have been recovered most often.[31,92,238,377] Although several studies have argued that the lack of seasonal variation for intussusception suggests that wild-type rotavirus does not cause intussusception,[71,72,411,454] the possibility remains that many intestinal pathogens, including rotavirus, may cause intussusception, and multiple agents may account for the lack of a seasonal peak.

LABORATORY DIAGNOSIS

Rotavirus infection cannot be diagnosed on the basis of clinical presentation, even in combination with stool examination and nonspecific laboratory tests. Therefore, specific tests have been developed. Findings suggestive of rotavirus infection include a mildly febrile illness with vomiting and watery diarrhea that is occurring in the winter months in temperate climates, especially in patients 6 to 24 months of age. The presence of more severe dehydration also is suggestive. In the initial epidemiologic studies, electron microscopy was used for identification because of the large number of particles present in stools ($>10^{10}$/g) and the characteristic appearance of rotavirus. This technique largely has been replaced by enzyme immunoassay-based and latex agglutination tests, for which kits are available commercially. Both tests have good sensitivity compared with electron microscopy.[130,137,177,278,533] One problem noted in the past was false-positive results in neonatal stools with certain ELISA kits.[4,80,449,543] Inclusion of a rotavirus-negative capture antibody as a control in these kits could eliminate these false-positive reactions if it were used. However, this is rarely done.

Rotavirus also can be grown in tissue culture,[219,590,605] although the methods used for routine viral cultures do not detect rotavirus. However, live virus can be detected readily, even in stool specimens, by use of focus assays.[583] The serotype of cultured strains and virus in stools can be identified by use of monoclonal antibodies.[265] DNA probes[290,516] and, particularly, RT-PCR have been used effectively to identify genotypes as surrogates for serotypes.[171,189] Electrophoresis of extracted RNA also can identify rotavirus by its characteristic 11 segments and is used to define electropherotypes.[255,464,496] All these methods have proved useful as epidemiologic tools and in vaccine studies. Identification of electropherotypes is especially useful for epidemiologic studies because it allows identification of specific strains.

Rotavirus infection, both symptomatic and asymptomatic, also can be identified by changes in rotavirus antibody. ELISA assays are used most commonly to measure serum IgM, IgA, and IgG levels as well as stool and intestinal antibodies. Specific neutralizing titers also can be measured for each serotype of rotavirus by plaque reduction[236,604] or focus reduction assays.[24,52] One ELISA-based antigen reduction neutralization assay has been found to be better suited for the analyses of large numbers of specimens.[277] Serologic detection of infection is more difficult in the first months of life because of the presence of maternal antibodies. Detection of rotavirus IgA, which does not cross the placenta, has been used as a marker for previous infection in the first months of life.

PROTECTIVE FACTORS

Several studies have shown that breast-feeding protects against symptomatic rotavirus infections.[94,367,376] In one study, exclusive breast-feeding was found to be protective against severe rotavirus diarrhea, but no overall protection was present during the first 2 years of life, suggesting that breast-feeding simply postpones acquisition of rotavirus disease to an older age.[94] Similarly, cohort studies found that the highest incidence of rotavirus-associated diarrhea was in children aged 4 to 6 months, which coincided with the age when weaning from breast-feeding began.[406,450,493] A study also found that breast-feeding was protective against hospitalization for acute gastroenteritis caused by rotavirus in infants younger than 6 months.[128]

Although breast-feeding alone could be the protective factor, other factors, such as presence of maternal antibody and lack of opportunity for exposure, also could account for this period of protection. Supporting the role of human milk in protection against rotavirus is a study demonstrating that infants who received human milk with higher concentrations of the glycoprotein lactadherin were more likely to have asymptomatic rotavirus infections compared with those receiving milk with lower concentrations.[376]

TREATMENT

Treatment of rotavirus gastroenteritis is aimed largely at restoring the proper fluid balance in dehydrated patients. Emphasis has shifted from intravenous rehydration to oral rehydration with glucose-electrolyte solutions. The glucose in the solution enhances sodium and, thereby, water absorption in the intestine.[375] Several studies have shown the utility of this approach for treatment of rotavirus gastroenteritis.[479,490,491] The solution accepted by the World Health Organization contains 30 mEq/L of sodium, 30 mEq/L of potassium, and 30 mEq/L of bicarbonate, which is similar to other oral rehydrating solutions available commercially. Should oral rehydration efforts fail or in cases of severe dehydration and shock, fluid should be administered intravenously.

Other experimental approaches to treatment are based on the success of passive oral therapy in animals. Chronic rotavirus shedding has been treated successfully with human milk that contained rotavirus antibody.[494] Treatment and prophylaxis of normal children with immune colostrum, immunoglobulin, or milk from rotavirus-immunized cows also have been evaluated

with some success.[122,224,309,547] The treatment of normal children with one dose of human serum immunoglobulin given orally was reported to be effective in reducing the mean duration of diarrhea, viral excretion, and hospital stay,[207] and prophylaxis with formula supplemented with bovine antibody decreased the number of days with rotavirus diarrhea.[547] Trials of bismuth subsalicylate also have been conducted with some reported success,[150,510] as have trials with probiotics.[478]

Racecadotril (acetorphan), an enkephalinase inhibitor with antisecretory and antidiarrheal properties that decreases intestinal hypersecretion but not motility by preventing the breakdown of endogenous enkephalinase in the gastrointestinal tract, has been shown to be effective in the treatment of diarrhea in adults and children.[217,484] In one study, oral treatment with racecadotril decreased stool output by 46 percent in boys 3 to 35 months of age with watery diarrhea. A similar decrease was seen in boys with rotavirus infection.[484]

Nitazoxanide, a drug licensed to treat *Cryptosporidium parvum* and *Giardia lamblia* infections, was found to be effective in decreasing the time to resolution of rotavirus illness in children hospitalized with severe rotavirus diarrhea to an average of 31 hours for the nitazoxanide group compared with 75 hours in the placebo group.[470] In addition, tizoxanide, the active metabolite of nitazoxanide, inhibited replication of rotavirus in cell culture. For this study, only 50 children in Egypt were investigated; larger studies are planned.

NON–GROUP A ROTAVIRUSES

As described earlier, rotaviruses can be classified into seven groups (A to G). All seven groups are associated with diarrhea in animals, although only groups A, B, and C have been associated with disease in humans.[482] Of these, group A causes most illness. However, major epidemics of group B rotavirus have been reported in China, particularly in adults.[84,85,146,241] Seroprevalence studies have identified group B rotavirus infections in other areas such as Hong Kong, Myanmar, Thailand, Australia, Canada, England, Sweden, Africa, and the United States, although the prevalence is lower than that in the epidemic regions of China.[482] Group C infections have been reported largely from Japan,[288,334,403,431,556] but they also have been detected in the United States and elsewhere.[251,381,422,443,482,517,544] Unlike group A rotavirus, group B and C rotaviruses appear to cause disease predominantly in children older than 3 years and in adults.[146,288,334,382,403] Group B and group C rotavirus infections may be distributed widely, although the exact extent of infection has been limited by the poor assays that were available. If infection is suspected, the diagnosis is suggested by electron-microscopic detection of the typical rotavirus particles with a negative test result for rotavirus by the routine assays that detect only group A rotaviruses. The detection of typical RNA migration patterns by polyacrylamide gel electrophoresis of RNA also is suggestive. PCR and ELISA analyses have been reported.[187,248,382,499,544] Evidence of infection has been reported in Asia, Australia, Europe, Central and South America, Africa,* and the United States.[251] Serologic evidence has shown infection rates of 30 to 43 percent in England and the United States.[245,249,462]

Outbreaks caused by water-borne or food-borne spread of group B rotavirus in China[241] and group C rotavirus in Japan have been reported, although person-to-person spread also has been implicated.[146] As discussed before, outbreaks usually involve older children and adults,[146,288,382,403] but infants apparently can be infected.[251] Group C rotaviruses have been associated with extrahepatic biliary atresia.[459,497] Most recently, group C rotavirus RNA was detected in liver specimens from 10 of 20 patients with biliary atresia but in no controls.[460]

CHAPTER 186

Rubella Virus

James D. Cherry

Rubella (German measles) is a generally mild, exanthematous, infectious illness in which morbidity and mortality in children usually are minimal. However, infection in pregnancy may result in fetal infection, which usually is associated with considerable adversity for the developing infant. The rubella virus has only one known type.

HISTORY

In ancient history, rubella as a disease is lost among the other prominent exanthematous diseases (e.g., scarlet fever, measles, and smallpox). In an extensive review, Griffith[207] suggested that rubella was known to the early Arabian physicians under the name *al-hamikah*; they considered rubella a form of measles, however. Two German physicians, de Bergen in 1752 and Orlow in 1758, usually are credited with providing the first clinical descriptions of rubella as a specific entity.[207,557] In early writings, rubella generally was called *Röteln*.[164,557] However, because of the great interest of German physicians in the disease during the period from the mid-18th to the mid-19th centuries, the name *German measles* frequently was used in other countries.

In 1866, a Scottish physician named Veale[533] described 30 cases of German measles. In his paper, he gave the illness its present name, *rubella*. His opinion was that the German name Röteln was too harsh and foreign and that other possible names—*rubeola notha* and *rosalia idiopathica*—were too long for general use and could be confused with measles.[164] Other historical synonyms of rubella include rubeola, rubeola sine catarrho, rubeola epidemica, rubeola morbillosa, rubeola scarlatinosa, rosania, roseola, roseola epidemica, rosalia, scarlatina morbillosa, scarlatina hybrida, morbilli scarlatinosi, feuer masern, roséole, roséole idiopathique, rubéole, rougéole fausse, French measles, false measles, bastard measles, hybrid measles, and bastard scarlatina.[207]

In 1881 at the International Congress of Medicine in London, a consensus was reached that rubella is a distinct disease. Rubella was thought to be similar in some respects but not identical to measles or scarlatina. By the beginning of the 20th century, the clinical description of rubella was complete, except that joint manifestations had received curiously little notation.[15,116,164,207,336,438,517]

Rubella gained its present-day importance in 1941 when Gregg,[206] an Australian ophthalmologist, reported congenital defects in babies of mothers who had rubella during early pregnancy. In spite of considerable skepticism, Gregg's observations were confirmed quickly by Swan and colleagues[498,499] in Australia and other investigators in the United States and the United Kingdom.[149,414,421,557] By 1947, 28 communications describing 500 children with severe congenital defects associated with maternal rubella had appeared in the literature.[557]

In 1938, Hiro and Tasaka[244] demonstrated that rubella is a disease of viral etiology by transmission of disease to humans through the subcutaneous injection of filtered nasal washings. In 1942, Habel[214] was able to infect monkeys with nasal washings and blood from human cases. In 1962, rubella virus first was propagated in the laboratory; two investigative teams, Weller and Neva[556] and Parkman and colleagues,[379] using different techniques, reported the growth of rubella virus in tissue culture.

The isolation of rubella virus in 1962 paved the way for definitive study of the 1964 rubella pandemic. The results of extensive virologic, serologic, and epidemiologic investigation were presented at a Rubella Symposium in May 1965.[282] After the rubella virus was isolated in tissue culture, an intensive worldwide effort to develop vaccines was mounted. The accumulation of these experiences resulted in an extensive body of knowledge related to rubella and rubella immunization that was presented at the International Conference on Rubella Immunization in February 1969.[283] Live attenuated rubella virus vaccines were licensed for use in mid-1969 in the United States.[284,335] In the 38-year period since vaccine licensure and its universal use in the United States occurred, the yearly occurrence of rubella fell from 40,000 cases to 11 cases in 2005.[68,70,73,74,76,77,401,413,563]

At present, sustained transmission of rubella no longer occurs in the United States.[69,412]

PROPERTIES

CLASSIFICATION

Rubella virus is placed in the *Rubivirus* genus of the family *Togaviridae*.[158,447,568] At present, it is the only species in this genus. The virus is similar physiochemically to the other member of its family (alphavirus) but is unrelated serologically. Rubella virus has no invertebrate host (a characteristic of all alphaviruses), and humans are the only known vertebrate host.

PHYSICAL PROPERTIES

The rubella virion is spherical, with a diameter of 60 to 70 nm, and consists of a capsid protein (C) and two glycoproteins (E1 and E2).[84,301,318,388,447,568] E1 (relative molecular weight, 58,000) and E2 (relative molecular weight, 42,000 to 47,000) are glycosylated and are located on the viral surface membrane. E1 is the viral hemagglutinin that is found on 5- to 6-nm surface projections.[247,388] The nucleocapsid has a diameter of 30 to 40 nm and is composed of a polypeptide (C protein) and the genomic RNA. The nucleic acid of rubella virus is single-stranded RNA with a molecular weight of 3.2 to 3.8 $\times$ 10^7.[436] The outer coat of the virus (envelope) is lipoprotein in nature with host-cell lipid and virus-specified polypeptides.

Rubella virus is relatively sensitive to heat; it generally has been found to lose infectivity within 30 minutes at 56° C.[155,380,393] However, Kistler and Sapatino[276] observed that some infectivity persists even after heating for 60 minutes at 70° C. At 37° C in the presence of 2 percent serum, 90 percent is inactivated in 3

hours.[380] At 4° C, with protein stabilization, viral titers are maintained for 7 or more days. The virus is stable indefinitely at –60° C and below but labile at normal (–10° to –20° C) refrigeration temperatures. When it is stabilized with protein, the virus can survive several rapid freeze-thaw cycles without significant loss of titer.[441]

Rubella virus is sensitive to ultraviolet light. In 1 hour, a high-titer cell-free virus suspension was inactivated by an intensity of 1350 μW/cm^2; on the other hand, a tissue culture suspension of virus was not inactivated completely when it was exposed to a similar intensity of radiation.[276] Rubella virus is sensitive to visible light, and this photosensitivity can be potentiated by the basic dye proflavine.[46]

The virus also is sensitive to pH extremes of less than 6.8 and greater than 8.1.[81] The following chemicals rapidly inactivate rubella virus: ether, acetone, chloroform, deoxycholate, formalin, β-propiolactone, ethylene oxide, free chlorine, and 70 percent alcohol.[393] It is resistant to thimerosal.

ANTIGENIC COMPOSITION

Rubella virus infection of tissue culture cells results in the production of infectious virus that can be neutralized by specific antiserum. Specific viral antibodies can be identified by hemagglutination inhibition (HI), complement fixation (CF), precipitation in gel, platelet aggregation, passive hemagglutination, single radial hemolysis, latex agglutination, enzyme-linked immunosorbent assay (ELISA), and immunofluorescence.* Neutralization and HI identify antibodies that inhibit specific biologic functions of the virus, whereas the other assays identify only the formation of antigen-antibody complexes. The E1 glycoprotein is the predominant erythrocyte-binding and neutralization site of the virus.[519,551] Weak neuraminidase activity also has been associated with purified rubella virus.[24]

In 1967, Stewart and associates[490] reported that tissue culture–grown rubella virus produced hemagglutination of erythrocytes from chickens that were younger than 1 day old and from one goose and one lamb, but no hemagglutination was observed with adult chicken, guinea pig, and other red cell preparations commonly used. Subsequently, techniques involving careful control of test system diluents have revealed that red cells from many different animals are agglutinated by rubella virus.[306,449] Viral hemagglutinin is stable at –20° C for months and at 4° C for several weeks but is destroyed rapidly by heat.[182,217]

Sever and colleagues[464] first demonstrated that supernatant fluid from primary African green monkey kidney (AGMK) and RK-13 rabbit kidney tissue cultures contained useful complement-fixing antigens. Two distinct rubella complement-fixing antigens exist.[451] One of the antigens is similar in size and weight to both the hemagglutinin and infectious virus; the other "soluble" antigen is smaller, with a buoyant density of 1.08 g/mL. The soluble antigen is noninfectious and does not contain nucleic acid.[393] Rubella complement-fixing antigens retain their antigenicity after either treatment.

Two major small-particle antigens have been identified in the medium of tissue culture–infected cells by immunodiffusion.[298,299,452] These two soluble antigens are structural components of the virion, and natural infection with rubella virus results in the formation of serum precipitating antibodies. These antigens have been designated *theta* and *iota*. Their importance lies in the fact that antibody to the iota antigen rarely is noted in the serum of recipients of some rubella vaccines; therefore, they may be of value in studying vaccine-induced immunity.[64,300]

The E1 glycoprotein is the dominant surface molecule of rubella virus.[85] It is the main target of the humoral antibody response for both detection and elimination of the virus. HI and neutralization sites have been localized to a small segment of the E1 glycoprotein ($E1_{245}$ to $E1_{285}$).

Seventeen T-cell epitopes have been identified with the lymphoproliferation assay.[85,347] They involve the capsid protein and E1 and E2 glycoproteins.

Molecular analysis of rubella virus epidemiology from 1961 to 1997 in North America, Europe, and Asia found no major antigenic variations.[175] Further phylogenetic analysis of a collection of 103 E1 gene sequences from rubella viruses isolated from 17 countries from 1961 to 2000 found the existence of at least two genotypes.[577] Rubella genotype 1 isolates were predominant in Europe, Japan, and the Western Hemisphere, whereas genotype 2 isolates were limited to Asia and Europe.

TISSUE CULTURE GROWTH

Rubella virus grows in many different tissue cultures, including cell strains, cell lines, and primary cells.[123,321,322,380,393,567,568] Cell sources include mature and embryonic tissue from humans and other primates, rabbits, swine, dogs, birds, hamsters, and cattle. In tissue culture, growth of rubella virus can be identified by either its cytopathic effect or its ability to interfere with the growth of another tissue culture–susceptible virus.

The method used most commonly for primary isolation of rubella virus from clinical material is the interference technique with primary AGMK cells.[379] In this system, nonadapted rubella virus grows readily but does not produce a cytopathic effect. Infection is demonstrated in AGMK tissue culture by the failure of a typical enterovirus cytopathic effect to occur after the culture is challenged with echovirus 11 or another suitable enterovirus. A common alternative to the AGMK–echovirus 11 interference system for primary isolation of rubella virus is use of the RK-13 rabbit kidney cell line, in which infection can be identified by cytopathic effect. For laboratory study and determination of neutralizing antibody, many different cell lines (e.g., RK-13, BHK-21, and LLC-MK2) can be used. The highest titers of rubella virus are produced in the BHK-21 and Vero cell lines.

Kinetic studies in tissue culture indicate that virus adsorption is complete within 90 minutes and that the eclipse period lasts approximately 12 hours. The first new virus noted is cell associated; it is followed in 2 to 4 hours by extracellular virus. In primary cell culture, titers of both cell-associated and free virus reach 10^3 $TCID_{50}$/mL by the fourth day; peak titers are not attained until approximately the 17th day. In all cell systems, chronic infection occurs but is limited in some cultures by the cytopathic effect. Rubella virus induces the formation of plaques in several cell lines.

ANIMAL SUSCEPTIBILITY

Although natural infection is known to occur only in humans, several other primates have been infected experimentally.[321,380,393] In addition to primates, rabbits, hamsters, ferrets, guinea pigs, and suckling mice all have been infected with rubella virus.

EPIDEMIOLOGY

In contrast to measles and other diseases having clearly apparent dramatic cycles, knowledge of rubella epidemiology has been acquired primarily during the last 75 years. Major events during this period that stimulated interest in its epidemiology were the observation of teratogenicity in 1941,[206] the isolation of the virus

*See references 33, 39, 83, 86, 87, 147, 148, 160, 172, 240, 299, 300, 319, 384, 393, 434, 435, 530, 568, 578.

in the early 1960s,[379,556] and the pandemic of 1964. Unfortunately, rubella was not a reportable disease in the United States until 1966, so considerable gaps exist in the available information. At present, we are in a new epidemiologic era because of the widespread use of rubella vaccine. Predicting the incidence of rubella today must take into account the extent and method of vaccine use in the population under surveillance.

INCIDENCE AND PREVALENCE

Epidemic Behavior

The epidemic pattern of rubella in selected areas of the United States in the pre-vaccine and early vaccine eras is presented in Figure 186–1. The number of reported cases of rubella and congenital rubella syndrome by year in the vaccine era is presented in Figure 186–2. The rubella epidemic cycle usually is described as one of 6- to 9-year intervals, with each cycle consisting of a build-up and fall in incidence during the course of a 3- to 4-year period.[253,254] However, a close look at Figure 186–1 suggests that the basic pattern in the pre-vaccine era was a 3.6-year cycle. Of the 11 peaks from 1928 to 1968, all but two occurred in a 2- to 4-year span, with a median of 3 years. Over and above the 3-year cycle is the better known 6- to 9-year cycle of major disease. Pandemics occurred in the periods 1941 to 1944 and 1963 to 1965.

Since the introduction and widespread use of rubella vaccine in the United States, epidemic rubella has occurred only once on a national scale (see Fig. 186–2).[70,72,411] In 1991, 1401 and 47 cases of rubella and congenital rubella syndrome, respectively, were reported. The number of cases of rubella and congenital rubella syndrome by year from 1998 to 2005 is presented in Figure 186–3.[68] At present, rubella virus no longer is circulating in the United States, and the cases that occurred in the more recent years were importations.[69,412] In countries in which effective universal childhood immunization had not been achieved, epidemics continued to occur periodically. Epidemic rubella was documented in the former Czechoslovakia in 1972; in Australia in 1969 to 1970, 1975 to 1976, 1993 to 1996, and 2003; in Israel in

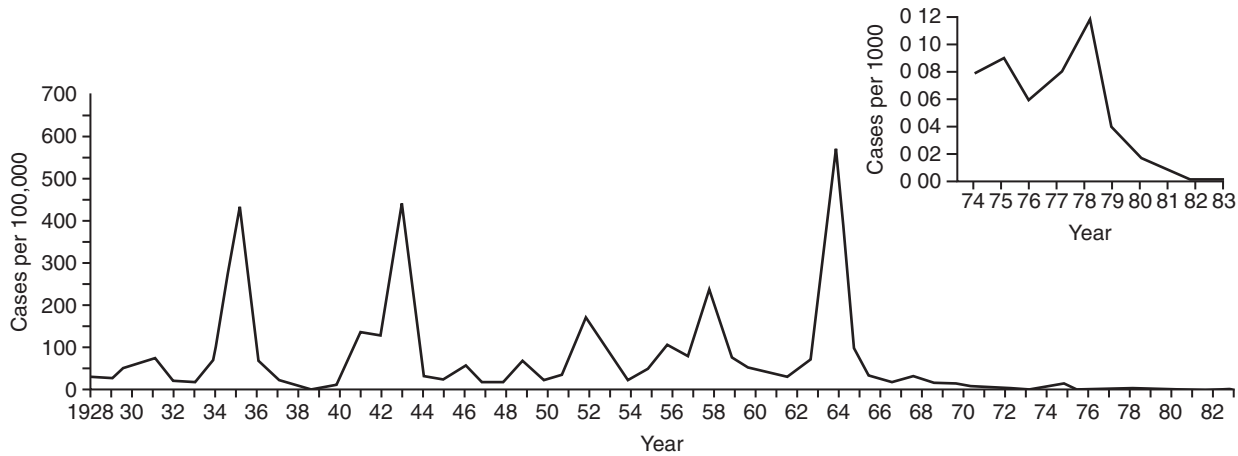

Figure 186–1 Rubella incidence in 10 selected areas (Maine, Rhode Island, Connecticut, New York City, Ohio, Illinois, Wisconsin, Maryland, Washington, and Massachusetts) of the United States, 1928 to 1983. *(From Williams, N. M., and Preblud, S. R.: Rubella and congenital rubella surveillance, 1983. M. M. W. R. CDC Surveill. Summ. 33:1SS-10SS, 1984.)*

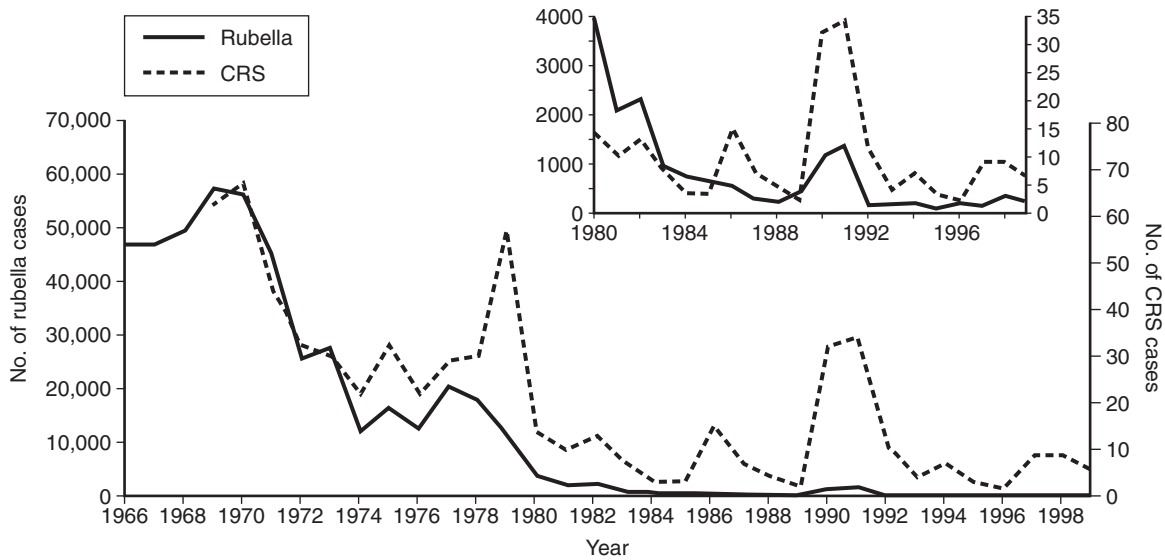

Figure 186–2 Number of reported cases of rubella and congenital rubella syndrome (CRS) in the United States from 1966 to 1998. *(From Reef, S. E., Frey, T. K., Theal, K., et al.: The changing epidemiology of rubella in the 1990s: On the verge of elimination and new challenges for control and prevention. J. A. M. A. 287:464-472, 2002. Copyright 2002, American Medical Association.)*

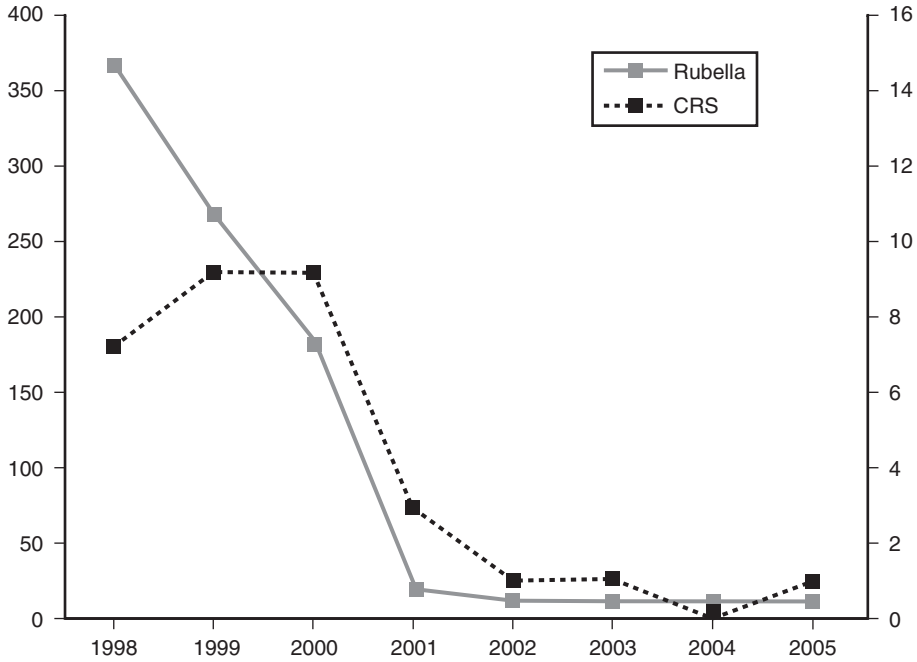

Figure 186–3 Number of reported cases of rubella and congenital rubella syndrome (CRS) in the United States from 1998 to 2005.[68]

1972, 1979, and 1983; in Japan in 1975 to 1977 and 1982 to 1998; in Brazil in 1981 and 1997 to 2001; in the United Kingdom in 1971 to 1973, 1978, and 1983; and recently in a number of European countries.*

The incidence of rubella varies with the epidemic cycle, the number of susceptible people within a population group, and the intrapersonal contact within the group. In closed populations such as military training centers and institutions for the mentally handicapped, the attack rate after the disease is introduced approaches 100 percent in susceptible individuals.[256,257,302] Introduction of disease in the family also affects virtually all susceptible persons.[183,184] In community epidemics, attack rates in susceptible people are estimated to range from 50 to 90 percent.

Age Groups

The age distribution of reported rubella cases and estimated incidence rates in Illinois, Massachusetts, and New York City for 1966 through 1968 and the entire United States for 1985 through 1987[76] are presented in Table 186–1. In the period immediately before the vaccine was introduced (1966 to 1968), the attack rate was highest in the 5- to 9-year-old age group, and the incidence was high in preschool-aged children. The overall reduction in the rate of rubella from the pre-vaccine era to 1987 was 99.2 percent. However, 50.2 percent of the cases reported in the period 1985 through 1988 were in persons older than 19 years; in the pre-vaccine period (1966 through 1968), the percentage in this age group was 10.2. In 1999, 75 percent of the reported cases occurred in persons older than 19 years.[413] During the period 1980 to 2002, outbreaks of rubella have occurred in prisons,[79] in colleges and universities,[78] in hospitals,[80,400,492] at work sites,[77,198,413] in communities with high foreign-born populations,[413] and among the Amish in six areas of the United States.[74]

Because rubella was not a reportable disease in the United States until 1966, few age-specific incidence or prevalence data relating to epidemic disease are available. In Table 186–2, age-specific attack rates are presented for two communities during epidemic rubella in 1964.[104] The attack rate curves during epidemic rubella in 1964 are similar to the curve for the pre-vaccine nonepidemic period from 1966 to 1968 seen in Table 186–1. The overall attack rate during the 1964 epidemic in the two communities was 23 percent. Eighty-six percent of the cases occurred in children younger than 15 years. In 1999, 272 cases of rubella were reported in the United States, and of the 269 with known ages, only 14 percent occurred in children younger than 15 years.[413]

Antibody prevalence by age group in the pre-vaccine era in the St. Louis area is presented in Figure 186–4.[91] As can be seen, rubella HI antibody prevalence went from less than 10 percent in children younger than 3 years of age to almost 80 percent in

pre-adolescents. Surveys of adolescents and young women of child-bearing age conducted before 1969 generally have indicated an immunity rate (HI antibody titer ≥1:8) of approximately 75 to 85 percent.[105]

Immunity to rubella as indicated by the curve in Figure 186–4 obviously is affected by epidemic periods. With epidemic disease, the curve itself most probably maintains the same slope, but it moves to the left; prevalence of antibody in each age group of children increases significantly (perhaps 10-30%). However, studies in the pre-vaccine era on sera from young adults indicate that the percentage of susceptible persons in this age group is affected only slightly by epidemic disease.[105,163,461,467,567] In a survey of sera from 600 pregnant women in 1962, Sever and associates[467] noted that 17.5 percent had no detectable antibody. In a similar study in 1966 in which the mean age was slightly less (23.6 versus 25.6 years), the percentage without detectable antibody was 7.8. Other surveys of rubella antibody in the sera of young adults acquired after the 1964 pandemic indicate a susceptibility rate in the 15- to 20-percent range, similar to pre-1964 data.[105,459,467]

Effect of Vaccination

Rubella vaccine was licensed for use in the United States and many other countries in 1969, and it has been used extensively for more than 35 years.[75,401,413,549] The immunization effort in the United States initially focused on children.[128,280,284] A secondary goal was to immunize seronegative postpubertal girls and women of child-bearing age, but little effort was extended in this area until 1978. The overall effect of the immunization effort in the United States on the young adult population is difficult to interpret. As noted in Table 186–1 and subsequent data, the reported number of cases and the incidence of rubella decreased significantly from the pre-vaccine period until the present.[68,70,413,549] A marked reduction in the number of reported cases of congenital rubella also has occurred since 1969 (see Figs. 186–2 and 186–3). However, the actual number of cases and the incidence of rubella in adolescents and young adults did not decrease until 1981, and 58.2 percent of all patients in the period 1985 through 1987 were 15 years of age (see Table 186–1). Also alarming was the marked upswing in the number of congenital rubella cases in 1990 and 1991.[73,413] Antibody survey data reported between 1981 and 1993 indicate that 5 to 25 percent of the adolescent and young adult populations in the United States were susceptible to rubella.*

In four studies in which prevalence of rubella antibody was analyzed by the vaccination status of the participants, differences were significant.[294,341,372,420] Between 87 and 96 percent of vaccinated persons had rubella antibody, whereas only 70 to 80 percent of nonvaccinated persons had antibody.

U.S. serosurvey data for the period 1988 to 1994 found the following seropositive rates by age group: 6 to 11 years, 91.8 percent; 12 to 19 years, 82.6 percent; 20 to 29 years, 84.6 percent; 30 to 39 years, 88.7 percent; 40 to 49 years, 92.5 percent; 50 to 59 years, 93.7 percent; and 60 years and older, 95.7 percent.[145] In this survey, persons born from 1970 to 1974 were found to have the lowest rate of seropositivity (78%). For the period 1999 to 2004, the overall U.S. seropositivity level was 91.3 percent. Selected age-related rates in children aged 6 to 11 years and adolescents aged 12 to 19 years were 96.2 percent and 93.7 percent, respectively.[260] Seropositivity was 91.5 percent among women and 88.0 percent among men.

In contrast to the immunization program in the United States, which focused on children and elimination of epidemic rubella, immunization efforts in the United Kingdom and many other countries initially were aimed at girls aged 11 to 14 years, with selective immunization of women of child-bearing age. This approach would not be expected to disrupt the epidemic pattern of rubella but only to decrease disease in young adult women. Serologic surveys in the United Kingdom indicated a significant

*See references 124, 140, 172, 272, 294, 372, 373, 420, 454, 488, 493, 541.

reduction in the number of seronegative persons in the target population.[99,218,341-343,425,514] In one study in which 10,000 serum samples were analyzed, 93 to 96 percent of females born after 1956 (who would have been offered rubella vaccine in school) were found to have antibody, whereas only 80 to 89 percent of those born before 1954 were found to have antibody.[99] In spite of the high level of antibody prevalence in women of child-bearing age, rubella infection in pregnancy and congenital rubella continued to be a major problem in the United Kingdom.[343,514] From 1971 to 1982, 625 cases of congenital rubella were reported, and from 1974 to 1981, 3273 women had their pregnancies terminated because they were infected with rubella or had been in contact with a person with rubella in England and Wales.[514]

In Finland, where initial immunization in 1975 involved 11- to 13-year-old girls and after 1982 involved a two-dose program for all children, the susceptibility rate in 1992 for 16- to 19-year-old girls was 3 to 5 percent, whereas for boys it was 30 percent.[527]

In Sweden, the initial immunization program, which began in 1973, targeted school girls, susceptible women after pregnancy, and women at special risk; their second program, which began in 1982, was a universal two-dose schedule at 18 months and 12 years.[49] The rate of susceptibility in pregnant women in Sweden decreased from 12 percent in 1975 to below 2 percent in 1994.

Recent serosurveys from around the world have noted varied rates of seropositivity in adults.[102,127,138,264,520] In Jordan, 90.9 percent of women of child-bearing age were immune, but only 83 percent of younger women aged 15 to 19 years were immune.[264] In Catalonia, Spain, 98.1 percent of adults had antibody to rubella[138]; in Israel, approximately 95 percent of women of child-bearing age were immune to rubella, whereas only approximately 85 percent of men of similar age were immune.[102] In this serosurvey, as many as 40 percent of adolescent men were rubella nonimmune, but only approximately 5 percent of similarly aged women were nonimmune. In Taiwan, prevalence of rubella antibody in women varied markedly by birth cohort.[520] Rubella antibody was undetectable in 29.2 percent, 7.3 percent, and 8.3 percent of cohorts born before 1971, between 1971 and 1976, and after 1976, respectively. In Argentina in 2002, 91.2 percent of women of child-bearing age had antibody to rubella.[127]

Congenital Rubella

Congenital rubella was not a reportable disease in the United States until 1966, so good data on incidence and prevalence during epidemics of rubella are not available. In the 1964 to 1965 rubella epidemic in the United States, 20,000 cases of congenital rubella occurred, 5000 therapeutic abortions were performed, fetal wastage in excess of 6250 was reported, and more than 2100 neonatal deaths occurred.[105] Estimates of the risk of acquiring congenital rubella after maternal infection vary considerably in different studies. In general, studies performed before 1964, which included nonepidemic periods, tended to underestimate the risk, whereas early retrospective studies after epidemics resulted in high incidence values.[164] Clearly, however, the individual risk of acquiring congenital rubella depends on the month of pregnancy in which maternal infection occurs. Sallomi[433] analyzed eight published studies that met his rigid criteria and noted the following rates of anomalies by gestational age when maternal infection occurred: weeks 1 to 4, 61 percent; weeks 5 to 8, 26 percent; and weeks 9 to 12, 8 percent. In pregnancies complicated by rubella in weeks 1 to 8, only 36 percent ended in normal live births, 39 percent ended in abortion or stillbirth, and 25 percent produced gross fetal anomalies. Peckham[383] noted that 85 percent of infants born to mothers infected during the first 8 weeks of pregnancy had detectable defects during the first 4 years of life. Infection at other times during pregnancy revealed the following rates of detectable defects: 9 to 12 weeks, 52 percent; 13 to 20 weeks, 16 percent; and after 20 weeks, no defect. Other studies indicate a risk of malformation of 3 percent and a risk of abortion and stillbirth of 4 percent when intervals from conception to acquisition of rubella are greater than 12 weeks.[101]

Infection with rubella virus confers lifelong immunity against clinical illness, but asymptomatic re-infection does occur. Asymptomatic re-infection is noted frequently in pregnant women, but it generally has not been considered a risk to the fetus. However, in rare instances, re-infection has resulted in severely damaged babies.[1,23,26,60,125,419,552]

TRANSMISSION

Rubella infection generally is thought to be spread by the respiratory route. Although definitive evidence supporting this assumption is not available, data from volunteer projects and studies of natural disease strongly support this view.[204,238,445] Infected persons regularly shed large concentrations of virus in the nose and throat, and droplets of secretions are released into the environment, which allows respiratory-to-respiratory transmission. Also possible is that the initial hosts may contaminate their own hands and then transmit the infectious agent to environmental surfaces or directly to contacts. In this circumstance, new hosts can acquire infection through the fomite-hand-respiratory or hand-hand-respiratory route.

In experimental transmission studies, Green and colleagues[204] noted that efficient transmission of infection to susceptible persons required prolonged, repeated contact; after a brief, single contact, only one in five children acquired disease, whereas all but one of 17 subjects with prolonged, repeated contact were infected. Although the period of communicability has never been determined accurately, almost 100 years ago the period of infectivity was noted to precede the eruptive phase of illness.[207] Volunteer studies indicate that virus is present in nasopharyngeal secretions from 7 days before to 14 days after the onset of rash.[204,238] Maximal shedding and presumably maximal transmissibility occur for an 11-day period of 5 days before to 6 days after the appearance of rash. Infants with congenital rubella shed virus from the nose and throat for many months and have been responsible for the spread of virus to susceptible contacts.[255,443]

SEASONAL PATTERNS

Rubella is a disease of winter and spring, with the largest number of cases in the United States occurring in March, April, and May.[104,105] This seasonal pattern occurs in years with both a high and a low incidence of rubella. Presumably, some transmission and sporadic illness occur throughout the year in large urban areas.

GEOGRAPHIC DISTRIBUTION

Although clinical rubella had gone unrecognized in many countries in Africa, Asia, and South and Central America, serologic surveillance indicates that it was present throughout the world.[101] In remote islands, rubella may not be endemic, so large segments of the population may be susceptible.[53,242] In these locales, the introduction of rubella results in epidemic infection that involves approximately 90 percent of the susceptible population. In populated areas of the world in the pre-vaccine era, rubella was both endemic and epidemic, and between 80 and 90 percent of the adult population had serum rubella antibody.[101] An interesting note is that in the pre-vaccine era in several well-populated large islands that were not remote (Jamaica, Taiwan, Barbados, Trini-

dad, Hawaii, and Japan), a smaller percentage of the total population had antibody, and rubella was not endemic.[101,154,184,202]

OTHER FACTORS

Sex

The incidence of clinical rubella is similar in boys and girls.[104,105] In adults, more cases of rubella are reported in women.[105] This finding possibly is the result of interest and concern related to congenital rubella rather than a true difference on the basis of sex. Of interest is that in rubella vaccine trials, girls have been noted to have geometric mean convalescent-phase antibody titers higher than those of boys.[339,480]

Mitchell and associates[349] studied the IgG, IgM, and IgA antibody responses in men and women to rubella virus structural proteins (E1, E2, and C). IgA E2 antibodies did not develop in men, but they did in women. Men had lower IgG antibody to E2, an earlier onset of E1-specific IgG and IgM antibodies, and a greater proportion of total antibody against E1 than women did. In another study, Mitchell[346] reported that men had a more rapid cell-mediated immune response to whole, inactivated rubella virus and a panel of rubella virus peptides after reimmunization than women did.

Genetics

Hattis and associates[234] showed that individuals differ in their ability to transmit rubella. During a rubella epidemic, they noted a small number of persons who had high potential for transmitting virus to susceptible persons ("spreaders"). Most persons demonstrated only minimal virus transmission ("nonspreaders"). Honeyman and colleagues[248,250] suggested that the ability to spread rubella virus is favored by the cell surface antigen HL-A1 or the combination of HL-A1 and HL-A8. In a rubella vaccine trial, Spencer and associates[480] noted that 44 percent of persons with high rubella HI antibody titer (≥1:512) responses had HL-A28. In this study, a high convalescent-phase geometric mean antibody titer also was noted to occur in subjects with the AB blood type.

Ovsyannikova and associates[376] recently studied human leukocyte antigen haplotypes in the genetic control of immune response to measles-mumps-rubella (MMR) vaccine. They found that DRB1*04-DQB1*03-DPB1*03 was associated with high lymphoproliferative responses to rubella vaccine virus. The same haplotype was associated with lower rubella virus IgG antibody levels.

PATHOLOGY AND PATHOGENESIS

VIRAL INFECTION

The sequence of events in uncomplicated, postnatally acquired rubella is presented in Table 186–3. Although much is known about rubella infection in humans, considerable gaps regarding specific events exist.[204,236-238,445] Estimates for the timing of events in rubella infection (see Table 186–3) have come from volunteer inoculation studies. In many instances, artificial inoculation has resulted in a reduction in the length of the incubation period of clinical disease. This finding suggests that the size of inoculum is important in the initial generation of human infection. It also helps explain the rather wide boundaries of the incubation period noted in many clinical studies.[207,336,438]

The primary site of infection is the respiratory epithelium of the nasopharynx. Initial infection of the respiratory epithelium apparently is minor; a more important event is early spread of virus to the regional lymphatics. In volunteers given 100 $TCID_{50}$ of rubella virus intranasally, viral multiplication at the respiratory site was noted on the third day.[445] After viremia develops, extensive nasopharyngeal infection occurs. In persons who have received either attenuated or unattenuated virus by the subcutaneous route, nasopharyngeal shedding in varying concentrations always occurs.[92,93,204,445] Concentrations of virus generally are greater in specimens collected from the nose than in those from the throat.

Viremia peaks just before the onset of exanthem and disappears shortly thereafter. In contrast, virus continues to be present consistently in the nasopharynx for a 6-day period after the onset of rash and occasionally for an additional week thereafter.[204] In addition to the blood and nasopharynx, other sites from which rubella virus has been recovered are the lymph nodes,[181] urine,[445] cerebrospinal fluid,[484] conjunctival sac,[237] breast milk,[57] synovial fluid,[241] and lungs.[469] In patients with rubella, the virus was recovered from the skin at sites both with rash and without rash.[236,237]

TABLE 186–3 The Sequence of Rubella Viral Infection in Uncomplicated Primary Disease

Day	Event
0	Rubella virus from the respiratory secretions of an infected person comes in contact with the epithelial surface of the nasopharynx of a susceptible person. Localized infection in the respiratory epithelium is established, and virus spreads through lymphatics and possibly by transient viremia to regional lymph nodes
1-22	Viral replication in localized areas of the nasopharynx and regional lymph nodes
3-8	First evidence of nasopharyngeal viral shedding
6-20	Viremia (virus free in serum and associated with leukocytes)
8-14	Establishment of infection in the skin and other viremic sites, including generalized nasopharyngeal involvement
10-17	Maximal viremia and viruria
10-24	Maximal nasopharyngeal viral shedding
17-19	Viremia decreases and then ceases. Viral content at viremic sites rapidly diminishes

From references 204, 236-238, 445.

IMMUNOLOGIC EVENTS

Antibody

After having natural or vaccine rubella viral infection, patients regularly have an antibody response. Serum antibodies to different rubella viral antigens can be measured by HI, CF, neutralization, immunofluorescence, precipitation, radioimmunoassay, ELISA, single radial hemolysis, passive hemagglutination, latex agglutination, and platelet aggregation.*

In natural postnatal rubella infection, HI and neutralizing antibodies appear 14 to 18 days after exposure, at the time of the rash. HI antibody titers usually peak approximately 2 weeks after the onset of clinical illness, stay at a high level for several weeks, decrease about fourfold during the course of a year's time, and then generally persist for life. Immunofluorescence, ELISA, radioimmunoassay, and latex agglutination reveal antibody patterns similar to those determined by HI.[240] Antibody detected by

*See references 14, 39, 114, 135, 159, 191, 200, 219, 240, 246, 300, 304, 319, 333, 334, 345, 361, 384, 393, 462, 464, 513, 534, 538, 564, 578.

passive hemagglutination does not appear until 3 to 4 weeks after the onset of illness, and that detected by single radial hemolysis is delayed until 1 to 2 weeks after onset. In an Amazon Indian tribe, the geometric mean rubella HI antibody titer 12 years after infection, with no intercurrent rubella exposure, was 1:33.[40] The pattern of the neutralizing antibody response is similar to the HI antibody response, except that the peak is delayed slightly. Brody and colleagues[53] noted that all but 10 percent of an island population had rubella neutralizing antibody 22 years after the time of epidemic illness.

CF antibody first appears approximately a week after HI and neutralizing antibody, peaks approximately 1 month after illness, and in general does not persist as long as does either HI or neutralizing antibody. On occasion, the CF antibody response is delayed and appears 1 month after the exanthem, with peak titers occurring 2 to 5 months later. Sever and colleagues[465] noted CF antibodies in only 44 percent of persons with neutralizing antibody who were studied 10 to 20 years after illness. The use of an antigen prepared by alkaline extraction has increased the sensitivity of CF, but low levels of antibody still are best identified by HI, ELISA, or neutralization.[393,450]

After natural infection occurs, precipitating antibodies develop to both theta and iota antigen.[299] Antibody to theta antigen appears early, parallels HI antibody, and is persistent. In contrast, the response to iota antigen is delayed, with a slow rise in concentration during a 2- to 3-month period. Five years after infection has occurred, anti-iota antibody cannot be detected.

After immunization has been administered, the antibody response pattern varies according to the type of vaccine used.[41,300,369,395,396,444,544] With RA 27/3 vaccine, the serum antibody response is similar to that after natural disease, except that the peak HI and neutralizing antibody titers attained usually are lower. Serum antibody responses noted after HPV-77 and Cendehill vaccine viral infection are different from those found after natural infection in that CF and anti-iota antibodies are noted only irregularly and then in minimal concentration.

Primary rubella virus infection, either naturally acquired or vaccine induced, is characterized by the initial appearance of antibody in the IgM and IgG serum components.[29,38,118,134,213,381,382,485] In general, the IgM-specific response is short-lived and not detectable more than 8 weeks after the onset of infection. On occasion, it has been detected in the serum for extended periods.

IgA nasal HI, ELISA, and neutralizing antibodies also occur regularly after natural viral infection. After immunization, the nasal antibody response varies with the type of vaccine and the route of administration.[5,9,117,120,369,393] After subcutaneous immunization with HPV-77 vaccine is given, rubella-specific nasal IgA antibody is a rare finding; it occurs in most subjects who receive RA 27/3 vaccine administered intranasally and in approximately half of those given this vaccine by the subcutaneous route.

Specific Cell-Mediated Responses

Rubella-specific, cell-mediated lymphocyte responses regularly occur after infection with rubella virus.*

Steele and associates,[487] using an in vitro lymphocyte-mediated cytotoxicity assay, first noted that lymphocytes from persons who previously had rubella caused cell destruction in a tissue culture chronically infected with rubella virus. Rubella antigen–specific, cell-mediated immunity also has been demonstrated in lymphocyte cultures by blast transformation, production of migration-inhibition factor, and production of interferon.[59,249,357,478,508,536,537] With vaccination, rubella-specific, cell-mediated immunity first was noted to occur 7 days after immunization, with peak responses at 3 weeks.[536,537] Honeyman and associates[249] noted that the rubella antigen–specific, cell-mediated response commenced 1 week before the humoral immune response occurred in both natural and vaccine-induced rubella viral infection. They also noted that the cell-mediated response was of greater magnitude and duration after natural disease than after immunization. Rossier and associates[427] studied cloistered nuns and noted that specific cell-mediated immunity to rubella virus persisted until they reached 79 years of age in the probable absence of re-infection.

Morag and colleagues[357] demonstrated the specific appearance of cell-mediated immunity in tonsillar lymphoid tissue after natural infection or intranasal immunization with rubella vaccine. This responsiveness was conspicuously low after vaccination was administered by the subcutaneous route. In most instances, the presence of cell-mediated responsiveness correlates with the presence of antibody; specific rubella lymphocyte transformation has been noted in the absence of antibody, however.[478] The magnitude of the rubella-specific, cell-mediated response is suppressed during pregnancy.[508]

McCarthy and colleagues[323] identified potential determinants of human cellular immunity to rubella virus by using synthetic peptides representing well-defined sequences of rubella virus structural proteins. They used the following peptide subsequences: two capsid domains (C_1 to C_{29} and C_{64} to C_{97}), a glycoprotein E1 domain ($E1_{202}$ to $E1_{283}$), and a glycoprotein E2 domain ($E2_{31}$ to $E2_{105}$). All but the C_{64} to C_{97} subsequences stimulated specific lymphoproliferative responses in peripheral blood mononuclear cells in 25 to 50 percent of immune subjects. The immunodominant T-proliferative epitope (C_{14} to C_{29}) was recognized by only 50 percent of the peripheral blood mononuclear cells of the study population. Relatively immunodominant T-cell epitopes vary among different persons.

Using a lymphocyte proliferation assay, Mitchell and associates[348] reported positive cell-mediated immune responses to 16 peptides, including six that contained antibody neutralization domains after revaccination.

Nonspecific Responses

A large number of nonspecific, immunologically related responses can be demonstrated during rubella virus infections. Niwa and Kanoh[364] performed a comprehensive study of these responses in 85 children and adults during an epidemic of rubella. They noted a decreased number of total leukocytes, neutrophils, and T cells initially, which returned to normal values within 1 week. Some patients had slightly elevated levels of serum IgM, and total hemolytic complement was elevated in 12 of 30 patients. Marked increases in C4 and C9 also were present. In addition, they noted a marked insensitivity to dinitrochlorobenzene and purified protein derivatives in many patients. Atypical lymphocytes, autoantibodies, and reduced blastogenesis as measured by phytohemagglutinin (PHA) stimulation were noted in some patients. Other studies consistently have demonstrated a reduction in the lymphocyte response to PHA.[56,63,185,262,289,314,325] In general, this reduction lasts less than 1 month, and infections with attenuated strains of rubella vaccine virus are less immunosuppressive than are infections with unattenuated rubella virus.

Hyypiä and colleagues[262] noted that during rubella virus infection, the proportion of suppressor-cytotoxic T cells was increased and the proportion of helper-inducer T cells was decreased. Polyclonal activation of B cells was associated with these findings.[263]

Zaknun and coworkers[574] noted a marked increase in urine neopterin levels in two children with acute rubella. Their levels increased dramatically 4 days before the onset of exanthem.

FETAL EVENTS

Viral Infection

A considerable amount of information about fetal infection became available from extensive studies during the 1964 epidemic of rubella,* and further information has been obtained more recently from both natural and vaccine viral infections.[43,136,146,293,390,458,531,572] In spite of the number and extent of investigations performed to date, we know little about transmission of the virus to the fetus in maternal infections in the latter half of pregnancy.

With maternal infection during the first trimester, placental infection regularly occurs and often persists throughout the remainder of the pregnancy. In the therapeutic abortion studies of Alford and associates,[8] fetal infection occurred in approximately 50 percent of placental infections. However, other studies have revealed almost identical isolation rates from both placental and fetal tissue.[410,507] Persistent infection is the usual outcome of first-trimester fetal infection. This fetal infection usually involves multiple organs, and virus can be isolated at birth regularly from the throat, rectum, and urine.[255,391]

Little is known about events in second- and third-trimester maternal rubella infection. Most probably, placental infection is a regular occurrence, and transmission of virus to the infant in utero also may occur regularly. Because few infants have defects when they are born after maternal rubella infection in the second and third trimesters, a careful search for rubella infection in these infants by virologic or serologic methods rarely has been conducted. Random studies seem to indicate that rubella virus often infects the fetus after the first trimester, and occasionally the infection becomes persistent.[119,136,227,255,353,539,560] Other studies have failed to show virologic or serologic evidence of infection in infants in whom maternal rubella occurred in the second and third trimesters.[94,354,491]

With maternal rubella infection, the cervix also is involved, so fetal infection could occur by the ascending route as well as by primary placental infection.[458,531] In addition, fetal infection has resulted from maternal disease that occurred before conception.[162,561,572]

Rubella virus can be recovered regularly after birth from infants with congenital rubella. The percentage of infants with persistent infection decreases during the course of the first year of life; by their first birthdays, between 10 and 20 percent of children still shed virus in nasopharyngeal secretions.[110,410] Rawls and colleagues[410] were unable to isolate virus from the throats of 15 congenitally infected infants after they reached 18 months of age, and Sever and Monif[466] and Cooper and Krugman[110] were unable to demonstrate persistence of nasopharyngeal virus in older children. A 4.5-year-old boy with congenital rubella was found on one occasion to be shedding rubella virus in the throat.[470]

Immunologic Findings

SPECIFIC ANTIBODY. Humoral antibody in a congenitally infected fetus is acquired transplacentally from the mother and is produced actively by the fetus. In a normal maternal-fetal relationship, transport of antibody to the fetus is minimal until the midpoint of the second trimester (16 to 20 weeks).[7,8] With first-trimester maternal infection (transplacentally acquired), rubella antibody titers in serum amount to only approximately 5 percent of maternal values. The fetal immune system becomes functional during the second trimester,[295] and small amounts of specific rubella fetal IgM antibody can be detected. From the midpoint of pregnancy, antibody levels in the developing fetus rise so that at birth, the maternal and infant values are similar. Although the values of total antibody are similar, the composition is different. Maternal antibody at the time of delivery usually is composed entirely of IgG. In contrast, the infant titer consists of fetal IgM, presumably fetal IgG, and occasionally fetal IgA and transplacentally derived maternal IgG.

Long-term rubella antibody patterns in congenitally infected infants after birth are different from those of their mothers or from those of a group of children with acquired disease.[108,226,274,522] Cooper and colleagues[108] monitored a group of 223 mothers of children with congenital rubella and noted that at the end of 5 years, all still had detectable HI antibody and the geometric mean titer for the group had undergone a fourfold reduction. In contrast, 5-year follow-up of the congenitally infected infants revealed a 16-fold decline in geometric mean titer; 8 of 29 infants had serum HI antibody titers less than 1:8 when they were examined at 5 years of age. Other investigators have observed similar declines in rubella antibody titers of congenitally infected infants.[226,274,522]

Another unique aspect of rubella antibody in congenitally infected infants is the persistence of specific IgM. Cradock-Watson and colleagues[121] studied 40 infants with congenital rubella and noted that IgM antibody persisted for approximately 6 months in most cases and for up to 2 years in a few children. de Mazancourt and colleagues[129] studied the antibody response to rubella virus structural proteins in infants with congenital rubella syndrome and found that the immunoprecipitation patterns were different from those in sera from postnatally infected adults. The sera from congenitally infected infants had little or no C-specific antibody, occasionally only antibody to E1 was precipitated, E1 protein was precipitated in relative excess of E2 protein, and the relative amount of E2 antibody was greater than antibody to E1.

SPECIFIC CELL-MEDIATED IMMUNITY. Rubella-specific, cell-mediated immune responses have been studied in children with congenital rubella by the following assays: lymphocyte-mediated cytotoxicity, lymphocyte transformation, lymphocyte interferon production, and leukocyte migration-inhibition factor production.[58,180] By all methods of study, infants with congenital rubella have decreased rubella-specific, cell-mediated responses compared with persons who previously had acquired rubella postnatally. Buimovici-Klein and associates[58] noted that the degree of suppression correlated with the time of in utero infection: the earlier in pregnancy the maternal infection, the greater the depression of specific cell-mediated responses. In the study of an infant with late-onset congenital rubella syndrome, Verder and associates[535] noted decreased activity of killer and natural killer cells and alloreactive direct cytotoxic cells. Their data indicated that defective cytotoxic effector cell function was the primary cause for failure to eliminate virus in the illness.

NONSPECIFIC RESPONSES. Desmyter and colleagues[132] noted that infants with congenital rubella produced normal amounts of interferon after receiving measles immunization. They also found that the clinical response and antibody development in these measles-vaccinated children were similar to those in normal children. Lebon and associates[296] noted that sera collected from rubella-infected fetuses and infants with congenital rubella contain an acid-labile interferon. Michaels[337] observed that infants with congenital rubella who still were shedding virus in their throat or urine had depressed antibody responses to diphtheria and tetanus toxoids. White and colleagues[559] reported decreased in vitro lymphocyte blast transformation responses to vaccinia and diphtheria toxoid antigens in children with congenital rubella in comparison to normal children. They also noted

depressed skin reactivity to intradermal *Candida* antigen in the congenital rubella group. Buimovici-Klein and associates[58] observed a marked reduction in lymphocyte transformation after PHA stimulation in their congenital rubella group. The most marked defect was seen in children in whom maternal rubella occurred during the first 8 weeks of pregnancy. Pukhalsky and associates[403] noted that rubella immunization resulted in defective lymphocyte response to a mitogen (PHA). After immunization, serum interferon-α was slightly increased at day 7 and then fell significantly so that it was not measurable at day 30 in several subjects. The interferon-α/interleukin-10 ratio significantly decreased after immunization.

PATHOLOGY

Postnatally Acquired Disease

Almost no data on the histologic findings in uncomplicated rubella are available, but occasionally, postmortem tissue has been studied from patients with encephalitis. Giuliani and associates[195] studied lymph nodes from patients with rubella and noted edema, reticulum cell hyperplasia, and loss of the usual follicular morphologic features. Sherman and associates[469] reported six cases of rubella encephalitis and noted the autopsy findings in three cases. They specifically searched all organs for inclusion bodies, syncytial giant cells, focal cellular necrosis, and unusual proliferative changes, but none of these was found. Only mild, nonspecific, follicular hyperplasia in the spleen and lymph nodes was seen. Histologic examination of the brain of a 7-year-old girl who died of encephalitis revealed diffuse swelling, nonspecific degeneration, and a sparse, mononuclear perivascular and meningeal exudate.

A synovial biopsy specimen in a woman with rubella arthritis revealed scattered areas of fibrinopurulent exudate and synovial cell hyperplasia; inflammatory cell infiltration composed mainly of lymphocytic cells was present, and vascularity was increased.[573]

Congenital Infection

In contrast to postnatal rubella, the pathologic process of congenital infection has been studied extensively.*

Table 186–4 summarizes the main pathologic findings by anatomic location or system in congenital rubella. As noted, defects in congenital rubella result from both specific cell damage and cellular deficiency. Although specific cellular necrosis is important in certain early lesions such as in the inner ear, of greater overall importance are the secondary effects of generalized vascular damage. Also of presumed major importance is the noncytolytic cellular infection characteristic of rubella virus. It results in mitotic arrest and a reduction in the total number of cells in many organs.

CLINICAL MANIFESTATIONS

POSTNATAL ILLNESS†

Although clinical rubella is a distinctive exanthematous disease, its features are not as clearly discernible as are those of measles or chickenpox. The exanthematous illnesses caused by enteroviruses, adenoviruses, and other common respiratory viruses often are clinically similar or identical to those of rubella (see Chapter 64). Because of these other viral illnesses that simulate rubella, descriptions of clinical rubella made before modern virologic diagnostic techniques became available are not always accurate, particularly when rubella in infants and young children is described because exanthems caused by other viruses occur most commonly in these age groups. Unfortunately, in spite of the availability of a vast amount of clinical material collected during the rubella epidemic of 1964, most clinical knowledge relating to postnatally acquired rubella was formulated before the present virologic era.

Incubation Period

Although prodromal complaints and lymphadenopathy frequently precede the development of exanthem in rubella, the incubation period in most studies has been calculated as being from the time of exposure to the onset of rash. Almost a century ago, Michael[336] reviewed the incubation periods in 59 different reports and noted a variation of 5 days to 4 weeks. However, in most reports, the minimal incubation time was 14 days or more and the maximum was 17 to 21 days. The mean incubation period from modern reviews is considered to be 18 ± 3 days.

In carefully controlled studies, Green and colleagues[204] noted an incubation time of 13 to 15 days to the onset of rash after the intramuscular inoculation of serum from rubella-infected patients and a longer incubation time (16 to 21 days) in cases acquired by contact with ill patients. In similar volunteer studies in young adults, Schiff and colleagues[445] noted that the onset of rash occurred 11 to 12 days after the administration of 100 $TCID_{50}$ of tissue culture–grown rubella virus. The investigators attributed this shorter incubation period to a larger inoculum than that occurring in natural transmission.

Prodromal Period

Complaints before the onset of rash in rubella vary with age. In young children, the first evidence of disease usually is the appearance of rash. On occasion, mild coryza and diarrhea precede the development of exanthem in younger patients. In contrast to the lack of prodrome in children, adolescents and adults usually have symptoms before the onset of rash.[88,161,209] In one study, 94 percent of college students with rubella had prodromal complaints. In decreasing order of frequency, the reported symptoms were eye pain, sore throat, headache, swollen glands, fever, aches, chills, anorexia, and nausea.[161] Gross and associates[209] reported prodromal upper respiratory complaints, including malaise, cough, sore throat, red eyes, and runny nose, in 65 percent of an infected adolescent study group.

Prodromal symptoms usually precede the onset of rash by 1 to 5 days. In the studies of Green and associates[204] involving volunteers, the onset of lymphadenopathy commonly was noted 5 to 7 days before the onset of rash. In contrast, Schiff and colleagues[445] observed the appearance of lymphadenopathy only 1 day before the rash appeared; fever was noted 1 to 4 days before the onset of rash, and most of the volunteers also had malaise and sore throat. Pain on lateral and upward eye movement occurs frequently and occasionally is distressing.[88,161]

Exanthem Period

The rubella exanthem appears first on the face. Spread of the rash is centrifugal from the head toward the hands and feet. The progression, extent, and duration of the exanthem vary considerably. In a typical case, the rash involves the entire body during the first 24 hours, begins to fade on the face during the second

TABLE 186–4 Pathologic Findings in Congenital Rubella

Anatomic Location or System	Gross and Microscopic Findings	References
Placenta	Perivascular mononuclear cellular infiltration in the deciduas	374
	Edema, fibrosis, and necrosis of villi; cytoplasm inclusion bodies noted in swollen Hofbauer cells in villous stroma	
Generalized growth retardation	Subnormal number of cells in many organs	362
Nervous system	Chronic meningitis with infiltrates of large mononuclear cells, lymphocytes, and plasma cells in the leptomeninges	422, 423, 474, 509
	Vascular degeneration, ischemic lesions, and retardation of myelinization throughout brain	
Eye	Lens: cataract, cortical liquefaction, and spherophakia	45
	Iris and ciliary body: necrosis of ciliary body, iridocyclitis, iris atrophy, and pigmentation defects	
	Retina: posterior pigmentary disturbances	
	Cornea: usually normal; occasional endothelial degeneration	
	Optic nerve: posterior bowing	
Ear	Hemorrhage in fetal cochlea resulting in epithelial necrosis	176, 177, 547
	Inflammatory cells in stria vascularis	
	Adhesions between Reissner membrane and tectorial membrane	
	Sacculocochlear degeneration of Scheibe (strial atrophy, collapse of Reissner membrane, atrophy of organ of Corti, rolled-up tectorial membranes, and collapse and degeneration of sacculus) noted after birth	
Cardiovascular	Common heart defects in order of frequency: patent ductus arteriosus, pulmonary artery stenosis, ventricular septal defect, and atrial septal defect (These rubella-induced lesions do not differ from similar non–rubella-induced lesions.)	4, 150, 170, 278, 279, 551
	Myocarditis with swelling of muscle fibers and loss of striations; necrosis	
	Intimal proliferation of major arteries	
Pulmonary	Chronic interstitial pneumonia with large mononuclear cells, lymphocytes, and plasma cells within interstitial spaces and alveoli	278, 389, 474
Liver	Hyalinization and swelling of hepatocytes, hematopoiesis, and multinucleated giant cells	152, 153, 489, 494
Skin	Purpuric lesion: focal areas of erythropoiesis in dermis and upper subcutaneous adipose tissue	65, 277
	Chronic reticulated rash: acute and chronic inflammatory cells and histiocytes in dermis	
	Edema in dermal papillae	
Bone	Thinning of metaphyseal trabeculae and decrease in number of osteoblasts and osteoclasts	411, 429, 457, 558
	Many plasma cells in metaphyses and cartilaginous epiphyses and around vessels	
	Occasional giant cells with cytoplasmic inclusions	
	Thinning of cartilage	
Muscle	Focal abnormalities: very small fibers with darkly staining nuclei and muscle bundles containing empty connective tissue tubes	480
Teeth	Necrosis of enamel-forming epithelial cells	210, 516
Hematologic	Transient thrombocytopenia with decreased megakaryocytes in bone marrow; increased platelet adhesiveness and platelet agglutinins	30, 98, 398, 408
	Lymph node consistent with histiocytosis; unorganized cell mass made up of mononuclear cells with dense round nuclei and irregularly shaped cytoplasm	
Immunologic	Spleen: fibrosis	98, 221, 397, 417
	Loss of normal architecture and absence of germinal centers in spleen and lymph nodes	
	Dysgammaglobulinemia usually with decreased IgG and IgA and elevated IgM	

day, and has disappeared from the body by the end of the third day. The characteristic rash is erythematous, maculopapular, and discrete (see Fig. 64–3). Its appearance on an adolescent's face occasionally is confused initially with an exacerbation of acne. Frequently, the rash is only macular with a scarlatiniform appearance. In some patients, the rash is present for less than a day, although sometimes it persists for 5 days or longer. Particularly in adults, the exanthem frequently is pruritic. This complaint is troublesome because it often leads the patient as well as the physician to attribute the rash to an allergic cause rather than rubella virus infection.

The exanthem occasionally progresses to confluence with a morbilliform appearance. In these cases, the rash usually is less coppery and pinker than that in measles and heals without desquamation or brownish discoloration. The typical picture of erythema infectiosum (slapped-cheek appearance and reticular rash) has been observed in rubella-infected patients. Balfour and associates[21] described eight children with erythema infectiosum from whom rubella virus was recovered concurrently and two additional children with serologic evidence of rubella infection. The preliminary results of volunteer studies with a virus recovered from one of the patients in this study produced a slapped-cheek appearance but a nonreticulated rash in four of five men. One 3-year-old child from whom the author recovered rubella virus had typical erythema infectiosum.[88] A 14-month-old girl had a roseola-like illness and arthritis.[241]

In the volunteer studies of Schiff and associates,[445] the rash was noted to be pink-red and maculopapular. It appeared initially on the face, chest, upper part of the arms, and shoulders and then spread rapidly over the abdomen, back, and thighs. It developed

into an erythematous blush on the face and abdomen. The median duration was 3 days, with extremes of 2 and 5 days. No pruritus was noted.

Rubella infection without rash is a rather common occurrence. In some patients, the infection is without symptoms; in other persons, careful questioning reveals prodromal symptoms, and lymphadenopathy is found on examination. Green and associates[204] noted that approximately 25 percent of exposed children who became infected had subclinical infection. In an intensive study of 46 susceptible children and adults, all but one subject had clinical symptoms with infection[460]; 60 percent of the group had both rash and characteristic posterior auricular or suboccipital lymphadenopathy, and 40 percent had lymphadenopathy without rash. In another study of rubella in an institution for retarded children, Horstmann and associates[257] noted that only approximately half the children who became infected had a rash. Of nine children without rash, significant posterior auricular lymph node enlargement developed in five. Buescher[55] reported a subclinical-to-clinical infection ratio in a military recruit population of 6.5:1.

Lymphadenopathy is a major clinical manifestation of rubella. The most characteristic enlargement occurs in the suboccipital and posterior auricular nodes, but generalized involvement occurs as well. In the volunteer studies of Schiff and colleagues,[445] the lymph node enlargement usually lasted between 5 and 8 days. In two outbreak studies involving adolescents and young adults, posterior auricular and suboccipital lymphadenopathy was noted in all patients with rash.[161,209] In contrast to these findings, Landrigan and associates[290] noted that only 47 percent of children and 58 percent of adolescents had similar lymph node enlargement during epidemic rubella illness. Although a frequent suggestion is that the finding of exanthem and suboccipital lymphadenopathy is pathognomonic for rubella, this suggestion is incorrect. In young children, similar involvement is seen frequently with enteroviral and adenoviral infections. In adolescents and young adults, the association more strongly indicates rubella, but infectious mononucleosis, *Mycoplasma pneumoniae* infection, acquired toxoplasmosis, and other possibilities also must be considered.

The occurrence of fever in rubella varies; when it does develop, the temperature usually is elevated only minimally. In children with experimentally induced rubella, Krugman and Ward[285] noted that 5 of 13 had temperatures of 38° C (100.4° F) or higher. Two children had maximal temperatures of 38.5° C (101.6° F). Schiff and colleagues[445] noted that all nine infected volunteers had fever with a median duration of 5 days. Landrigan and associates[290] found fever in 74 percent of children and only 47 percent of adolescents; Gross and coworkers[209] observed fever in only 6 of 17 adolescents. On occasion, children with apparent rubella have been noted to have markedly elevated temperatures. Few such cases have undergone virologic study, so some doubt must be raised regarding whether the illnesses were induced by rubella virus or were caused by other viral agents more commonly associated with marked febrile responses, such as enteroviruses and adenoviruses. I have seen an 8-year-old boy with virologically and serologically confirmed rubella with a temperature of 40° C (104° F) on the day before the appearance of his rash. The 14-month-old girl with arthritis described by Hildebrandt and Maassab[241] had a temperature as high as 40.5° C (105° F).

In 1898, Forchheimer[165] described what he thought was the enanthem of German measles. He described pinhead-sized macular lesions with a rose-red color on the soft palate and uvula that appeared at approximately the time of the exanthem and lasted less than 24 hours. This exanthem has not been identified in children I have examined; however, petechial lesions on the soft palate and uvula have been seen occasionally. Mild pharyngitis is not an uncommon occurrence. Other symptoms and signs in rubella include mild conjunctivitis, sore throat, coryza, cough, and headache.

The duration of illness in uncomplicated rubella varies considerably. Most patients would continue normal activity if the rash were not present. In general, full return to normal activity occurs within 3 days. A small number of adults are bothered by persistent headache, eye pain, and pruritus for 7 to 10 days.

The white blood cell count in rubella tends to be low. Schiff and colleagues[445] found leukopenia in all nine volunteers. In these subjects, leukopenia paralleled the pattern of fever, with onset occurring 24 hours before the rash was manifested and persistence lasting for 4 to 5 days. Before rubella could be confirmed by both specific serologic and virologic methods, many experts thought that rubella could be confirmed accurately by characteristics of the white blood cell count.[243,261] Leukopenia was found at the onset of disease; the total count rose to a high-normal value during a 10-day period. Relative neutropenia was noted by Hynes[261] in many patients; one patient had a neutrophil count of 868 cells/mm^3 on the first day of illness. Plasma cells, Türk cells, or both were noted in acute rubella in all cases studied by Hynes[261] and Hillenbrand.[243] A Türk cell is a developing plasma cell that is 25 to 40 μm in diameter and contains a 15- to 30-μm nucleus. The nucleus has two to five prominent nucleoli and a well-defined, light reticulum. The cytoplasm often is vacuolated. Twenty-five percent of the patients studied by Hynes[261] had elevated erythrocyte sedimentation rates during the first week of illness.

Complications

JOINT INVOLVEMENT. The incidences of reported cases of arthritis and arthralgia vary considerably in different studies.[35,82,187,209,268,290,473,526,557] In general, both arthralgia and arthritis occur more commonly in adults than in prepubertal children. Women are afflicted more often than are men. In a large outbreak in Bermuda in 1971, 42 percent of 125 patients studied complained of joint pain or discomfort.[268] Three patients had swelling of the joints. The prevalence of joint symptoms increased from 18 percent in the 0- to 9-year-old age group by approximately 20 percent increments per decade; 73 percent of those older than 30 years had symptoms. Joint complaints generally were more common in females than in males older than 10 years. This difference was most marked in the 10- to 20-year-old age group. Landrigan and associates[290] studied the location of joint symptoms in adolescents and found that the fingers were involved most often; the knees and wrists also were implicated commonly.

Yanez and associates[573] studied 11 patients with rubella arthritis. In all instances, multiple joints were involved. The onset of arthritis occurred 1 to 6 days after the beginning of the exanthem and lasted 3 to 28 days (mean, 9 days). The erythrocyte sedimentation rate was elevated in three of seven cases, and one patient had markedly positive latex test results. The white blood cell count was below 5000 cells/mm^3 in five of seven patients. One woman had bilateral carpal tunnel syndrome. Four children with transient carpal tunnel syndrome accompanying rubella virus infection have been described.[42] Panush[378] noted serum hypocomplementemia with rubella arthritis in a 25-year-old woman.

The possibility that rubella viral infection is related to rheumatoid arthritis has been studied on several occasions.[48,128,317,370,576] Martenis and colleagues[317] described a 21-year-old woman in whom rheumatoid arthritis developed after typical rubella with arthritis. Deinard and associates[128] found that all serum specimens from 80 patients with rheumatoid arthritis contained rubella HI antibody. In contrast, only 86 percent of an equal number of nonarthritic controls and a group of persons with other forms of arthritis had measurable rubella antibody titers. Ogra and associates[370] noted that patients with juvenile rheuma-

toid arthritis had IgM and IgG serum rubella antibody levels that were four to six times higher than those observed in controls during rubella infection. They also noted specific staining for rubella virus antigen in the synovial fluid of 33 percent of these patients with juvenile rheumatoid arthritis. Grahame and associates[199] repeatedly recovered rubella virus from the synovial fluid of six patients with inflammatory oligoarthritis or polyarthritis during a 2-year period.

NEUROLOGIC MANIFESTATIONS. Encephalitis is a rare complication of rubella.* Sherman and colleagues[469] noted 6 cases of encephalitis in an epidemic during the spring of 1964 that involved approximately 30,000 children. This rate of encephalitis (1 per 5000 cases) is similar to the rate of 1 per 6000 noted in Detroit in 1942.[316] Rubella encephalitis is clinically similar to encephalitis from measles virus infection but is thought to be less severe. Mortality and morbidity rates have varied considerably. Sherman and colleagues[469] noted that three of six children studied in Pittsburgh died of this complication during the spring of 1964, whereas in Atlanta during the same epidemic period, six patients recovered uneventfully.

The onset of encephalitis usually occurs 2 to 4 days after the rash appears, but occasionally, rash and neurologic symptoms occur at the same time; in other instances, the appearance of encephalitis is delayed as much as 1 week after the onset of illness. Examination of cerebrospinal fluid usually reveals mild pleocytosis (20 to 100 cells/mm^3), with most cells being lymphocytes. The protein content is normal or slightly elevated, and the sugar concentration is normal.

Kenny and associates[273] studied seven survivors of rubella encephalitis 1 year after their illnesses and could find no significant loss of intellectual function. Five of the seven had abnormalities on electroencephalography, and two patients had minor neurologic abnormalities. Gibbs and colleagues[190] found abnormal electroencephalographic tracings in 6 of 45 children with uncomplicated rubella.

Other neurologic complications associated with rubella include progressive panencephalitis, carotid artery thrombosis, myelitis, optic neuritis, Guillain-Barré syndrome, and peripheral neuritis.†

Of particular interest is the common occurrence of numbness, tingling, and other symptoms consistent with neuritis during rubella infection. Cuetter and John[122] studied 20 patients with complaints of neuritis accompanying rubella and could find no objective sensory deficits or nerve conduction abnormalities.

Wolinsky and colleagues,[569] Lebon and Lyon,[297] and others have described a slowly progressive and fatal nervous system disorder with rubella that was similar to subacute sclerosing panencephalitis. This illness has occurred as a late manifestation of congenital rubella and also has occurred in children who acquired their initial infection in childhood.[51]

THROMBOCYTOPENIA. Thrombocytopenic purpura occurs in rubella at an incidence of 1 per 3000 cases.[30] Children are afflicted more frequently than are adults, and girls are affected more often than are boys.[21,212,265,310,358,377,486,548] The median interval between the onset of exanthem and the occurrence of purpura is approximately 4 days. On occasion, rash and purpura develop simultaneously; often, however, the hemorrhagic manifestations do not become apparent until 2 weeks after the exanthem develops. The illness usually is self-limited, but its duration varies from a few days to several months; although deaths caused by hemorrhagic complications have occurred, recovery is the general rule.

OTHER COMPLICATIONS. Myocarditis and pericarditis are rare complications of rubella.[181] A 30-year-old woman was noted to have erythema multiforme exudativum and arthritis with apparent clinical rubella.[178] In an outbreak that involved 46 military recruits, testicular pain was a complaint in 25 percent.[448]

During a rubella epidemic in Japan in 1976 in which 79 patients were studied, 71 percent were noted to have mild catarrhal or follicular conjunctivitis.[225] Six patients had epithelial keratitis that persisted for 2 to 7 days. Seventeen patients had preauricular lymph node swelling in association with their eye findings. During the same epidemic, 13 cases of hemolytic anemia (including 2 cases of hemolytic-uremic syndrome) were noted after the patients had infection with rubella virus.[525] During an epidemic of rubella in Japan, Sugaya and colleagues[496] found that 7.5 percent of 241 patients had liver involvement.

CONGENITAL RUBELLA

From Gregg's original observation in 1941 of congenital defects in babies born to mothers who had rubella during early pregnancy until the pandemic of 1964, congenital rubella syndrome was considered to include only some combination of abnormalities involving the eyes, ears, brain, and heart. However, observations in 1964, supported by new virologic and serologic techniques, revealed a far more complex congenital rubella syndrome picture: rubella syndrome was expanded to include many new anatomic findings and to acknowledge the reality of chronic persistent infection.

Congenital rubella is the result of in utero fetal infection, which usually occurs during the first 12 weeks of pregnancy. The fetal infection generally is subacute or chronic and may result in abortion, stillbirth, congenital malformations, active processes at birth (such as thrombocytopenia, encephalitis, or hepatitis), and, rarely, infected infants without defects. Table 186–5 summarizes the clinical findings in congenital rubella, an estimation of their frequency, and their main characteristics.

General: Infant Death and Growth Retardation*

The most common manifestation of congenital rubella, readily apparent at birth, is generalized retardation of growth. Between 50 and 85 percent of all babies weigh less than 2500 g although gestational age is normal. Virtually all babies with intrauterine growth retardation have one or more other stigmata of congenital rubella. After birth, babies with intrauterine growth retardation often demonstrate continued growth retardation. In some instances, the failure to thrive is severe. Others show a normal growth pattern, but the child is proportionally small. The mortality rate of children with congenital rubella is high during the first year of life, with death specifically related to congenital pneumonia, heart defects and myocarditis, hepatitis, thrombocytopenia, encephalitis, immune deficiency, and failure to thrive.

Eye Findings†

Approximately a third of all babies with congenital rubella have cataracts. Cataracts may be bilateral or unilateral and are either central in location with a surrounding clear zone or diffuse. In most instances, cataracts are present at birth, but occasionally they are not observed until later in infancy. Retinopathy

TABLE 186–5 Frequency and Main Characteristics of Clinical Findings in Congenital Rubella Virus Infection

Clinical Findings	Frequency (%)	Main Characteristics	Selected References
General			
In utero death	10-30	Spontaneous abortion; stillbirth	203, 226, 433
Intrauterine growth retardation	50-85	Generalized effect	96, 170, 171, 226, 228, 255, 279, 303, 312, 328, 398, 429, 430, 446, 475, 509
Extrauterine growth retardation	10	Failure to thrive	228, 303, 328, 338, 381, 509
Neonatal and infant deaths	10	Due to pneumonia, heart disease, hepatitis, thrombocytopenia, failure to thrive, immune deficiency, encephalitis	112, 203, 226, 279, 430, 446, 509
Eye			
Cataracts	35	Present at birth	17, 32, 45, 112, 171, 189, 203, 226, 228, 255, 278, 279, 328, 360, 430, 440, 446, 474, 509, 521, 523
Retinopathy	35	Present at birth; usually does not cause problems with vision	45, 103, 111, 189, 203, 226, 255, 280, 281, 328, 521, 523
Microphthalmos	5	Usually associated with cataract	45, 151, 189, 255, 279, 430, 455, 509
Glaucoma	5	Usually present at birth	45, 111, 226, 228, 255, 279, 430, 455, 463
Cloudy cornea	Rare	Usually present at birth; resolves spontaneously	45, 228
Severe myopia	Rare	Usually present at birth; defect may progress	107
Hypoplasia of the iris	Rare	Present at birth	45, 428
Strabismus	5	Associated with other eye defects	227, 328, 371
Iridocyclitis	Rare	Transient; associated with other eye defects	474
Auditory			
Nerve deafness	80-90	May be bilateral or unilateral; moderate or severe; often not recognized early	17, 47, 130, 151, 171, 203, 211, 226, 228, 288, 328, 344, 387, 392, 446, 463, 521, 523, 528
Central deafness	5	Often associated with other central nervous system defects	224
Middle ear damage	5	Usually associated with nerve deafness	418
Intraoral, Nasal, and Facial			
Cleft palate or lip	Rare		151, 203, 446
Dental abnormalities	Rare		65, 210, 328
Micrognathia	Rare		253, 446
Chronic rhinitis	Rare	Transitory finding	392
High-arched palate	Rare		226
Neurologic			
Motor defects	10	Associated with mental and other neurologic defects	328, 463, 575
Hyperirritability (tremors)	Rare	Transitory finding	423
Microcephaly	Rare		17, 228, 255, 328, 463, 509, 546, 562
Mental retardation	10-20	Associated with other stigmata	107, 203, 224, 226, 326, 463, 495
Full anterior fontanelle	10	Transitory finding related to meningoencephalitis	109, 430
Meningoencephalitis	10-20	Transitory finding but may last for 1 year	131, 228, 278, 279, 392, 430, 474, 509
Spastic diplegia and quadriparesis	Rare	Associated with other stigmata	109, 131
Seizures	Rare	Frequently transitory and related to meningoencephalitis	131, 229, 328, 392
Hypotonia	Rare	Transitory defect	130, 131
Brain calcification	Rare		387, 389, 474, 509
Cerebral arterial stenosis	Rare		224
Anencephaly	Rare		446
Encephalocele	Rare		446
Meningomyelocele	Rare		495
Behavior disorders	10-20	Frequently related to deafness	107, 130
Central language disorders	5		157, 203, 555
Autism	5		107, 157, 224
Aqueductal occlusion or hydrocephalus	Rare		203, 436
Poor balance	Rare		130, 575
Progressive panencephalitis	Very rare	Has onset during adolescence	518, 554

TABLE 186–5 Frequency and Main Characteristics of Clinical Findings in Congenital Rubella Virus Infection—cont'd

Clinical Findings	Frequency (%)	Main Characteristics	Selected References
Cardiovascular			
Patent ductus arteriosus	30	Frequently associated with other defects	17, 32, 151, 171, 226, 228, 233, 266, 278, 353, 463, 474, 509, 523, 551
Pulmonary arterial hypoplasia, supravalvular stenosis, valvular stenosis, and peripheral branch stenosis	25	Frequently associated with other defects	171, 226, 228, 233, 266, 463, 472, 523, 551
Aortic stenosis	2-5		170, 233, 471, 540, 551
Ventricular and atrial septal defects	2-5		32, 463, 523, 551
Tetralogy of Fallot	2-5		151, 228
Myocarditis and myocardial necrosis	10		4, 151, 278, 279, 353, 509, 551
Intimal fibromuscular proliferation of many arteries	5		150
Ventricular aneurysm	Rare		532
Pulmonary			
Interstitial pneumonitis	5-10	May be acute, subacute, or chronic	44, 151, 228, 278, 279, 353, 387, 389, 392, 446, 474, 509, 562
Tracheoesophageal fistula	Rare		446
Respiratory distress	Rare	Secondary to acute pneumonia	328
Gastrointestinal			
Esophageal atresia	Rare		446
Hepatitis	5-10	Associated with other evidence of disseminated disease	17, 151, 153, 228, 351, 352, 489, 509
Obstructive jaundice	5		278, 279, 353, 423, 474
Chronic diarrhea	Rare	Related to failure to thrive and immune deficiency	392, 509
Pancreatitis	Rare	May lead to diabetes in later life	61, 139
Duodenal stenosis	Rare		133
Jejunal or rectal atresia	Rare		151
Genitourinary			
Undescended testicle	Rare	Cause-and-effect relationship with rubella infection in doubt	328, 474
Polycystic kidney, ectopic kidney, renal agenesis, or bilobed kidney	Rare	Cause-and-effect relationship with rubella infection in doubt	150, 151, 331
Hypospadias	Rare	Cause-and-effect relationship with rubella infection in doubt	45, 171, 474
Duplication of ureter	Rare	Cause-and-effect relationship with rubella infection in doubt	32
Renal artery stenosis	Rare		327
Hydroureter and hydronephrosis	Rare	Cause-and-effect relationship with rubella in doubt	229, 387, 463, 474
Inguinal hernia	Rare	Cause-and-effect relationship with rubella in doubt	229, 387, 463, 474
Nephritis and nephrocalcinosis	Rare		474, 509
Testicular agenesis	Rare	Cause-and-effect relationship with rubella in doubt	151
Orthopedic			
Bone radiolucencies	10-20	Radiolucencies in metaphyses of long bones	228, 328, 387, 398, 407, 411, 429, 430, 457, 546, 558, 562
Pathologic fractures	Rare		429
Bone deformities	Rare		88, 203, 309
Clubfoot	Rare		446
Myositis	Rare	Transitory defect	481
Skin			
Dermal erythropoiesis (blueberry muffin syndrome)	5	Transitory defect; usually associated with severe disease	277
Chronic rash	Rare		65, 222
Dermatoglyphic abnormalities	5		2, 10, 404
Dimples	Rare		220
Endocrine			
Diabetes mellitus	Rare		169, 267, 329
Thyroid disorder	Rare		107
Precocious puberty	Rare		107
Growth hormone deficiency	Rare		402

TABLE 186–5 Frequency and Main Characteristics of Clinical Findings in Congenital Rubella Virus Infection—cont'd

Clinical Findings	Frequency (%)	Main Characteristics	Selected References
Hematologic			
Thrombocytopenic purpura	5-10	Usually associated with severe disease with high death rate; transitory	17, 30, 32, 36, 111, 171, 228, 255, 279, 287, 328, 387, 392, 398, 407, 408, 429, 430, 446, 463, 542
Hemophagocytic syndrome	Rare		31
Hemolytic anemia	Rare	Transitory	350, 387, 408
Hypoplastic anemia	Rare	Transitory	109, 287
Extramedullary hematopoiesis	5-10	Usually associated with severe disease	509
Immunologic			
Thymic hypoplasia	Rare		224
Dysgammaglobulinemia	Rare		101, 221, 397, 417, 475
Asplenia	Rare		254
Reticuloendothelial			
Generalized lymphadenopathy	10		109, 171, 222, 509
Hepatosplenomegaly	10-20	Usually associated with severe disease; transitory	32, 279, 398, 430, 446, 463
Genetic			
Chromosomal abnormalities	Rare	Cause-and-effect relationship with rubella not established	13, 367

consisting of pigmentary defects occurs commonly in congenital rubella and is useful diagnostically, but it rarely adversely affects visual acuity. Microphthalmos occurs relatively frequently and usually is unilateral. Cataracts frequently are associated with microphthalmos.

Congenital glaucoma occurs in approximately 5 percent of congenitally infected infants. This defect usually is present at birth, but it often is overlooked. Diagnosis must be established early if sight is to be preserved.

Auditory Defects*

Sensorineural deafness is the most common manifestation of congenital rubella; almost all patients have some degree of hearing impairment. The hearing loss usually is bilateral but may be unilateral. Frequently, the only manifestation of congenital infection is deafness. An important note is that deafness is overlooked frequently in infancy, and children incorrectly are considered to be mentally retarded. All children born to mothers who had rubella during the first half of pregnancy should undergo evaluation of their hearing several times during the first 5 years of life, regardless of whether they have other manifestations of congenital infection.

Neurologic Findings†

Between 10 and 20 percent of all infants with congenital rubella have active meningoencephalitis at birth. Manifestations of this infection include one or more of the following: a full anterior fontanelle, irritability, hypotonia, seizures, lethargy, and head retraction and arching of the back. Examination of the cerebrospinal fluid reveals elevated protein and mild pleocytosis. Later neurologic disease, such as mental and motor retardation, can be related to the severity and persistence of the initial meningoencephalitis. Active central nervous system infection has been demonstrated for a year or more.

Behavior disorders occur commonly in children with deafness and often cannot be associated with apparent meningoencephalitis. Congenital rubella children with generalized retardation of growth and a proportionally small head often have normal intelligence. In contrast, the prognosis for mental development in a child with true microcephaly is poor.

Chronic progressive panencephalitis has developed in a small number of adolescents with congenital rubella, similar to measles-related subacute sclerosing panencephalitis.

Cardiovascular Findings*

In severe congenital rubella with multisystem involvement, myocarditis occurs and often is a cause of death. Of the structural defects of the heart, patent ductus arteriosus is the most common. It may be the only lesion noted, but two thirds of patients have other lesions as well. Pulmonary artery stenosis is the next most common defect. It may involve the main pulmonary artery or its branches. Pulmonary valvular stenosis is the third most frequent defect. Pulmonic valvular or arterial stenosis and patent ductus arteriosus commonly occur together.

Other Manifestations†

The other manifestations of congenital rubella can be separated into three categories: manifestations related to active persistent infection, structural defects, and delayed manifestations of congenital rubella.

†See references 4, 10, 13, 17, 30, 32, 36, 44, 45, 61, 65, 88, 100, 101, 107, 109, 112, 139, 150, 151, 153, 169, 171, 193, 203, 220-222, 224, 228, 229, 255, 267, 277-279, 287, 309, 329, 350-353, 367, 387, 389, 392, 397, 398, 402, 408, 411, 417, 423, 429-431, 446, 457, 463, 468, 474, 475, 481, 489, 494, 509, 542, 546, 558, 562.

MANIFESTATIONS RELATED TO ACTIVE PERSISTENT INFECTION. This category encompasses a broad constellation of clinical events that largely were unknown before the pandemic of 1964. Collectively, they frequently are called the expanded congenital rubella syndrome and include interstitial pneumonitis, hepatitis, nephritis, bone radiolucencies, myositis, dermal erythropoiesis, chronic rash, thrombocytopenic purpura, hemolytic and hypoplastic anemia, immunologic deficiency, generalized lymphadenopathy, hepatosplenomegaly, meningoencephalitis, and myocarditis. Most infants with the expanded rubella syndrome clinically have low birth weight, exanthem caused by thrombocytopenia or dermal erythropoiesis or both, hepatosplenomegaly, and jaundice. Radiographs usually reveal long bone radiolucencies. Respiratory distress caused by both diffuse pulmonary disease and myocarditis occurs commonly, and meningoencephalitis usually is evident. The duration of chronic infection in these babies varies. Approximately 20 percent of survivors still are shedding virus at 1 year of age. Between 10 and 20 percent of babies with hepatosplenomegaly and thrombocytopenia die during the first year of life.

STRUCTURAL DEFECTS. Other than deafness, eye defects, and cardiac anomalies, which have been discussed previously, the association of other malformations with congenital rubella infection is less well established. Malformations such as tracheoesophageal fistula, jejunal atresia, inguinal hernia, and others recorded in Table 186–5 occur frequently without evidence of in utero infection. Because they are noted only sporadically in babies born after maternal rubella, they possibly are chance associations rather than cause-and-effect relationships.

DELAYED MANIFESTATIONS. The following delayed manifestations of congenital rubella that were not present in early life have been noted: endocrinopathies, deafness, ocular damage, vascular effects, and progressive rubella panencephalitis.[468] Of particular importance is the association between endocrine abnormalities and autoimmunity.[100] In one study of 201 deaf adolescents with congenital rubella, 23.3 percent had positive thyroid microsomal or thyroglobulin antibodies, and of these patients, 19.6 percent had thyroid gland dysfunction. Patients with congenital rubella have an increased incidence of insulin-dependent diabetes mellitus.[193] In a 40-year observation study of 280 Japanese patients with congenital rubella syndrome, only three of the patients developed insulin-dependent diabetes.[503]

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Postnatally Acquired Disease (see also Chapter 64)

Because no pathognomonic finding in rubella exists, the clinical diagnosis in an individual case often is difficult to establish. However, as with other exanthematous diseases, the key to establishing a diagnosis is careful elicitation of historical data. Rubella is an epidemic disease with a high clinical rate of expression of exanthem. Therefore, it is unusual, when proper investigation is performed, not to find the contact case or other cases in the community. Season also is an important consideration. Rubella generally occurs in the winter and spring, whereas enteroviral exanthems, which are the greatest masqueraders in young children, occur mainly in the summer and fall.

The incubation period also is important in separating rubella from exanthems caused by common enteroviruses or respiratory viruses. In rubella, the incubation period is long (18 ± 3 days), whereas the period in the other illnesses usually is much shorter (3 to 7 days). Age also is important. Today, rubella mainly is an illness of adolescents and young adults, and enteroviral exanthems are uncommon findings in patients at these ages.

The nature of fever also is useful in establishing the diagnosis of rubella. Temperature higher than 38.5° C (101.5° F) is an unusual occurrence in rubella but common with enteroviral exanthems, measles, and *M. pneumoniae* infection. In general, a past history of rubella infection is not particularly reliable. However, if a past illness can be documented by year, season, and symptoms, accurate information may be obtained. Useful characteristics of the rubella exanthem are its mild, erythematous, maculopapular, and discrete nature; marked pruritus in adolescents and adults; and an acneiform appearance on the face in adolescents.

Although suboccipital and posterior auricular lymphadenopathy often is thought by some investigators to be pathognomonic, its presence in nonrubella exanthems often leads to undue concern. In general, in a young child, suboccipital and posterior auricular lymphadenopathy occurs as commonly with enteroviral illnesses as with rubella. In young adults, however, this lymphadenopathy is much more useful because the enteroviral differential consideration is less of a problem. Similar lymphadenopathy does occur with acquired toxoplasmosis, infectious mononucleosis, and *M. pneumoniae* infection. A major problem in the differential diagnosis in adults is allergy. However, fever (even low grade), lymphadenopathy, headache, and eye pain, which are common events in rubella, should occur rarely in contact or other simple allergies.

Congenital Rubella

Establishing the diagnosis of congenital rubella in infants with known maternal exposure generally is not difficult. However, examining an apparently normal child at periodic intervals during the first few years of life is important so that deafness and subtle neurologic defects are not missed. The diagnosis of congenital rubella after an uneventful pregnancy is more difficult to make. All babies with evidence of intrauterine retardation of growth or stigmata suggestive of congenital infection should undergo virologic and serologic study for rubella as well as for other infectious agents. Determination of the amount of serum IgM also can be useful in the study of babies with intrauterine retardation of growth or babies born to mothers in whom rubella or other infection was suspected to have occurred during pregnancy.[491] Values greater than 21 mg/dL during the first week of life strongly indicate congenital infection; normal values do not rule out congenital infection, however.

SPECIFIC DIAGNOSIS

Postnatally Acquired Disease

Rubella viral infection can be diagnosed specifically by isolation of virus from nasal or throat specimens in AGMK or other sensitive tissue culture systems or by polymerase chain reaction (PCR)[114,115]; by the observation of a significant change in value of HI, ELISA, immunofluorescence, CF, or neutralizing antibody in two sequential serum samples; or by the demonstration of specific rubella IgM antibody in a single serum sample. Most often today, the diagnosis of rubella is attempted by the use of a single serum test for identifying rubella IgM antibody.* A number of commercial rubella IgM immunoassays are now available, and in general their sensitivity and specificity ranges vary from 75 to 95 percent and from 85 to 100 percent, respectively.[135,513] Determination of rubella-specific IgM antibody in saliva 7 to 42 days

*See references 12, 22, 33, 34, 67, 83, 87, 117, 135, 148, 160, 167, 194, 251, 315, 334, 359, 382, 453, 476, 513, 534.

after the onset of illness also has been shown to be both sensitive and specific.[406] Although these tests are practical, one should realize that the specificity and sensitivity of all routinely used tests are not 100 percent accurate. False-positive results occur all too frequently and commonly lead to unnecessary interventions. When the diagnosis is critical, such as with suspected rubella in pregnancy, a wise approach is to study IgG antibody in paired sera collected 1 to 2 weeks apart in addition to determining IgM antibody.

Unfortunately, a rise in IgG antibody titer as well as an IgM positive test result can occur in re-infection as well as in primary infection. Because re-infection in a pregnant woman is very unlikely to lead to damage to the in utero fetus, distinguishing primary infection from re-infection is important and can be done by measuring the avidity of rubella IgG antibody.[219,246,405] In primary infection, the avidity is low, whereas it is high in re-infections.

Congenital Rubella

The best method for establishing a definitive diagnosis of congenital rubella is viral isolation or PCR. Specimens for viral culture or PCR should be obtained from the nose, throat, urine, buffy coat of blood, and cerebrospinal fluid. Because of transplacental passage of maternal IgG, establishment of the diagnosis of congenital rubella in the neonatal period by serologic methods is fraught with difficulty. Usually, specific rubella IgM antibody can be demonstrated with presently available techniques. In questionable cases, follow-up studies comparing infant and maternal antibody values often establish the diagnosis. If the infant's value is the result solely of transplacentally acquired antibody, it should drop fourfold to eightfold by the time the infant reaches 3 months of age and continue to fall to nondetectable values by 6 to 8 months of age. However, the antibody value in some congenital infections also may fall, so disappearance of antibody in serum does not rule out in utero infection completely. Also in questionable cases, the study of IgG rubella antibody avidity may be useful.[239,405]

The retrospective diagnosis of congenital rubella in late infancy and the second year of life has been difficult to make. However, researchers have shown that affected children have low avidity of specific IgG antibody, and, therefore, a retrospective diagnosis of congenital rubella can be made by specific avidity assays.[239] Also useful for the serologic diagnosis of congenital rubella during the prenatal and newborn periods are rubella IgG peptide-based enzyme immunoassay and rubella immunoblot assay.[326] Newborns who were infected during the first 12 weeks of gestation have reduced levels of antibodies directed at both the linear E1 epitope (SP15) and the topographic E2 epitope.

Fetal rubella can be diagnosed in amniotic fluid samples by reverse transcription–PCR.[416,504]

Qualitative Demonstration of Rubella Antibody

The original screening method for rubella antibody was HI. Today, HI has been replaced by more rapid and easier tests involving enzyme immunoassay, erythrocyte agglutination, and latex agglutination. In general, all are both highly sensitive and specific.[86,159]

TREATMENT

POSTNATALLY ACQUIRED DISEASE

Uncomplicated Rubella

No specific therapy is necessary or indicated for uncomplicated rubella. Starch baths may be useful in adults with troublesome pruritus. Of importance is that affected patients understand that they are contagious and that transmission of infection to a pregnant woman could have serious consequences.

Complications of Rubella

On occasion, arthritis can be severe in adults. When weight-bearing joints are affected, rest is encouraged. Symptoms readily respond to aspirin therapy; corticosteroids are not indicated. In rubella encephalitis, care is supportive, with adequate maintenance of fluids and electrolytes.

Thrombocytopenia usually is self-limited; however, severe bleeding has occurred on occasion. Splenectomy is not indicated. Corticosteroid therapy often is used, but with little evidence of specific benefit in rubella-infected patients. In patients who do not recover rapidly and in those with severe bleeding, treatment with intravenous immunoglobulin should be considered.

MANAGEMENT OF EXPOSED PREGNANT WOMEN

Ideally, all pregnant women should have received rubella vaccine previously or been shown to have rubella antibody by an appropriate serologic test. If a pregnant woman is exposed to a person with rubella and the history of previous immunization or antibody presence is unknown, an immediate blood specimen should be obtained and a rubella antibody test performed. If antibody to rubella is demonstrated, no action is necessary. Susceptible rubella-exposed women should undergo careful clinical observation for fever, lymphadenopathy, or exanthem for a 4-week period. If illness occurs, a nasal specimen should be cultured for rubella virus and serum should be examined for rubella IgM antibody. A second serum specimen should be submitted for rubella antibody examination. If illness occurs, a specimen should be collected 1 to 2 weeks later; if the woman has no illness, the second serum specimen should be collected 6 to 8 weeks after the exposure. If rubella antibody seroconversion is noted or specific IgM antibody is demonstrated, the risk of fetal infection and malformation is considerable. Because false-positive rubella IgM antibody test results are not rare occurrences, all tests that yield positive results should be repeated for confirmation (by another assay and in another laboratory if possible). Because IgM antibody can occur in re-infections and fetal risk is then minimal, determining the avidity of IgG antibody also may be useful.[219,246,405] The patient should be so advised, and therapeutic abortion should be discussed.

In situations of known exposure of a susceptible pregnant woman in which therapeutic abortion is not possible and exposure can be documented to have taken place within 72 hours, my opinion is that 20 mL of immunoglobulin should be administered immediately. The use of immunoglobulin is controversial, but in certain controlled situations, it has been effective in preventing disease.[53,340,442,529]

MANAGEMENT OF PREGNANT WOMEN WITH AN EXANTHEM THOUGHT TO BE RUBELLA

In this circumstance, if previous rubella serologic study results are available, they are extremely useful. If previous serum antibody has been noted, the mother should be reassured that the present illness is not likely to be rubella. However, because false-positive rubella screening results do occur, a wise approach is to carry out rubella serologic study and, when possible, also viral culture. An acute-phase serum should be examined for rubella-specific IgM antibody. A second serum specimen should be collected 1 to 2 weeks after the disappearance of the rash. If rubella antibody has risen significantly or IgM antibody is demonstrated,

it is highly likely that congenital infection has occurred and that anomalies may result. Again, a wise approach is to confirm IgM positive test results and, if available, do IgG rubella antibody avidity study. In this circumstance, the woman should be counseled about therapeutic abortion.

If a previous serum rubella antibody value is not available, a serum sample should be collected immediately and another collected 2 to 3 weeks later. These sera should be examined as paired specimens for rubella antibody and analyzed for specific rubella IgM antibody. If a rubella antibody rise is demonstrated or the presence of rubella IgM is noted, one must assume that rubella viral infection has occurred, and the patient should be advised about the risk of congenital infection and the possibility of therapeutic abortion.

MANAGEMENT OF CHILDREN WITH CONGENITAL RUBELLA

Isolation Procedures

Most babies with congenital rubella remain actively infected at the time of birth, are contagious, and therefore should be placed in isolation. Room isolation and urine precautions are the major necessities. The isolated baby should be cared for only by persons known to be seropositive for rubella. Because rubella viral shedding has been known to occur for a year or more in some babies, isolation of infants with congenital rubella should be continued for this duration unless repeated viral cultures have proved negative.

After the child is discharged from the hospital, no special precautions are necessary in the household setting. However, the parents should be advised of the potential risk to pregnant visitors.

Neonatal Period

As noted, the clinical manifestations of congenital rubella are varied, and in many infants, no symptoms are manifested during the first few months of life. In these apparently asymptomatic infants, no particular management problems are encountered. In other neonates, symptoms of continued viral infection are readily apparent and frequently are severe. In these infants, the following findings are important: pneumonia, thrombocytopenia, eye findings, heart defects, hyperbilirubinemia, and hepatosplenomegaly.

Although purpura and petechiae secondary to thrombocytopenia may be impressively severe in these infants, true hemorrhagic difficulties have not been a major problem. Corticosteroid therapy does not seem to be indicated, but considering treatment with intravenous immunoglobulin might be worthwhile. Careful evaluation of the eyes is important. Of immediate concern is the search for corneal clouding because its presence probably indicates infantile glaucoma. Cataracts and retinopathy also should be sought carefully. Infants with glaucoma should be referred immediately for ophthalmologic evaluation and therapy. Children with cataracts or retinopathy also should be referred, but therapy for cataracts is best delayed until the child reaches a later age.

Respiratory distress secondary to extensive viral involvement should be managed similar to other neonatal respiratory disease: assisted ventilation and careful attention to arterial blood gas values and pH. Although jaundice secondary to congenital rubella infection rarely is severe, standard criteria for the treatment of hyperbilirubinemia should be followed. Hepatosplenomegaly may be marked in some instances but is of no therapeutic concern.

Cardiac evaluation should be the same as in affected infants without rubella. Specifically, congestive cardiac failure should be treated vigorously; in malignant conditions (patent ductus arteriosus, coarctation of the aorta), lifesaving surgery should be contemplated.

Long-term Problems

DEAFNESS. Hearing disability is the most frequent abnormality after infection with congenital rubella; more than 80 percent of infected infants have some degree of hearing disability. In many instances, deafness is the only clinical manifestation of congenital rubella, and because the establishment of this diagnosis in early infancy is difficult, the diagnosis frequently is delayed. However, early diagnosis of deafness and institution of proper educational programs are the most productive measures in the long-term management of children with congenital rubella. All too frequently, poor medical advice has been responsible for the delay in making an appropriate diagnosis and providing therapy. Any time that a mother suspects that her child is deaf, specific audiometric testing should be performed. Many general practitioners, pediatricians, and even otolaryngologists think that hearing cannot be tested in infants. This concept must be discouraged vigorously; at proper centers, a severely deaf child can be recognized in virtually all instances.

If deafness is diagnosed, the child should be referred immediately to a training program. Information about training programs can be obtained from the Alexander Graham Bell Association for the Deaf, 3417 Volta Place, NW, Washington, DC 20007, *http://www.agbell.org*; and the John Tracy Clinic, 806 West Adams Boulevard, Los Angeles, CA 90007, *http://www.johntracyclinic.org*. In virtually all instances, severely deaf children should be enrolled in an education program before or during the second year of life, and the child should be fitted with a proper auditory amplification device. Although deafness in congenital rubella is sensorineural, a surprising finding is that conduction defects also are noted in many older children. For these children, other aspects of otolaryngologic care may be indicated.

EYE PROBLEMS. All children with eye problems (cloudy cornea, glaucoma, cataracts, retinitis, strabismus) should be referred at an early age for ophthalmologic evaluation. Glaucoma needs immediate attention. Decisions about cataract surgery should be left to the discretion of the ophthalmologist but, in general, are well deferred until after the end of the first year. Retinopathy, although frequently impressive on ophthalmoscopic examination, rarely causes much visual defect. Strabismus is managed as it is in children without rubella. Advice on eye problems in congenital rubella can be obtained from the American Foundation for the Blind, 11 Penn Plaza, Suite 300, New York, NY 10001, *http://www.afb.org*.

HEART PROBLEMS. Congenital heart disease secondary to in utero rubella infection should be managed as heart disease is in children without rubella. Of importance is that the children be referred to cardiac centers where sophisticated diagnostic techniques and cardiac surgery facilities are available for correctable lesions.

MUSCULOSKELETAL PROBLEMS. Isolated musculoskeletal defects are relatively uncommon findings in congenital rubella. However, when the symptoms indicate, referral to a cerebral palsy clinic is useful, both for specific therapeutic modalities and for the camaraderie of group therapy for the children as well as the parents.

CENTRAL NERVOUS SYSTEM PROBLEMS. Careful analysis of the data available suggests that many infants who have been labeled retarded actually are children with auditory or visual defects who have not had proper diagnosis and training for their handicaps. No child with congenital rubella should be labeled

mentally subnormal until extensive audiologic and ophthalmologic investigations and perhaps specific therapy have been performed. Probably only approximately 10 percent of all congenitally infected rubella children have a central nervous system defect that precludes normal development.

IMMUNOLOGIC DEFECTS. A small number of children with congenital rubella have been noted to have specifically low levels of serum IgG. These infants have systemic continued viral infection and in general do poorly. Although outcome studies are not available, administration of immune serum globulin (intramuscular or intravenous immunoglobulin) to these infants periodically seems prudent.

MULTIPLE HANDICAPS. All too frequently, children infected in utero with rubella virus suffer from one or more of the handicaps mentioned. Care of these infants and children requires many different resources and modalities of therapy. Frequently, the physician is the one who must coordinate both the diagnostic and the long-term educational efforts that are necessary for optimal progress of an affected child. In addition to the Alexander Graham Bell Association for the Deaf, the John Tracy Clinic, and the American Foundation for the Blind, already mentioned, the following agencies may be helpful to physicians or the parents of congenital rubella children: United Cerebral Palsy Research and Educational Foundation, 1600 L Street, NW, Suite 700, Washington, DC 20036-5602, *http://www.ucpa.org*; Easter Seal Research Foundation, 230 West Monroe Street, Suite 1800, Chicago, IL 60606, *http://www.easter-seals.org*; The Arc of the United States, 1010 Wayne Avenue, Suite 650, Silver Spring, MD 20910, *http://www.thearc.org*; and Maternal and Child Health Division, Department of Health and Human Services, Parklawn Building, 5600 Fishers Lane, Rockville, MD 20852, *http://www.hrsa.gov*.

PREVENTION

ACTIVE IMMUNIZATION: LIVE ATTENUATED RUBELLA VIRUS VACCINE

At present, one attenuated rubella virus vaccine is available for use in the United States (RA 27/3 strain grown in WI38 human embryonic lung tissue culture). Vaccination can be expected to produce antibodies in more than 95 percent of those immunized.[20,307,394,444,480,544,549,553] Antibody titers after RA 27/3 vaccination are slightly lower than those after natural infection, but they have been demonstrated to persist for an 11- to 15-year period with a pattern similar to that occurring after natural infection, even in the absence of re-exposure to rubella virus.[41,258,394]

Because of universal immunization, indigenous rubella has been eliminated.[69,412] Finland's vigorous two-dose immunization program also resulted in the elimination of indigenous rubella.[385,386]

Recommendations for Use

For complete information about rubella immunization, the reader is referred to the most recent recommendations of the Immunization Practices Advisory Committee of the U.S. Public Health Service,[70,75] the recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics,[11] and the vaccine manufacturer's product information.

Rubella vaccine is recommended for all children 12 months of age or older, adolescents, and adults, particularly women, unless otherwise contraindicated. Vaccination of children protects them from rubella and thus prevents them from subsequently spreading it. Vaccination of susceptible postpubertal women confers individual protection from rubella-induced fetal injury. Vaccination of adolescents or adults in population groups such as those in colleges, places of employment, or military bases protects them from rubella and reduces the chance of epidemics occurring in partially immune groups.

Rubella vaccine should not be administered to infants younger than 1 year of age because persisting maternal antibodies may interfere with seroconversion. When rubella vaccine is part of a combination vaccine that includes measles antigen, it should be administered to children approximately 12 to 15 months of age. A second dose of MMR vaccine is recommended at school entry. Children who have not received rubella vaccine at the optimal age should be vaccinated promptly. Because a history of rubella is not a reliable indicator of immunity, all children for whom vaccine is not contraindicated should be vaccinated.

Vaccination of all unimmunized prepubertal children and adolescents as well as of adult women in the child-bearing age group must be emphasized. Because of the theoretical risk to the fetus, women of child-bearing age should receive vaccine only if they are not pregnant and understand that they should not become pregnant for 3 months after receiving the vaccination.

Educational and training institutions such as colleges, universities, and military bases should seek proof of rubella immunity (a positive serologic test result or documentation of previous rubella vaccination) from all students and employees in the child-bearing age. Nonpregnant women who lack proof of immunity should be vaccinated unless contraindications exist.

For the protection of susceptible female patients and female employees, persons working in hospitals and clinics who might contract rubella from infected patients or who, if infected, might transmit rubella to pregnant patients either should have serologically demonstrated immunity to rubella or should receive the vaccine.

Routine premarital serologic testing for rubella immunity would enhance efforts to identify susceptible women before pregnancy. Prenatal or antepartum screening for rubella susceptibility should be undertaken and vaccine administered in the immediate postpartum period—before hospital discharge. Previous administration of anti-Rh_0(D) immunoglobulin (human) or blood products is not a contraindication to vaccination; however, 6- to 8-week postvaccination serologic testing should be performed for confirmation of seroconversion in those few who have received the globulin or blood products. Obtaining laboratory evidence of seroconversion in other vaccinees is not necessary.

No evidence has shown that live rubella virus vaccine given after exposure prevents illness or that vaccination of a person incubating rubella is harmful. However, because a single exposure may not result in infection and postexposure vaccination would protect a person in the event of future exposure, vaccination is recommended unless it is otherwise contraindicated.

Adverse Reactions

Vaccination in young children rarely is associated with any symptoms. On occasion, rash, lymphadenopathy, mild fever, and upper respiratory symptoms have been observed.

More severe reactions have been noted rarely in children but have been an occasional problem in adults. Most of these complications were reported in association with the previously available vaccines, but complications with the RA 27/3 vaccine also have been noted.[20,143] Particularly troublesome are arthralgia and arthritis.*

*See references 16, 27, 95, 113, 201, 305, 356, 368, 399, 483, 502, 505, 506, 510-512, 545.

These complaints occur most commonly in adults. Arthralgia develops in approximately 25 percent of susceptible postpubertal females after they have received the RA 27/3 vaccination, and approximately 10 percent have been reported to have arthritis-like signs and symptoms.[37,208,399] Infrequently, chronic or recurrent arthralgia, sometimes with arthritis or neurologic symptoms, including paresthesias, carpal tunnel syndrome, and blurred vision, reportedly have developed in susceptible vaccinees, primarily adult women.[75,259] One group of investigators has reported the frequency of chronic joint symptoms and signs in adult women to be as high as 5 to 11 percent[510-512]; however, other data from the United States and other countries suggest that such complications caused by RA 27/3 vaccine are rare or perhaps nonexistent.[113,166,174,232,366,477,482]

Other complications, mainly with vaccines other than RA 27/3, include polyneuropathies (catcher's crouch, carpal tunnel syndrome, neuritis, and myeloradiculoneuritis),[90,95,192,216,275,365,437] marked lymphadenopathy,[88] and vasculitis and myositis.[223]

Geiger and associates[188] noted a persistent rubella virus infection in a 16-year-old boy with acute lymphoblastic leukemia in remission who was vaccinated. The virus was identified in the patient's peripheral blood mononuclear cells 8 months after immunization. In contrast, persistent infection could not be demonstrated in 10 children with symptomatic human immunodeficiency virus type 1 infection.[173]

Contraindications

Administration of live rubella virus vaccine is contraindicated in women who are pregnant; in individuals with altered immune states, such as immunodeficiency, leukemia, lymphoma, and generalized malignant disease; or in patients treated with steroids, alkylating drugs, antimetabolites, and radiation. In addition, rubella vaccination should not be performed during febrile illnesses or when viral interference from another agent might preclude a "take" from the rubella immunization. Rubella immunization also, in most instances, should be deferred after the administration of blood products, including immune serum globulin (for duration, see table in reference 11, p. 445).

Inadvertent Rubella Immunization in Pregnancy

From January 1971 to April 1989, the Centers for Disease Control and Prevention observed to term 321 known rubella-susceptible pregnant women who had been vaccinated with rubella vaccine within 3 months before or 3 months after conception.[75] Ninety-four women received HPV-77 or Cendehill vaccine, 1 received a vaccine of unknown strain, and 226 received RA 27/3 vaccine. None of the 324 infants born to these women had malformations compatible with congenital rubella, but five of the infants had serologic evidence of subclinical infection.

In conjunction with a nationwide measles-rubella vaccination campaign in 2001, the fetal risk associated with rubella vaccination during pregnancy was studied in Costa Rica.[18] The study involved 1191 mother and child pairs, and no adverse pregnancy outcomes or cases of congenital rubella syndrome occurred.

PASSIVE IMMUNIZATION

The use of immunoglobulin for the prevention of rubella has been controversial for many years.* However, my opinion is that its use is indicated in certain circumstances. The specific indication for immune serum globulin is for the prevention of rubella in a woman thought to be susceptible to rubella who is in the first 20 weeks of pregnancy. If the exposure can be documented clearly as one to a specific, single person with rubella and immunoglobulin is given within 72 hours of that exposure, both maternal disease and congenital infection likely can be prevented. On the other hand, if the exposure was more general in nature (e.g., a schoolteacher exposed to a child or children in the school setting), the woman probably was exposed for a considerable time before she realized the exposure. Therefore, because immunoglobulin probably will be administered too late (well into the incubation period of her disease and after viremia), congenital infection is not likely to be prevented. The dose of immunoglobulin for the prevention of rubella during pregnancy is 20 mL intramuscularly.

QUARANTINE AND DISEASE CONTAINMENT

Patients with rubella should not have contact with susceptible persons until the rash has disappeared. Containment of rubella is a vital part of the prevention policy in the United States today. Rubella is a reportable disease, and compliance is the obligation of all physicians and other health care professionals. Reporting cases of rubella enables public health workers to organize vaccination programs so that small outbreaks of disease can be prevented from developing into major epidemics.

CHAPTER 187

ALPHAVIRUSES

CHAPTER 187a

EASTERN EQUINE ENCEPHALITIS

Theodore F. Tsai

Eastern equine encephalitis (EEE) is an arthropod-borne viral infection of humans, horses, and other vertebrates that occurs in North and South America. In North America, infections recur in highly focal, primarily coastal locations in association with the habitat of *Culiseta melanura*, the enzootic vector. Birds are the amplifying hosts, and humans and horses are infected incidentally.

ETIOLOGIC AGENT

EEE virus is an antigenically distinct member of the *Alphavirus* genus in the *Togaviridae* family. On the basis of nucleotide differences, it has been inferred that EEE and Venezuelan equine encephalitis diverged 1000 to 2000 years ago, with a subsequent division of EEE virus into North American and South American varieties.[7,43,45] South American strains can be differentiated by monoclonal antibodies and by short-incubation hemagglutination-inhibition tests.

North American strains collected over a broad geographic and temporal span demonstrate remarkable genetic stability in one or two major lineages, with minor local divergences occurring within isolated geographic loci. South American strains are genetically heterogeneous. They have been isolated in northward-migrating birds captured in the United States, but they have never been shown to become established.

ECOLOGY

Equine cases have been reported as far north as Quebec, Ontario, and Alberta provinces; in South America, EEE viral activity has been reported from the Caribbean, Mexico, Guatemala, Honduras, Panama, Colombia, Venezuela, Peru, Guyana, and Brazil and as far south as Argentina.[4,8,23,49] The viral transmission cycles in the Caribbean and South America are not well characterized but apparently involve small mammals, birds, and *Culex (Melanoconion)* mosquitoes.[23]

In North America, the distribution of virus activity closely follows the distribution of freshwater swamps on the Eastern Seaboard, Gulf Coast, and other inland areas and corresponds to the distribution of the principal enzootic vector, *C. melanura*.[10,19,23] *C. melanura* feeds nearly exclusively on birds, so various epizootic (bridging) vectors are responsible for infecting humans and horses.[20,27,31,33,47] Numerous species may be involved, including *Coquillettidia perturbans*, *Aedes sollicitans*, *Aedes vexans*, and *Aedes canadensis*.

Infection and viremia are subclinical in most native birds, whereas whooping cranes and exotic birds such as emus, house sparrows, ring-necked pheasants, Pekin ducks, and chukar partridges may become ill and die of infection.[3,12,13,48,52] Outbreaks resulting in thousands of deaths have occurred in commercial pheasant flocks, in some instances perpetuated by cannibalistic pecking or preening of persistently infected quills.[3] Illness and deaths in pigs, goats, calves, rodents, and other mammals also have been reported.[24,39]

C. melanura is found in and near freshwater swamps, where larval stages breed in acidic waters associated with mucky peat soils. These foci (from north to south) are found in upland red maple, coastal white cedar, and southern loblolly bay biotypes.[10,23]

The viral overwintering mechanism has not been elucidated, but the remarkable permanence of endemic foci is a strong argument for overwintering in local reservoirs.[10,30,31,33,39]

EPIDEMIOLOGY

EEE is a rare sporadic infection; a median of three cases occurs annually in the United States[35] (Fig. 187–1). The states with the highest rates of infection show an average annual incidence of less than 1 per 10 million (Fig. 187–2). However, these estimates obscure the remarkably consistent and focal distribution of cases on the Atlantic and Gulf Coasts, from Ontario to Texas, and in isolated pockets of activity inland.[4,8] For example, until 1995, all human cases in Massachusetts had occurred east of Highway 495 in Essex, Norfolk, Plymouth, Bristol, and Middlesex counties; the six southernmost counties account for most of the epizootic activity in New Jersey; and foci of EEE viral activity recur in upstate New York counties near Syracuse, southwestern Michigan, northeastern Indiana, and northeastern Florida.[11,31] Outbreaks of human cases caused by North American viral strains have been reported from Jamaica, Trinidad, and the Dominican Republic.[5,16] Isolated epizootics with sporadic human cases have occurred in South America.[49] The unpredictability of risk is underscored by the occurrence of a case in a United Kingdom tourist who had a brief itinerary in Massachusetts.

Viral transmission, reflected in equine cases, occurs all year in Florida, although the peak incidence is from May to September.[6] Human cases have appeared as early as February and as late as December in Florida, with a peak occurring from June to August.

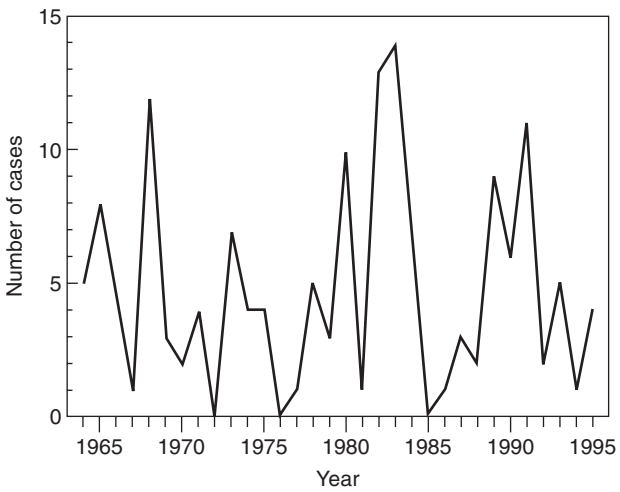

Figure 187–1 Reported cases of eastern equine encephalitis by year, 1964 to 1995.

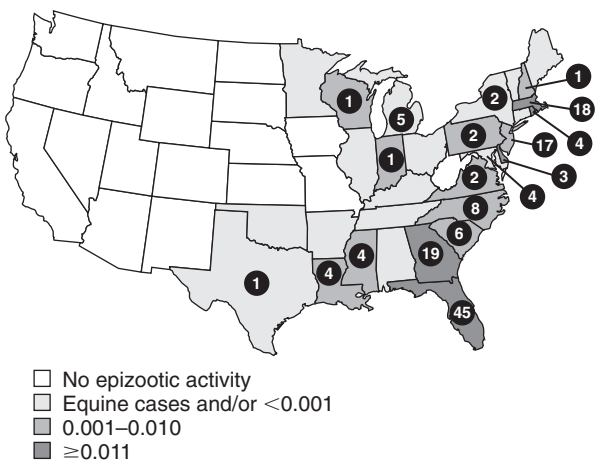

Figure 187–2 Reported cases and average annual incidence (per 100,000) of eastern equine encephalitis by state, 1964 to 1995.

In the Northeast, cases usually appear in late summer, from August to September, and as late as the third week in October.[35]

Cases occur chiefly at the extremes of age. However, serologic studies performed during a New Jersey outbreak disclosed that infection occurs with equal frequency in all age groups, thus indicating that biologic responses to infection rather than factors associated with exposure were responsible for the lower attack rates in young and middle-aged adults.[25] The ratio of inapparent infections to cases was highest in the middle years of life (29:1) and lowest in children younger than 4 years (8:1) and adults older than 55 years (16:1).[25]

Family clusters were observed in this epidemic and in the 1947 Louisiana outbreak.[29] In the New Jersey study, family members of cases had twice the rate of inapparent infections as the general population did, and in the southern Louisiana outbreak, two fatal cases and two seropositive members were observed in the same family.[25,29] Clusters of equine cases on a single premise are reported frequently.

Asymptomatic infections are uncommon occurrences, and long-term residence in an enzootic area leads to only a slight increase in population immunity. For example, even in an unusually active focus in southern New Jersey, only 7 percent of persons who had resided there 45 years or more had neutralizing antibody.[25] In serosurveys of endemic foci in Massachusetts, evidence of past infections was found in 0.5 to 0.7 percent of residents,[44] and a post-epizootic serosurvey of at-risk Connecticut pheasant farmers showed no evidence of infection.[37]

Specific behavioral risk factors have not been described; however, residence or outdoor activity near swampy habitats has been reported anecdotally as a possible contributing factor.

CLINICAL MANIFESTATIONS

EEE is a fulminant encephalitis with rapid progression to coma and death in one third of patients.* In infants and children, an abrupt onset of fever, irritability, and headache is followed closely by lethargy, confusion, seizures, and coma. The often desperately ill infants may have a bulging fontanelle, meningismus, high temperature, and generalized flaccid or spastic paralysis.[1,17,22,51,53] Some patients are evaluated initially for status epilepticus. The prodrome in adults and older children usually is brief, with nonspecific symptoms of fever, headache, and dizziness followed by clouding of the sensorium and rapid deterioration to coma. Remarkably, some patients have a prolonged prodrome lasting longer than a week, with a waxing and waning course of nonspecific symptoms, which may be associated with a better prognosis.[42,44,51] Various neurologic deficits have been described; in some cases, unilateral seizures, hemiparesis, hemiplegia, and aphasia have indicated focal areas of involvement.[15,40,42]

The peripheral leukocyte count usually is elevated with a shift to the left. White blood cell counts of 20,000/mm^3 are typical, ranging as high as 60,000 with 55 to 89 percent neutrophils.[44] Cerebrospinal fluid (CSF) usually shows a polymorphonuclear pleocytosis with a total leukocyte count ranging from 500 to 2000/mm^3. The initial neutrophilic pleocytosis of 60 to 100 percent may persist into the second week before shifting to a predominance of mononuclear cells.[45] CSF protein level is elevated and glucose concentration is reduced in most cases. Erythrocyte counts higher than 500/mm^3 are found in some cases.

Imaging studies disclose only cerebral edema in three quarters of patients. However, focal rim-enhancing lesions and areas of low alteration with mass effect have been observed on computed tomographic scans in the frontal cortex, thalami, midbrain, and

*See references 1, 2, 11, 15, 17, 18, 21, 26, 36, 40, 42, 44, 51, 53.

lentiform nuclei.[15,40,42] Isointense diffusion-weighted images and hyperintensity on apparent diffusion coefficient images early in the course of illness in one case suggested vasogenic edema in the T2-weighted hyperintense areas.[26] Electroencephalographic tracings with focal or background slowing have been associated with a favorable outcome, whereas disorganized background activity, a burst-suppression pattern, and high-voltage delta slowing have been associated with a poor prognosis.[44]

Mild nonencephalitic illnesses usually are not diagnosed. However, in the 1959 outbreak in New Jersey, fever, headache, nausea, vomiting, and sore throat were common symptoms in 19 patients who had serologic evidence of infection. A third of the patients had illnesses sufficiently severe to motivate them to consult their physicians.[25] Other patients with bladder dysfunction, dysesthesias, weakness, and signs of myelitis have been described.[9,34] One case of infection during pregnancy has been reported. The third-trimester infection was severe, but the woman recovered from encephalitis and coma and delivered an apparently normal baby. Serologic studies of the neonate's blood were not performed.

PATHOLOGY

Pathologic changes in the brain are characterized by lesions in the cortical and deep gray matter, with varying degrees of neuronal loss from mild to extensive focal necrosis.[14,41] Viral antigen is found predominantly in neurons and only occasionally in astrocytes.[21] Rare viral particles have been identified by electron microscopy in principally extracellular locations.[2,32] Neutrophils predominate in cellular infiltrates in the meninges, vascular cuffs, and foci of tissue damage in the cortex and brain nuclei of patients dying acutely; at later stages, neutrophilic infiltrates are replaced by mononuclear cells.[2,14,21,41] Immunohistochemical examination of one patient disclosed a predominance of helper T cells in perivascular infiltrates, with some B lymphocytes. The most intense inflammatory reaction occurred in areas where antigen-positive neurons were absent, presumably where cell lysis already had occurred. Perivascular macrophages contained cleared viral antigen, but antigen could not be demonstrated in vascular endothelial cells.[21]

PATHOGENESIS

After peripheral inoculation of experimental animals, local viral replication occurs at a low level or may be undetectable. Viremia develops after this eclipse period, with disseminated infection of the spleen, liver, and kidneys noted in monkeys and guinea pigs and infection of the spleen, heart, and lungs observed in mice. Infectivity can be demonstrated in the brain only after viremia and infection in the viscera are established, thus suggesting that invasion of the central nervous system occurs by hematogenous spread.[41] Neurologic injury is associated with vasogenic edema in the earliest stages and subsequently with virus-induced cytolysis and host inflammatory responses.[26]

The immune response in humans presumably is similar to that observed in experimental alphavirus infections in mice, in which host resistance depends on rapid elaboration of a humoral immune response.

PROGNOSIS AND SEQUELAE

The case-fatality ratio is 33 percent among reported cases and is highest in the elderly; outcome is best in young adults aged 20 to 59 years, in whom the case-fatality rate is 24 percent.[35] Patients with a long prodromal illness (>4 days) have a better prognosis, which is consistent with the protective effect of a peripheral antibody response in the pre-neuroinvasive phase.[44]

Residual neurologic damage is observed more often in young children. In a Florida series, serious sequelae were seen in four of seven survivors younger than 5 years and in one of ten survivors in other age groups.[6] Similar findings were reported in a follow-up of epidemic cases in Massachusetts: seven of eight survivors younger than 3 years of age had neurologic sequelae, and only one of four surviving adults had residua.[1,19] Neurologic impairment ranged from mild unilateral spasticity to profound mental retardation, seizure disorders, and quadriplegia.

DIAGNOSIS

A specific laboratory diagnosis usually is made from serologic studies. Isolation of virus from CSF is unusual. The virus should be sought from brain biopsy tissue or autopsy material. EEE virus grows rapidly in a variety of cell lines, including Vero A549 and MRC-5 cells, and causes widespread cytopathic effect in several days.[46] Specific identification of viral isolates can be accomplished rapidly by immunofluorescent or immunoperoxidase techniques. EEE virus has been identified by immunofluorescence and by electron microscopy in brain tissue.[2,21,32] Viral antigen in viremic bird blood, infected mosquito pools, and infected equine brains can be detected directly by antigen capture enzyme-linked immunosorbent assay. Polymerase chain reaction analysis of CSF has been reported but has not been evaluated extensively.[45]

Serologic testing is available in many state laboratories. Virus-specific IgM usually can be detected in acute serum and CSF samples.[38] Indirect immunofluorescence, neutralization, and hemagglutination inhibition also are sensitive procedures. Antibodies often are present in the first week of illness. Neutralizing antibody appears 3 to 4 days after the onset of illness, and hemagglutination-inhibition (HI) antibody appears with almost equal rapidity.[25] Both HI and neutralizing antibodies appear to be long-lived.[25] Complement-fixing (CF) antibody is slower to rise and can be noted 11 days after onset, with diagnostic fourfold rises often appearing only in the third week after onset.[25] The peaks of both HI and CF titers are observed 3 to 4 weeks after onset.[26] CF antibody declines more rapidly. Measurable CF antibodies were found in approximately 50 percent of persons infected 8 years earlier in one study, although the effects of re-exposure could not be ruled out in this endemic area.[25]

The low prevalence of EEE antibody in the general population suggests that detection of EEE viral antibody in the acute serum of a patient with encephalitis indicates a high probability of that diagnosis. Applying the Bayes theorem, if the "rate" of EEE is 1 in every 2000 cases of encephalitis, if HI antibody to EEE is present in 100 percent of cases in the first week of illness, and if the prevalence of HI antibody in the general population is 0.05 percent, the presence of EEE in a patient with encephalitis who has demonstrable EEE antibody in a single serum specimen is a certainty. Thus, the probability of the diagnosis is high when specific antibody is found in any (i.e., acute) serum specimen.

DIFFERENTIAL DIAGNOSIS

The fulminant clinical course of EEE and the laboratory findings of neutrophilic leukocytosis and polymorphonuclear pleocytosis in the CSF may suggest bacterial cerebritis or meningitis. Because no specific therapy is available, EEE should be a diagnosis of exclusion after effort has been made to diagnose and to treat empirically against bacterial and herpes viral infections.

TREATMENT

Specific treatment is unavailable. Therapy aimed at supporting cardiorespiratory function, homeostasis of fluid, electrolyte balance, and control of cerebral edema and convulsions may be lifesaving. In a single case, intravenous immunoglobulin and glucocorticoids, given for their potential immunomodulatory effects, were associated with survival in an elderly patient.[26]

PREVENTION

An effective killed vaccine is licensed for horses, but no human vaccine is licensed. An investigational killed vaccine, available under investigatory permit, is used to protect laboratory personnel. Vaccination of the general public is not feasible as a public health measure because of the low incidence of disease.

Climatologic studies have shown a correlation between outbreaks and heavy rainfall in the summer of an epidemic year and in the preceding fall.[30,33,35] Although such predictors would have considerable utility in guiding control measures, outbreaks of EEE have been too few for their validity to be tested. Isolation of Highlands J virus, which shares a common enzootic cycle with EEE virus, often peaks 2 to 3 weeks before the appearance of EEE virus in *C. melanura*.

Surveillance and public health interventions to prevent EEE have been shown to be economic when they are balanced against the direct and indirect costs of even one human case.[50] Infection rates in *C. melanura* of 0.39/1000 have been highly predictive of risk for human cases in areas of Massachusetts surveyed during a 26-year interval.[28] Larviciding of swampland to control *C. melanura* is difficult because of the large areas involved, the potential toxic effects in fish and other wildlife, and the relative inaccessibility of the larvae. Emergency application of adulticides to control epizootic vectors is indicated when viral, mosquito, and animal surveillance suggests a risk for epizootic transmission. Public health advisories to avoid outdoor activity near enzootic foci and closure of campgrounds and parks in these locations may be necessary when viral transmission indices suggest a high level of risk. The use of repellents and avoidance of outdoor activity 1 to 2 hours after sunset, when many mosquitoes are most active, may reduce the risk of exposure; however, some vector *Aedes* spp. are daytime biters.

CHAPTER **187b**

Western Equine Encephalitis

Theodore F. Tsai

Western equine encephalitis (WEE) is an endemic and enzootic acute central nervous system (CNS) infection of humans and horses in the western part of the United States, Canada, Mexico, and parts of South America. In North America, *Culex tarsalis*, the principal mosquito vector, also maintains the virus in an avian enzootic cycle.

ETIOLOGIC AGENT

WEE and other alphaviruses (group A arboviruses) form a genus of principally mosquito-borne viruses in the family *Togaviridae*.[43,61] Three of the eight viruses constituting the WEE antigenic complex are found in North America: Highlands J, Fort Morgan, and WEE viruses; among them, only WEE virus is a human pathogen. Much of what is known about the molecular biology of alphaviruses has been inferred from studies of the Sindbis (the type species and a member of the WEE complex) and Semliki Forest viruses.

Alphaviruses are small, enveloped, positive-stranded RNA viruses. Virions are spherical and 69 nm in diameter (including the length of their glycoprotein spikes), with a lipid bilayer enveloping a nucleocapsid core containing the 11.7-kb RNA viral genome. Glycoprotein spikes embedded in the viral envelope bind to cell membrane receptors and initiate infection by endocytotic fusion. The viral and lysosomal membranes fuse in a pH-dependent step, and the viral nucleocapsid is released into the cell cytoplasm, where RNA and protein synthesis occurs. The 5′ terminal two thirds of the RNA genome encodes four nonstructural proteins, and the 3′ terminal third of the RNA genome encodes the three structural proteins. The 30-kd nucleocapsid and two 50-kd glycoproteins—E1 and E2—are translated as a polyprotein from subgenomic 26S RNA. The envelope proteins—E1 and E2—are assembled in trimers of a single E2 protein and an E1 dimer. Eighty such trimer spikes are arranged in an icosahedral lattice on the virion surface.[9] Capsid proteins assemble with the viral genome in the cytoplasm and then bud through the virally modified cell membrane and acquire an envelope.

The E1 glycoprotein possesses a group-reactive hemagglutinin and group-reactive epitopes linked to cross-protection and cell-mediated cytotoxic effects. E1 also mediates viral cellular membrane fusion. Epitopes on E2 are linked to cell receptor recognition, viral neutralization and clearance, and neurovirulence and cellular apoptosis.[65]

Molecular genetic studies indicate that WEE virus arose more than 1000 years ago as a recombinant of eastern equine virus and an ancestral, now extinct, Sindbis-like virus, with the recombinant having acquired the neurotropic potential of eastern equine encephalitis virus while retaining the antigenic characteristics of the non-neurotropic Sindbis virus.[19,43,55,62,63] Alphaviruses are thought to have originated in the New World with separate introductions, presumably by birds, to the Old World, resulting in establishment of the present-day Sindbis-like viruses and Semliki Forest–related viruses. A slow rate of evolution, circa 10^{-4} nucleotide changes per year (versus 10^{-2}/year for other RNA viruses), probably reflects the natural pressure on viruses constrained to replicate in both insect and vertebrate cells.[63]

ECOLOGY

WEE virus is transmitted in an enzootic cycle to mosquitoes, birds, and other vertebrate hosts.[46,47,51] Horses and humans are dead-end hosts, but severe CNS infection may develop. Although WEE has been a public health and veterinary problem primarily in the western United States and Canada, the geographic range of the virus includes Mexico, Guyana, Brazil, Uruguay, and Argentina. Epizootics in horses, accompanied by small numbers of human cases, were reported in 1972 and 1983 in Argentina, where the virus apparently is transmitted by *Aedes albifasciatus* to introduced European hares and possibly birds. In addition, a distinct sylvatic subtype of WEE virus is transmitted in the subtropical Chaco province.[3,6]

In the United States, the geographic distribution of the virus and *C. tarsalis*, its principal vector, includes the western and central United States, southern Canada, and Mexico. A related virus—Highlands J virus, isolated from *Culiseta melanura* in the eastern United States—overlaps in its range in the east central part of the United States. Highlands J virus causes encephalitis in horses and possibly in humans.[35]

In the western region of the United States, *C. tarsalis* breeds in ground pools found on pasture lands; in irrigation wastewater; and at the margins of lakes, ponds, marshes, and flooded riversides. Some of these aquatic habitats are shared by birds that participate in the amplification of virus in nature.[46,47,51]

The female mosquito becomes infected after feeding on a viremic bird (or mammal). After an extrinsic incubation period of 7 to 9 days, when the virus propagates in the mosquito and the salivary glands become infected, the mosquito can transmit virus to other birds or mammals (amplifying hosts) or to humans and horses (dead-end hosts).

Passerine (perching) birds, especially sparrows and finches, have proved to be particularly important in amplification of the virus. In midsummer, the mosquito shifts its host-seeking activity to mammals. The shift may be influenced by an increase in the defensive behavior of nestling birds, which are its preferred host. The shift corresponds temporally to the appearance of cases in horses and people and appears to be a critical element enabling *C. tarsalis* to function as both an enzootic and an epizootic vector. In California, an auxiliary *Aedes melanimon*–jackrabbit *(Lepus californicus)* cycle has been demonstrated.

The overwintering mechanism for WEE virus has not been elucidated. However, virus has been recovered from adult *Aedes dorsalis* mosquitoes collected as larvae from a coastal area of California, thus indicating a possible role for vertical transmission of the virus in mosquitoes in some locations. Arguments also have been advanced for viral overwintering in adult mosquitoes and in persistently infected mammals, birds, and poikilotherms (snakes, frogs, and turtles). In Canada, *Aedes* spp. and *Culiseta inorata*, which emerge in the spring before *C. tarsalis* does, have been proposed as early amplifying vectors.[34]

Numerous climatologic and biologic indices with various degrees of predictive value have been shown to correlate with the occurrence of WEE outbreaks; these indices include vector population size, mosquito infection rates, and virus transmission rates to sentinel chickens or wild-caught sparrows. Such transmission indices are monitored in surveillance activities by public health agencies; however, their sensitivity, specificity, and predictive value for forecasting epidemics have been difficult to evaluate because of the sporadic nature of outbreaks.[64] A retrospective analysis of a 21-year experience in California showed correlation between average daily numbers of *C. tarsalis* females and the occurrence of human encephalitis.[41] In a Texas study, house sparrow infection and antibody rates were the best predictors of human disease, and *C. tarsalis* light trap indices were of borderline significance.[25]

Physical measures associated with the incidence of disease in humans or transmission of virus to sentinel species include the ambient air temperature, the snow pack in mountains providing runoff water, the river flow rate, the soil temperature inversion date (the date that the surface soil temperature exceeds the subsurface soil temperature), and the date when 50 or more days of 70° F (21° C) temperature have accumulated. Snow pack and river flow rate are associated with an abundance of irrigation water and flooding, which in turn are associated with the availability of breeding habitats and mosquito population size.[7,24,46,47]

Longitudinal and intraseasonal observations show that high temperatures are associated with a reduced risk of human disease. High ambient air temperature (>89.6° F [32° C]) decreases mosquito survival, adversely affects the competence of *C. tarsalis* to become infected with and to transmit WEE virus, and limits host-seeking activity.[50] In a model of global warming, higher temperatures are predicted to move the range of WEE viral transmission northward.[47]

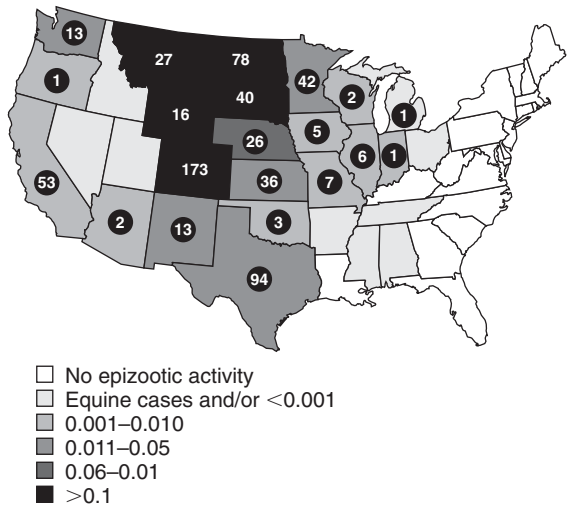

Figure 187–3 Reported cases and average annual incidence (per 100,000) of western equine encephalitis by state, 1964 to 1995.

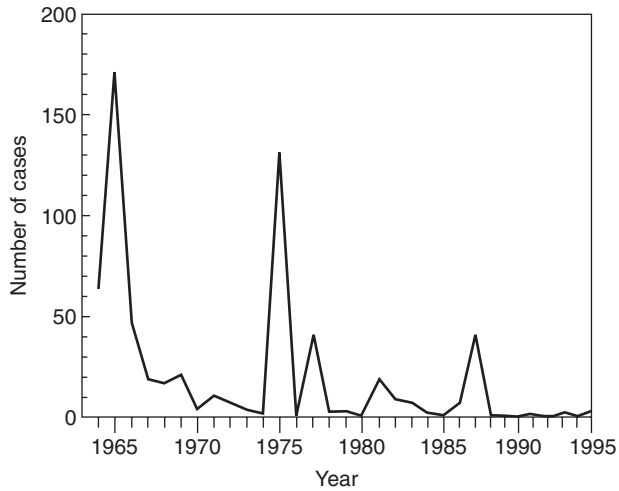

Figure 187–4 Reported cases of western equine encephalitis by year, 1964 to 1995.

EPIDEMIOLOGY

WEE occurs sporadically and in epidemic form, principally in Canadian provinces and states west of the Mississippi River (Figs. 187–3 and 187–4). Infections occur mainly in rural areas, where water impoundments, irrigated farmland, and naturally flooded sites provide breeding habitats for *C. tarsalis*; however, the increasingly rare interface between vector mosquitoes and humans has resulted in a point seroprevalence of 1 to 2 percent even in locations where the virus is transmitted in an enzootic cycle.[49] The annual median number of cases between 1964 and 1995 was only four, and only four cases were reported between 1988 and 1997, a lower incidence than that for eastern equine encephalitis. Historically, however, periodic outbreaks have led to scores or hundreds of cases (see Fig. 187–4).

Recurrent endemic and epidemic transmission was recorded in the Yakima Valley, Washington (1939 to 1942); California's Central Valley (1939 to 1952); the north central states and Canadian provinces, including Minnesota, North and South Dakota, Alberta, Manitoba, and Saskatchewan (1941 and 1975); and the high plains panhandle of Texas (1963 to 1966).[13,20,26,45] The largest outbreak on record, in 1941, resulted in more than 3400 human cases in Minnesota, North and South Dakota, Nebraska, Montana, Alberta, Manitoba, and Saskatchewan; equine cases were estimated to number in the hundreds of thousands. The outbreak centered in North Dakota, where the attack rate for the state was 167 cases per 100,000.[13,29] In 1952, an outbreak in California's Central Valley led to 348 reported cases, an incidence of 36 cases per 100,000 residents.[26] More recent outbreaks resulted in 277 cases in the central United States and Manitoba in 1975 and 40 cases in the central and mountain states in 1987.[11,30,34]

Most cases occur between June and September (Fig. 187–5), often preceded by cases occurring in horses several weeks earlier. Surveillance of equine cases is a widely used approach to assess the risk for epidemic transmission. However, the low frequency of laboratory-confirmed diagnoses, vaccination, and underreporting limit the precision of equine surveillance as a predictive marker.[42]

Several risk factors for acquiring WEE have been identified:

1. Attack rates usually are highest at the extremes of age[2] (Fig. 187–6). The experience from the 1952 California outbreak showed that a third of cases occurred in infants younger than 1

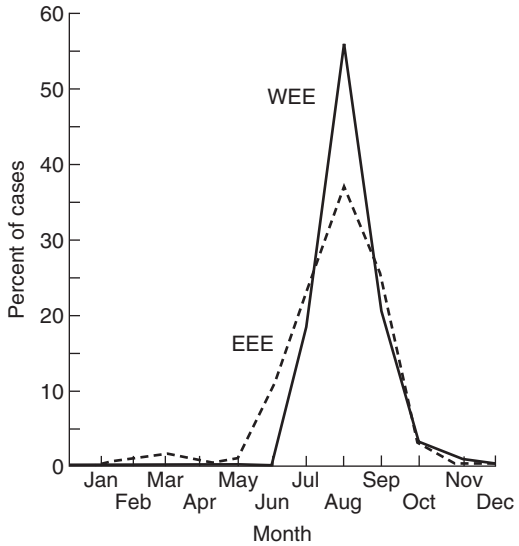

Figure 187–5 Reported cases of western and eastern equine encephalitis by month, 1972 to 1989.

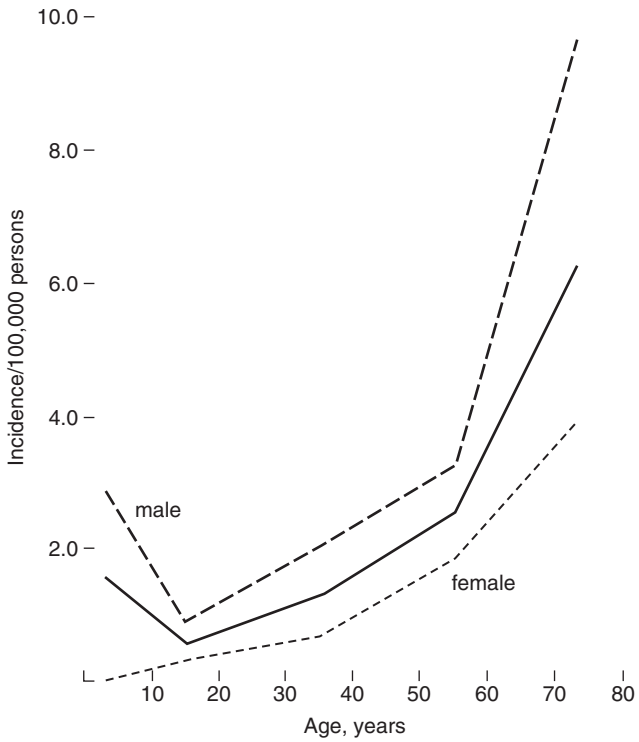

Figure 187–6 Age- and sex-specific incidence of western equine encephalitis, Colorado, 1987. – – –, male; —, total; - - -, female.

year.[26,47] Other reports confirm the bimodal pattern of an elevated risk in infants, a declining risk in children and young adults, and a gradual increase in risk in the elderly.

2. Attack rates in males are twofold higher than those in females in every age group[2] (see Fig. 187–6). Biologic differences in susceptibility to infection may account for the observed disparity in infancy, and greater occupational and recreational exposure outdoors might be responsible for the differences in adults. In the 1981 outbreak in Manitoba, 21 of 25 cases were in males; the four affected women were widows who maintained their premises alone.[11]

3. Rural residence is associated with attack rates 1.5 to 5 times higher than those for urban residence (Table 187–1). Counties lying in major river drainage areas and with more irrigated acreage have had the highest incidence of equine and human disease[2] (Fig. 187–7).

4. Agricultural occupation has been suggested as a risk factor in several studies.

5. Length of residence in areas where WEE is endemic is associated inversely with a risk of developing illness. Acquired immunity, through asymptomatic or mild infection, accumulates with length of residence; in endemic areas, the point prevalence of specific antibody previously approached 20 percent by adulthood.[46,47]

CLINICAL MANIFESTATIONS

The clinical illness ranges from a nonspecific syndrome of headache and fever to aseptic meningitis, meningoencephalitis, and frank encephalitis. The estimated case-infection ratio is 1:58 in children 1 to 4 years of age, but it declines to 1:1150 in adults.[16,47,51]

The onset of illness typically is abrupt, with sudden fever, headache, malaise, chills, and nausea and vomiting,[4,13,23,45] occasionally preceded by signs of an upper respiratory infection. Signs of CNS infection gradually become evident as dizziness, drowsiness, increasing headache, stiff neck, and disorientation develop during the course of hours or days. Infants typically have a sudden cessation in feeding, fussiness, fever, and protracted vomiting. The prodromal interval is abbreviated, and convulsions and a lethargic unresponsive state develop rapidly.

On examination, patients appear somnolent and may have signs of meningeal irritation. The sensorium is depressed, and patients may alternate between agitation and somnolence. Generalized muscle weakness is present, and deep tendon reflexes are diminished. Focal neurologic signs suggesting herpes encephalitis have been reported in anecdotal cases[1,5]; however, in the 1941 Minnesota outbreak, only 3 of 226 cases reported had unilateral weakness.[13]

In infants, the fontanelle may be tense or bulging, often accompanied by spastic paresis and generalized convulsions. The frequency of seizures is related inversely to age; they occur with greatest frequency in infants younger than 3 months (75-80% of cases), whereas in 2- to 4-year-old children, seizures have been reported in 15 percent of cases.[33]

The peripheral leukocyte count is unremarkable. Cerebrospinal fluid (CSF) obtained at an early stage in the illness generally

exhibits normal glucose concentration, elevated protein level, and a leukocyte count between 10 and 300/mm^3.[30] Mononuclear cells usually predominate.

Five instances of late third-trimester infection in pregnant women have been reported to result in perinatal illness or encephalitis.[10,33] The women's illnesses had an onset 0 to 10 days before delivery, and the infants became ill on the fifth and sixth postpartum days. Teratogenic effects of infection occurring earlier in gestation have not been reported for WEE virus but are suspected for other group A arboviruses.[36]

PATHOLOGY

Specific pathologic changes are confined to the CNS.[4,30,39] On gross examination, the brain appears normal or may be congested and swollen, with minimal changes observed in the meninges. Microscopic lesions affecting gray and white matter appear throughout the brain but predominate in the basal ganglia. Disseminated small focal abscesses infiltrated with neutrophils are a distinctive feature. The vessels appear congested, and small focal hemorrhages or diffuse extravasations of erythrocytes are present along with neutrophilic infiltration of the vascular wall and endarteritis. Vascular lumina may be occluded by endothelial proliferation and swelling.

Extensive patchy areas of demyelination are found throughout the brain. Older lesions appear as sharply circumscribed, punched-out plaques. Secondary microglial reaction in demyelinated areas is minimal.

The spinal cord is affected in the same fashion, with focal, perivascular, and diffuse lesions attracting both polymorphonuclear and mononuclear cells. Lesions predominate in the central gray matter.

PATHOGENESIS

Peripheral inoculation of experimental animals with WEE virus is followed by viral replication in various extraneural sites before invasion of the CNS (including the peripheral site of inoculation, viscera, muscle, and perhaps vascular endothelial cells) occurs.[27,31,40,67]

Host resistance and recovery from infection depend chiefly on an effective antibody response. Antibody contributes to recovery by a variety of means, including viral neutralization and antibody-mediated restriction of viral gene expression.[18,65] Interferon may contribute to containment of local viral spread in the CNS. Antibodies are protective and may be cross-protective to other alphaviruses. Antibodies to the E2 glycoprotein typically are virus specific and associated with neutralization and protection. Antibodies to E1 exhibit greater cross-reactivity with other alphaviruses.[61] Immune serum given to monkeys prophylactically protects them from challenge with WEE virus, and passive protection has been demonstrated in monkeys inoculated with WEE virus and treated with immune serum within 24 hours.[67] However, immu-

notherapy in monkeys is uniformly unsuccessful in preventing death once signs of CNS infection have appeared. In guinea pigs peripherally inoculated with WEE virus, immunotherapy given within 24 to 48 hours of inoculation leads to survival of some animals and delayed death in others.[40] In one human case, passive immunization led to a delayed antibody response and was followed by the development of parkinsonism.[17]

The age-dependent virulence of specific Sindbis virus strains has been linked to the immaturity of the suckling mouse T- and B-cell repertoire. Fibroblasts from newborn but not weanling mice are susceptible to Sindbis virus infection, and viral infection of immature mouse neurons leads to apoptotic cell death. Mature neurons are protected against apoptosis by induction of the *bcl-2* oncogene, whose products convert the infection to a persistent nonlytic infection. Viral persistence in the brain of recovered mice is modulated by antibody.[18]

PROGNOSIS

Major neurologic sequelae of WEE, including quadriplegia, hemiplegia, spasticity, intracerebral calcifications, developmental delay in children, and epilepsy, have been reported in approximately 13 percent of cases.[12,14,23,68] The risk for development of serious neurologic sequelae in infants is triple that of other age groups, and 30 percent of recovered infants younger than 1 year remain seriously impaired.[14,16,60] In infants younger than 1 year, convulsions during the acute phase of illness were associated with a greater risk of poor long-term outcome, including continued seizures. Multiple intracranial calcifications were observed in one recovered infant with persistent seizures.[59] Minor psychiatric or neurologic deficits remained in approximately one fourth of children and adults monitored for 18 months after infection.[14] Central apnea has been reported as a complication of encephalitis in two adult cases.[66]

Parkinson syndrome has been a residual effect in at least 15 cases of adults surviving WEE.[17,38,57,58] Its onset may be immediate or delayed for several years after recovery from the illness. Two retrospective investigations of patients with idiopathic Parkinson disease found no difference between cases and controls in seroprevalence to several arboviruses, including WEE virus.

The case-fatality rate in reported cases in the United States from 1955 to 1978 was 3 to 4 percent. In outbreaks in the central portion of the United States and Canada in 1941, 1975, and 1981, approximately 7 to 9 percent of patients died, with higher fatality rates in the elderly.

DIAGNOSIS

Virus rarely can be recovered from blood or CSF, but it can be isolated readily from the brain of fatal cases. In a few attempts, WEE virus has been isolated from brain biopsy material; in principle, rapid diagnosis can be made by immunofluorescent identification of WEE viral antigen in brain biopsy tissue. The virus can be isolated readily in Vero cell culture or in suckling mice.[58] Nucleic acid–based sequence amplification of CSF appears to be sensitive and specific.

IgM capture enzyme-linked immunosorbent assay (ELISA) is the preferred serologic procedure.[32] IgM antibody usually is present in acute serum within a week after the onset of illness, and its presence is presumptive evidence of recent infection. IgM often can be detected in CSF before it can be identified in serum, and its presence, which indicates intrathecal production of antibody, confirms a recent CNS infection.[32] Identification of virus-specific IgM in serum and CSF by immunofluorescence also is possible; however, this approach is somewhat less sensitive than is IgM capture ELISA and may be confounded by the effects of rheumatoid factor.

Hemagglutination-inhibition and neutralizing antibodies are elevated in the first week of illness in most cases, and a diagnostic fourfold rise in titer usually is observed in the second week. Complement-fixing antibody is slower to rise, with fourfold changes delayed until the third to fifth week after onset. The complement-fixation response may be blunted in older patients.[60]

Neutralizing and hemagglutination-inhibition antibody titers have considerable longevity, with minimal decay noted 30 months after onset. In contrast, complement-fixing antibody is relatively short-lived, and its presence is a useful indicator of recent infection, particularly in endemic areas where long-term residents may have neutralizing and hemagglutination-inhibition antibody from previous exposure. Only two thirds of patients are estimated to show complement-fixing antibody 2 years after onset, and less than 15 percent have residual complement-fixing antibody after 5 years.[60]

DIFFERENTIAL DIAGNOSIS

The clinical findings in patients with encephalitis seldom are sufficiently characteristic that a specific diagnosis can be made on clinical grounds alone. Fever, vomiting, signs of meningeal irritation, and confusion are nonspecific features of encephalitis and cerebral edema. Early symptoms in infants, such as fever, lethargy, and vomiting, may be even less specific.[28]

Furthermore, the peak occurrence of arboviral infection in midsummer to late summer temporally overlaps the seasonal occurrence of other CNS infections by enteroviruses (e.g., echovirus 13, which recently has become epidemic in the United States), leptospires, free-living amebae, and mosquito-borne West Nile and St. Louis encephalitis. CNS signs may be prominent in other summertime diseases, such as Rocky Mountain spotted fever, heat stroke, shigellosis, and lead encephalopathy. High priority should be given to establishing a specific diagnosis of treatable conditions, such as herpes and enteroviral infection, while bearing in mind that dual arboviral and enteroviral infection has been reported.[5]

Other causes of CNS infection without an established summertime seasonality that also should be considered in the differential diagnosis include fungal, mycobacterial, and partially treated bacterial meningitis; brain abscess and infected subdural collections; bacterial endocarditis; toxoplasmosis; cat-scratch disease; and infections with rabies virus, mumps virus, herpes simplex virus, Epstein-Barr virus, human herpesvirus 6, adenovirus, lymphocytic choriomeningitis virus, and human immunodeficiency virus. Parainfectious disorders such as postinfectious viral encephalitis, acute cerebellar ataxia of childhood, mycoplasmal infection, neuroblastoma with opsoclonus, and Reye syndrome also may enter into the differential diagnosis. Vascular disorders formed the largest single group of disorders mimicking herpes encephalitis in several studies. Drugs (such as trimethoprim-sulfamethoxazole, penicillin, isoniazid, phenazopyridine, ibuprofen, tolmetin, sulindac, and carbamazepine), high doses of bismuth, OKT3 antibody, and vidarabine also may cause aseptic meningitis or encephalopathy.

Because of the potential for their overlapping circumstances of exposure, diethyltoluamide (DEET) encephalopathy should be excluded. DEET-containing insect repellents have been implicated as a cause of seizures and encephalopathy after brief cutaneous exposure (see later).

Valuable clues to the diagnosis of an arbovirus infection are gleaned from a history of travel, residence, or occupational and recreational activities within the appropriate incubation period. Suspected cases should be reported to public health officials.

TREATMENT

Specific antiviral therapy is not available. Supportive treatment of acutely ill patients includes monitoring of cardiorespiratory function, fluid and electrolyte balance, and intracranial pressure. A case of laboratory infection treated with immune equine serum resulted in recovery; however, acute Parkinson syndrome developed in this patient and coincided temporally with serum sickness resulting from immunotherapy.[17]

PREVENTION

Killed vaccine prepared in chick embryo fibroblast culture is available in the United States under an investigatory permit for laboratory and field personnel who are at risk for occupational exposure. Effective killed vaccines are available for horses and usually are administered in bivalent or multivalent formulations (with eastern equine encephalitis, Venezuelan equine encephalitis, and influenza viruses). Vaccination of the general public, even in endemic areas, is not a practical consideration because of the low risk of disease. Personal protective measures include avoidance of outdoor activity during the hours of peak mosquito activity at dusk and use of repellents.

The Centers for Disease Control and Prevention (CDC) recommends repellents containing DEET or picaridin (KBR3023) as active ingredients.[7,8,15,21,44] DEET is absorbed readily through the skin, and its absorption and absorption of oxybenzone, a common sunscreen preparation, are increased when they are used in combination. Some authorities recommend that sunscreens be applied first and more liberally, followed by insect repellent applied sparingly because of concerns about the potential neurotoxicity of DEET.[7,53,54] Three cases were fatal. In one recovered child, encephalopathy and seizures developed after only two applications. In an additional child, seizures and encephalopathy occurred after the child had cutaneous and respiratory exposure to DEET in an automobile with closed windows. Additional cases of seizures in patients who used small quantities of DEET have been reported, but whether these events were coincidental in populations in which the prevalence of DEET use is high is unclear.[8] DEET may have an effect on ammonia metabolism; in one case, encephalopathy occurred in a patient with partial ornithine carbamoyltransferase deficiency.[22] DEET is a proven neurotoxin when it is ingested; however, the incidence of neurologic side effects after cutaneous exposure is unknown. Nonetheless, avoiding formulations containing DEET in high concentration is prudent; when it is applied simultaneously with sunscreen, DEET repellency is unhampered but ultraviolet protection may be reduced. Precautions for the prudent use of repellents as recommended by the CDC and U.S. Environmental Protection Agency (EPA) are listed in Table 187-2.

Repellents containing oil of lemon eucalyptus (but not "pure" oil of lemon eucalyptus) and registered with the EPA as repellents also may provide a similar level of protection.

Permethrin, a synthetic pyrethroid available as a 0.5 percent aerosol (Permanone), is both insecticidal and a repellent.[8,15,56] Permethrin is extremely effective in reducing the incidence of bites of mosquitoes and ticks when it is sprayed on clothing and shoes, and it also can be applied to tents, mosquito nets, and other gear.[15,55] Its use on the skin is not approved, except as treatment of scabies and head lice.

Prevention is focused primarily on interruption of the transmission of virus from mosquitoes to humans. In many localities where WEE is endemic, mosquito abatement districts monitor mosquito populations, virus infection rates in the vector population, or evidence of transmission of virus to wild or sentinel birds and chickens to provide a basis for predicting epidemic transmission and for emergency mosquito control.[37,52]

TABLE 187–2 Precautions to Reduce Potential Adverse Reactions from Repellents

DEET is approved for use on children older than 2 months. Read and follow label instructions.
Repellents should be applied only to exposed skin and clothing (as directed on the product label). Do not use under clothing.
Never use repellents over cuts, wounds, or irritated skin.
Avoid mucosal contact—do not apply to the eyes and mouth, and apply sparingly around the ears. When using sprays, do not spray directly onto the face; spray on the hands first and then apply to the face.
Do not allow children to handle this product, and do not apply to children's hands. When using on children, apply to your own hands and then put it on the child.
Do not spray in enclosed areas. Avoid breathing a repellent spray. Avoid ingestion, and do not use it near food.
Use just enough repellent to cover exposed skin and clothing. Heavy application and saturation are unnecessary for effectiveness; if biting insects do not respond to a thin film of repellent, apply a bit more.
After returning indoors, wash treated skin with soap and water or bathe. This precaution is particularly important when repellents are used repeatedly in a day or on consecutive days. Also, wash treated clothing before wearing it again.
Pregnant and nursing women should minimize the use of repellents.
If you suspect that you or your child is reacting to an insect repellent, discontinue use, wash treated skin, and then call your local poison control center. If you go to a physician, take the repellent with you.
Specific medical information about the active ingredients in repellents and other pesticides is available at the National Pesticide Information Center at 1-800-858-7378.

Modified from U.S. Environmental Protection Agency recommendations. Available at http://www.epa.gov/pesticides/factsheets/chemicals/deet/htm.

As a general rule, *C. tarsalis* densities exceeding 10 to 15 females per trap night and mosquito infection rates greater than 5 to 10 per 1000 signal a risk for epizootic transmission. Evidence of seroconversion in sentinel chickens and observations of equine cases are further indications that human cases may occur.

CHAPTER **187c**

Venezuelan Equine Encephalitis

Theodore F. Tsai

Mosquito-borne Venezuelan equine encephalitis (VEE) arguably is the most important viral zoonosis in Latin America. The

disease, known locally as *peste loca*, has occurred in combined epizootics and epidemics at regular intervals since the 1920s, sometimes leading to hundreds of thousands of human and equine cases. Between 1935 and 1961, 11 outbreaks were reported, and from 1962 to 1973, epizootics recurred in every year except 1965.[14,35] The virus was isolated from horse brain in 1938 during an outbreak in Venezuela. Although outbreaks have arisen principally in northern South America, especially from Colombia and Venezuela, in a remarkable period between 1969 and 1971, epizootics and epidemics were reported from Colombia, Venezuela, Ecuador, Peru, all the countries of Central America (except Panama), Mexico, and the state of Texas.[11,21,35] Subsequently, no major epizootics or epidemics were recognized until a large outbreak emerged in Venezuela and Colombia in 1995.[24,31,32,38] Molecular phylogenetic analyses performed in the wake of that outbreak suggested that epizootic strains arise spontaneously from sylvatic viral strains circulating silently in nature.[2,5,19,38]

ETIOLOGIC AGENT

VEE virus is antigenically distinct from other alphaviruses but is itself a complex of antigenically and ecologically distinct viral subtypes[23,28,36,37,40] (Table 187–3). Epizootic subtypes IAB and IC are so named because they have been associated with major outbreaks in horses. Sylvatic viral subtypes circulate in silent cycles of rodent- or bird-mosquito transmission and in general do not cause encephalitis in equines. Both epizootic and sylvatic viral strains cause human illness.

VEE virus is thought to have evolved approximately 1400 years ago from a now extinct ancestral alphavirus in one of two extant lineages of New World alphaviruses represented by eastern equine encephalomyelitis and VEE viruses.[23] Because epizootic VEE viral strains had never been isolated from nature except during epizootics, their reservoirs and the mechanisms by which they emerge to cause outbreaks had remained a puzzle. However, recent molecular phylogenetic analyses have found a close genetic relationship between the epizootic IC and the sylvatic ID strains, thus suggesting that these epizootic strains might arise spontaneously by mutation from naturally circulating ID virus.[2,5,37] Other outbreaks have had an iatrogenic source from improperly inactivated equine vaccine.[15,16,23,25,37,38]

Comparisons of the attenuated TC-83 vaccine strain of VEE virus and the epizootic IAB parent virus and mutations of virulent infectious clones have shown that changes associated with attenuation occur principally in genes encoding the E2 and E1 glycoproteins but also in the 5′ nontranslated region.[2,5,15,28] Attenuation is associated with reduced neuroinvasiveness (faster clearance from blood and lower viremia levels) as well as reduced neurovirulence (minimal histopathologic changes after intracerebral inoculation of horses).

VEE virus rapidly produces cytopathic effects in a variety of cell cultures, including Vero, LLC-MK2, and BHK-21, and in primary chicken and duck embryo cells. Epizootic strains cause lethal infections in horses, donkeys, mules, rabbits, and dogs. In certain guinea pig strains, pathogenicity is correlated with equine virulence.

EPIDEMIOLOGY AND ECOLOGY

Epizootics and concurrent epidemics of VEE caused by the IAB and IC strains typically have led to thousands and, on at least one occasion, hundreds of thousands of cases in humans and equines. Most such outbreaks have occurred in Venezuela and Colombia and have been caused by IC viruses (see earlier) (Fig. 187–8).[24,27,37,38] The circumstances leading to the emergence of outbreaks are poorly understood, but outbreaks often have occurred in arid areas during years of heavy rainfall and flooding, especially during the dry season.[35] The importance of a nonimmune horse population to amplify the virus has been underscored in the most recent outbreak in 1995, which occurred in areas of Colombia and Venezuela where equine immunizations had lapsed.[24,31,32,38] Equines are the most important vertebrate amplifying host because high levels of viremia develop and are sustained in equines, and they provide a large surface area for biting mosquitoes. Numerous species of mosquitoes and other blood-feeding insects, among them *Aedes taeniorhynchus*, a salt marsh mosquito, and *Psorophora confinnis*, found in ground pools, can transmit the virus from horse to horse and from horse to human.[30]

Infections are transmitted rapidly among animals and to people such that outbreaks can disseminate at rates of several miles per day. The epidemic curve of human cases usually follows the equine epizootic by several weeks, and epidemic transmission ceases when the number of susceptible horses has been exhausted by immunization or natural infection.[12,35]

The role of other animals, including humans, in sustaining epidemic viral transmission has been investigated in urban outbreaks, during which household clustering of cases has been observed, and in recent outbreaks, during which few horses were

TABLE 187–3 Viruses in the Venezuelan Equine Encephalomyelitis Complex

Subtype	Variety	Pattern of Transmission	Location	Transmission Cycle
I	AB	Epizootic	South, Central, and North America	Various mosquitoes and biting insects–equines
	C	Epizootic	Northern South America	Various mosquitoes and biting insects–equines
	D	Enzootic	Ecuador, Panama, Colombia, and Venezuela	*Culex (Melanoconion) ocossa* and *panocossa*–rodents, aquatic birds
	E	Enzootic	Central America	*Culex (Melanoconion) taeniopus*–rodents
	F	Enzootic	Brazil	Unknown
II (Everglades)		Enzootic	Southern Florida	*Culex (Melanoconion) cedecei*–rodents
III	A			
	Mucambo	Enzootic	South America	*Culex (Melanoconion) portesi*–rodents
	B			
	Tonate	Enzootic	South America	Unknown
	Bijou Bridge	Unknown	Western North America	*Oeciacus vicarius*–birds
	C	Enzootic	Peru	Unknown
	D	Enzootic	Peru	*Culex (Melanoconion)–Proechimys* spp.
IV (Pixuna)		Enzootic	Brazil	Unknown
V (Cabassou)		Enzootic	French Guiana	Unknown
VI		Enzootic	Argentina	Unknown

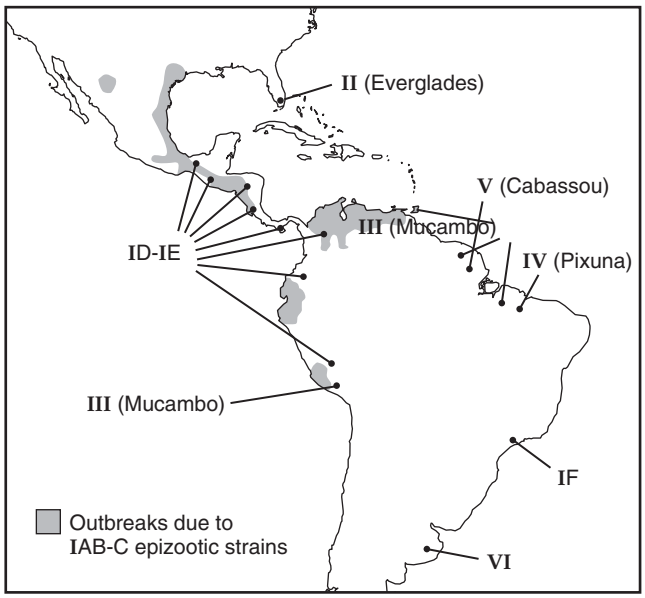

Figure 187–8 Locations of Venezuelan equine encephalitis (VEE) outbreaks caused by type IAB-IC epizootic strains and locations where VEE sylvatic subtypes have been recognized.

kept in the community. VEE virus levels in human blood are sufficiently high to infect mosquitoes, and virus also has been isolated from the pharynx of ill persons, indicating the possibility of person-to-person transmission by mosquitoes such as *Aedes aegypti* or by direct close contact.[2,29] Although such transmission mechanisms may account for some cases, a household survey found that rates of apparent secondary transmission were no higher than the underlying community attack rate.[24,31] Community attack rates of 20 to 50 percent have been recorded, and the brief course of epidemics in intervals as short as 1 month underscores the considerable force of epidemic transmission.

The series of epizootics beginning in Guatemala in 1969 and reaching Texas in 1971 was caused by an IAB virus that is almost genetically identical to the 1943 Trinidad donkey (epizootic IAB) virus used in inactivated vaccines, thus leading to the conclusion that these outbreaks were iatrogenic and caused by the use of inadequately inactivated equine vaccine.[16,37] Another outbreak in Argentina was traced to a similar cause.

In contrast to the epizootic strains, sylvatic VEE viruses are avirulent in horses and cause a low level of viremia after infection, subclinical or mild illness, and minimal inflammatory change after direct intracerebral inoculation.[34] However, outbreaks of enzootic IE-like viruses rarely have caused outbreaks and deaths in horses (e.g., in Chiapas, Mexico, in 1993). The viruses are maintained in mosquitoes, principally *Culex (Melanoconion) taeniopus* in marshy coastal lowlands, in rodents, and in aquatic birds. In coastal lagoons in Panama, ibises *(Endocinus albus)* and spoonbilled ducks *(Cochlearius cochlearius)* appear to serve as intermediate hosts.[1] VEE subtype II virus, the Everglades virus, is enzootic among cotton rats and other small mammals in the Everglades swamp and probably over a much larger area of Florida but rarely has caused human illness.[6,9] The other VEE virus found in the United States, Bijou Bridge virus, is a nonpathogenic virus thought to have evolved from South American subtype III virus transferred as recently as 40 years ago, probably by a migrating bird.

VEE infections caused by sylvatic strains can be considered "diseases of place" that occur sporadically in persons who enter sylvatic habitats where the viruses are maintained.[1,8] Sporadic cases and rare outbreaks among soldiers in field bivouacs have been reported, but seroprevalence rates in local populations range as high as 75 percent in some locations (e.g., Chiapas, Mexico).[13,26] Many infections are undoubtedly undiagnosed. Bridge vectors, mosquitoes that feed on mammals in the enzootic transmission cycle and subsequently on humans, usually are responsible for these infections.

Numerous cases and outbreaks of VEE have occurred in laboratories when infective aerosols were generated in laboratory procedures.[17] Laboratory manipulations should be undertaken only in BL-3 laboratories and by immunized personnel.

CLINICAL MANIFESTATIONS

The incubation period is brief—2 to 5 days—and in many accounts, the onset of illness was so sudden that it was timed to an exact hour.[17] Fever, chills, headache, myalgia, and malaise are the earliest symptoms, and illness quickly leads to prostration. Photophobia, neck stiffness, backache, conjunctivitis, and sore throat are also common symptoms that occur in approximately one quarter or more of cases. Gastrointestinal complaints, especially nausea and vomiting, and, to a lesser degree, loose stools or diarrhea are reported frequently.[4]

Physical examination discloses severe prostration and few specific findings. The face may appear hyperemic; inflammation of the pharynx is common; and occasionally, tonsillitis, palatal ulcers, or petechiae are observed. The cervical lymph nodes may be enlarged and tender. Conjunctivitis and conjunctival suffusion are noted frequently. Nuchal rigidity can be elicited in 10 percent of cases, more often in children. Despite the disease's name, confusion, agitation, and mild disturbances in consciousness suggesting encephalitis are present in only 5 to 10 percent of cases, and patients with significant neurologic findings, such as cranial nerve palsy, motor weakness and paralysis, seizures, and coma, usually account for less than 5 percent of all cases.[4,24,25] In epidemics, neurologic findings and encephalitis occurred more commonly in children; however, sporadic cases, including encephalitis caused by VEE subtype II (Everglades) and III (Tonate) viruses, have occurred in middle-aged or elderly adults.[9,13] The fatality rate among patients with encephalitis is 10 to 25 percent, or about 0.5 percent of all cases.[24,25]

In many patients, the illness has an apparently biphasic course; seizures, projectile vomiting, and ataxia occur several days after the onset of fever, followed rapidly by a complete resolution of symptoms. Sequelae such as nervousness, forgetfulness, recurrent headache, and easy fatigability are common occurrences and may persist for months or even up to 1 year. Motor abnormalities usually resolve without residual deficit; however, rarely, sensory and motor abnormalities may persist. Long-term effects on psychometric examination have been reported.[18]

Experimental observations in animals suggest that congenital infection may lead to central nervous system anomalies such as porencephaly, micrencephaly, and hydrocephalus.[19] A similar pattern of structural brain abnormalities has been observed in virus culture–positive fetuses aborted during outbreaks.[38,39] Pancreatic beta-cell infection occurs in experimentally infected animals and has led to speculation that VEE may be followed by diabetes, but epidemiologic studies have failed to find an association.[18]

The principal clinical laboratory finding is leukopenia (<4500/mm^3), the nadir of which occurs on the fourth day of illness.[4,8] After the onset of illness, the absolute neutrophil count declines from normal values to 500 to 2000; total lymphocytes are depressed at the onset of illness and gradually recover after 1 week. The platelet count may be diminished below 100,000 mm^3, and lactate dehydrogenase and hepatic transaminases may be elevated moderately. Cerebrospinal fluid shows a lymphocytic

pleocytosis of up to several hundred cells, moderately elevated protein level, and normal or slightly depressed glucose concentration.

PATHOLOGY AND PATHOGENESIS

VEE virus is both lymphotropic and neurotropic.[7,33] Pathologic changes are observed consistently in the lymph nodes, spleen, lungs, liver, gastrointestinal lymphoid tissue, and brain, with inflammatory infiltrates of mononuclear and polymorphonuclear cells. The lymph nodes and spleen show pronounced lymphoid depletion and necrosis of the germinal centers, along with neutrophilic infiltration and lymphophagocytosis. The selective depletion of lymphoid follicles, with sparing of the paracortical areas and the thymus, suggests that VEE virus principally destroys B cells. These histopathologic changes are reflected in the early lymphopenia seen in the peripheral blood. The liver shows patchy hepatocellular degeneration typical of viral hepatitis. A diffuse interstitial pneumonia with a mixed intraseptal inflammatory cell infiltrate is a consistent finding, and some cases also exhibit intraalveolar hemorrhage, secondary bronchopneumonia, or both. The brain shows only congestion and edema in most cases. Mild, often focal meningitis and changes associated with encephalitis, perivascular inflammatory infiltrates, and neuronal degeneration are found in a large number of cases.[7] The consistent presence of congestion and edema in various organs and the necrotizing vasculitis seen in some cases suggest that vascular endothelial cells may be a target of infection. This speculation is supported by the observation of VEE viral antigen in the vascular endothelial cells of experimentally infected animals. Secondary immune-mediated destruction of infected vascular endothelia and lymphoid cells may account for delayed clinical manifestations.

LABORATORY DIAGNOSIS

VEE virus can be recovered from blood during the first 3 days of illness in at least 75 percent of cases, although isolates have been made after 6 days.[3] Virus also has been recovered from throat swabs in approximately 25 percent of cases.[21] Specimens should be inoculated onto Vero or other susceptible cell cultures, but only in a laboratory with BL-3 level containment because of the risk of laboratory aerosol-associated infection. As an alternative to viral isolation, genomic sequences in acute viremic blood can be detected rapidly and with high sensitivity by polymerase chain reaction. Establishing the subtype of VEE viral isolates is vital because subtypes IAB and IC have a potential for epidemic spread. Isolates can be identified rapidly with subtype-specific monoclonal antibodies.

IgM capture enzyme-linked immunosorbent assay is the recommended serologic procedure. Both serum and cerebrospinal fluid specimens can be tested by this means. Elevated virus-specific IgM in a single serum or cerebrospinal fluid specimen is diagnostic and often obviates the need for a second paired serum. An epitope-blocking assay can differentiate antibody responses among serotypes.[36]

DIFFERENTIAL DIAGNOSIS

The self-limited acute febrile illness that characterizes most VEE cases resembles infection caused by dengue, Oropouche, Mayaro, group C bunyaviruses, and various other arboviruses. The epidemic occurrence of cases may suggest dengue or Oropouche fever; however, the absence of rash and hemorrhagic manifestations and an association with equine deaths strongly indicate VEE until it is disproved. Eastern and western equine encephalitis overlap with VEE in some areas of Latin America, but only sporadic human cases have been recognized. Clinical recognition of sporadic VEE caused by sylvatic viruses is difficult; the diagnosis should be entertained in patients with central nervous system infection and an appropriate exposure history.

TREATMENT AND PREVENTION

No specific treatment is available. Symptomatic treatment with antipyretics and fluids alone is sufficient in most cases. In patients with encephalitis, anticonvulsants may be needed, and intensive supportive care, especially early recognition and treatment of secondary pneumonia, may improve the outcome. Combinations of short interfering RNAs and passive immunization with humanized monoclonal antibodies are under investigation as therapeutic interventions.

Immunization with experimental live attenuated TC-83 vaccine is indicated for laboratory and field personnel with a high risk of exposure to VEE virus.[22] However, the vaccine is immunogenic in only 85 percent of vaccinees, and significant side effects consisting of fever, stiff neck, malaise, and myalgia develop in approximately 20 percent of vaccinees.[10] Previous vaccination with alphaviral vaccines may interfere with response to TC-83, but after immunization with experimental inactivated TC-84 vaccine, antibody will develop in approximately 75 percent of persons who had failed to respond to TC-83.[10,20] Safer candidate vaccines that may provide better protection against respiratory infection are being investigated.

Immunization of equines with TC-83 vaccine is the best approach to preventing the emergence of outbreaks. Inadequately inactivated vaccine prepared from epizootic IAB strains poses a danger of producing iatrogenic outbreaks and should be used only if appropriate safety and quality assurance standards of vaccine production have been met. Because the live vaccine provides rapid immunity after a single dose, it is the most effective approach in combating outbreaks. Attenuated vaccine is available commercially in certain Latin American countries, but in the United States, only inactivated vaccine formulated with western and eastern equine encephalitis and equine influenza and tetanus antigens is licensed. An improved candidate vaccine, V3526, has been shown to be efficacious in horses.[10]

Mosquito control with a combination of larvicides and adulticides may be indicated to mitigate large outbreaks. Taking precautions against mosquito bites, such as using repellents, staying in well-screened or air-conditioned areas when possible, and wearing long-sleeved shirts and long pants, is advised for persons who cannot avoid traveling to areas experiencing epidemics.

CHAPTER **187d**

CHIKUNGUNYA

Scott B. Halstead

Chikungunya is a benign, dengue-like syndrome characterized by the abrupt onset of fever, arthralgia, maculopapular rash, and leukopenia. The term in Makonde means "that which bends up" and refers to the characteristic symptom of arthralgia.[33] In historical times, the terms *knokkel koorts*, *abu rokab*, *mal de genoux*, *dengue*, *dyenga*, and *3-day fever* have been given to epidemics probably caused by chikungunya virus.[10]

The classic account widely cited as being the initial description of epidemic dengue fever is that of David Bylon,[7] who was *staads chirurgyn* to the City of Batavia (Jakarta) in 1779. Dr. Bylon, who himself contracted the illness, wrote the following:

> It was last May 25, in the afternoon at 5:00 when I noted while talking with two good friends of mine, a growing pain in my right hand, and the joints of the lower arm, which step by step proceeded upward to the shoulder and then continued onto all my limbs; so much so that at 9:00 that same evening I was already in my bed with a high fever. . . .
>
> It's now been three weeks since I . . . was stricken by the illness, and because of that had to stay home for 5 days; but even until today I have continuously pain and stiffness in the joints of both feet, with swelling of both ankles; so much so, that when I get up in the morning, or have sat up for a while and start to move again, I can not do so very well and going up and down stairs is very painful.

This account of a febrile illness of acute onset with involvement of the joints clearly suggests that the disease was chikungunya (see the section on clinical manifestations).

In the same year in Cairo and Alexandria, Egypt, another outbreak of disease occurred that bears a close resemblance to chikungunya.[10,52]

An important pandemic of chikungunya occurred in the years 1870 to 1873; it appeared first on the East African coast and then on the Arabian coast and in Port Said, Egypt. From there, it was carried to Mumbai and Calcutta, India, and Java. The 1870 outbreak led to the discovery that the Swahili word for this disease is *ki-dinga pepo*.[15] Further, the term *denga* or *dyenga* had been used to designate the disease in Africa in an earlier outbreak in 1823; this pandemic of "dengue" had spread with the slave trade to the Caribbean, where in 1827 and 1828 an extensive outbreak occurred in the West Indies. In Cuba, the Spanish word *dengue* was used first. No further outbreaks of chikungunya occurred in the American hemisphere, and during the course of time, the term *dengue* was applied to the disease caused by dengue viruses. Written or serologic evidence exists of chikungunya pandemics in India in 1824 and 1825, 1871 and 1872, 1923, 1964 to 1965, and 2006.[10]

Chikungunya virus was isolated first by inoculation of blood into suckling mice from an explosive dengue-like epidemic in Tanganyika in 1952.[48]

ETIOLOGIC AGENT

CLASSIFICATION

According to epidemiologic criteria, chikungunya virus is arthropod-borne because it is transmitted by several species of mosquito. With the use of antigenic relationships demonstrated by hemagglutination inhibition and complement fixation, chikungunya is placed in the *Alphavirus* genus of the family *Togaviridae*.[30] Antisera prepared to chikungunya virus show strong cross-reactions with o'nyong-nyong by complement fixation and virus-dilution neutralization. Mayaro and Semliki Forest viruses, however, demonstrate only weak cross-reactions by hemagglutination inhibition and no reactions by complement fixation with chikungunya antigen. Cross-comparisons by plaque-reduction neutralization tests have shown little relatedness among alphaviruses.[54] Similar results have been obtained by fluorescent antibody technique.

Phylogenetic analysis of the E1 envelope glycoprotein from 18 strains divides chikungunya virus into three distinct genotypes corresponding to their geographic origin.[45] One chikungunya clade consists of viruses from Senegal and Nigeria and represents the West African genotype. These viruses had only 78 to 85 percent nucleotide sequence identity to viruses of the Central/East African genotype and the closely related Asian genotype. The phyletic grouping is consistent with the introduction of East African strains into Asia within a period 50 to 310 years ago.[45] The African and Asian strains of chikungunya virus are not antigenically separable with the use of mouse immune sera.[41] Although differences in plaque size and heat stability have been described between these strains, these differences might be attributable to the high number of mouse passages by the prototype African strain. Wild-type strains from all genotypes share the property of autointerference and production of hemorrhagic enteritis (Halstead, S. B., unpublished data, 1965).[20]

MORPHOLOGY

Chikungunya virions are spherical particles approximately 42 nm in diameter.[26] They possess a lipid-containing envelope with fine projections. The central core, approximately 25 to 30 nm in diameter, is roughly hexagonal in cross section and contains a nucleocapsid of uncertain symmetry. Together with other alphaviruses, the genome is a positive-sense, single-stranded RNA of 12 kb that is messenger active and specifies the viral structural and nonstructural protein, including the polymerase. After an initial round of RNA replication, a subgenomic RNA of approximately 4 kb (26S RNA) is produced. This RNA encodes the viral structural proteins, which include two envelope and capsid proteins.[27] The gene is translated from the 5′ end, where genes for nonstructural proteins are located. Assembly of virus particles at the cell surface occurs by a budding process involving incorporation of the "core" virus precursor into virus particles.[26] Host-cell membranes are modified during infection and contain viral antigen when incorporated into viral envelopes. The protein hemagglutinin spikes are mounted on a phospholipid envelope.

GROWTH

Intracerebral inoculation of chikungunya virus produces death in infant mice, rats, and hamsters. Serial passage of the virus in mice has resulted in selection of a strain with a short incubation period that is lethal to weanling mice.[48] Virus grows to titers of 10^8 to 10^9 infectious doses per milliliter. Low-passage material is highly infectious for humans during routine laboratory handling, and therefore appropriate precautions should be taken by laboratory workers. It is difficult to distinguish chikungunya from o'nyong-nyong virus serologically, but suckling mice that are susceptible to chikungunya are hardly susceptible to o'nyong-nyong virus.

If a mouse brain seed suspension of low-passage virus is prepared and inoculated into other mice at a 1:5 or 1:10 final concentration, death may be delayed significantly, may be sporadic, or may not occur at all. This difference is due to autointerference.[20] Low-passage strains recovered in suckling mice characteristically demonstrate autointerference on inoculation at dilutions below 1:100.

Chikungunya virus produces a cytopathic effect in primary hamster kidney cells and in BHK-21, BSC-1, Vero, FL, HeLa, and rhesus kidney cells.[30] Virus multiplies in *Aedes aegypti*, *Aedes vittatus*, *Aedes albopictus*, *Anopheles stephensi*, and *Culex fatigans* continuous cell lines and in a cell line derived from *Drosophila*. Plaque assays have been described in LLC-MK2, Vero, and BHK-21 cells and in duck and chick embryos.[30]

TRANSMISSION

Chikungunya virus has been recovered from wild *A. aegypti* in Tanzania, Nigeria, India, and Thailand; from *Aedes africanus* in Uganda and Bangui; from *Aedes furcifer-taylori* in South Africa and Senegal; and from *Aedes luteocephalus* and *Aedes dalzieli* in Senegal.[2,16,18,29,37,39] Occasional isolates have been recovered from *Mansonia fuscopennata* in Uganda and from *C. fatigans* in Thailand and Tanzania.

Transmission to humans has been demonstrated with the *A. furcifer-taylori* group; transmission to monkeys or mice has been demonstrated with *A. aegypti*, *A. albopictus*, *Aedes calceatus*, *Aedes triseriatus*, *Aedes togoi*, *Aedes pseudoscutellaris*, *Aedes polynesiensis*, *Anopheles albinanus*, *Mansonia africana*, *Erethmapodites chrysogaster*, and *Aedes apicoargenteus*.[30,36,44,51]

Tesh and colleagues[55] examined *A. albopictus* strains from 13 geographic locations from Hawaii to Africa and found considerable variation in susceptibility to infection by oral feeding. The 50 percent oral infective dose (ID_{50}) of a Hawaiian *A. albopictus* strain for a wild-type virus from India was $10^{5.4}$ plaque-forming units per milliliter. The amount of virus replicated by different mosquito strains varied between $10^{4.6}$ and $10^{7.4}$ plaque-forming units per mosquito. These observations, plus a mathematical model of chikungunya virus transmission developed by deMoor and Steffens,[17] suggest that major factors in determining the endemicity of chikungunya may be arthropod related. Tesh and associates[55] suggested that susceptibility to oral infection and the amount of virus replicated may be under genetic control, whereas deMoor and Steffens[17] found mosquito longevity to be the most important determinant in epidemic transmission of chikungunya.

Serologic studies have demonstrated repeatedly the presence of antibodies in humans throughout the moist forests and semiarid savannas of East and West Africa.[1,18,39,49] Most recorded chikungunya infections in people occur in areas infested with *A. aegypti*. The epidemiology in these areas is similar to that of other *A. aegypti*–borne diseases and parallels the distribution of the vector. When *A. aegypti* mosquitoes are abundant in occupied dwellings, infection rates can be expected to be highest in women and children who are at home during daylight hours. When *A. aegypti* is found in public buildings, schools, and hospitals, outbreaks may involve persons in occupational patterns. Characteristically, chikungunya pandemics are explosive. Studying *A. aegypti* in laboratory mice, Rao and colleagues[46] documented mechanical transmission. Viremia in humans may be as high as 10^8 infectious doses per milliliter.[46] Because the extrinsic incubation period in *A. aegypti* is relatively long, the explosive nature of chikungunya outbreaks is explained best by mechanical transmission.

The large chikungunya epidemic on Réunion Island was transmitted by *Aedes albopictus*. This outbreak was unusual because of its large size. However, as is characteristic of *A. albopictus* outbreaks, the epidemic proceeded at a deliberate pace for a period of many months. Because *A. albopictus* breeds outside houses, the outbreak did not respond to anti-mosquito efforts such as space spraying that would have effectively interrupted virus transmission by *A. aegypti*.[47,53]

EPIDEMIOLOGY

HOST RANGE

Chikungunya virus has the ability to replicate in a broad spectrum of vertebrate species. Newborn mice, hamsters, rats, rabbits, guinea pigs, and kittens all can be infected by subcutaneous inoculation of field strains of chikungunya virus,[12] which produces viremia, sickness, and, in most instances, death. Adult rabbits, mice, rats, and chickens inoculated peripherally have an asymptomatic viremia followed by an antibody response. Neutralizing or hemagglutination-inhibition antibodies to chikungunya have been recovered occasionally from sera obtained from ungulates. Attempts to infect cattle, goats, sheep, or horses experimentally failed to produce either viremia or an antibody response.[37] Vervet monkeys and baboons are infected readily. Rhesus monkeys were infected by intravenous and intramuscular inoculation and had viremia titers in excess of 10^7 mouse LD_{50}. *A. aegypti* transmitted virus to rhesus monkeys and could be infected by biting viremic animals.

Chikungunya antibodies have been found in vervet monkeys, baboons, chimpanzees, and red-tailed monkeys in Zimbabwe, South Africa, and Uganda.[35] The zoonotic status of chikungunya virus in Asia has not been studied carefully.

In Africa, zoonotic transmission to subhuman primates is surmised to take place in a wide variety of habitats, with transmission occurring in the forest canopy, at ground level, or both.[36] Chikungunya appears to be enzootic throughout much of eastern, central, southern, and western Africa.[30] Subhuman primate populations are affected in epizootics, which involve critical numbers of the susceptible population, followed by disappearance of the virus. Thus, chikungunya may maintain itself in wildlife populations by constantly moving epizootic activity, in much the same fashion as respiratory and enteric virus infections are maintained in humans. To expect that intercurrent and epidemic human infections in Africa are related to epizootic activity seems reasonable. Many putative or identified chikungunya vectors feed on people as well as on subhuman primates.

GEOGRAPHIC DISTRIBUTION

When susceptible human and *A. aegypti* populations are above the threshold level required for transmission, a person-mosquito-person cycle is established. This cycle probably is responsible for most of the large urban outbreaks of chikungunya studied during the past 40 years. In Africa, chikungunya outbreaks have been reported from Uganda, Tanzania, Zimbabwe, South Africa, Angola, Zaire, Nigeria, and Senegal.[30] This distribution best fits the present location of virus research laboratories. A reasonable assumption is that chikungunya is endemic throughout sub-Saharan Africa.

In February 2005, chikungunya cases appeared on Réunion Island. The epidemic continued for more than 18 months, and by July 2006, there had been nearly 300,000 cases, with 219 deaths attributed to the disease. Cases spread from Réunion to nearby islands of Mauritius, Madagascar, and the Seychelles.[53] Tourists on Indian Ocean islands who acquired chikungunya disease brought infections to European countries, creating a scare that epidemics would soon occur.[31]

According to historical evidence, chikungunya has spread from the African enzootic focus and caused large pandemics throughout both the Asian and American tropics.[10,15,52] Pandemics have swept India in 1824, 1871, 1902, 1923, 1964 to 1965, and 2006, with Sri Lanka (formerly Ceylon) involved in 1965 and 2006.[10] In the 19th century, chikungunya epidemics were reported in the Indonesian archipelago. An extensive serologic survey using the plaque-reduction neutralization test has suggested chikungunya activity possibly during World War II in Kalimantan and Sulawesi, Indonesia. During the late 1950s and early 1960s, chikungunya appears to have established itself endemically in Southeast Asia and was transmitted continuously in urban populations in Thailand, Cambodia, and South Vietnam, possibly into the 1970s.[13,22,59] Involvement of urban populations in Burma appears to have been intermittent, with outbreaks recorded in 1963 and from 1970 to 1973.[38] A large chikungunya epidemic affected much of Indonesia in 1983 and 1984 (Slemons, R. D., personal communication) and Burma in 1984 and 1985.[57] Chikungunya virus was isolated in Australia in 1989.[23] Serologic evidence of chikungunya virus infection has been found throughout the Philippines, possibly during World War II; since then, localized outbreaks have occurred in Manila, Philippines, in 1967 and Negros, Philippines, in 1968[3,9,34] and as recently as 1986.[14] From 1990 to 1995, chikungunya remained endemic at low levels in Thailand, Myanmar (formerly Burma), and Indonesia.[56] Little or no chikungunya virus infection has been reported in the 20th century in Papua New Guinea, the Solomon Islands, Vanuatu (formerly New Hebrides), the Caroline Islands, the Pacific Islands, or any of the American tropics.[54]

A pertinent question to ask is why chikungunya and dengue viruses do not have an identical geographic distribution although both are transmitted by *A. aegypti*. The question may be answered partially by differences in the transmission of chikungunya and dengue. The threshold for infection of chikungunya virus in *A. aegypti* is relatively high: approximately $10^{5.6}$ mouse infectious doses are required to infect 50 percent of adult females.[55] The infection threshold of female *A. aegypti* for dengue virus is similar.[19] However, *A. aegypti* mosquitoes infected with chikungunya virus transmit virus to vertebrates poorly, whereas dengue-infected mosquitoes transmit with great regularity.[19] Thus, transmission of chikungunya virus would be expected to occur only in areas with high human susceptibility rates and consistently high densities of *A. aegypti* and possibly by mechanical transmission.

CLINICAL MANIFESTATIONS

The incubation period of chikungunya fever usually is 2 to 4 days. In infants, the disease typically begins with the abrupt onset of fever, followed by flushing of the skin. Febrile convulsions may occur in as many as one third of patients. After 3 to 5 days of fever, a generalized maculopapular rash and lymphadenopathy are noted. Conjunctival injection, swelling of the eyelids, pharyngitis, and symptoms and signs of upper respiratory tract disease are common manifestations. No enanthem occurs. Some infants have a biphasic fever curve, and arthralgia may be severe, although it is not seen frequently.[5,11,21,28,43]

In older children, fever develops acutely and is accompanied by headache, myalgia, and arthralgia involving various joints. Residual arthralgia is an uncommon occurrence. An early macular blush and a maculopapular rash accompany or immediately precede defervescence. At the same time, marked lymphadenopathy occurs. Febrile convulsions are observed commonly. Hemorrhagic findings, including a positive tourniquet test result, are rare events.[5,11,21,28,43]

TABLE 187–5 Chikungunya and Dengue in Children: Comparison of Duration of Illness

Rights were not granted to include this table in electronic media. Please refer to the printed publication.

Arthralgia or arthritis is the most conspicuous feature of chikungunya in adults. Usually, patients can identify the precise time of onset and the joint first affected in a chikungunya illness. Swelling and redness of joints and even the pinnae of the ear may occur.[11]

Although dengue and chikungunya illnesses are similar, important distinguishing features are summarized in Tables 187–4 through 187–8 from clinical data obtained from children in Thailand.[21,43]

Table 187–4 shows the abrupt onset and early severity of chikungunya versus dengue illnesses, many of which came to medical attention only several days after the onset of fever.

Chikungunya virus infections are shorter in duration than are dengue virus infections (Table 187–5). Almost half of children with chikungunya had a fever that ended within 72 hours after onset, whereas the median duration of dengue fever was 2 days longer.

Many constitutional signs and symptoms occur with similar frequency in chikungunya and dengue viral infections and cannot be used to differentiate the illnesses clinically (Table 187–6). However, a terminal maculopapular rash, arthralgia or arthritis, and conjunctival injection were more common symptoms in chikungunya than in dengue (Table 187–7). Shock has been reported infrequently in chikungunya.[11,50,58] It was not observed in Thai cases.[43] Changes in taste perception, post-illness bradycardia, and post-illness depression or asthenia are found rarely in chikungunya; these manifestations are distinctive findings in patients with dengue.

Hemorrhagic phenomena rarely occur with chikungunya virus infection. The frequencies of hemorrhagic findings in chikungunya and primary and secondary dengue viral infections in Thai children are compared in Table 187–8. The frequency of minor hemorrhagic manifestations in outpatient and inpatient dengue did not differ significantly from that in chikungunya cases. However, petechial rash and spontaneous hematemesis or melena developed only in hospitalized dengue cases.

Brighton and Simson[5] divided chikungunya cases into four groups: (1) patients who experienced joint pain but after days, weeks, or months fully recovered, (2) patients who experienced little spontaneous joint pain but found it was exacerbated by exercise, (3) patients with residual joint stiffness, and (4) patients with residual joint pain and swelling. Approximately 8 percent of all patients fell into the last two groups. Most of these studies are composed of adult patients. Little is published describing chikungunya arthritis in children.

PATHOGENESIS AND PATHOLOGY

The pathologic process of fatal human chikungunya illness has not been studied extensively.[58] Wild-type chikungunya strains produce a hemorrhagic enteritis in mice and hamsters.[20]

DIAGNOSIS

The differential diagnosis includes the viral causes of dengue fever syndrome. In Australia and the western Pacific area, Ross River fever is a frequent cause of epidemic, arthropod-borne, viral arthralgia.

By classic test methods, the diagnosis depends on demonstration of a significant increase in antibody after an illness. With use of a single serum sample collected 5 or more days after onset, detection of antibodies of the IgM class is possible with an IgM capture enzyme-linked immunosorbent assay (ELISA).[8,57] Ordinarily, a serum sample collected within 5 days of the onset of fever will not contain hemagglutination-inhibition, complement-fixation, or neutralizing antibodies.[11,21] Neutralizing and hemagglutination-inhibition antibodies generally are present

TABLE 187–6 Chikungunya and Dengue in Children: Comparison of Frequency of Clinical Findings

	Hospitalized				Outpatient			
	Chikungunya (32 cases)		Dengue (142 cases)*		Chikungunya (17 cases)		Primary Dengue (27 cases)*	
Findings	Number†	Percent	Number†	Percent	Number	Percent	Number	Percent

in samples collected 2 weeks or more after the onset of fever. Neutralizing antibody can be measured by the virus-dilution method in suckling mice (or weanling mice with use of the Ross high-mouse passage strain) or by the serum-dilution method in any of a variety of tissue cultures or plaque assay techniques. The detection of IgM-containing ELISA antibodies or a fourfold or greater rise in antibodies in paired sera is diagnostic of a recent infection.

Virus may be identified by use of polymerase chain reaction or by isolation of the agent by inoculation of acute-phase serum or other suspect materials intracerebrally in 1- to 2-day-old mice or in tissue cultures. On initial passage, death may occur within 2 to 5 days after inoculation. An autointerference phenomenon is noted if low-dilution mouse-to-mouse passages of infected mouse brain are performed. Passage at a 10^{-3} dilution or higher avoids this effect.

Vero cells and suckling mice are equally effective for primary isolation.

TREATMENT

Treatment is supportive. Chikungunya symptoms are refractory to aspirin or other nonsteroidal anti-inflammatory drugs. However, one report demonstrated that chloroquine phosphate (250 mg/day) provides prompt relief from chronic arthralgia in a high proportion of sufferers.[4] Anecdotal reports from India during the 2006 epidemic describe similar efficacy, including relief of acute-phase symptoms. In cell cultures in vitro, chloroquine has some antiviral activity against chikungunya. Controlled trials are in progress.

Bed rest is advised during the febrile period. Antipyretics or cold sponging should be used to keep the body temperature below 40° C (104° F).

Analgesics or mild sedation may be required to control pain. Post-illness arthritis may require continued treatment with anti-inflammatory agents and graduated physiotherapy.

Salicylates, because of their hemorrhagic potential, are contraindicated.

Febrile convulsions are treated with phenobarbital given intravenously or orally and continued until the temperature is normal. Severe or intractable convulsions may respond to intravenous diazepam.

Children who have lost excessive fluid because of vomiting, fasting, or thirsting and who cannot take oral fluids may require intravenous rehydration. Individuals with severe hemorrhagic phenomena should be studied for underlying hemostatic disorders.

PROGNOSIS

In a few instances, isolation or serologic evidence of recent infection has been obtained in persons with severe hemorrhagic findings or in individuals dying during an acute febrile illness.[11,28,40,50,58] In addition to hemorrhage, neurologic and myocardial involvement has been reported during chikungunya infection in adults.[11,14] In adults, arthralgia may persist for weeks, and exercise may prolong this symptom. Typically, pain shifts from joint to joint and is worse in the morning and on first use of the joint. Swelling of ankles, wrists, and fingers occurs frequently. In older patients, the sequelae may resemble rheumatoid arthritis. A post-illness destructive arthropathy has been reported.[6] Chikungunya virus infection might coincide with other pathologic processes and result in death of the individual.[40] Carefully studied, virologically documented cases have shown neither thrombocytopenia nor severe neutropenia.[28] Until more is known of the pathogenesis of chikungunya virus infection, estimation of the frequency with which death can be attributed directly to chikungunya fever will be difficult.

Infants with chikungunya may experience residual neurologic deficits after febrile convulsions.

PREVENTION

Formalin-treated chikungunya virus (Ross strain) grown in African green monkey kidney cells produces a satisfactory immune response and resistance to challenge when it is administered in three divided doses in monkeys.[24] A vaccine prepared under similar conditions produced hemagglutination-inhibition, complement-fixation, and neutralizing antibody responses in susceptible human volunteers.[25] A comparative study from the same laboratory was made of formalin-inactivated chikungunya vaccines prepared from the virus propagated in African green monkey kidney monolayers and concentrated chick embryo suspension cultures.[60] The latter vaccine was significantly more protective to mice against live homologous virus challenge and stimulated the production of four to five times more circulating antibodies than did the vaccine prepared with virus grown in African green monkey kidney cultures. Nakao and Hotta,[42] studying chikungunya grown in BHK-21 cells, found that ultraviolet-inactivated preparations were significantly more immunogenic than were formalin-treated virus. Tween-ether–extracted virus preparations also have been found to be immunogenic. A live attenuated chikungunya vaccine has been developed.[32] After the pandemic of 2006, the disability and deaths attributed to chikungunya renewed interest in development and licensing of chikungunya vaccines.

At present, prevention consists of avoiding mosquito bites. For urban outbreaks in most of the Asian and African tropics, the regimen for individual protection and for chronic and emergency control is the same as has been described for dengue. When other vectors are involved, measures designed to combat *A. aegypti* may fail. In such outbreaks, expert entomologic advice will be needed to design appropriate preventive measures.

For control of mosquitoes, epidemic measures, and health education, see Chapter 188d.

CHAPTER **187e**

Ross River Virus Arthritis

John G. Aaskov

"Epidemics" of a benign disease causing polyarthralgia and rash were first described in Australia in 1927.[55] Following the recovery of the causative agent and the advent of serologic tests able to diagnose Ross River virus infection, epidemic polyarthritis has been recognized as endemic in Australia and has occurred as epidemics in numerous Pacific nations. Approximately 4000 cases of epidemic polyarthritis are reported in Australia each year, with a peak of 7800 cases in 1996.

Some confusion has been generated recently by use of the term *Ross River fever* to describe clinical Ross River virus infections because fever does not develop in more than half of those with clinical disease.[52] Additional confusion has been generated by efforts to describe any polyarthritis caused by an Australian arbovirus as epidemic polyarthritis. The term *epidemic polyarthritis* should be used to describe only clinical disease caused by Ross River virus.

ETIOLOGIC AGENT

Investigations of an epidemic of polyarthritis in southern Australia in 1956[10,67] suggested that an alphavirus was the causative agent. This agent was confirmed when Ross River virus was isolated from *Aedes vigilax* mosquitoes collected beside Ross River, near Townsville in northern Australia, and shown, on serologic grounds, to be the causative agent of epidemic polyarthritis.[22,25] Although the first isolation of virus from a human was from a febrile child without arthritis,[21] subsequent use of mosquito cell lines enabled numerous isolations to be made of Ross River virus

from epidemic polyarthritis patients in Australia and the Pacific Islands.[8,26,60,70]

Ross River virus is related serologically to Getah and Bebaru viruses in the Semliki Forest virus subgroup.[19] Nucleotide sequencing has confirmed this close relationship among Ross River, Getah, and Semliki Forest viruses.[59] Phylogenetic analysis of a short (505 nucleotide) region of the E2 and E3 genes of Ross River virus suggested the existence of three or four genotypes of this virus.[62] No association has been observed between any particular genotype and disease in humans.

Cryoelectron microscopic studies[15,58,72] suggest that the nucleocapsid of Ross River virus is approximately 400 Å in diameter and has a T = 4 quaternary structure. It is surrounded by a membrane bilayer that is penetrated by 80 spikes, also arranged in a T = 4 lattice. Each spike is a trimer of heterodimers of the envelope glycoproteins E1 and E2. The E2 protein makes contact with heparin on the surface of host cells, and antibodies that combine with this protein neutralize infection in vitro.[68,71]

The virus can be adapted to grow to high titer in the muscle and brain of day-old mice, in which it causes paralysis and death.[50,53] Ross River virus also grows to high titer in vertebrate and mosquito cell lines.[8]

TRANSMISSION AND EPIDEMIOLOGY

Ross River virus is endemic in all mainland states of Australia and in Papua New Guinea. No transmission of Ross River virus had been reported from the Pacific island states involved in the 1979 to 1980 epidemic (Fiji, Samoa, Tonga, Cook Islands)[5,26,45,60,70] until 2003, when cases of epidemic polyarthritis began to be detected in travelers who had visited Fiji.[46] Sporadic cases, without local virus transmission, have occurred in Europe and the United States in tourists and military personnel returning from Australia.

Isolation of Ross River virus from more than 20 species of mosquitoes,[61] in particular *A. vigilax*[25,37] and *Culex annulirostris*,[24,37] and the presence of antibody to the virus in almost as many species of animals, particularly mammals,[22,23] suggested a mammal-mosquito cycle with humans as an incidental host. However, improved laboratory diagnostic services have shown clinical infection in humans occurs year-round, although most cases are seen in the late summer and in autumn, and most patients are city dwellers.[7,52] Taken together with the explosive spread of disease during the 1979 to 1980 epidemic of Ross River virus infection in the Pacific,[5,26,60,70] this virus appears to be maintained in either of two cycles, mammal-mosquito-mammal or human-mosquito-human, with movement of virus between the two. Evidence also has been obtained of transovarial transmission of Ross River virus in *Aedes* mosquitoes.[44,47]

Patients may be viremic for up to 7 days after the onset of symptoms.[8,60] The incubation time from infection to the onset of symptoms may vary from 1 to 27 days, 7 to 9 days being the usual interval in endemic areas.[30]

In endemic areas, the ratio of subclinical to clinical infection may be as high as 50:1,[7] but during outbreaks, the ratio can be reduced to 4:1 or less.[5,39] Approximately 1.5 percent of humans living in northern Australia are infected with Ross River virus each year,[7] but the rates are much higher in some areas.[17,18]

Infection rates are the same in both sexes, and early reports that clinical disease was more common in females than in males[20,52] are not supported by Australian national data for the past decade. An association between HLA-DR7 and clinical disease also has been observed.[36]

Ross River virus has been shown to cross the placenta in mice[3] and humans.[6] In mice, the result is extensive postpartum mortality,[3] but in humans, no evidence of morbidity or mortality in children infected in utero has been found.

CLINICAL MANIFESTATIONS[10,20,22,27,28,38,52,54]

Epidemic polyarthritis occurs as a mild to severe illness characterized by joint pain, particularly in the knees and the small joints of the hands and feet. Frequently, the joint pain is accompanied by a maculopapular or vesicular rash on the trunk and limbs and sometimes by fever or chills or both. Sore throat, lymphadenopathy, paresthesia and tenderness of the palms and soles, exanthems, and, more rarely, petechiae have been observed. Most patients experience several weeks of painful arthritis followed by a slow decrease in the severity of symptoms during the 30 to 40 weeks required by most for recovery.[2] Infrequently, symptoms may persist for a year or more,[28] and some patients may experience episodes of severe arthritis during convalescence. One study has linked Ross River virus infection to a chronic fatigue syndrome.[41]

In a small proportion of patients (<0.1%), clinical disease may develop without arthritis.[21] Rare cases of glomerulonephritis,[33] hematuria,[11] and central nervous system symptoms[1,48,57,63] accompanying Ross River virus infection in humans also have been reported.

The severity and duration of symptoms are age related. Most clinical disease occurs in adults, who also have the most severe and prolonged symptoms. Teenagers may be incapacitated for only a few days and asymptomatic after 1 to 2 weeks.

The only other species known to develop clinical disease (musculoskeletal symptoms) after a natural infection with Ross River virus is equines.[13]

PATHOLOGY

The pathogenesis of Ross River virus disease in humans is not understood. The literature describing the pathologic process of Ross River virus infection in mice is extensive,[50,53,64] but with one exception,[51] very little similarity between the patterns of disease in humans and in mice exists.

Synovial tissue from patients with epidemic polyarthritis may show a marked mononuclear leukocyte infiltrate with small amounts of fibrin deposition and synovial-cell hyperplasia.[40,69] No virus or viral antigen has been detected in synovial tissue from patients with epidemic polyarthritis, but a 250-nucleotide fragment of the viral genome was detected by reverse transcription–polymerase chain reaction (RT-PCR) in synovium from 2 of 12 patients 5 weeks after the onset of symptoms.[69] Ross River virus has been shown to replicate for a similar period in human synovial cells maintained at 35° C in vitro.[42] Whether virus persists in joints as long as symptoms are present remains unclear, and ethical and technical constraints prevent this issue's being explored in a systematic manner.

Fluid from affected joints consists almost entirely of mononuclear leukocytes at all stages of disease.[16,29,31] Human synovial fibroblasts infected with Ross River virus in vitro produce elevated levels of mRNA coding for chemoattractants and other mediators, such as monocyte chemoattractant protein 1, interleukin-8, granulocyte-macrophage colony-stimulating factor, and tumor necrosis factor–α, but elevated levels of the proteins for which they code have not been demonstrated.[49]

No evidence of immune complexes or complement activation in arthritic joints has been found, and viral antigen can be detected (in macrophages) for only 5 to 7 days after the onset of symptoms, despite the persistence of arthritis for 30 to 40 weeks.[32] No significant levels of anticollagen antibodies could be detected in serum from epidemic polyarthritis patients.[35] Neither anti–Ross River virus antibody levels nor a primary, virus-specific, cell-mediated immune response to Ross River virus infection correlated with the presence or absence of arthritis in human infections.[4] In patients with epidemic polyarthritis, a nonspecific

immunologic response (natural killer cells) correlated well with the presence or absence of arthritic symptoms.[2,4] Functional natural killer cells have been recovered from the knee of a patient with epidemic polyarthritis,[40] and natural killer cells have been found to kill autologous synovial tissue in vitro.[2]

A rash develops in approximately 30 percent of patients with epidemic polyarthritis.[52] The dermis underlying these lesions contains a perivascular infiltrate of CD8+ T cells and some monocytes and macrophages.[34] No immunoglobulin or complement deposition has been observed in these lesions, although Ross River virus antigen was detected in basal epidermal and eccrine duct epithelial cells.[34]

DIAGNOSIS

The signs and symptoms of a Ross River virus infection (see earlier) are too nonspecific to permit establishment of a diagnosis on clinical grounds alone. Most clinical diagnoses of epidemic polyarthritis are confirmed by use of an indirect enzyme-linked immunosorbent assay (ELISA)[56] to detect Ross River virus–specific IgM antibodies in serum collected 7 to 10 days after the onset of symptoms. Various forms of this assay are available now from commercial suppliers. IgM can be detected for approximately 3 months after the onset of disease.[7]

In rare cases (perhaps less than 1 in 5000), anti–Ross River virus IgM antibody production may persist for years. Assays for serum anti–Ross River virus IgA might be an alternative to IgM assays because the duration of IgA production is shorter than for IgM.[14] However, such IgA assays have not been adopted by routine diagnostic laboratories. More recently, indirect ELISA assays that measure the avidity of anti–Ross River virus antibody have been shown to be able to discriminate between recent and old infections with this virus.[43]

Although virus sometimes can be isolated from seronegative, acute-phase sera,[5,8,26,60,70] this procedure is not performed in most routine diagnostic laboratories. A number of mostly unpublished RT-PCR protocols[66] have been developed for the detection of Ross River virus RNA, but they are less sensitive than is virus isolation for the detection of virus and are not used routinely for the diagnosis of human disease.

Because epidemic polyarthritis is an arthritic disease, care must be taken to avoid false-positive results caused by the presence of rheumatoid factor when indirect ELISA is used to detect anti–Ross River virus IgM antibodies. Such precautions include removal of IgG or rheumatoid factor before testing sera or performing tests for rheumatoid factor in parallel with ELISA.

Another source of false-positive diagnoses is the production of anti–Ross River virus IgM antibody caused by polyclonal B-cell activation after infection of a Ross River virus immune host with Epstein-Barr virus, cytomegalovirus, *Coxiella burnetii*, or *Plasmodium* spp.

Other viral infections to be considered when a patient is suspected of having epidemic polyarthritis include infections with Barmah Forest, Sindbis, Kunjin, or rubella viruses.

TREATMENT AND PROGNOSIS

No specific antiviral therapy is available, although experimental evidence suggests that interferon-γ may ameliorate acute disease.[65] Nonsteroidal anti-inflammatory medication or steroids[12] have been used to treat patients with severe disease or prolonged symptoms, but the efficacy of such treatment has not been evaluated in any systematic manner. Rest, while maintaining mobility and muscle tone, appears to provide significant relief.

Epidemic polyarthritis has not been shown to progress to chronic joint disease.

PREVENTION

A killed virus vaccine is being developed.[9] In urban areas, public health mosquito control programs reduce mosquito numbers, but elimination of mosquito exposure for those with outdoor occupations and pastimes is impossible. Personal protection (insect screening of houses, wearing of protective clothing, and application of insect repellents) is the only reliable way to avoid being infected.

CHAPTER **187f**

Other Alphaviral Infections

Theodore F. Tsai

O'NYONG-NYONG

The virus name is derived from the Acholi term meaning "very painful and weak," which describes the acute constitutional symptoms and polyarthritis associated with the disease of the same name.[13,23] The virus is related closely to chikungunya virus, but unlike most arboviruses, it is transmitted by anopheline mosquitoes in an interhuman cycle analogous to that of malaria in rural Africa. Apart from the human-to-human epidemic cycle, the natural transmission cycle and involvement of other vertebrate hosts are largely unknown. The disease first came to attention in, arguably, the largest arboviral epidemic ever recorded. After emerging in Uganda in 1959, the epidemic spread to South and West Africa and produced an estimated 2 million cases before the outbreak died out spontaneously 3 years later. The disease apparently had disappeared from East Africa, although the virus was isolated sporadically from mosquitoes until 1996, when only the second ever recognized outbreak appeared, in Uganda.[13] In retrospect, the virus had been circulating at low levels in the area several years before this epidemic occurred. Human and animal infections have been documented serologically in Nigeria, Sierra Leone, Ghana, and Chad. Factors underlying emergence of the virus, its natural reservoir, and the reasons for its disappearance can only be surmised, but exhaustion of susceptible human hosts is a likely explanation for the cessation of epidemic transmission. Clinically, the disease is similar to chikungunya, although lymphadenopathy is more pronounced and mimics, in some cases, the enlarged cervical lymph nodes of sleeping sickness.[2] Virus can be isolated from acute-phase blood samples, or the diagnosis can be confirmed serologically by detection of specific IgM. Personal protective measures against malaria (e.g., use of bed nets) should be effective against acquiring infection.

IGBO-ORA FEVER

Igbo-Ora virus has been determined genetically to be a subtype of o'nyong-nyong virus and, like it, is transmitted by anopheline mosquitoes and (without adaptation) is nonpathogenic in suckling mice.[19] The viral transmission cycle has not been defined. Sporadic cases and small outbreaks have been reported from Igbo-Ora and Ibadan, Nigeria, the Ivory Coast, and the Central African Republic. Based on a single case description, the illness consists of fever, polyarthritis, and pharyngitis.

BARMAH FOREST FEVER

Barmah Forest fever occurs only in Australia, where it has been a sporadic and occasionally hyperendemic infection leading to a polyarthropathy indistinguishable from that of Ross River fever.[6,21,23] The viral transmission cycle seems to share features with that of Ross River virus; however, independent outbreaks have occurred in locations where both viruses are enzootic, thus indicating differences in their transmission cycles or human susceptibility. Seroprevalence to Barmah Forest virus is generally lower. Anecdotal cases complicated by central nervous system signs and glomerulonephritis have been reported.[12,23] Serologic diagnosis is straightforward in most cases, with little cross-reaction between the viruses.

SINDBIS FEVER

Sindbis virus was named after a district north of Cairo, Egypt, where it first was isolated. It is the prototype of an antigenic complex that also includes western equine encephalitis virus and several Sindbis viral subtypes, including Ockelbo and related strains isolated from Scandinavia and the Babanki strain from West Africa. Two genotypes consisting of the South African/Scandinavian strains and the Australian/Asian strains have been defined. The close genetic relationship of the South African and Scandinavian strains indicates a recent introduction to Europe, possibly by a migrating bird.

The virus is distributed widely over four continents, although only sporadic cases have been reported from Asia and Australia. Transmission is endemic and occasionally hyperendemic in Africa and Scandinavia. The virus is transmitted to birds by various species of *Culex* mosquitoes, and humans are infected when virus transmission "spills out" of the enzootic cycle by the intervention of bridging vectors that feed on viremic birds and later on humans.

Endemic infections occur with varying intensity in areas of Africa.[10,17] Seroprevalence rates range from a few percent to 20 percent in some areas. Outbreaks producing hundreds to thousands of cases have been described. Concurrent transmission with West Nile virus, transmitted in the same avian cycle, is common. In South Africa, transmission occurs during the austral summer from December to April. Infections rarely may be acquired during travel.[4]

An endemic focus in Scandinavia (between 60 and 63 degrees latitude in Sweden) was recognized after a series of outbreaks in 1981 led to several hundred cases in Sweden, Norway, Finland, and adjacent areas of western Russia called, locally, Ockelbo fever, Pogosta disease, and Karelian fever.[5,15,18] Seroprevalence is low, around 5 percent. By estimation from seroprevalence rates, 600 to 1200 clinical cases may occur annually in Sweden alone. Most cases occur from July to September in middle-aged adults exposed to forested areas while picking berries or mushrooms or during other recreational activities. Outbreaks seem to peak at 7-year intervals.

Acute arthralgia and rash are the principal features of the illness. They may be preceded by mild fever, headache, and myalgia, but patients may have arthralgia alone, and children may exhibit fever and nonspecific symptoms alone. The joints, especially the ankles, wrists, knees, fingers, and toes and less often the hips, shoulders, elbows, neck, and back, are involved symmetrically. The joints appear swollen, and movement is limited. The Achilles and wrist tendons may be inflamed as well, sometimes causing nerve entrapment and paresthesias. Some patients are confined to bed and unable to walk, but typically, the joint pain and stiffness lead to a lesser degree of discomfort and compromised function. A fine papular and sometimes pruritic rash appears on the trunk and extremities (including the palms and soles) but usually spares the face and head, and after a few days the rash develops a stained appearance and disappears. Lesions on the hands and feet may vesiculate. Joint symptoms resolve within 3 to 4 months in approximately 60 percent of cases; however, in the remainder, symptoms may persist for 3 to 4 years.[11,23] Serologic evidence of infection in patients with central nervous system signs has been reported from China.[7]

The illness is not differentiated easily from West Nile fever, which is transmitted under similar epidemiologic circumstances, and has been mistaken for rubella. The diagnosis is confirmed serologically by detection of specific IgM in acute-phase serum samples. IgM is detectable for months in some patients. The virus can be isolated, but not reliably, from acute-phase capillary blood and from skin lesions. Viral genomic products can be detected in skin biopsy samples.[9]

Treatment is symptomatic. Persons who choose to enter sylvatic transmission foci in the summer should apply mosquito repellents and dress appropriately.

MAYARO FEVER

Infections are highly prevalent in the forested areas of South and Central America, where Mayaro virus is transmitted among *Haemagogus* mosquitoes, marsupials, and small mammals, somewhat analogous to the jungle cycle of yellow fever. Seroprevalence rates increase with age to higher than 50 percent in native populations in some locations. The virus was isolated first from sporadic fever cases on Trinidad and named after the island's Mayaro district.[1] Outbreaks have occurred in Bolivia, Pará (a state in Brazil), and Surinam, principally in men occupationally exposed to forested sites and in residents of adjoining villages, as well as in travelers returning from Central America.[3,20,22,24] Urban epidemic transmission is a hypothetical risk if the virus were introduced to *Aedes aegypti*–infested cities. The virus is placed in the Semliki Forest antigenic complex; its Una subtype causes arthritis in horses.

The illness consists of acute polyarthritis and rash.[23] Joint swelling, pain, and stiffness principally involve the hands, wrists, ankles, toes, elbows, and knees. The hands may be so swollen that they cannot be closed, and joints of the lower extremities may be so painful that patients limp or are unable to walk. Milder cases may occur, however. The morbilliform rash is difficult to distinguish from rubella, with individual or coalescent papular lesions occurring on the trunk and extremities and usually sparing the face. Rash occurs more often in children than in adults. Mild fever, pharyngitis, conjunctivitis, headache, and lymphadenitis occur in some patients. The constitutional symptoms resolve rapidly, but the joint symptoms may wax and wane for several weeks or months. Pneumonitis and renal dysfunction that have been described in some cases may have been caused by concurrent infections. Transient leukopenia usually develops; some patients have had mild elevations in liver enzyme activities and bilirubin concentration. A fatal case of yellow fever was reported in a patient recovering from Mayaro fever.

The illness is differentiated from other tropical febrile illnesses with rash and musculoskeletal pain by the specific involve-

ment of the joints and the sylvatic setting of exposure. Some patients have features closely resembling rubella. Virus can be isolated from acute-phase blood specimens, but laboratory confirmation by IgM serology is sensitive, specific, and more practical. Symptoms are treated with nonsteroidal anti-inflammatory drugs and rest. Repellents should be used when sylvatic-enzootic foci cannot be avoided.

SEMLIKI FOREST VIRAL INFECTION

Febrile illnesses with severe persistent headache have been reported from Central and West Africa, where Semliki Forest virus is transmitted principally by forest *Aedes* mosquitoes.[16] The virus appears to be a common cause of infection in horses as well. The MeTri subtype has been implicated serologically in encephalitis cases in Vietnam; its transmission cycle has not been described. A fatal case of encephalitis in a laboratory worker has been reported.[8]

Flaviviridae

CHAPTER 188

FLAVIVIRUSES

CHAPTER 188a

ST. LOUIS ENCEPHALITIS

Theodore F. Tsai

Until the recent introduction of West Nile virus, St. Louis encephalitis was the most important arboviral infection in the United States because of its leading role as a cause of widespread epidemics. Encephalitis is the principal clinical manifestation, although milder central nervous system (CNS) syndromes do occur, especially in children. The virus is transmitted between birds and *Culex* mosquitoes; humans are incidental hosts.

ETIOLOGIC AGENT

The St. Louis encephalitis (SLE) virus is a member of the family *Flaviviridae* (group B arboviruses) within the antigenic complex that also includes Japanese encephalitis, Murray Valley encephalitis, and West Nile viruses.

Analysis of the E glycoprotein sequences of strains from the United States and Central and South America has identified three

genotypes corresponding to origins in the eastern and western United States and South America. Strains from a more than 60-year interval diverge by less than 10 percent in the total E gene nucleotide sequence, thus indicating a highly constrained viral adaptation to vector and vertebrate hosts. Strains from the three principal genotypes differ in biologic characteristics; epidemic-associated strains from the Ohio and Mississippi river basins and Florida display greater virulence in mice than do strains from the western United States associated with an endemic pattern of transmission.[13,40] Multiple viral genotypes with distinct biologic characteristics may be transmitted in relatively delimited areas within a region as small as a county in some years and more widely in others.[13,28]

ECOLOGY

SLE virus is transmitted in an enzootic cycle among birds and *Culex* mosquitoes in three distinct cycles associated with its four principal vector species: *Culex tarsalis* in the western and central United States, *Culex pipiens* and *Culex quinquefasciatus* in the east central and Atlantic states, and *Culex nigripalpus* in Florida. *Culex salinarius* and *Culex restuans* may have accessory roles in viral amplification and transmission (Fig. 188–1).[31,34,39,64]

In the western United States, *C. tarsalis*, which also is the vector of western equine encephalitis (WEE), serves as both an enzootic and epizootic vector. This species feeds chiefly on birds early in the summer and switches to mammalian hosts, including humans, in midsummer. The transmission cycles of West Nile and SLE viruses overlap in the eastern United States and also with WEE viruses in the West. Sparrows, finches, and other small birds, and especially their nestlings, are the principal amplifying hosts.[37] In the West, human infections result from encounters with the vector along natural and artificial waterways, irrigated farmland, and other breeding sites found chiefly in rural agricultural areas. The recent introduction of West Nile virus into an overlapping transmission cycle may have an effect of modulating SLE virus transmission because West Nile virus–infected birds are more refractory to development of infection and viremia with SLE virus than the reverse.[22]

In the Ohio and Mississippi valleys and on the Gulf Coast, infections are acquired in the peridomestic environment where *C. pipiens* and *C. quinquefasciatus* are, respectively, the enzootic vectors in northern and southern states. The mechanism by which the virus overwinters is not known; however, several observations suggest that the virus could persist locally in a resident vertebrate host (e.g., birds, bats), with resumption of viremia contributing to the reinitiation of local transmission in the spring.[2] Other data suggest that the virus could overwinter by transovarial (vertical) transmission in *C. pipiens* complex mosquitoes or in overwintering adult mosquitoes.[5,42]

The intermittent occurrence of urban SLE outbreaks has been associated with climatic factors, such as an antecedent mild winter, wet spring, and dry hot summer.[39] Snowpack and the resultant availability of irrigation water and an area supportive of mosquito breeding appear to be highly predictive of viral transmission in southern California.[68] In a model of global warming, SLE transmission is predicted to move to northern latitudes and, in existing endemic areas, to become seasonal in the spring and fall.[52] Periods of drought followed by a briefer wet interval have been associated with viral transmission in Florida.[17,59]

EPIDEMIOLOGY

The epidemiologic patterns of SLE virus transmission reflect human interactions with reservoirs of the virus and its principal mosquito vectors.[30,31,39,64] In western states (Fig. 188–2), perennial transmission of WEE and SLE virus leads to an endemic pattern of transmission, but epidemics are limited by a high level of immunity in the population.[53,66] Infections occur chiefly in rural areas in association with the habitat of the vector. Combined WEE-SLE outbreaks have taken place typically in rural agricultural areas and their small towns.[29] Studies in Texas indicated that an overlap of urban and rural cycles contributed to an urban outbreak in Dallas after introduction of the virus to the urban *C. quinquefasciatus* cycle from rural *C. tarsalis*.[25,30,31]

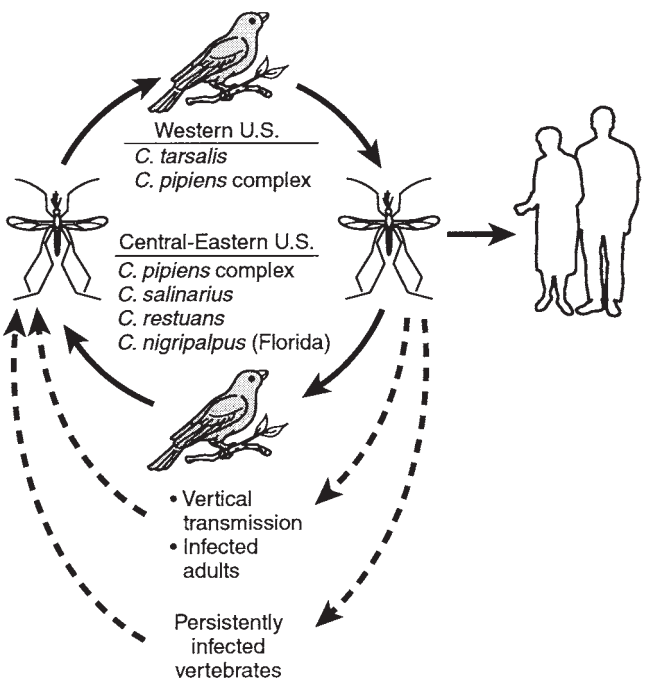

Figure 188–1 Transmission cycles of St. Louis encephalitis virus in North America. *Culex* mosquito vectors differ geographically: *C. tarsalis* in the West, *C. pipiens* and *C. quinquefasciatus* in the Ohio and Mississippi valleys, and *C. nigripalpus* in Florida. Epidemics occur when intense viral transmission in the enzootic cycle "spills over" and results in human infections. The viral overwintering mechanism, possibly in mosquitoes or persistently infected vertebrates, has not been proved *(broken lines)*.

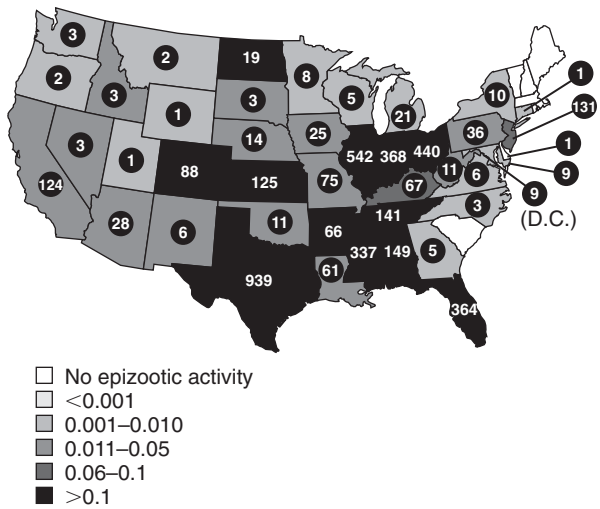

Figure 188–2 Reported cases and crude incidence of St. Louis encephalitis per 10,000 by state, 1964 to 1994.

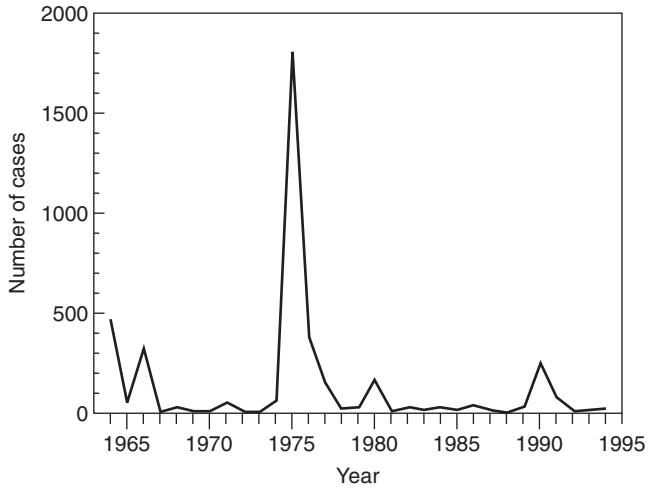

Figure 188–3 Reported St. Louis encephalitis cases by year, United States, 1964 to 1994. A nationwide epidemic in 1975 produced more than 2000 cases.

Epidemics frequently have occurred in urban locations or their peripheries. In 1975, a nationwide epidemic led to outbreaks in Houston, Chicago, Memphis, and Detroit as well as smaller outbreaks in rural towns throughout the South and Midwest (Fig. 188–3). Outbreaks in large urban centers generally have been associated with attack rates of fewer than 40 cases per 100,000 residents and often have clustered in low socioeconomic status areas, the most recent example occurring in Louisiana in 2003.[15,25,27,39,50,64,65,70] In recent urban outbreaks, homelessness and infection with human immunodeficiency virus (HIV) have been the principal risk factors for acquiring SLE.[47,67] However, in the 1933 St. Louis outbreak, attack rates were highest in wealthy areas where open sewers, streams, ponds, and weeds were prevalent; and in other outbreaks, lush vegetation around houses, which provides shelter for *C. nigripalpus*, and closed sewer systems clogged with grass clippings were factors associated with high attack rates in upper socioeconomic areas.[17,38]

In *C. pipiens*– and *C. quinquefasciatus*–borne outbreaks, epidemic attack rates are 1.2 to 3 times higher in females than in males, possibly reflecting increased exposure of females to these peridomestic vectors,[35,39,65] whereas in western *C. tarsalis*–borne outbreaks, attack rates are usually higher in males.[29,53] A similar observation has been made in Florida, where SLE attack rates are highest in working-age males.[18,38,45] *C. nigripalpus* and *C. tarsalis* are most active in twilight hours, and outdoor activity during these periods is associated with a greater risk of exposure.

Most cases occur in late summer or early fall (Fig. 188–4). However, in Florida, epidemics have continued through mid-December.[38,58] In the 1975 nationwide epidemic, outbreaks appeared first in the southeastern states in June, followed by an appearance in northern foci later in the summer and fall.[39]

The most important risk factor for acquiring neuroinvasive SLE is advanced age.[32,39] Age-specific attack rates are lowest in children and rise steadily in adulthood, with attack rates 5 to 40 times higher in persons older than 60 years than in those younger than 10 years. During outbreaks, infections occur uniformly in all age groups, with as many as 300 asymptomatic infections for each clinically apparent case. Therefore, the higher clinical attack rates in the elderly are a function of susceptibility and not exposure.[32,39] The clinical expression of illness is more severe and the case-fatality rate is also highest in the elderly. The biologic basis for this age-related risk probably reflects aging of the immune system as well as comorbidities compromising cerebrovascular integrity.[11] In addition, a secondary peak of increased risk is seen in infants.[65]

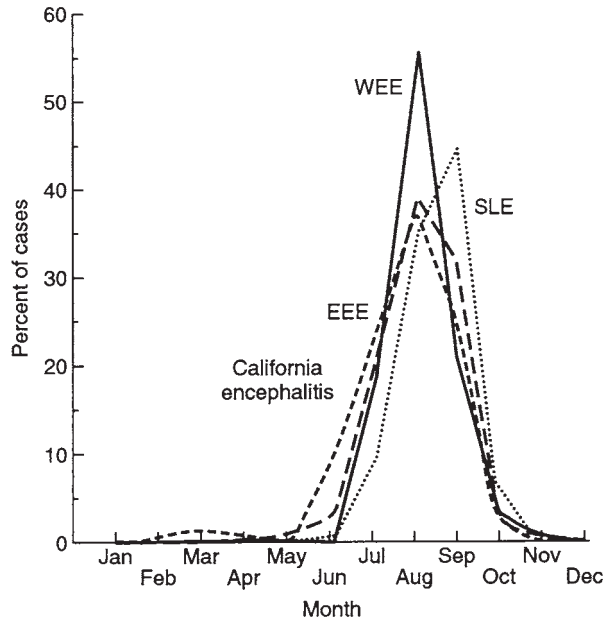

Figure 188–4 Reported arboviral encephalitis by etiology and month of onset, United States, 1972 to 1989.

In the West, where SLE infections are endemic, an increasing level of immunity associated with length of residence leads to an adult population with lower susceptibility (11% in the most recent serosurvey[53]). Consequently, cases often are seen in children and young adults. In a Florida outbreak, immunity to other flaviviruses (mainly from previous dengue infection) also was shown to protect against the acquisition of SLE.[8]

Sporadic SLE cases acquired in tropical America (Jamaica, Surinam, French Guiana, northern Argentina, and possibly Brazil) principally have resulted in mild febrile illnesses. However, an increasing seroprevalence rate with age indicates a higher frequency of endemic infection than is clinically apparent.[1,15,18,61,62]

CLINICAL MANIFESTATIONS

Clinical manifestations range from a mild influenza-like illness to fatal encephalitis.[9,51,56,70] A case definition that stratifies cases into clinical syndromes of encephalitis, aseptic meningitis, and febrile headache[9] (Table 188–1) has proved useful in surveillance (Fig. 188–5). Although children as a group exhibit milder symptoms, encephalitis develops in more than half of confirmed and presumptive pediatric cases, and 95 percent have objective clinical signs of CNS infection.[6,7,70]

SLE cannot be differentiated easily from other viral CNS infections on the basis of clinical features. Photophobia, headache, fever, nausea and vomiting, malaise, and neck stiffness are typical early symptoms. In approximately half of reported cases, an abrupt onset of weakness, incoordination, disturbed sensorium, or other neurologic signs may occur; but equally often, patients have nonspecific symptoms with subtle changes in coordination or mentation during a prodromal phase lasting several days to more than a week. Convulsions have been reported in a third of adult cases.[67]

In addition to fever and signs of meningeal irritation, patients nearly uniformly exhibit alterations in state of consciousness, such as restlessness, confusion, lethargy, delirium, or coma. Neurologic examination usually reveals general weakness, hyperreflexia, and tremulousness, but focal deficits are unusual findings.

TABLE 188–1 Definitions of Clinical Syndromes Caused by St. Louis Encephalitis

Encephalitis* (including meningoencephalitis and encephalomyelitis)
Acute febrile illness (oral temperature ≥37.8° C (≥100° F)
One or more signs in either of the following categories:
Altered level of consciousness (confusion, disorientation, delirium, lethargy, stupor, coma)
Objective signs of neurologic dysfunction (convulsion, cranial nerve palsy, dysarthria, rigidity, paresis, paralysis, abnormal reflexes, tremor)
Aseptic meningitis*
Acute febrile illness
Signs of meningeal irritation (stiff neck with or without Kernig or Brudzinski sign)
No objective signs of neurologic dysfunction
Febrile headache*
Acute febrile illness
Headache (also may have other systemic symptoms, such as nausea or vomiting)
No signs of meningeal irritation or neurologic dysfunction

**Cerebrospinal fluid pleocytosis is present in patients with encephalitis and aseptic meningitis; it also may be found in patients with the syndrome of febrile headache. Modified from Brinker, K. R., and Monath, T. P.: The acute disease.* In *Monath, T. P. (ed.): St. Louis Encephalitis. Washington, DC, American Public Health Association, 1980, pp. 503-534.*

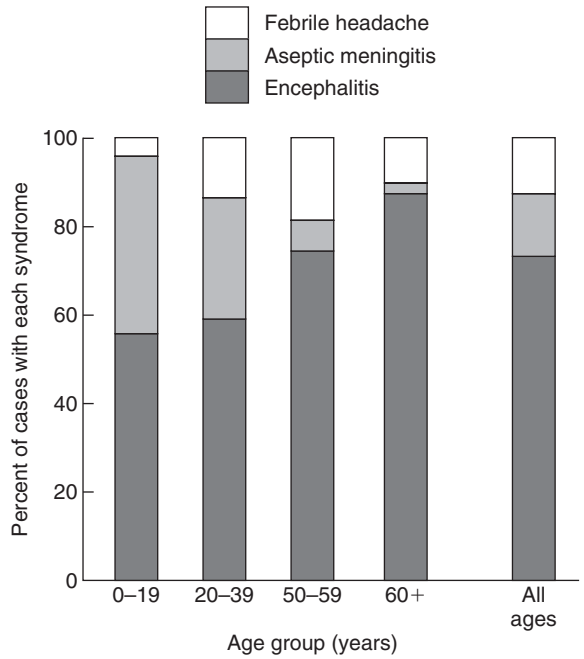

Figure 188–5 Distribution of St. Louis encephalitis cases by clinical syndrome and age. Although mortality rates and disease severity increase with age, most cases in children are clinical encephalitis. *(Data from Zweighaft, R. M., Rasmussen, C., Brolnitsky, O., et al.: St. Louis encephalitis: The Chicago experience. Am. J. Trop. Med. Hyg. 28:114-118, 1979.)*

Cranial nerve palsies, especially those involving nerves VII, IX, and X, occur in 10 to 25 percent of cases.[9] Clinical signs of increased intracranial pressure have been reported in a few patients. Unusual localizing neurologic signs have been described in patients with involvement of the midbrain, thalamus, or brain stem. In a 4-year-old girl, paralysis of upward gaze was associated with a brain stem infection.[28] Ataxia has been observed in a fourth of the cases in children, and opsoclonus has been reported in several cases in young adults.[20,21,67] In a series of 26 children with SLE, convulsions were observed in 8, 6 of whom had focal seizures; however, enteroviruses were isolated concurrently in 5 of the 8 patients.[6,49] A confirmed case has been reported in an infant as young as 19 days.[69] In most cases, the fever abates 4 to 7 days after onset, and clinical improvement is evident early in the second week of illness. Polyradiculopathy and transverse myelitis have been reported.[9,57]

The peripheral leukocyte count is elevated modestly, with a shift to the left in most patients. Cerebrospinal fluid (CSF) usually contains fewer than 100 leukocytes/mm^3, with a median value between 100 and 200. However, in some cases, fewer than 10 cells and occasionally no cells are discovered in the CSF. An increasing ratio of mononuclear to polymorphonuclear cells is observed on successive examinations. CSF protein rarely exceeds 200 mg/dL, and hypoglycorrhachia is unusual.[9]

In one series, elevated serum aldolase levels suggested a myopathic process, and muscle biopsy and electromyography disclosed lower motor neuron dysfunction, possibly from spinal root involvement. Moderate transaminase elevations have been reported in 19 to 48 percent of adult patients. Decreased serum osmolality attributed to inappropriate secretion of antidiuretic hormone was observed in a fourth to a third of cases in two series.[9,10]

Urinary incontinence, frequency, or retention and pyuria or proteinuria have been reported in adult patients, and viral antigen was detected on cells in the urinary sediment by immunofluorescence in one report.[33] Lower motor neuron lesions may have been the mechanism for bladder symptoms in some patients.

Electroencephalographic abnormalities have included focal discharges, including periodic lateralized epileptiform discharges, but more consistently show diffuse generalized slowing.[6,10,67] Computed tomographic scans may be normal, but magnetic resonance images have disclosed T2-weighted hyperintense abnormalities in the substantia nigra, consistent with edema.[12]

PATHOLOGY

Pathologic changes are found predominantly in the midbrain, thalamus, and brain stem but also in the cerebral cortex and cerebellum. Lesions are observed in the spinal cord in some cases.[55,60,63] The leptomeninges are affected to a variable degree with edema, small hemorrhages, and round-cell infiltration.

Perivascular and parenchymal inflammation is prevalent in the brain nuclei and scattered in the white matter of the brain stem and spinal cord and subcortical and deep cerebral areas. Nodular collections of inflammatory cells composed of lymphocytes, microglial cells, and monocytes are found in proximity to or surrounding degenerating neurons characterized by eccentric nuclear displacement, nuclear pyknosis, and cellular contraction. Vascular infiltrations and thrombosis have not been described, as they have in WEE and eastern equine encephalomyelitis. Focal demyelination, which is observed in WEE, has not been characteristic of SLE.

Transmission electron microscopy may provide a pathologic diagnosis on tiny tissue fragments.[16]

PATHOGENESIS

After infection, viral replication occurs locally and in regional lymph nodes. After this eclipse phase, blood-borne (viremic) dissemination ensues, with secondary sites of replication occurring in muscle, endocrine, lymphoreticular, and other tissues and, in less than 1 percent of infections, in the CNS. Vascular endothelial cells may have a role in actively transporting virus from the

capillary lumen to the brain and in supporting secondary viral replication.[19] Conditions that compromise cerebrovascular integrity and disrupt the blood-brain barrier may predispose to neuroinvasion; for example, concurrent CNS cysticercosis may be a risk factor for acquiring Japanese encephalitis, a related flaviviral infection. Although some experimental studies suggest that CNS invasion occurs through the olfactory epithelium, pathologic studies of Japanese encephalitis cases indicate widespread involvement of the brain stem, deep nuclei, and cortex, most consistent with hematogenous infection.

Recovery from flaviviral encephalitis depends on early intrathecal synthesis of antibodies and viral clearance by macrophages. The inflammatory response in related CNS infections consists of helper-inducer T cells and, to a lesser degree, B lymphocytes infiltrating the perivascular space and parenchyma from the blood. Macrophages and activated microglial cells in the perivascular space and parenchyma, respectively, are responsible for viral clearance. Outcome is determined by the comparative rates of viral spread and neuronal infection, the migration of inflammatory cells into the CNS, and the rapidity of the antibody response. Production of interferon is elicited in the brain of human SLE patients, but its role in limiting the spread of virus in the CNS is unclear.[34] The clinical course of SLE in HIV-infected persons has not been significantly different from that of other cases; however, few patients have been studied.

Resistance and susceptibility to some flaviviral infections in mice have been linked to genes associated with permissiveness to infection and the immune response. Environmental factors that influence susceptibility to flaviviral infection in experimental models include stress from cold or isolation, reticuloendothelial cell blockade, and heavy metal intoxication.

DIAGNOSIS

A laboratory diagnosis of SLE usually is made serologically, although virus rarely has been recovered in the acute phase of illness from blood.[30] Virus can be sought from brain and other organs obtained by biopsy or at autopsy by inoculation of Vero cell cultures and suckling mice intracerebrally.[14] However, nucleic acid sequence–based amplification to detect virus in CSF and brain may be more sensitive. Viral antigen has been demonstrated in brain sections and in urinary cell sediment.[33,54]

IgM capture enzyme-linked immunosorbent assay (ELISA) is the preferred serologic screening procedure.[41] Intrathecal production of virus-specific IgM reflects recent infection because virus-specific IgM can be detected in serum or CSF in 75 percent or more of specimens obtained within 4 days of onset. In most patients, IgM levels decline in the convalescent sample and disappear approximately 4 months after onset, although IgM persisted at high titer in a few patients for 6 months.[66] In areas where SLE is endemic, virus-specific IgM carried over from the previous transmission season potentially could lead to an erroneous diagnosis. The indirect immunofluorescent antibody procedure offers a similar capacity for rapid diagnosis; however, it is less sensitive than ELISA, and IgM rheumatoid factor can lead to a false-positive result. Differentiation of antibody responses to West Nile virus, particularly during simultaneous outbreaks of the infections, has been aided by development of a duplex assay.[26,35]

Hemagglutination-inhibition, complement-fixing, and neutralizing antibody assays are used only in reference laboratories but may provide clues to the timing of infection.

The serologic response in a primary flavivirus infection is usually type specific, but repeated infections lead to broad heterologous responses that are often difficult to interpret. Human infections with indigenous flaviviruses (e.g., Rio Bravo, Powassan) other than SLE are rare occurrences; however, in patients with antecedent yellow fever immunization or infection with dengue virus acquired in areas of the United States where dengue was previously endemic (e.g., Texas, Florida) or acquired during travel or residence abroad, a broadly reactive flavivirus antibody response may obfuscate the diagnosis. Recent immigrants with preexisting dengue antibodies are the most common source of flaviviral antibodies in most areas of the United States.

DIFFERENTIAL DIAGNOSIS

In an endemic setting, clinicians should consider SLE principally in the differential diagnosis of patients with aseptic meningitis or acute encephalitis. However, in the context of an outbreak, the diagnostic threshold should be lowered to include patients with less specific findings, especially acute febrile illnesses with headache, and patients who exhibit confusion or are encephalopathic without fever. Increased suspicion of SLE in mildly ill patients should be directed particularly at children and young adults, in whom the infection often is manifested without meningoencephalitis.

The clinical findings of SLE cannot be distinguished easily from those of other CNS infections. However, focal neurologic deficits are less characteristic of SLE and should suggest other diagnoses.[43] The combination of global confusion and tremulousness in SLE may suggest a metabolic encephalopathy, and in elderly patients, the initial manifestations of SLE can overlap the signs and symptoms of a cerebrovascular accident.

West Nile encephalitis and SLE are virtually identical in their clinical findings, their predilection for the elderly, and other epidemiologic features, including late summer seasonality, urban locus of epidemic transmission, and similar *Culex*-bird transmission cycles, such that individual cases cannot be differentiated except by specific laboratory testing.[26,35,36]

The progression of symptoms and localizing signs associated with herpes encephalitis contrasts sharply with the clinical findings in SLE, in which localizing signs are less usual. Enteroviral infections have an overlapping summer seasonality but often are associated with clustering of illnesses in families and other epidemiologic clues of person-to-person spread. Skin eruptions, respiratory symptoms, pericarditis, myocarditis, and conjunctivitis are helpful distinguishing characteristics. Concurrent enterovirus infection and SLE may be associated with an increased risk of convulsions during the acute phase of illness.[6,49] Enteroviral infections can be confirmed by detecting viral genomic sequences in CSF by polymerase chain reaction, by IgM capture ELISA, or by recovery of virus from stool or CSF. Primary HIV, human herpesvirus 6, and mumps virus infections are other common infections that should be entertained in the differential diagnosis. A third of patients with mumps encephalitis do not have associated parotid gland swelling.

Adenoviral encephalitis is a rare infection in children, more severe than SLE, and sometimes associated with hepatic and other extraneural sites of infection. The presence of lymphoreticular involvement and typical hematologic features should suggest the clinical diagnosis of Epstein-Barr virus infection.

Partially treated bacterial meningitis and parameningeal pyogenic infections are the principal bacterial causes to exclude. Cat-scratch fever can be manifested as fever and encephalopathy mimicking arboviral encephalitis.[46] Convulsions associated with *Shigella* enteritis and ataxia associated with typhoid fever potentially could be interpreted as a primary CNS infection. Tuberculous meningitis is typically a subacute illness; evidence of active extraneural sites of infection should be sought. A low CSF glucose level is a clue to the diagnosis.

In urban areas or where parental occupational exposure may occur, lead intoxication remains an important potential cause of encephalopathy in summer. Hyperthermia associated with sus-

tained exposure to elevated environmental temperature likewise may lead to encephalopathy with convulsions, signs of raised intracranial pressure, and evidence of hepatic dysfunction. This constellation of symptoms also may suggest Reye syndrome. However, Reye syndrome typically occurs in the winter and spring after a respiratory viral infection and is characterized by hypoglycemia and an elevated blood ammonia level. Patients with salicylism exhibit similar clinical findings, but a history of salicylate ingestion, an elevated anion gap early in the course of illness, and an elevated blood salicylate level should suggest that diagnosis.

TREATMENT

Supportive therapy, as outlined in the earlier sections, should be aimed at maintaining cardiorespiratory function and fluid and electrolyte balance, controlling convulsions, and monitoring and maintaining normal intracranial pressure.[36] No specific antiviral therapy is available.

PROGNOSIS

The principal risk factor for a fatal outcome is advanced age (see Fig. 188–5).[9,30,32,39,65,66] Among all cases reported to the Centers for Disease Control and Prevention from 1955 to 1971, 8 percent died, but the age-specific mortality rate in persons 60 years or older was 19.5 percent. Fatality rates as high as 38 to 80 percent were recorded in the 1933 St. Louis outbreak in patients who were 60 to 89 years of age. Mortality rates in children have ranged from 2 to 5 percent, with the highest risk in children younger than 5 years. The overall case-fatality rate in an outbreak in Hermosillo, Sonora (involving principally children), was 20 percent.[15] The high fatality rate in this instance is anomalous because fatality rates are usually lower in *C. tarsalis*–borne SLE outbreaks in the West. The role of neurocysticercosis as a risk factor for acquiring SLE should be examined in view of its potential involvement as a risk factor for Japanese encephalitis (see the subchapter Japanese Encephalitis).

In adults, coma, a low CSF leukocyte count (<100 cells/mm^3), and underlying hypertensive vascular disease have been factors associated with a fatal outcome.[11] Risk factors for mortality in children have not been described.

Recovery from SLE usually is complete or associated with soft sequelae such as emotional disturbances, dizziness, headache, memory impairment, and tremor.[4,23,24,44] In one study of 193 cases, 25 percent of children who were 1 to 4 years of age at the time of infection had serious neurologic sequelae, the highest rate of any age group.[48] The incidence of sequelae was 10 percent in children aged 5 to 9 years. Children who were younger than 1 year at the time of infection appeared to be spared any serious sequelae. Deficits in motor and intellectual function were reported in some cases. Convulsions were not a significant residual abnormality. The same cohort monitored at intervals of 6 months to 14 years had no perceptible residual differences in intelligence quotient compared with the normal population. In case reports, persistent ataxia of the extremities and trunk and dysarthria were reported as residual findings in a 4-year-old patient and a case of postinfectious encephalomyelitis after a mild illness.[26,58]

No deleterious effects of SLE on the outcome of pregnancy have been reported. However, infection with Japanese encephalitis virus in the second trimester resulted in transplacental viral transmission and abortion, whereas infection in the third trimester was not associated with fetal damage. In experimentally infected mice, vertical transmission led to learning deficits in congenitally infected pups.[3]

PREVENTION

Preventive public health efforts have focused on surveillance of viral activity in the enzootic cycle to predict epidemic activity. In many east central states, weekly serologic surveys of captured wild birds and sentinel chickens are conducted to detect rising seroprevalence rates that reflect viral amplification[42] and an increased risk for human infection. The abundance of female vector mosquitoes and increased viral infection rates in vectors also have been correlated with a risk of epidemic transmission.[68]

When viral activity is elevated, ground and aerial application of insecticides is aimed at reducing the infected adult vector population. If insecticides are applied early enough, viral amplification potentially can be attenuated and epidemic transmission aborted.

Avoidance of outdoor activity during the twilight and evening hours, use of repellents appropriately, and repair of screens or installation of air conditioners in residences are simple but effective measures that reduce exposure to adult mosquitoes. Improvement of drainage and removal of containers that could serve as mosquito breeding sites are important steps in preventing the disease.

A vaccine is not available, nor is vaccination of the general public a realistic preventive measure because of low attack rates and the intermittent and focal nature of outbreaks. However, if a vaccine or chemoprophylactic were available, selective administration to a targeted population, particularly the elderly, might be appropriate in an outbreak. A West Nile virus vaccine under development potentially could provide cross-protection against SLE. Passive immunotherapy and short interfering RNA molecules are under investigation as therapeutic modalities.

CHAPTER **188b**

West Nile Virus

José R. Romero

HISTORICAL BACKGROUND

West Nile virus (WNV) was isolated first from the blood of a 37-year-old African woman in December 1937 in Omongo, West Nile district, in the Northern Province of Uganda while researchers were attempting to isolate yellow fever virus.[171] In the same report, these investigators demonstrated that sera from patients recovering from Japanese encephalitis virus could neutralize WNV. Shortly thereafter, this finding was confirmed and expanded to document that WNV was antigenically related not

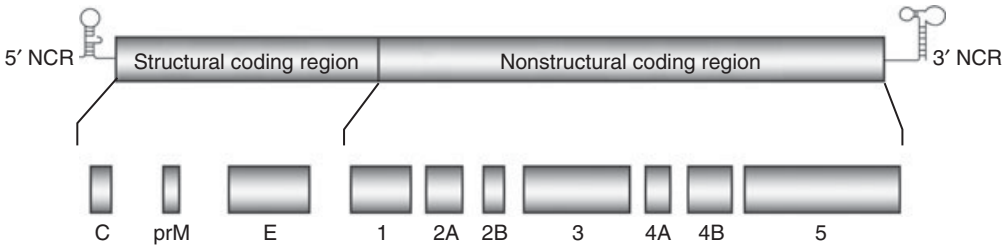

Figure 188–6 Organization and protein products of the West Nile genome.

only to Japanese encephalitis virus but also to St. Louis encephalitis virus.[172]

In 1950, Melnick and coworkers[118] isolated WNV from the blood of three healthy children in Egypt, thereby demonstrating that WNV was not confined to a single geographic location. Before 1999, WNV was known to be endemic to Africa, the Middle East, Europe, west and central Asia, and Oceania. With its incursion into the United States in 1999[6,131] and subsequent spread throughout North America, Central America, and the Caribbean,[45,97,151] WNV has established a worldwide distribution.

The first reports of WNV as a cause of outbreaks of febrile illness came from Israel in the early 1950s and ultimately led to its being associated with a clinical entity coined West Nile fever.[13,63] Studies performed by Taylor and colleagues[180] at the U.S. Naval Medical Research Unit in Egypt in the early 1950s provided information about the epidemiology of WNV infection and clinical picture of West Nile fever in children. This information was augmented by the seminal report by Marberg and colleagues[113] describing the clinical characteristics of serologically and virologically confirmed cases of West Nile fever among adolescent and young adult military personnel during a 1953 epidemic in Israel. Sporadic reports of central nervous system (CNS) complications associated with WNV infection followed closely after the early clinical descriptions of West Nile fever and pointed to the neuropathogenic potential of WNV.[12,72,150,175,176,178] Further characterization of West Nile neuroinvasive disease followed as additional outbreaks of WNV were reported.

During the past half century, outbreaks of WNV have occurred worldwide. Notable human outbreaks include Israel, 1951-1954, 1957, and 2000; France, 1962; South Africa, 1974; Algeria, 1994; Tunisia, 1997; Romania, 1996; and Russia, 1999.* Two of the largest epidemics recorded occurred in South Africa in 1974 and the United States in 2003. During the former, an estimated 18,000 cases of West Nile fever occurred.[45,72]

After the introduction of WNV into the North American continent in 1999, cases of West Nile fever and neuroinvasive disease remained at relatively low levels through 2001 and exploded in 2002 and 2003 when 4156 and 9862 cases, respectively, of WNV infection were reported to the Centers for Disease Control and Prevention (CDC).[75] The 2002 epidemic of WNV in the United States resulted in the largest epidemic of neuroinvasive West Nile disease ever recorded, with nearly 3000 cases reported.[137] Currently, WNV has superseded all autochthonous North American arboviruses as the single most important cause of arboviral disease in the United States.[36] The magnitude of the number of WNV infections is exemplified by an estimate, based on 2003 national blood donor screening data for WNV infection, that 735,000 cases of WNV infection occurred that year.[20]

*See references 13, 39, 45, 48, 54, 63, 72, 105, 141, 146, 181.

VIROLOGY

West Nile virus is a member of the *Flaviviridae* family of RNA viruses.[84,109] The viral family is composed of three genera: *Flavivirus*, *Pestivirus*, and *Hepacivirus*. WNV is a member of the *Flavivirus* genus and falls within the Japanese encephalitis virus serocomplex along with Cacipacore, Japanese encephalitis, Kunjin, Murray Valley encephalitis, St. Louis encephalitis, Usutu, and Yaoundé viruses. Kunjin virus, which is endemic to Australia and Asia, is a subtype of WNV. Members within the Japanese encephalitis virus serogroup are antigenically related to each other.

WNV is a spherical, enveloped virus measuring approximately 50 nm in diameter. The viral envelope is derived from the lipid bilayer of the host cell and surrounds the approximately 25-nm nucleocapsid core of the virion. The host cell–derived envelope is modified by the insertion of two viral proteins: E (envelop protein) and M (membrane protein).

The genome of WNV is a single-stranded, positive-sense (messenger sense) RNA molecule measuring 11,029 nucleotides in length (Fig. 188–6).[103,109] Two noncoding regions (5′ and 3′) flank the 10,302-nucleotide viral single open-reading frame and measure 96 and 631 nucleotides, respectively. The open-reading frame is organized as 5′-C-prM-E-NS1-NS2A-NS3-NS4A-NS4B-NS5-3′ and is transcribed into a single polyprotein of 3434 amino acids.[103,109] The N-terminal portion of the polyprotein consists of viral structural proteins, whereas the remainder of the protein contains the nonstructural (NS) proteins. The viral polyprotein is co- and post-translationally processed by host proteases and the viral protease NS2B-NS3 to yield three structural (E, prM, C) and seven NS (1, 2A, 2B, 3, 4A, 4B, and 5) proteins.

Viral attachment, membrane fusion, and viral assembly are mediated by the E protein. The search for the cellular receptors of WNV has identified the integrin $\alpha_v\beta_3$ and the lectins DC-SIGNR and DC-SIGN as capable of binding WNV in vitro.[40,48] However, whether they are physiologically relevant in vivo remains to be documented. Once bound to its receptor, WNV gains entry into the cell through endocytosis; after a pH-dependent change occurs in the conformation of the E protein, the viral and host endosomal membranes fuse. The viral nucleocapsid then is released into the cytoplasm of the cell. Viral replication is thought to occur on the membrane of the rough endoplasmic reticulum. The C or capsid protein binds to the viral RNA genome and forms a ribonucleoprotein complex required for packaging of the genome.[127] The immature virions are assembled, accumulate in vesicles, and bud into the endoplasmic reticulum. The immature virions are processed as they traverse the secretory pathway. Immature viral particles contain a premembrane (prM) protein that blocks premature viral fusion by the E protein. The prM protein is cleaved to the M protein by the trans-Golgi protein furin during the egress of the mature virion from the secretory pathway. Virions are transported to the cell membrane in vesicles and ultimately released through exocytosis.

The NS proteins regulate viral transcription and translation as well as attenuate host immune responses to WNV.[109,159] The NS1 protein serves as a cofactor for the viral replicase. Host interferon responses are inhibited by NS2A. This protein also may play a role in viral assembly. The NS3 protein is a protease and requires NS2B as a cofactor for activity. It also possesses NTPase and helicase activities. NS proteins 4A and B modulate interferon signaling. The NS5 functions as the RNA-dependent RNA polymerase and a methyltransferase.

Phylogenetic analysis of WNV isolates from around the world has demonstrated the existence of two lineages.[14,103,160] Strains that comprise lineage 2 are found exclusively in sub-Saharan Africa and Madagascar. In contrast, lineage 1 strains are found in geographically dispersed regions around the world and can be subdivided into three clades.[104] WNV strains from Africa, Europe, the United States, the Middle East, and Russia cluster within clade 1a. Kunjin virus and India WNV strains form clades 1b and 1c, respectively.

A correlation appears to exist between genotype/lineage and virulence phenotype.[104] Viruses from lineage 1 have been associated with outbreaks of West Nile neuroinvasive disease, whereas those from lineage 2 appear to cause only asymptomatic infection or West Nile fever. Neurovirulence data by use of a murine model corroborate this finding, indicating that lineage 1 strains of WNV are more neuroinvasive than are those of lineage 2.[10]

WNV strains isolated from birds and a human during the 1999 outbreak in the United States and a WNV strain isolated in 1998 from a dead goose in Israel have been shown to be closely related.[103] Phylogenetic analysis of the prM protein and E glycoprotein has demonstrated that they share greater than 99.8 percent nucleotide homology, indicating that the current North American strain of WNV almost certainly originated in the Middle East.

EPIDEMIOLOGY

In temperate climates, WNV infections occur seasonally during the summer months, coinciding with periods of increased activity of its mosquito vectors. The peak period of activity for transmission of WNV to humans in the United States, Europe, and the Mediterranean basin generally is from July through October.[137,192] However, as WNV has spread southward in the United States, the period of reported transmissions has increased, with human cases being reported as early as April and as late as December.[75] Year-round transmission may be possible in tropical climates.[145]

Infections of humans (i.e., epizootic infection) by WNV are incidental to its enzootic life cycle and, with rare exception, result in a "dead-end" infection without subsequent human-to-human transmission. Epizootic transmission of WNV occurs when sufficient numbers of mosquitoes that bite both birds and humans become infected to allow transmission to humans. Important risk factors for the acquisition of human WNV infection are the amount of time spent outdoors when mosquitoes are biting, the presence of dead birds in the neighborhood, the exposure to mosquitoes, and the vegetation cover suitable for harboring potentially infected adult mosquitoes.[19,71,125]

The enzootic cycle of the WNV requires replicative phases in its mosquito vectors and avian (or other) hosts. After WNV-infected blood meal has been ingested, the virus penetrates the mosquito's gut.[62] Viral replication then takes place in the salivary glands and nervous system of the mosquito. In mosquito tissues, WNV is nonlytic and results in persistent infection for the lifetime of the vector.

Mosquitoes play an important role in trans-generational and trans-seasonal maintenance of the WNV enzootic cycle. Female *Culex pipiens* mosquitoes have been documented to transmit WNV vertically to F1 progeny.[51] In addition, WNV can survive the winter by overwintering in hibernating female mosquitoes, as documented with *C. pipiens*, which thereby serve as a source of WNV to initiate the enzootic cycle the following spring.[130]

Although numerous mosquito species have been found to be infected with WNV, ornithophilic members in the *Culex* genus are the principal vectors for the transmission of WNV around the world. These include *C. pipens* and *Culex quinquefasciatus* in Europe, *Culex perexiguus* in North Africa and the Middle East, *Culex univittatus* in sub-Saharan Africa, *Culex tritaeniorhynchus* in south Asia, *Culex annulirostris* in Australia, and species of the *Culex vishnu* complex in India.[96]

Although WNV has been found in 59 of the 173 North American species of mosquitoes, only about a half-dozen are considered to be important vectors for transmission to humans.[75] As in other regions of the world, *Culex* spp. of mosquitoes are important vectors[75]; *C. pipens* (the northern house mosquito) and *C. quinquefasciatus* (the southern house mosquito) are considered to be the predominant vectors in the northeast and southern/southwestern United States, respectively. *Culex tarsalis* is a predominant vector west of the Mississippi River. *Culex nigripalpus* and *Culex salinarius* may be important vectors in regions where they are abundant. Last, *Culex restuans* also has been found to be a significant contributor to WNV-positive mosquito pools. Although arthropods can be infected with WNV, they are not thought to be important in transmission of WNV.

Birds are thought to be the principal amplifying hosts for WNV. Nearly 200 species of North American birds are susceptible to infection by WNV.[96] However, only birds capable of sustaining high-titer viremia for significant periods are capable of infecting the mosquitoes that feed on them. In vivo experiments using *C. tarsalis* have shown that 74 to 100 percent of mosquitoes consuming blood meals containing $10^{7.1}$ plaque-forming units (PFU) per milliliter become infected. In contrast, 36 percent or fewer mosquitoes become infected after the consumption of blood containing $10^{4.9}$ PFU/mL.[65] As a point of comparison, on the basis of blood tested of viremic blood donors, the maximum viral load in human blood is approximately $10^{3.2}$ PFU/mL.[75] This finding would indicate that humans fail to produce blood viral titers of sufficient magnitude to infect mosquitoes. Most mammals also fail to have sufficient levels of viremia to permit transmission to mosquitoes.

Song birds (Passeriformes), shorebirds (Charadriiformes), owls (Stringiformes), and hawks (Falconiformes) develop adequate viremia to infect mosquitoes feeding on them (pigeons and ducks do not). House finches, house sparrows, common grackles, and, in particular, corvids such as crows, magpies, and jays have been shown to be highly infectious to mosquitoes.[75,96] In addition, they have a high mortality rate after acquiring infection with WNV. Die-offs of avian species serve as epidemiologic markers for WNV activity in the environment.[67,126]

Unlike mammals, some amphibians appear to be capable of sustaining levels of viremia that potentially could be sufficient to infect mosquitoes and may serve as competent reservoirs for their infection. In the United States, alligators *(Alligator mississippiensis)* infected with WNV produced sufficient viral loads to infect mosquitoes.[95] In Russia, the lake frog *(Rana ridibunda)* may be a host for WNV.[75,98]

In areas where WNV traditionally has been endemic, seroprevalence studies document that most individuals acquire WNV infection during childhood. Such early acquisition of WNV infection results in large portions of the adult population with serologic evidence of immunity to WNV and may attenuate the occurrence of large outbreaks of WNV infection. Studies conducted in the 1950s in Egypt documented that a rapid rise in the presence of antibodies occurred in children aged 1 to 4 years such that by the time children were 4 years of age, 50 to 80 percent

had neutralizing or complement-fixing antibodies to WNV.[118,180] Similar patterns of acquisition of WNV-specific antibodies have been documented in the Sudan, Central Africa, and Nigeria.[131,173,180] Interestingly, more recent studies conducted in Egypt indicate that the seroprevalence rates in children and young adults, although still high, may be decreasing.[42,44] One can speculate that mosquito abatement programs and, possibly, changes in lifestyle have resulted in decreasing numbers of infections in children.

Seroepidemiologic studies conducted in areas where recently introduced WNV has resulted in large outbreaks of West Nile fever and neuroinvasive disease document low seroprevalence rates among the general population.[112,125,128,181] Investigation of the seroprevalence of WNV infection after an outbreak of WNV in Romania following the first major WNV epidemic in Europe found it to be 4.6 percent.[181] After the initial North American outbreak of West Nile encephalitis in New York in 1999, the seroprevalence at the outbreak's epicenter was found to be approximately 2.6 percent.[125] Overall, the reported post-epidemic seroprevalence, ranging from 2.6 to 14 percent in regions where WNV has been introduced recently, is too low to protect against future large-scale outbreaks of WNV disease.[45,128]

Unfortunately, detailed seroepidemiologic information about rates of WNV infection specific to children in the United States is scarce. After an outbreak of WNV in northeast Ohio, the county-wide seroprevalence rate was found to be 1.9 percent. However, among children younger than 17 years, the seroprevalence rate was nearly 3.5 times higher: 6.4 percent.[112]

Multiple novel, non–vector-borne modes of WNV transmission were identified during the North American epidemics. Transfusion-associated transmission of WNV was reported for the first time in 2002, when 23 cases were confirmed.[121,144] Four of the cases occurred in children younger than 18 years. Three of the children had immunocompromising conditions (acute myeloid leukemia, rhabdomyosarcoma, stem-cell transplant). The three children received platelet infusions and developed West Nile meningoencephalitis; all survived. The sole adolescent was a victim of a motor vehicle accident and received a transfusion of red blood cells. This patient subsequently became an organ donor and was implicated in four cases of transplantation-associated transmission of WNV.[27,85]

As a result of transfusion-associated WNV transmission, national screening of blood donations for the presence of WNV by nucleic acid amplification–based testing was initiated in June of 2003. From 2003 to 2005, a total of 1425 presumptive viremic donors from 41 states were reported to the CDC and their donations removed from the donor pool. Although active screening was performed, six probable or confirmed cases of transfusion-acquired WNV infection occurred in 2003, one in 2004, and two in 2006; they most likely were attributable to donations containing very low levels of virus.[34,37,121]

In addition to transmission that occurs through transfusion of blood products, seven cases of WNV transmission through organ transplantation have been documented.[27,35,85] The risk of acquiring West Nile neuroinvasive disease is approximately 40 times greater in organ transplant recipients than in the general population.[99] Unlike blood donations, organ donations currently are not required to be screened by nucleic acid amplification for WNV infection, nor is it performed routinely.

Confirmed or suspected maternal-fetal and maternal-infant vertical transmission of WNV has been reported.[3,29,30,74,136] In the most rigorously documented case,[3,30,74] confirmed maternal WNV infection occurred during the 27th week of gestation. The infant, delivered at 38 weeks of gestation, was found to have bilateral chorioretinitis, severe bilateral white matter loss in the temporal and occipital lobes, and tissue destruction in a temporal lobe. The presence of WNV-specific IgM was confirmed in cord blood, infant serum, and cerebrospinal fluid (CSF), although the CSF contained red blood cells. Maternal serum also contained WNV-specific IgM at the time of birth. The WNV genome was detected in the umbilical cord tissue and placenta by reverse transcription–polymerase chain reaction (RT-PCR). No WNV genome was detected in the infant's CSF.

Evaluation of 71 pregnancies reported to the CDC's WNV pregnancy registry failed to identify any confirmed cases of congenital WNV infection.[136] However, three infants who lacked evidence of anti-WNV IgM in cord blood or infant serum at the time of delivery subsequently were found to have serologic evidence of infection that may have been acquired congenitally. A breast-fed term infant, whose mother had onset of West Nile neuroinvasive disease 6 days before delivery, developed West Nile meningitis at 10 days of age. Another breast-fed infant, born to a woman with acute West Nile fever at the time of delivery, was noted to have a transient rash at birth. No serum or cord blood was available for testing. However, at 1 month of age, the infant was found to have WNV-specific IgM antibodies. In the final case, the infant's mother had a febrile illness 3 weeks before delivery. The infant appeared to be healthy at birth but at 7 days of age developed seizures. Evaluation of the infant at 17 days of age found lissencephaly and West Nile encephalitis with WNV-specific IgM antibodies detectable in the CSF. Because two of the infants were breast-fed, the possibility exists that WNV was transmitted in that manner. In addition, in none of the cases could the possibility of mosquito-borne transmission of WNV be excluded conclusively. This report also failed to link WNV infection during pregnancy with an increased frequency of spontaneous abortion, premature birth, or low birth weight.

WNV has been detected in the breast milk of infected women.[29,136] At least one case of possible transmission of WNV associated with breast-feeding has been reported.[29,73,136] The mother received packed red blood cell transfusions on the first and second postpartum days. Ten days post partum, the mother developed headache followed by fever. On evaluation, she was found to have CSF pleocytosis and the presence of WNV-specific IgM in the CSF. The infant was breast-fed for the first 17 days of life, and although the infant was clinically asymptomatic, a serum sample obtained at 25 days of age was found to have WNV-specific IgM. At this time, the risk of WNV transmission from mother to infant through breast-feeding is unknown. The current state of knowledge about transmission of WNV through breast milk does not warrant a change in breast-feeding recommendations.

Additional nontraditional modes of WNV transmission continue to be identified. Confirmed or possible transmission of WNV has been reported through laboratory exposure, percutaneous injury, aerosol inhalation, and dialysis.[31-33,70]

With the exceptions of Alaska and Hawaii, every state in the United States has reported human, mosquito, avian, or animal WNV activity (Fig. 188–7). From 1999 to 2005, 19,706 cases of WNV infection were reported to the CDC (Table 188–2). Neuroinvasive syndromes accounted for 8384 cases (42.5%), WNV fever was reported in 10,876 cases (55.2%), and 443 cases of unspecified disease accounted for the remainder. During the same period, 785 deaths (4%) were reported.

Epidemiologic and clinical data about WNV infections specific to children are beginning to emerge.[73-75] For the same time period, 1177 cases (6%) of WNV infection were reported in children and adolescents younger than 19 years.[73] Three deaths were reported in children aged 1 month, 14 years, and 15 years. Two of the children who died of neuroinvasive disease had underlying medical conditions: one had an immunodeficiency and the other lissencephaly.[75,135]

In adults, encephalitis and meningoencephalitis account for approximately 60 percent of West Nile neuroinvasive syndromes.[6,22,39,94,131,136,165,180,188] Meningitis has been reported to occur in approximately 15 to 40 percent of those with West Nile

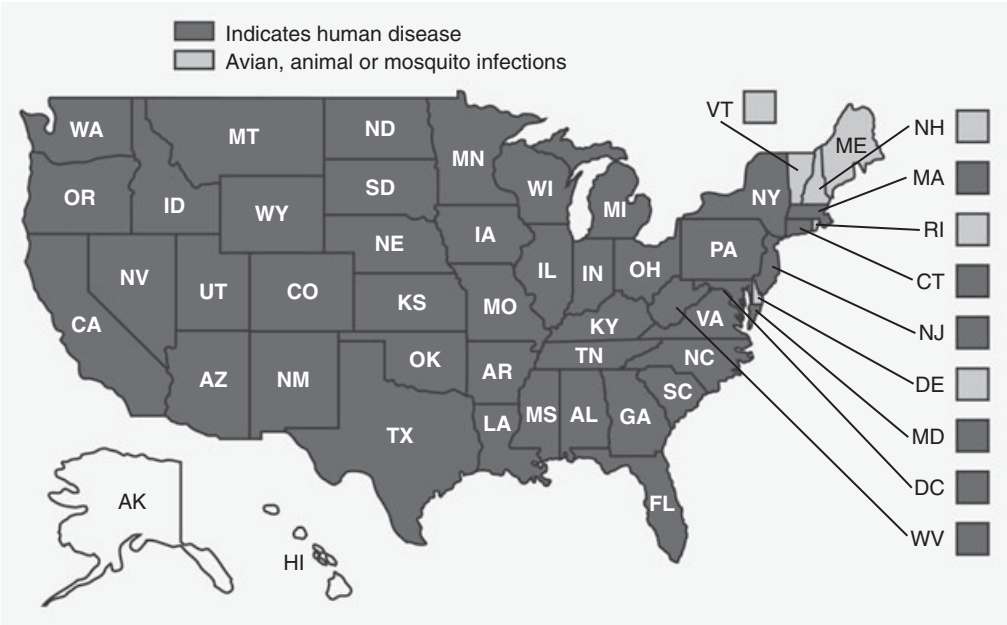

Figure 188–7 West Nile virus activity in the United States in 2006.

TABLE 188–2 West Nile Virus Infections in the United States, 1999-2005

Year	Deaths	Total Cases	Meningitis-Encephalitis	Fever	Unspecified

neuroinvasive disease. WNV also has been linked to the development of acute flaccid paralysis syndrome, which occurs in approximately 10 percent of cases of neuroinvasive disease.[28,86,94,107,131,162-164]

The distribution of WNV syndromes among children has been difficult to define because of underreporting of pediatric cases of West Nile infection.[73] From 2002 through 2004, 1051 cases of WNV infections in children younger than 19 years were reported to the CDC.[75] WNV neuroinvasive disease was reported in 30.2 percent (317) of cases. Approximately a third of these incidents occurred in children younger than 10 years. The distribution of disease caused by WNV was defined in a subset of 150 cases of patients younger than 19 years reported in 2002.[74] Twenty-seven percent of cases were classified as West Nile fever, 70 percent had neuroinvasive disease, and 3 percent were classified as unknown illness. Meningitis, encephalitis, and unspecified neuroinvasive disease accounted for 38, 28, and 34.3 percent, respectively, of the definable cases of CNS disease. Thirty-seven percent (55 cases) of children in this cohort were younger than 10 years.[74] More recently, the reported disease distribution among 261 cases of WNV infections in children during 2004 and 2005 was 50 cases of encephalitis (19%), 54 cases of meningitis (21%), 136 cases of West Nile fever (52%), and 21 cases (8%) of unknown or other clinical presentations.[73] Flaccid paralysis was reported in five children of this cohort.

Taken together, the available information about the distribution of West Nile neuroinvasive disease in children indicates that in individuals younger than 19 years, the predominant West Nile neuroinvasive syndrome appears to be meningitis.[166] In addition, acute flaccid paralysis developing as a result of WNV infection appears to occur less frequently in children than in adults.[173]

PATHOGENESIS[160]

The pathogenesis of West Nile encephalitis has been explored in animal model systems.[50,53,153,189] Subcutaneous inoculation of WNV is thought to result in WNV infection and replication in Langerhans dendritic cells.[21] Under control of interleukin-1β, activated Langerhans cells migrate to regional lymph nodes and result in a primary viremia that develops after the virus reaches the systemic circulation through the thoracic duct. In mice, peak viremia occurs by the second day after infection and clears by the sixth day. Virus subsequently can be detected in spleen, brain, and spinal cord. Because of the simultaneous appearance of virus in the brain and the spinal cord, a hematogenous route for the CNS infection has been postulated. Similar to human infections, CNS infection in mice and hamsters results in infection of the neurons of the brain stem and the spinal cord, resulting in meningoencephalitis and an acute flaccid paralysis–like syndrome similar to that seen in humans. Several mechanisms have been postulated for the neuronal injury seen in WNV infection[168]: viral injury to infected neurons through apoptosis; targeting of infected

neurons by cytotoxic T lymphocytes; and neuronal death as a result of bystander injury.

The mechanism by which WNV gains access to the CNS is not fully understood. Recently, WNV binding to Toll-like 3 receptor has been shown to result in Toll-like 3 receptor–dependent inflammatory response with resultant production of tumor necrosis factor–α and interleukin-6.[184] Tumor necrosis factor–α may modulate the ability of WNV to invade the CNS, inducing breakdown of the blood-brain barrier. Additional postulated mechanisms through which WNV may breach the blood-brain barrier include infection or passive transport through the choroid plexus epithelial cells or the endothelium, infection of olfactory neurons, transport within infected immune cells that traffic into the CNS (Trojan horse mechanism), and retrograde axonal transport in infected peripheral neurons.[159]

Cessation of the viremia occurs by the sixth day in mice and is coincident with the appearance of type-specific antibody response. Viral clearance from all tissues is complete by 2 to 3 weeks after infection. Humoral immunity is essential to the recovery from WNV infection as demonstrated by the uniform death of B cell–deficient mice.[50] B cell–deficient mice could be protected from lethal infection by the passive transfer of serum from infected and immune wild-type mice. γδ T cells that secrete interferon-γ may control viral replication through direct antiviral mechanisms and contribute to adaptive immune responses.[159]

Although clearance of WNV from the CNS and other tissues depends primarily on humoral immunity, cytotoxic T cells also play a role.[169,185] Increased mortality rates in association with higher and sustained WNV loads in the CNS and spleen were observed in mice deficient in $CD8^+$ T cells or class I major histocompatibility complex molecules. In addition, control of WNV infection in the CNS requires interferon-α/β. Interferon-α/β also may help increase the survival of neurons. Last, chemokines such as CXCL10 and CCL5 and their ligands CXCR3 and CCR5 aid in the recruitment of $CD4^+$ and $CD8^+$ T cells and monocytes to the CNS.[159]

CLINICAL MANIFESTATIONS

Most WNV infections in children and adults result in subclinical disease. In general, WNV infection in children more frequently results in asymptomatic infection or milder disease than that in adults.[39,63,131,166,179] A recent report documented that children were 4.5 times more likely to become infected with WNV during an epidemic but 110 times less likely to develop neuroinvasive disease.[112] In another report, the estimated incidence of neuroinvasive disease was 1.4/100,000 in children aged 5 to 17 years compared with 14.3/100,000 in individuals aged 18 years or older.[101] In adults, multiple reports have identified increasing age as the single most significant risk factor for the development of neuroinvasive disease as well as adverse outcome.[131,145] The incidence of severe neurologic disease is 10 times higher in individuals aged 50 to 59 years and 43 times higher in persons aged 80 years or older compared with those 20 years of age or younger. Chronic illnesses, such as hypertension, diabetes mellitus, cardiovascular disease, and alcohol abuse, have also been identified as risk factors for severe disease.[15,129,131,145] These factors have not been linked to an increased risk for the development of severe disease in children.

In the early 1950s, therapeutic inoculation of WNV into patients with malignant neoplasms in advanced stages resulted in a high incidence of development of encephalitis among recipients and pointed to the role of immunosuppression as a risk factor for West Nile neuroinvasive disease.[176] This finding subsequently was substantiated by the recognition that transplant recipients were 40 times more likely to develop West Nile neuroinvasive disease.[85,99,100,154] Reports of West Nile neuroinvasive disease in immunocompromised children are consistent with immunosuppression as a risk factor in this population also.[4,56,79,154,177] Reports also have indicated that the use of immunomodulating agents such as infliximab, rituximab, methotrexate, and fludarabine may predispose to the development of severe WNV infection.[9,38,116]

Approximately 20 percent of infected adults develop West Nile fever. Because of the fever's mild nature, only about half of individuals with West Nile fever ever seek medical attention. WNV neuroinvasive syndromes (encephalitis, meningitis, meningoencephalitis, acute flaccid paralysis) develop in less than 1 percent (1 in 140 to 320) of adults infected with WNV.[20,125,131,145,181,182] The occurrence of West Nile neuroinvasive disease in children is significantly less.[101,112] In one study, it was calculated to occur in approximately 1 in 4200 infected children.[112]

The incubation period of WNV infection ranges from 2 to 14 days but usually is 2 to 6 days.[22,63,96,113] Viremia may be present from approximately 2 days before to approximately 4 days after the onset of the illness.[64] In immunosuppressed individuals, incubation periods up to 3 weeks have been reported and may exhibit prolonged periods of viremia.[85,144]

In children[41,56,63,74,82,113,191] and adults, West Nile fever is an influenza-like febrile illness characterized by an abrupt onset of fever that typically ranges from 38° C to 40° C. It is accompanied by fatigue, malaise, anorexia, headache, myalgias, and weakness.[22,63,113,145,187] Ocular pain on eye movement has been reported.[64,114] A diffuse nonpruritic, macular, papular, or morbilliform exanthem and diffuse lymphadenopathy also may be seen. On occasion, it has been described as petechial.[17,41] The rash spares the palms and soles. The exanthem may be present more frequently in children than in adults, regardless of the WNV syndrome.[18,41] Neck pain and photosensitivity often are reported. Gastrointestinal complaints such as nausea, vomiting, abdominal pain, and diarrhea may occur. Sore throat and cough also have been reported. The illness generally is short-lived, lasting only 3 to 6 days.[63,82,113] Convalescence, however, may take many weeks and is characterized by fatigue.[63,113,186]

Other non-neurologic WNV syndromes that have been reported include cardiac dysrhythmias,[76] myocarditis, pancreatitis, hepatitis, rhabdomyolysis,[117,121] myositis, and orchitis.[6,17,79,116,131,191]

Although cases of West Nile neuroinvasive disease have been reported in children,* most of the information about these clinical syndromes has been derived from reports that have involved predominantly adults.† However, on the basis of a limited number of pediatric cases and series, the clinical presentation in children appears to parallel that of adults.[166] Although discussion of each of the neuroinvasive syndromes individually (i.e., meningitis, encephalitis, acute flaccid paralysis) is convenient, one should recognize that patients may have components of each in their clinical presentation. Last, the clinical findings in West Nile neuroinvasive disease in children and adults are not sufficiently distinct to distinguish them from other viral meningitides or encephalitides.

The onset of West Nile meningitis tends to be abrupt with fever, headache, and neck stiffness and meningeal signs (Kernig and Brudzinski signs).‡ Photophobia and phonophobia may be present. The headache pain may be severe enough to warrant the use of narcotic analgesics. Weakness frequently is reported.[41,56] Additional associated symptoms may include those seen with

†See references 6, 15, 22, 25, 38, 39, 86, 94, 107, 131, 145, 157, 162-165, 180, 188.

‡See references 2, 15, 22, 39, 41, 46, 56, 73, 74, 80, 94, 101, 131, 145, 165, 166, 181, 188, 189, 191.

West Nile fever: gastrointestinal and respiratory symptoms (i.e., nausea, vomiting, diarrhea, sore throat, cough), rash, and lymphadenopathy. Dyskinesias in the form of tremors, myoclonus, or parkinsonism may also occur.

The reported clinical findings of West Nile encephalitis in children* are similar to those described in adults.[15,22,39,46,131,145,166,181] The onset of frank encephalitis may be preceded by a brief period or "prodrome" of fever, headache, rash, and malaise consistent with West Nile fever. In some cases, the appearance of fever is coincident with the onset of mental status changes. The mental status changes may range from a mild confusional state to severe encephalopathy and coma. Generalized weakness is a common component of the clinical spectrum of encephalitis. Paresis or palsies may be present. Ataxia, dysmetria, tremors, myoclonus, and parkinsonism may be seen.[41,123,133] Signs of bulbar dysfunction, such as dysarthria, dysphagia, and respiratory failure, have been reported. If a component of meningitis is present (i.e., meningoencephalitis), signs and symptoms described before for meningitis may also be present. Seizures have been reported in children[4,24,56,92,135,155,177] but occur in less than 10 percent of adult cases of West Nile encephalitis.[15,18,94,131] Focal seizures and neurologic signs may occur and mimic that of herpes simplex virus encephalitis.[155,183]

Acute flaccid paralysis in association with WNV infection was reported first in 1979[58] and may occur in the absence of meningitis or encephalitis. Several reports of acute flaccid paralysis, alone or in association with encephalitis, developing after the occurrence of WNV infection in children have been published.[17,56,77,157] The onset of the paralysis occurs early in the illness, usually within the first 72 hours.[162] Pain in the affected limb preceding the onset of weakness is reported in most cases.[162] Patients exhibit asymmetric weakness, hypotonia, and absent or diminished deep tendon reflexes. Pain or sensory function in the affected limbs remains intact.[6,86,94,107,157,162] However, at least one report has documented electrophysiologic evidence of sensory fiber loss in association with severe spinal cord involvement.[52] It is postulated that this finding could be explained by damage to neurons in the dorsal root ganglia. Tremor, myoclonus, and parkinsonism are common findings.[163,165] In severe cases, changes in bowel and bladder function or quadriplegia may occur. Involvement of the brain stem motor nuclei of the vagus and glossopharyngeal nerves can result in dysphagia, dysarthria, and acute respiratory failure requiring assisted mechanical ventilation.[17] Patients with dysphagia and dysarthria are at greater risk for the development of respiratory failure.[162]

Ocular manifestations of WNV infection include chorioretinitis, vitritis, and uveitis.[7,166] Chorioretinitis has been described in congenital and postnatal WNV infections[3,7,166] and may be more common than is realized.[76] Postnatal cases of West Nile chorioretinitis have been reported solely in adults. The lesions are reported to cluster in the temporal and nasal regions of the peripheral retina and have been described as multifocal and "target-like." One suggestion is that the distribution and appearance of the lesions are sufficiently distinct to be considered characteristic for WNV infection.[78] In the sole reported case of congenital WNV infection, the infant had a large chorioretinal scar involving the retina of the right eye. Mild chorioretinal scarring was observed in the far temporal periphery.[3,7] Vitritis also has been reported in children and can lead to blurring and loss of vision.[191]

Other rarely reported neurologic manifestations of West Nile neuroinvasive disease in adults include optic neuritis, myelitis, Guillain-Barré syndrome,[1] and polyradiculitis.[143]

*See references 4, 17, 24, 41, 48, 49, 56, 73, 74, 79, 92, 123, 135, 154, 155, 177, 183.

OUTCOME

Although complete recovery from West Nile fever is expected, it may take several weeks before children and adults return to pre-illness levels of health.[63,143] In their report, Watson and colleagues[187] found that the median time to complete recovery in adults was 60 days. Post-illness fatigue was reported in 98 percent, and the median duration of fatigue was 36 days. Sixty-one percent of patients reported muscle weakness of a median duration of 28 days. Other symptoms that persisted for longer than 7 days were reported in more than half of the subjects and included headache, muscle pain and aches, difficulty concentrating, joint pain and aches, and sensitivity to light. Of those who worked or attended school, nearly 60 percent reported absenteeism of more than 7 days.

Neurologic outcome of children after West Nile neuroinvasive disease has not been assessed systematically. The published case reports of West Nile neuroinvasive disease in children are most likely biased by the disease severity or outcome and limited by a lack of long-term follow-up of patients. As such, reliable information about the outcome of West Nile encephalitis and acute flaccid paralysis is lacking. However, on the basis of the review of 45 reported cases of West Nile neuroinvasive disease in children and adolescents for whom clinical and outcome information was provided,* recovery from meningitis appears to be complete in children ($N = 20$). Among cases of encephalitis, meningoencephalitis, and acute flaccid paralysis ($N = 25$), approximately 50 percent of children were reported to have neurologic sequelae at the time of last medical encounter or at the time the report was submitted. The reported sequelae among children include seizures, weakness, paralysis, gait disturbances, motor difficulties, language and speech deficits, dysphagia, behavior problems, cognitive deficits, mental retardation, difficulty concentrating, difficulties with memory and comprehension, facial palsy, hypertonicity, and persistent vegetative state.†

The reported sequelae of West Nile neuroinvasive disease in adults include fatigue, fever, weakness, difficulty concentrating, memory loss, depression, paresis, tremor, myoclonus, and parkinsonism.[22,25,93,140,165,188] Between 50 and 65 percent of individuals will have evidence of neuropsychiatric dysfunction at the time of discharge.[188] Sejvar and colleagues[165] documented that the neuropsychiatric outcome at 8 months for patients with meningitis and encephalitis was generally favorable. All patients with meningitis had returned to work and reported having normal or near-normal function. In cases of severe encephalitis, achievement of premorbid function levels without evidence of residual disability was observed in most of the patients. Patients recovering from West Nile acute flaccid paralysis fared variably. Although the degree of initial paralysis was not correlated with long-term outcome in an early report,[23] a more recent publication indicates that the degree of initial paralysis may be an important indicator of long-term outcome.[163] The greatest recovery in strength occurred during the first 4 months after paralysis.[163]

Although reports of death in children as a result of WNV infection are rare,[26,61,73,79,111] WNV outbreaks associated with significant pediatric mortality rates (12.9%) have been documented.[49,105] Case-fatality rates in adults have ranged from 4 to 18 percent.[15,22,39,57,94,131,145,165,188] Hospitalized persons 75 years or older are nine times more likely to die than are younger patients. Other reported independent risk factors for death have been change in level of consciousness and anemia at presentation.[39]

LABORATORY FINDINGS

As is the case with the clinical findings of WNV infections, routine laboratory studies are nonspecific and do not provide conclusive evidence about the etiologic agent. Similar to those in adults, hematologic findings in children include leukocytosis, leukopenia, normal total white cell count, and lymphopenia.[4,41,48,101,155,177,183,189,191] Pediatric and adult cases of encephalitis hyponatremia have been reported.[17,39,188] Elevations of transaminases and creatine kinase may be seen in children with hepatitis and myositis.[17,191]

Cytochemical evaluation of the CSF generally reveals an abnormal white cell count and protein concentration.* A predominantly lymphocytic pleocytosis with, generally, fewer than 200 cells/mm^3 is a frequent finding. Cell counts of more than 2000 cells/mm^3 have been reported. Early in the infection, the CSF may show a polymorphonuclear cellular predominance that later shifts to a lymphocytic pleocytosis.[43] A mildly increased protein concentration of less than 100 mg/dL generally is seen. However, considerable variation in CSF protein concentration has been reported in patients with West Nile encephalitis. A normal CSF glucose concentration generally is observed.

ELECTRODIAGNOSTIC STUDIES

Electrodiagnostic study findings are abnormal in most patients with West Nile encephalitis.† Electroencephalographic abnormalities have included diffuse irregular slow waves, focal sharp waves, and subclinical electrographic seizures. An anterior preponderance of slow waves has been suggested as characteristic of West Nile encephalitis.[59] Reports of focal electroencephalographic findings suggestive of herpes simplex virus encephalitis have been reported in children.[155,183]

In patients with acute flaccid paralysis, electromyography and nerve conduction studies document normal nerve conduction velocities, normal or reduced compound muscle action potentials, and normal sensory nerve action potentials consistent with anterior horn cell disease.‡ Electrophysiologic documentation of severe loss of sensory fibers exists.[52]

NEUROIMAGING

Magnetic resonance imaging is more sensitive than is computed tomography in identifying CNS abnormalities in patients with West Nile neuroinvasive disease. However, even in cases of severe encephalopathy, magnetic resonance imaging may fail to find any abnormalities.[18] Reported magnetic resonance imaging findings in cases of West Nile neuroinvasive disease appear as hyperintense signal on T2-weighted and fluid-attenuated inversion recovery images and are nonenhancing and of normal intensity on T1 weighting.[86,147] In children and adults, lesions tend to be seen more frequently in the deep gray matter of the brain and, in particular, the basal ganglia, posterior thalami, and substantia nigra.§ Leptomeningeal and paraventricular enhancement may also be seen.[17,154] Focal abnormalities occasionally may be seen, as noted in two cases of children with encephalitis in whom focal enhancement of the right temporal lobe was noted.[48,57,183]

In cases of acute flaccid paralysis, abnormal T2-weighted signals may be seen in the spinal cord gray matter.[2,77,86,107] In a case of a child with acute flaccid paralysis, magnetic resonance imaging of the spine documented edema of the anterior horns of the cervical spinal cord.[77]

VIRAL CULTURE AND NUCLEIC ACID AMPLIFICATION DETECTION OF WEST NILE VIRUS

Multiple reports have documented that WNV can be detected from the blood and brain of infected individuals by use of mouse inoculation or cell culture.[13,61,63,64,70,81,118,171,176] However, this approach to establishing the diagnosis of WNV infections is of limited utility because of lack of sensitivity due to the brevity of the viremia, which begins approximately 2 days before and persists until approximately 4 days after the onset of the illness.[64,145,176] In addition, because of the potential risk to laboratory personnel, attempts to isolate WNV from human specimens should be undertaken only in an appropriate biocontainment environment (i.e., biosafety level 3 containment).

RT-PCR, using a fluorescent probe in a 3′ exonuclease assay (TaqMan), and real-time accelerated reverse transcription loop-mediated isothermal amplification assays for the detection of WNV have been developed.[102,142] Both have been shown to be more sensitive than conventional PCR for the detection of WNV genome. Diagnosis of acute WNV infections by nucleic acid amplification–based detection of WNV genome from blood and CSF clinical specimens also has limitations due to the short period of viremia.[102,145] Although genome could be detected in all brain tissue specimens tested, only 57 percent of CSF specimens and 14 percent of sera from patients with serologically confirmed infection were positive by a real-time RT-PCR assay.[102] Nucleic acid amplification–based detection of WNV has not been proven to be useful for the clinical diagnosis of WNV infections, but it has been extremely valuable in the screening and detection of asymptomatic viremia in blood donors.[122]

DETECTION OF WEST NILE VIRUS–SPECIFIC ANTIBODIES

Given the limitations of virologic and nucleic acid amplification–based diagnostic assays, detection of virus-specific antibodies forms the mainstay for establishing the diagnosis of WNV infections. In cases of neuroinvasive disease, the presence of WNV-specific IgM in serum and CSF increases by 10 percent per day the first week of illness such that it is usually detectable in 70 to 80 percent of patients by the eighth day after onset of illness.[76,179] Interestingly, WNV-specific IgM may persist for long periods in serum and CSF of acutely infected individuals.[156] Roehrig and colleagues[156] documented that 58 percent of samples obtained approximately 500 or more days from onset of West Nile encephalitis were in the positive or equivocal range for WNV-specific IgM.[156] Similarly, WNV-specific IgM has been detected in the CSF for up to 199 days after onset of illness.[90]

The inter-flavivirus cross-reactivity of anti-flaviviral IgG antibodies is well recognized. Traditionally, confirmation of anti-flaviviral antibody specificity requires the use of a functional antibody assay such as the plaque reduction neutralization test.[110] Although multiple reports have documented greater specificity of anti-flaviviral IgM antibodies and, in particular, those of WNV-specific IgM antibodies,[114,115,179] cross-reactions may still occur. On the basis of cross-reactivity with related flaviviruses (i.e., Japanese encephalitis virus and St. Louis encephalitis virus), an algorithm for the use of CDC-developed IgM capture enzyme-linked immunosorbent assay (MAC-ELISA) has been developed to differentiate human WNV and St. Louis encephalitis virus

*See references 4, 6, 18, 22, 24, 41, 43, 48, 56, 77, 79, 83, 94, 101, 131, 133, 135, 145, 154, 155, 164, 165, 170, 177, 183, 188, 189, 191.
†See references 2, 4, 18, 28, 48, 77, 79, 86, 94, 106, 107, 131, 135, 155, 164, 165, 177, 183.

infections.[115] The algorithm compares the positive-to-negative ratios of WNV-specific and St. Louis encephalitis virus–specific IgM determined in a CDC-standardized MAC-ELISA and has a positive predictive value of 97.8 percent for detection of WNV in the midst of an epidemic. This algorithm has not been validated for commercial MAC-ELISA kits. In the absence of use of the CDC MAC-ELISA, confirmation of WNV infection may require documentation of presence of WNV functional (neutralizing or hemagglutination inhibition) antibodies.

The diagnosis of WNV infection currently relies on the detection of WNV-specific antibodies in CSF or paired serum samples.[1,76,166] The MAC-ELISA is the most sensitive and commonly used diagnostic assay. It is capable of detecting IgM antibodies in CSF 3 to 5 days into the clinical illness and 3 or more days earlier than detectable serum antibody.[179] The finding of WNV-specific IgM in the CSF of a child with a clinically compatible CNS syndrome generally is considered diagnostic of acute neuroinvasive infection. However, as discussed previously, persistence of WNV-specific IgM antibodies for as long as 199 days in the CSF has been reported.[90]

Detection of WNV-specific IgM antibodies in serum from a single specimen may not be diagnostic of WNV infection because of its prolonged persistence in serum.[156,166] When only serum is used for establishing a diagnosis, a second serum sample should be obtained at least 2 weeks later to document a fourfold increase in specific antibody titers with use of a functional assay such as neutralization or hemagglutination inhibition.[166] Serologic cross-reactions among St. Louis encephalitis virus, WNV, and Powassan virus may occur[182] and can confound the diagnosis in those regions where multiple viruses are endemic. Serologic testing ideally should include a battery of region-specific arboviral antigens. Confirmatory assays, such as viral neutralization with the plaque reduction neutralization test, are available at many local and state public health laboratories or from the CDC's Division of Vector-Borne Infectious Diseases. The sensitivities and specificities of commercially available tests for the detection of WNV-specific antibodies may vary. An attenuated immune response may occur in immunocompromised hosts and result in a delayed antibody response.[144] As such, serologic assays should be interpreted with caution in this population, and adjuncts such as nucleic acid amplification should be used to establish the diagnosis.

NEUROPATHOLOGY

Gross examination of the brain, spinal cord, and meninges generally is unremarkable but may demonstrate evidence of edema. In severe cases, the leptomeninges may show a perivascular monocytic infiltrate on microscopic examination.[181] Although the parenchymal findings of West Nile encephalitis can be seen distributed in nearly all areas of the CNS, the deep nuclei (thalamus, caudate, lentiform nuclei), the substantia nigra, and other regions of the brain stem (in particular the pons and medulla), cerebellum, and spinal cord[22,66,91,131,139,158,181] may be more severely involved.

The CNS pathologic changes are the result of direct viral replication in neuronal and, less so, glial cells as well as the cytotoxic immune response to infected cells.[22] WNV demonstrates a penchant for infecting neurons. Viral antigen is detectable in neurons of fatal cases.[6,22,66,177] Neuronal pyknosis or neuronophagia is seen. Features in fatal cases of West Nile encephalitis include perivascular mononuclear inflammatory infiltrates composed predominantly of B lymphocytes, $CD8^+$ T lymphocyte–dominant microglial nodules in the brain parenchyma, and focal mononuclear inflammation along the cranial nerve roots of the medulla.[6,16,57,66,131,158] In the cerebellum, the Purkinje cell layer demonstrates inflammation, neuronal loss, and gliosis.

In cases of acute flaccid paralysis, WNV demonstrates a penchant for infection of the anterior motor neurons. The anterior horns of cervical and lumbar regions are the most severely involved areas.[16,57,66] Evidence of neuronophagia, neuronal loss, and perivascular monocytic infiltrates have been found.[16] Loss of ganglionic neurons, nodules of Nageotte, and perivascular lymphocytic aggregates have been seen in the dorsal roots and sympathetic ganglia.[16,57]

TREATMENT

Treatment of West Nile fever and neuroinvasive syndromes is primarily supportive. In the case of West Nile encephalitis and meningoencephalitis, close monitoring of respiratory status is essential. Patients with severe muscle weakness, paralysis, dysphagia, or dysarthria may require mechanical ventilation.

No effective antiviral therapy currently is available for the treatment of WNV syndromes. Ribavirin, a broadly active antiviral, has been shown to be active against WNV in vitro and may have as its mechanism of action error-prone replication.[47,88] In the sole pediatric case report, ribavirin was administered orally to a 14-year-old with Hodgkin lymphoma and West Nile meningoencephalitis who recovered completely.[177] Although encouraging, a report of ribavirin in an unblinded, uncontrolled manner for the treatment of WNV infection in 37 patients during an outbreak in Israel in 2000[39] associated its use with a higher mortality rate. Bivariate analysis indicated that its use was associated with a greater likelihood of death (odds ratio, 6.7; 95% confidence interval, 3.0 to 15.2). Because this was an uncontrolled trial, selection bias for its use in more severely ill patients cannot be excluded. However, in a hamster model of WNV infection, ribavirin treatment alone increased the mortality rate.[124] These reports indicate that the use of ribavirin for the treatment of WNV infections appears to be unwarranted and unsupported at this time.

In cell culture and animal models, interferon alfa has been shown to be beneficial against WNV.[124] Although anecdotal reports[89,161] in humans suggest that the use of interferon alfa-2b may improve recovery from West Nile encephalitis, an open label, nonblinded trial did not indicate benefit.[166]

Work in animal models[11] and anecdotal reports[17,68,69,79,167] of the use of an intravenous immunoglobulin preparation containing a high neutralizing titer of anti-WNV antibodies (Omr-IgG-am) for the treatment of West Nile neuroinvasive disease in adults[68,69,167] and children[17,79] have been published. The limited information suggests a benefit from its use. A phase I/II blinded, clinical trial of this preparation in patients aged 18 years or older with West Nile encephalitis was completed recently in the United States.

PREVENTION

Prevention of WNV infections requires both community-based public health programs and personal measures. Mosquito abatement through elimination of mosquito breeding sites, use of larvicides to breeding areas, and application of pesticides targeted to adult mosquitoes are approaches used to reduce the abundance of mosquitoes in the environment.

The use and maintenance of door and window screens as physical barriers to prevent mosquitoes from gaining access to homes can limit exposure to mosquitoes. Similarly, during engagement in outdoor activities where mosquitoes are prevalent, the use of mosquito netting in sleeping quarters also may decrease exposure to mosquito bites. Individuals should use insect repellent on skin and clothes when exposure to mosquitoes is probable or possible. Repellents such as DEET, picaridin, and

lemon eucalyptus oil have been shown to be effective and provide long-lasting protection.[8] Soybean oil also has been shown to be effective as a mosquito repellent. Permethrin and DEET have been shown to be effective protection against mosquitoes when they are applied to clothing.

Last, avoidance of environments where mosquitoes are found to be in high concentrations as well as avoidance of outdoor activities during dusk and dawn, when mosquito activity is the highest, should be encouraged. Efforts to prevent transmission of WNV through blood transfusions has led to the use of nucleic acid amplification–based tests for the screening of donated blood. At this time, screening of organ donors for the possible presence of West Nile infection has not been recommended.[92]

Killed vaccines and recombinant canarypoxvirus vaccines for the prevention of equine WNV disease are available for use in the United States.[119,132] Live attenuated recombinant, recombinant subunit, and DNA vaccines for immunization against WNV disease in humans are in developmental stages.[5,108,120,134,149] A recombinant WNV–yellow fever virus vaccine and a WNV DNA vaccine have begun clinical testing.[120,134] Results of the double-blind clinical trial of the recombinant vaccine have been published.[120] An infectious clone of yellow fever 17D virus was used as the background for the homologous exchange and insertion of the WNV prM and E genes. The WNV E gene was mutated at three sites to reduce neurovirulence.[5] The chimeric WNV–yellow fever virus vaccine was well tolerated, and the incidences of adverse events were similar in both the vaccine and the placebo groups. A transient viremia was observed in 93 percent of recipients of chimeric vaccine. Within 14 to 28 days after a single dose of the WNV–yellow fever chimeric vaccine was administered, high levels of neutralizing antibodies were detected in 100 percent of the recipients by day 21 after vaccination. $CD8^+$ responses were induced in 93 to 100 percent of vaccine recipients.

CHAPTER **188c**

YELLOW FEVER

Duane J. Gubler

Yellow fever is a mosquito-borne viral disease of humans and lower primates that occurs naturally in tropical Africa and the Americas (Fig. 188–8). Epidemics, which can occur in both urban and rural areas, often are associated with severe hemorrhagic disease and high fatality rates.

HISTORY

Yellow fever was described as a disease entity first in 1648 in the Yucatan, Mexico. It apparently was part of a larger regional epidemic that affected the Caribbean islands and Central America from Barbados to Mexico from 1647 to 1649.[11] Although it was first described in the Americas, yellow fever virus, along with its principal urban epidemic mosquito vector, *Aedes aegypti*, most likely originated in Africa and was introduced to the New World by the slave trade. During the 17th, 18th, 19th, and early 20th centuries, epidemic yellow fever was a major public health problem in the Western Hemisphere. Large epidemics occurred in tropical America as well as in the United States (as far north as Boston) and Europe (as far north as England).[15] Epidemics

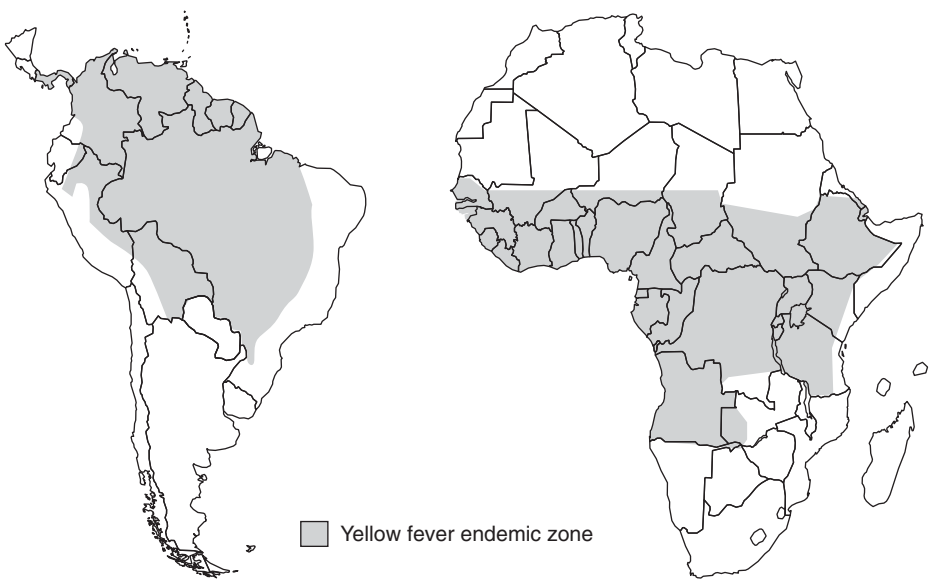

Figure 188–8 Geographic distribution of yellow fever in Africa and the Americas.

occurred primarily in port cities as a result of spread by sailing vessels and commerce.

After transmission by mosquitoes was documented by Reed and the Yellow Fever Commission in Cuba,[14] major efforts were undertaken to keep the disease in check by mosquito control. The first yellow fever virus was isolated in 1927. By 1938, an effective live attenuated virus vaccine had been developed. Yellow fever was controlled in the Americas by eradication of the mosquito vector of urban disease, *A. aegypti*, from most Central and South American countries. In Francophone countries of West Africa, yellow fever was controlled by mass vaccination programs. The result was the disappearance of major urban epidemics of yellow fever in both Africa and the Americas during the 1950s, 1960s, and 1970s. In the mid-1980s, however, the urban form of disease re-emerged in West Africa, with major epidemics in Nigeria and increased transmission in other countries.[9] Kenya experienced its first epidemic in history in 1993. In the Americas, *A. aegypti* has reinfested most Central and South American countries from which it had been eradicated, and urban centers of the American tropics are at their highest risk for epidemic urban yellow fever in more than 60 years.[2] Thus, the disease continues to be an important public health problem in both Africa and the Americas. Yellow fever transmission has never been recognized in Asia or the Pacific.

ETIOLOGIC AGENT

Yellow fever is caused by yellow fever virus, the prototype of the genus *Flavivirus*, family *Flaviviridae*. The genus *Flavivirus* contains 53 viruses, which are small (40 to 50 nm in diameter), spherical, and enveloped, with single-stranded RNA about 11 kb in length.[5] Many of the flaviviruses are very closely related antigenically, which has resulted in extensive cross-reactivity in most serologic tests, so a laboratory diagnosis is difficult to make. Yellow fever virus is part of an antigenic complex that is unique from other members of the family *Flaviviridae*.[3]

EPIDEMIOLOGY

Yellow fever viruses are maintained in natural zoonotic cycles involving lower primates and canopy-dwelling mosquitoes that breed in tree holes in the rain forests of both Africa and the Americas, called the jungle or sylvatic cycle of yellow fever.[9,11,15] Humans become involved accidentally when they encroach on this forest cycle. Humans thus infected may transport the virus back to a village or city during the incubation period of 2 to 14 days. If infected persons are fed on by urban *A. aegypti*, the virus then can be transmitted to other humans by mosquito bite after an extrinsic incubation of 8 to 10 days. Major urban epidemics are transmitted by this highly domesticated mosquito, which lives in close association with humans in most tropical cities of the world.[2]

Yellow fever occurs throughout much of sub-Saharan Africa and tropical America in the sylvatic cycle (see Fig. 188–8). In Africa, cercopithecoid and celobid monkeys are the main vertebrate hosts; infection rarely causes illness and death in these species. Year-round enzootic transmission by *Aedes africanus* occurs in the rain forests. In wet savanna areas bordering the rain forests of western and central Africa, transmission increases during the rainy season and decreases during the dry season. *Aedes furcifer*, *A. africanus*, and *Aedes leuteocephalus* are the main mosquito vectors in this "zone of emergence," and the virus is transmitted from monkey to monkey, monkey to human, and human to human. In the dry savanna zones, yellow fever activity is intermittent and takes place mainly during the rainy season, but it also occurs in major epidemics in urban areas, where stored water provides the ideal larval habitat for *A. aegypti*. In East Africa, *Aedes simpsoni (Aedes bromeliae)* provides the link between the *A. africanus* sylvatic cycle and humans in areas bordering gallery forests.

In tropical America, howler, spider, squirrel, owl, capuchin, and wooly monkeys all act as vertebrate hosts for yellow fever virus. Mosquitoes of the genus *Haemagogus* are the principal vectors in tropical American rain forests, where they feed in the canopy as well as at ground level. Other mosquito species, such as *Sabethes chloropterus*, *Aedes leucocelaenus*, and *Aedes fulvus*, may play secondary roles. Although most cases of yellow fever have been reported from Bolivia, Brazil, Venezuela, and Peru in recent years, the enzootic zone probably includes the rain forests of at least 10 countries (Colombia, Ecuador, Peru, Bolivia, Brazil, Venezuela, Guyana, Suriname, French Guiana, and Trinidad[17]) and involves "wandering" enzootic transmission among the monkey populations. The humans involved are mainly adult men who work in the forest.

Vertical transmission of yellow fever virus from an infected female mosquito through the eggs to her offspring plays an important role in survival and maintenance of yellow fever virus in enzootic cycles and has been demonstrated in nature in West Africa by isolation of the virus from male *A. furcifer* mosquitoes. Experimentally, *Haemagogus* and *A. aegypti* mosquitoes have been shown to be capable of vertical transmission. This mechanism is thought to be of major importance in survival of the virus during prolonged dry periods in both enzootic regions.

Urban epidemics of yellow fever have reappeared in West Africa in the past 17 years.[13] Unfortunately, surveillance is very poor, and the actual number of cases reported is thought to be grossly underestimated. For example, in Nigeria in 1986 and 1987, the number of reported cases and deaths during epidemics was 2612 and 973, respectively. Seroepidemiologic studies, however, estimated that the actual number of cases and deaths was 130,000 and 29,000, respectively.[13]

In the Americas, the last urban yellow fever epidemic occurred in 1942. Reinvasion of American tropical urban centers by *A. aegypti*, however, has placed more than 300 million susceptible individuals at risk. As might be expected, urban transmission has been reported recently. In 1998, urban transmission of yellow fever was documented in Santa Cruz, Bolivia.[16] Although not comprising a large number of cases, this outbreak underscores the high risk that many tropical urban centers have at the beginning of the 21st century. In addition, six fatal cases of yellow fever in travelers who visited South America (four cases) or Africa (two cases) in recent years have been confirmed. Three of these cases were U.S. citizens, and three were European. Why contemporary yellow fever epidemics have not occurred in the Americas, despite the high risk, is not known. The dramatic increase in transmission of dengue in urban centers of the American tropics in recent years possibly has resulted in a high prevalence of heterotypic flavivirus antibody that protects against severe yellow fever clinical illness. Another possibility is that the enzootic virus strains are not well adapted to urban transmission by *A. aegypti*.

Epidemic yellow fever has never been reported in Asia or the Pacific. The reason is not known, but both variation in mosquito vector competence and partial protection by heterotypic flavivirus antibody have been suggested as reasons that this virus has never become established in that part of the world. If urban epidemics do occur in the American tropics, however, the virus is expected to move very quickly to this and other permissive areas where urban *A. aegypti* mosquitoes are found; this movement undoubtedly would cause a major international public health emergency.

CLINICAL MANIFESTATIONS

Infection with yellow fever virus causes a spectrum of illness ranging from inapparent infection to severe yellow fever with the classic triad of jaundice, hemorrhage, and albuminuria, which is associated with a high case-fatality rate. Most yellow fever infections are manifested clinically as a mild to severe viral syndrome without symptoms of intoxication; 10 to 20 percent of infections may result in classic yellow fever.[8,11,12]

The incubation period may be as long as 13 days but generally is 3 to 6 days.[11] The onset of illness is abrupt, with fever, headache, backache, myalgia, nausea, and other nonspecific signs and symptoms. In mild cases, the illness will last for several days, after which recovery is uneventful and complete. In severe cases, prostration occurs commonly, and examination reveals congestion of the skin, conjunctivae, and mucous membranes. The pulse rate usually increases early in the illness, and blood pressure is normal. Leukopenia is a frequent finding, and mild albuminuria may be noted. The temperature generally ranges between 38.5° C and 40° C. Nausea and vomiting are common manifestations. Minor hemorrhagic manifestations such as epistaxis and bleeding gums may be observed. This period of infection may last for approximately 3 days, at which time the congestion declines and a relative bradycardia may occur despite the elevated temperature (Faget sign). The temperature falls to or below normal, and the patient feels better.

In most patients, this period of remission signals the beginning of convalescence; but in severe cases, it may last only a few hours, after which the patient enters a period of intoxication characterized by venous congestion and extreme bradycardia, despite a secondary rise in temperature. Nausea and vomiting are severe and associated with epigastric pain. Prostration, jaundice, marked albuminuria, and anuria are present. Hemorrhagic manifestations include hematemesis and melena.

The jaundice in some patients is not striking; it is difficult to detect in early disease and often is not detected until after death. The severity of hemorrhagic manifestations also varies greatly, but some hemorrhage can be found in most cases. As indicated earlier, minor hemorrhagic manifestations may be observed in the early stage of illness; severe hemorrhage usually develops late in the illness, although it may occur in fulminant cases as early as the second or third day. Hemorrhage may be so severe that it causes shock and death from blood loss. Albuminuria is one of the most common findings in yellow fever, and it occurs in all but very mild cases. It is present early in the illness and may increase rapidly. The albuminuria probably is related to renal involvement during the period of infection. Anuria, on the other hand, appears to be related to hepatic involvement and never is seen in the absence of other signs of liver infection.

Death may ensue as early as 2 to 4 days after onset but usually occurs after 7 to 10 days of illness in 20 to 50 percent of severe cases. In patients in whom death occurs later, autopsy generally reveals a cause other than yellow fever. Patients with severe infection often have lowered resistance to secondary infection, which may develop at the time of convalescence. Other complications include kidney abscess, pneumonia, suppurative parotitis, and skin infection. Convalescence usually is rapid and complete except for a general weakness that may last for several weeks. Permanent damage to the liver or kidneys is not apparent.

PATHOLOGY

The gross pathology in fatal cases of yellow fever is not striking.[12] The skin, sclerae, serosa, some internal organs, and subcutaneous fat usually have moderate icterus. Serous effusions, edema, and hemorrhages, including petechiae and purpuric lesions on the skin, conjunctivae, mucous membranes, stomach, duodenum, and bladder, often are present. Gastrointestinal hemorrhage may be prominent.

The most characteristic lesions caused by yellow fever virus are seen in the liver, although liver failure is not generally the cause of death. The liver may have a yellowish color and be enlarged and fatty in consistency. In typical cases, marked necrosis of the midzone of the lobule is present. The necrosis extends both centrally and peripherally and on average involves 80 percent of the lobule in fatal cases.[8,12] The cells bordering the central vein and portal areas usually are spared. Councilman and Torres bodies can be observed in hepatocytes. Little or no inflammatory response occurs, and the reticulin framework is preserved.

The kidneys generally are tense and swollen. Glomerular changes are minor, but acute tubular necrosis and fatty metamorphosis may be significant. Cloudy swelling, degeneration, and fatty infiltration may occur in the myocardial fibers. The spleen and lymph nodes are depleted of lymphocytes, and mononucleocytes or histiocytes accumulate in the follicles of the spleen. Edema and petechiae may be observed in the brain.

LABORATORY FINDINGS

Leukopenia and albuminuria are common findings in early stages of the disease. In severe cases, prolonged prothrombin and partial thromboplastin times, thrombocytopenia, fibrin split products, and elevated liver enzymes are observed. Total and conjugated serum bilirubin levels are elevated. Albumin levels in urine usually are less than 5 g/L, but in rare cases they may reach 40 g/L. The urine contains bile. Cerebrospinal fluid usually is normal but may be under increased pressure.

DIFFERENTIAL DIAGNOSIS

Clinically, yellow fever is difficult to differentiate from many other viral, bacterial, and parasitic infections, including other viral hemorrhagic fevers such as Lassa, Ebola, Marburg, and Rift Valley in Africa; the illnesses due to arenaviruses in the Americas; and dengue hemorrhagic fever in both continents. Other diseases that cause fever and jaundice, such as viral hepatitis, leptospirosis, falciparum malaria, tick-borne relapsing fever, typhus, typhoid, and Q fever, also should be considered in the differential diagnosis. A definitive diagnosis of yellow fever can be made only by use of the appropriate laboratory test.

LABORATORY DIAGNOSIS

Specific laboratory diagnosis requires isolation of the virus or serologic, nucleic acid amplification, or immunohistochemical tests. Virus can be isolated most easily from acute-phase serum taken during the first 4 days of illness, but it has been isolated as long as 14 days after the onset of illness as well as from the liver after death.[12] The most sensitive method of virus isolation is inoculation of mosquitoes followed by AP-61 cell culture from *Aedes pseudoscutellaris* mosquitoes. Vero cells and inoculation of suckling mice also can be used but are less sensitive. Polymerase chain reaction is highly sensitive, and yellow fever RNA can be amplified from these same tissues with a sensitivity higher than that of virus isolation.[6] Viral antigen can be demonstrated in the liver by immunohistochemical methods.[4] Either fresh or formalin-fixed tissue can be used with these techniques, which may be performed to establish a virologic diagnosis after virus has been cleared from the blood.

Serologic diagnosis depends on the collection of properly timed acute- and convalescent-phase serum samples to demonstrate a rise in specific antibody. Serologic tests commonly used to diagnose yellow fever include hemagglutination inhibition, complement fixation, and the plaque reduction neutralization test (PRNT) as well as newer tests, such as enzyme-linked immunosorbent assay (ELISA) for both IgG and IgM antibodies.[3] The immunofluorescent assay is used in some laboratories.

Antibodies detected by hemagglutination inhibition, PRNT, immunofluorescent assay, and IgM capture ELISA appear within 5 to 7 days after the onset of illness, whereas complement-fixation antibodies appear later, usually after 10 to 14 days. Hemagglutination-inhibition and PRNT antibodies persist at detectable levels for many years (>50) in most patients, whereas the duration of complement-fixation and IgM antibodies is uncertain, but they probably wane to undetectable levels after 12 to 18 months.

PRNT is the most sensitive and specific of the serologic tests. In patients who have had no previous flavivirus infection, this test can be used to make a specific diagnosis of yellow fever, as can IgM capture ELISA. Cross-reaction between yellow fever antigen and antibodies to other related flaviviruses complicates the serodiagnosis of this and other flavivirus diseases. Hemagglutination inhibition, immunofluorescent assay, and IgG ELISA are nonspecific tests in which considerable cross-reactivity with heterologous flavivirus antibodies occurs.

The use of yellow fever 17D vaccine in disease-endemic areas also may complicate serologic diagnosis. Vaccination induces low-titer (1:10 to 1:40) hemagglutination-inhibition and neutralizing antibodies but no detectable immunofluorescent or complement-fixation antibodies. Vaccination also induces IgM antibody, which may remain at detectable levels for as long as 18 months. Vaccination of individuals who have had a previous flavivirus infection induces an anamnestic response of heterotypic flavivirus antibodies at high titer (≥1:1280).

TREATMENT

Treatment of yellow fever is supportive because no specific therapy exists.[8,10] Currently, no antiviral drugs are available. Patients with severe disease requiring hospitalization should have complete bed rest with good nursing care and close monitoring of vital organ functions. Salicylates should be avoided, but mild sedatives may be helpful. Maintenance of fluid and electrolyte balance is critical. Guidelines for intensive care of severe yellow fever cases have not been established. Secondary bacterial infections may occur and should be treated with appropriate antibiotics.

PROGNOSIS

Mortality in all yellow fever infections is low (<5%), but in severe cases requiring hospitalization, it may be 20 to 50 percent.[8,12] The prognosis is poor for patients who enter a period of intoxication with rapidly increasing albuminuria, jaundice, fever, and severe hemorrhage. Patients in the terminal stage of illness usually are somnolent, have below-normal temperatures, and may have intractable hiccups.

PREVENTION AND CONTROL

The most practical and cost-effective method of preventing yellow fever is vaccination. A single dose of 17D vaccine provides effective, long-term (10 years) protection and should be used in the World Health Organization Expanded Program of Immunization in enzootic countries of Africa and the Americas.

The live attenuated 17D vaccine is prepared from infected chicken embryos and produces effective immunity in more than 95 percent of recipients.[12] Adverse reactions rarely occur, but in recent years, such events in elderly persons have been reported increasingly.[1] Infants younger than 4 months have a high risk for development of encephalitis and should not be vaccinated with the live attenuated 17D vaccine until they are 9 months of age. Pregnant women also should avoid being vaccinated because vaccine virus may infect the developing fetus, although the risk of adverse events associated with congenital infection is unknown. Finally, the live attenuated 17D vaccine should not be given to persons who are allergic to eggs or to those who are immunodeficient or receiving immunosuppressive drugs.

The other method of preventing yellow fever is mosquito control, especially during epidemic activity. The principal mosquito vector of urban yellow fever, *A. aegypti*, is a highly domesticated species that lives in and around the houses of humans.[2] It breeds primarily in artificial containers that collect rainwater or in domestic water storage containers. The most sustainable and effective prevention, therefore, is to control, discard, or chemically treat larval habitats in the domestic environment.[2] This process is labor-intensive but can be done with the help of the citizens in the community.

Some authorities recommend adult mosquito control with insecticide space sprays, primarily ultra-low-volume sprays. Recent field trials, however, have shown this approach to be ineffective unless portable sprayers are used to treat the inside of each dwelling. Because of the excessive cost and lack of efficacy of ultra-low-volume application of insecticides, this method is not recommended.

Patients suspected of having yellow fever should be protected from mosquitoes. The most effective protection is to use a mosquito net on the bed during the acute febrile period of illness. Alternatively, patients can be kept in screened rooms. Effective repellents are available to treat clothing and exposed skin.

CHAPTER **188d**

Dengue and Dengue Hemorrhagic Fever

Scott B. Halstead

Dengue fever is an acute febrile illness syndrome caused by several arthropod-borne viruses and characterized by biphasic fever, myalgia or arthralgia, rash, leukopenia, and lymphadenopathy. Synonyms are dengue and breakbone fever. Dengue hemorrhagic fever, a febrile disease caused by dengue viruses, is characterized by abnormalities in hemostasis and by leakage of fluid and protein from capillaries, which in severe cases results in shock (dengue shock syndrome). It is thought to have an immunopathologic basis. Synonyms are hemorrhagic dengue; acute infectious thrombocytopenic purpura; and Philippine, Thai, and Singapore hemorrhagic fever.

The dengue subgroup is composed of four antigenically distinct members.[21,48,56,96] From 1956, according to reports received by the World Health Organization (WHO), dengue viruses were thought to be responsible for more than 5,500,000 hospital admissions and 74,000 deaths in Southeast Asia, southern China, India, Sri Lanka, Pakistan, Cuba, Venezuela, Colombia, Guyana, Brazil, Puerto Rico, and Central America, mostly in vital, healthy children. In tropical Asian countries, dengue is among the 10 leading causes of death in children ranging in age from 1 to 15 years.[46]

The first outbreak that resembled a disease now recognized as dengue fever was described by Benjamin Rush in Philadelphia, Pennsylvania, in 1780.[11,103] Epidemics probably caused by dengue were common from the 18th to the 20th centuries in inhabitants of the Atlantic coastal areas of the United States and South America, the Caribbean islands, and the Mississippi basin.[103] Dengue viruses almost certainly were the cause of the 5- and 7-day fevers that occurred in European colonists in tropical Asia.[11] Similar epidemics occurred commonly in settlers in tropical Australia, where in 1905 *Aedes aegypti* was identified as a dengue vector by Bancroft.[72] Ashburn and Craig found the etiologic agent in human blood and showed that it could pass through a diatomaceous earth filter.[103] An intrinsic incubation period of 3 to 8 days in humans, an extrinsic incubation period of 8 to 11 days in mosquitoes, immunity in people and monkeys, and the nonsusceptibility of most domestic animals were demonstrated in the classic studies of Siler and Simmons and their coworkers[103,104] between 1924 and 1930. When dengue viruses were isolated in laboratory mice in 1943 and 1944, the modern era of dengue research began.[57,98] Two strains from Hawaii and Papua New Guinea failed to cross-protect humans. From this experiment, researchers recognized the existence of at least two different dengue viruses; they were named dengue virus type 1 and type 2.[97,98]

During most of the pre-virologic era, dengue viruses were thought to be the cause of a generally benign, self-limited febrile exanthem. However, death, shock, and severe hemorrhagic manifestations accompanied the classic dengue fever outbreaks in Australia in 1897 and thereafter for 15 years. Similar phenomena were recorded in Greece in 1928 and in Formosa in 1931.[35] This "new" syndrome was recognized again in Manila in 1954. It was called Philippine hemorrhagic fever because of a resemblance to the epidemic hemorrhagic fever then occurring in United Nations troops in the Korean Peninsula.[48] In 1956, Philippine hemorrhagic fever was associated with dengue when types 3 and 4 were recovered.[48] It now has become endemic throughout tropical Asia.[35,43,46] Since 1967, the terms dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS) have come into general use.[18]

In 1981, Cuba reported a severe outbreak involving more than 116,000 patients hospitalized within 3 months, 10,000 of whom had DHF/DSS.[63] In 1986, an epidemic of DHF/DSS occurred on Hainan Island, China[80]; in 1988, the Maldive Islands, Sri Lanka, and India were involved.[105,114] From about 1987, DHF/DSS outbreaks have occurred in Guyana, Venezuela, Brazil, Colombia, Central America, and, on a lesser scale, Puerto Rico.[46,83]

By epidemiologic criteria, dengue viruses are arthropod-borne (arboviruses) because they are transmitted biologically by various members of the genus *Stegomyia*.[72,75,103,104] Gene structure, replicative strategy, and antigenic relatedness place the dengue viruses in the family *Flaviviridae*.[56,115] At present, 68 members of the flavivirus family have been identified; 29 of them are established as human pathogens.[56] Cross-comparisons by plaque reduction neutralization tests have shown dengue viruses to be an antigenic subgroup with little relationship to other flaviviruses.[21] In addition to their antigenic relatedness and their ability to be transmitted by *Stegomyia*, each type of dengue virus produces a closely similar clinical syndrome in susceptible human beings.[36,97,103,104]

Dengue virions are spherical particles approximately 50 nm in diameter. The central core, approximately 25 nm in diameter, has icosahedral symmetry and contains a single plus strand of RNA. Dengue RNA consists of approximately 11,000 nucleotides coding from the 5′ end for core, premembrane, envelope, and five nonstructural proteins.[34] Large amounts of nonstructural protein 1 (NS1) are released from infected cells.[69] The envelope, which is studded with poorly resolved projections, is composed of many replicates of the envelope protein (54 kd) embedded in a lipid bilayer. When it is assembled on the virion, the envelope protein bears some epitopes unique to serotypes. Antibodies to these epitopes neutralize by hindering viral attachment or entry into cells. Other epitopes are shared between dengue viruses (dengue subgroup antigens) and other flaviviruses (group antigens).

Four clearly defined types exist, as determined by plaque reduction neutralization tests using antibodies raised by infection of monkeys or fluorescent antibody tests using monoclonal antibodies raised in mice.[21,94] Presumably, the cell attachment receptor differs for each dengue serotype and is blocked by neutralizing antibody.[49] The four types have distinctive genetic structures.[68,69,86,87,115,118] Phylogenetic studies suggest that human dengue viruses diverged from four zoonotic dengue types relatively recently, whereas the four zoonotic types evolved from a common ancestor in the more remote past.[115] Different dengue strains cluster in groups that differ genetically (genotypes).[15,16,68,69,86,110] Genotypes consist of viruses of similar genetic structure that usually circulate within one geographic area.[16,69,110] Genotyping can be used to trace the movement of dengue viruses between the continents. Of particular interest, a strain of dengue type 2 isolated in Jamaica in 1981 and the dengue 2 viruses recovered from 1981 Cuban DHF patients belong to a Southeast Asian genotype.[86,100] The most sharply divergent genetic differences are among human viruses and strains from Asian and African zoonotic cycles.[86,115]

Dengue virus can be grown in 1- to 2-day-old mice or hamsters by intracerebral inoculation or in various mosquitoes by oral

or parenteral inoculation. High mouse-passaged virus grows and produces deaths in weanling mice. Various tissue cultures of vertebrate and invertebrate origin support dengue virus growth in vitro, as reviewed in the following section.

TRANSMISSION

A. aegypti, a crepuscular daytime-biting mosquito, is the principal vector. All four virus types have been recovered from naturally infected *A. aegypti*.[35,42] In most tropical areas, *A. aegypti* is highly domesticated and breeds in water stored for drinking, washing, or bathing or in any container collecting fresh water. Dengue viruses also have been recovered from naturally infected *Aedes albopictus*, which breeds outdoors in vegetation.[29,35,43,75] Outbreaks in the Pacific area have been attributed to *Aedes scutellaris* and *Aedes polynesiensis*.

In urban areas, transmission of dengue may be explosive and involve as much as 70 to 80 percent of the population.[103] Because *A. aegypti* has a limited flight range, spread of virus is mainly by mobile viremic human beings.

Dengue viruses replicate in the gut, brain, and salivary glands of infected mosquitoes without apparent harm to adult mosquitoes.[90] Mosquitoes are infectious for a lifetime and as long as 70 days in experimental circumstances.[104] Because female mosquitoes take repeated blood meals, long-lived female mosquitoes have great potency as vectors. Several species of *Stegomyia* and *Toxorhynchites* are infected readily by intrathoracic inoculation, although the threshold of infection by oral feeding is higher.[89,90] *A. aegypti* and *Culex quinquefasciatus* can transmit dengue mechanically by interrupted feeding.[46,104] The contribution of mechanical feeding to the spread of dengue virus during epidemics has never been measured. Because of the "skittishness" of *A. aegypti* and its habit of feeding during the day when its intended victim is awake and often moving, interrupted feeding with simultaneous transmission to multiple hosts within a household must be a common occurrence.

A. aegypti preferentially feeds on people and hence is most abundant in and around human habitations. The mosquito breeds in clean water. Biting activity is reduced at temperatures below a wet bulb temperature of 14°.[23] Transmission of dengue in temperate countries is interrupted during winter weather, and dengue has not established itself endemically at latitudes above 25 degrees north or south. Breeding sites may be provided by humans through living habits, as in Thailand, where water is stored in and around homes in large earthenware jars.[35,42] In contrast, *A. aegypti* is not abundant in some parts of India because only small amounts of water are brought to homes from village wells for immediate use. Water in flower vases, household offerings, ant traps, coconut husks, tin cans, and rubber tires may supply breeding sites for *A. aegypti*.[29,42]

In the tropics, outbreaks of dengue generally coincide with the monsoon season. Eggs, which resist desiccation, are deposited inside water containers above the water line.[42] With the beginning of monsoon rains, a large number of eggs laid outdoors are hatched. Indoor populations do not show seasonal change. Temperature is important in controlling viral transmission. Evidence indicates that the extrinsic incubation period shortens with increasing mean temperatures; mosquito biting rates increase with increased temperature and relative humidity.[102]

In sylvan settings, dengue virus has been isolated from three subgenera of *Aedes*, namely, *Stegomyia*, *Diceromyia*, and *Finlaya*, some in circumstances suggesting the occurrence of transovarial transmission. This phenomenon has been demonstrated experimentally, but its contribution to maintenance of virus in a habitat is unknown.[91]

EPIDEMIOLOGY

HOST RANGE

Inoculation of strains of dengue with known human pathogenicity does not produce demonstrable infection in adult chickens, lizards, guinea pigs, rabbits, hamsters, or cotton rats.[101,104]

Subhuman primates generally are susceptible to infection by dengue viruses. Numerous species belonging to *Macaca*, *Cercopithecus*, *Cercocebus*, *Papio*, *Hylobates*, and *Pan* can be infected by the bite of virus-infected mosquitoes or by injection of infectious virus preparations.[38,101,104] Infection is essentially asymptomatic. Viremia occurs at levels sufficient to infect mosquitoes. Simmons and colleagues[104] were the first to note that wild-caught *Macaca philippinensis* resisted dengue infection whereas *Macaca fuscatus* (Japanese macaque) was susceptible. Work by Rudnick[93] in Malaysia has revealed a jungle cycle of dengue transmission involving canopy-feeding monkeys and *Aedes niveus*, a species that feeds on both monkeys and humans. Although the existence of a jungle dengue cycle in the Malaysian rain forest has been documented, the full geographic range of the subhuman primate zoonotic reservoir is not known. In the 1980s and 1990s, extensive epizootics of dengue virus type 2 involved subhuman primates over wide areas of West Africa.[88] Genetic and epidemiologic studies have shown that urban human dengue and jungle monkey dengue are relatively compartmentalized.[86,115] Urban dengue is vectored by anthropophilic mosquitoes, and the virus travels along routes of transportation. *A. aegypti* and susceptible humans are so abundant and so widespread that should dengue viruses be exchanged between humans and monkeys, detection would be extremely difficult. If, in the future, urban dengue is eliminated but vector mosquito populations are unabated, dengue viruses may once again be introduced from jungle cycles.

GEOGRAPHIC DISTRIBUTION

Outbreaks of dengue fever have been documented on every continent except Antarctica.[35] Evidence suggests that human dengue may have originated from enzootic or endemic foci in tropical Asia.[37,75] The probable spread of *A. aegypti* during historical times from Africa throughout the world provided an ecologic niche quickly occupied by several human viral pathogens: yellow fever, chikungunya, and the dengue viruses. During the 18th and 19th centuries, epidemics occurred in newly settled lands, largely because of the necessity for storage of domestic water in frontier areas. Isolated shipboard or garrison outbreaks often confined to nonindigenous settlers or visitors were reported in Africa, the Indian subcontinent, and Southeast Asia.[11,72,103] During World War II, dengue virus infections occurred commonly in combatants of the Pacific War and spread to staging areas not normally infected: Japan, Hawaii, and Polynesia.[38,46,97] DHF-like disease was described clinically in Thailand beginning in 1950 and in the Philippines from 1953; cases were confirmed etiologically as dengue in 1958 and 1956, respectively.[48] DHF first was described in Singapore and Malaysia in 1962, Vietnam in 1963, India in 1963, Ceylon (Sri Lanka) in 1965, Indonesia in 1969, Burma (Myanmar) in 1970, China in 1985, and Kampuchea and Laos from about 1985; major outbreaks have occurred in Sri Lanka and India since 1988, in French Polynesia since 1990, in Pakistan since 1998, and in Bangladesh since 1999.[1,26,37,38,80,105,114,119] DHF has occurred at consistently high endemicity in Thailand, Burma, Vietnam, and Indonesia.[43] In Thailand, it is the third ranking cause of hospitalization and death in children. Intermittent epidemics have involved Malaysia and the Philippines. The largest epidemic in history occurred in Southeast Asia in 1998, when

more than 490,000 hospitalizations and 4000 deaths were reported to the WHO.

During the past 20 years, major epidemics of all four dengue serotypes have occurred on several Pacific islands.[29,37,38,46]

American genotype dengue 2 virus circulated in the American hemisphere for hundreds of years and was the only virus to survive an intensive period of control of *A. aegypti* designed to eradicate urban yellow fever.[29] In 1963, an Asian strain dengue 3 was introduced into the Caribbean, dying out in the 1980s. Dengue viruses became fully established in the hemisphere after the introduction of a Southeast Asian dengue 1 in 1977.[22,83,86] Dengue 1 spread rapidly and now is endemic on the larger Caribbean islands and in Mexico, coastal Central America, and the tropical areas of Guyana, Venezuela, Colombia, Ecuador, Peru, and Brazil.[37,46,116] A sharp dengue virus type 2 epidemic in Cuba in 1981 involving 116,000 hospitalizations in a 3-month period led to island-wide control of *A. aegypti* and apparent eradication of the virus.[63,82] In 1981, an Asian dengue 4 was introduced into the Caribbean, spread widely, and now is endemic throughout the Caribbean basin. In 1986 and 1987, dengue virus type 1 spread through most of coastal Brazil and from there to Paraguay and to Peru and Ecuador.[22,29,83] In 1990, more than 9000 dengue cases were reported from Venezuela; 2600 of them were classified as DHF, and 74 deaths were associated with the epidemic.[83] Dengue virus types 1, 2, and 4 were isolated.[83] Shortly thereafter, DHF/DSS caused by dengue type 2 was reported from Brazil and French Guiana.[79,84] In 1994, dengue virus type 3 was introduced into the region.[53] In 1997, dengue virus type 2 with a Southeast Asian genotype was introduced into Santiago de Cuba and caused a sharp DHF/DSS outbreak observed only in individuals 20 years and older.[33]

Dengue virus types 1 and 2 have been recovered from humans with mild clinical illness in Nigeria in the absence of epidemic disease.[37] In 1983, dengue virus type 3 was isolated in Mozambique.[43,46] DHF/DSS has not been reported, and even dengue fever outbreaks are rare events. In this respect, Africa resembles the situation in Haiti, where multiple dengue serotypes are transmitted at high rates among a predominantly black population but severe disease is not recognized.[47]

CLINICAL MANIFESTATIONS

DENGUE FEVER

In classic dengue fever (seen most frequently in adults), after an incubation period of 2 to 7 days, patients experience a sudden onset of fever, which rapidly rises to 39.5° C to 41.4° C (103° F to 106° F) and usually is accompanied by frontal or retro-orbital headache. On occasion, back pain precedes the fever. A transient, macular, generalized rash that blanches under pressure may be seen during the first 24 to 48 hours of fever. The pulse rate may be slow in proportion to the degree of fever. Myalgia or bone pain occurs soon after onset and increases in severity. During the second to sixth day of fever, nausea and vomiting are likely to occur, and generalized lymphadenopathy, cutaneous hyperesthesia or hyperalgesia, aberrations in taste, and pronounced anorexia may develop.

One or 2 days after defervescence, a generalized, morbilliform, maculopapular rash appears, with sparing of the palms and soles. It disappears in 1 to 5 days. In some cases, edema of the palms and soles may be noted, and desquamation may occur. About the time of appearance of this second rash, the body temperature, which has fallen to normal, may become elevated slightly and establish the biphasic temperature curve.

Epistaxis, petechiae, and purpuric lesions are uncommon manifestations but may occur at any stage of the disease. Swallowed blood from epistaxis may be passed per rectum or be vomited and could be interpreted as bleeding of gastrointestinal origin. Gastrointestinal bleeding, menorrhagia, and bleeding from other organs have been observed in some dengue fever outbreaks.[85,111,117] Very clear evidence argues that peptic ulcer predisposes to gastrointestinal hemorrhage; in some cases, patients may exsanguinate during an otherwise normal dengue fever.[111] This syndrome is confused with DSS (see later) and contributes to a misunderstanding of the pathogenesis of severe dengue disease. The mechanism of the hemorrhagic diathesis that commonly occurs with dengue virus infection is not known, but speculation centers on platelet abnormalities. The DHF syndrome is differentiated from dengue fever by its association with thrombocytopenia and capillary leakage.[123]

After the febrile stage, prolonged asthenia, mental depression, bradycardia, and ventricular extrasystoles are noted commonly in adults.[72]

Primary infections with dengue virus types 2 and 4 are thought to be largely inapparent, particularly in children.[33,55,112,113] Primary infections with dengue virus types 1 and 3 in adults produce biphasic fever and rash as the most characteristic features of the dengue fever syndrome.[10,20,36,72,97,104] Manifestations vary with age and among patients. In infants and young children, the disease may be undifferentiated or characterized by a 1- to 5-day fever, pharyngeal inflammation, rhinitis, and mild cough. A distinctive mean incubation period, duration of illness, or spectrum of clinical findings could characterize disease with different dengue types, although these factors have not been studied carefully. Differences in mild dengue syndromes, hospitalized dengue cases (predominantly during secondary dengue virus infections), and chikungunya illnesses are illustrated in the section on chikungunya (see Tables 187–4 to 187–8).

Chikungunya virus infections produce a dengue fever syndrome. Because chikungunya and the dengue viruses are transmitted by the same vector mosquitoes, the diseases frequently are observed in the same patient populations. Chikungunya illnesses begin more abruptly than does dengue and are of shorter duration. Maculopapular rash, conjunctival injection, and myalgia or arthralgia occur more frequently in chikungunya than in dengue illnesses, but other features associated with both viruses are remarkably similar.[11,77]

DENGUE HEMORRHAGIC FEVER/DENGUE SHOCK SYNDROME

DHF/DSS is an acute vascular permeability syndrome accompanied by abnormal hemostasis. The incubation period of DHF/DSS is unknown but is presumed to be the same as that of dengue fever. In children, progression of the illness is characteristic.[18,76,77,123] A relatively mild first phase with an abrupt onset of fever, malaise, vomiting, headache, anorexia, and cough may be followed after 2 to 5 days by rapid deterioration and physical collapse. In Thailand, the median day of admission to the hospital after the onset of fever is day 4. In this second phase, the patient usually has cold and clammy extremities, a warm trunk, a flushed face, and diaphoresis. Patients are restless and irritable and complain of midepigastric pain. Frequently, scattered petechiae appear on the forehead and extremities, spontaneous ecchymoses may develop, and easy bruisability and bleeding at sites of venipuncture are common findings. Circumoral and peripheral cyanosis may occur. Respirations are rapid and often labored. The pulse is weak, rapid, and thready, and the heart sounds are faint. The pulse pressure frequently is narrow (≤20 mm Hg); systolic and diastolic pressure may be low or unobtainable. The liver may become palpable two or three fingerbreadths below the costal margin and usually is firm and nontender. Chest radiographs show unilateral (right) or bilateral pleural effusions. Approxi-

mately 10 percent of patients have gross ecchymosis or gastrointestinal bleeding. After a 24- or 36-hour period of crisis, convalescence is fairly rapid in children who recover. The temperature may return to normal before or during the stage of shock.

PATHOGENESIS AND PATHOLOGY

In rhesus monkeys experimentally infected with dengue virus by subcutaneous inoculation, virus replicates initially in the skin. Virus disseminates rapidly to regional lymph nodes and then to lymphatic tissue throughout the body.[73] Early in the viremic period, virus can be recovered only from the skin inoculation site and lymph nodes, whereas 2 to 3 days later, evidence of general dissemination to skin and other tissues is found. Virus is recovered from the skin, lymph nodes, and several leukocyte-rich tissues for up to 3 days after termination of viremia. Virus can be recovered from circulating leukocytes and from the skin only at the end of the viremic period. The number of sites from which virus can be recovered increases as the infection progresses. Intracellular infection is terminated abruptly 2 to 3 days after viremia ceases.

In humans, dengue viruses infect and replicate efficiently in intracutaneous Langerhans cells in vitro and in tissue explants.[124] Virus ultimately targets liver parenchymal cells, where infection produces apoptosis, but such cells may not serve as replicative hosts.[51] Late in infection, viral antigen is found associated with circulating B lymphocytes.[58] Fluorescent antibody, virus isolation, electron-microscopic, and in situ hybridization studies suggest mononuclear phagocytes as major infection hosts.[5,37-41,43,53a,78]

Animals infected initially with dengue virus type 1, 3, or 4 and then with dengue type 2 virus had higher viremia than when the same strain was inoculated into susceptible animals.[38,43] This phenomenon, in vivo antibody-dependent enhancement of dengue virus infection, provides an explanatory hypothesis of the immunopathogenesis of dengue in humans. Epidemiologic, clinical, and virologic studies of DHF/DSS in humans have shown a significant association between severe illness and infection in the presence of circulating dengue antibody, whether it is passively acquired from the mother or actively acquired from previous infection.[9,31,32,44,59,60,95,99] This circulating antibody has two biologic activities: neutralization of virus and enhancement of infection.[39,41] In Thailand, DHF/DSS developed in infants during dengue virus type 2 infection only when maternal neutralizing antibody had catabolized to low titer and infection-enhancing antibodies were left in circulation.[59] Similarly, in a prospective study of dengue virus infection in Thai children, DHF/DSS occurred in children who had circulating enhancing antibodies from a previous single dengue virus infection, but it did not occur in children whose first infection left them with low levels of cross-reactive dengue virus type 2 neutralizing antibody at the time of the second dengue virus infection.[60] A similar mechanism explains the failure of secondary infections to produce DHF/DSS with the American genotype dengue type 2.[116] American genotype dengue 2 viruses are significantly neutralized by human anti–dengue 1, whereas Southeast Asian dengue 2 viruses are not.[62] The full-length sequences of the American and Southeast Asian dengue 2 genomes reveal limited amino acid differences.[68]

In vitro studies of dengue virus type 2 demonstrated enhanced growth in cultures of human mononuclear phagocytes that were supplemented with very small quantities of dengue antibodies.[45] Investigators have proposed that the number of infected mononuclear phagocytes in humans with naturally or passively acquired antibody may exceed that in nonimmune individuals.[38,39,43] In serial blood samples taken early in the illness in children experiencing secondary dengue infections, enhanced viremia levels or enhanced levels of dengue NS1 predicted severe disease.[69,113] Vascular permeability is thought to result when infected cells are attacked by activated T lymphocytes, with the subsequent release of vasoactive cytokines.[3,27,28,38-41,64,74,92] Cytokine production should be quantitatively related to the number of infected target cells. The reduced risk for DHF/DSS in protein-calorie malnourished children[109] and the increased risk for DHF/DSS in girls versus boys are consistent with the hypothesis that a competent immune elimination system must be available to generate the cytokines that produce DHF/DSS.[38,40,46]

Evidence indicates the existence of a human dengue resistance gene. Epidemiologic studies of the 1981 Cuban outbreak demonstrated a higher risk for DHF/DSS in white than in black individuals.[31,63] A search for DHF/DSS in black children in Haiti revealed no cases, despite the presence of high dengue type 1, 2, and 4 infection rates and circulation of the Southeast Asian genotype dengue 2 viruses.[47] Several HLA antigens have shown differing frequencies in DHF/DSS cases and controls.[13] Early in the acute stage of secondary dengue virus infection, rapid activation of the complement system occurs.[8,81] During shock, blood levels of C1q, C3, C4, C5, C6, C7, C8, and C3 proactivator are depressed and C3 catabolic rates are elevated. The blood clotting and fibrinolytic systems are activated.[40,120] As yet, neither the mediator of vascular permeability nor the complete mechanism of bleeding has been identified unequivocally. The kinin system apparently is not involved. Recent studies suggest a role for tumor necrosis factor, interleukin-2, and interferon-γ.[64,92] Capillary damage allows fluid, electrolytes, protein, and, in some instances, red blood cells to leak into intravascular spaces.[121] This internal redistribution of fluid, together with deficits caused by fasting, thirsting, and vomiting, results in hemoconcentration, hypovolemia, increased cardiac work, tissue hypoxia, metabolic acidosis, and hyponatremia. A mild degree of disseminated intravascular coagulation, plus liver damage and thrombocytopenia, could contribute additively to produce hemorrhage.[120]

If tissue cultures or suckling mice are used for recovery of virus, dengue virus usually is absent in tissues at the time of death.[78] If patients experienced a second dengue infection, their tissue suspensions contain large quantities of dengue-neutralizing antibodies. The use of mosquito inoculation techniques improves viral isolation rates.[89,90,107] Genetic probes increase viral detection sensitivity still further.[51]

On pathologic examination, usually no gross or microscopic lesions are found that might account for death.[5] In rare instances, death may be caused by gastrointestinal or intracranial hemorrhage. Minimal to moderate hemorrhage is seen in the upper gastrointestinal tract, and petechial hemorrhage occurs frequently in the intraventricular septum of the heart, on the pericardium, and on the subserosal surfaces of major viscera. Focal hemorrhaging is seen occasionally in the lungs, liver, adrenals, and subarachnoid space. The liver usually is enlarged, often with fatty changes. Yellow, watery, at times blood-tinged effusions are present in serous cavities in approximately three fourths of patients. Retroperitoneal tissues are markedly edematous.

On microscopic examination, perivascular edema in soft tissues and widespread diapedesis of red blood cells can be seen. Maturational arrest of megakaryocytes may be noted in the bone marrow,[66] and increased numbers of such megakaryocytes are seen in the capillaries of the lungs, in the renal glomeruli, and in the sinusoids of the liver and spleen. Proliferation of lymphocytoid and plasmacytoid cells, lymphocytolysis, and lymphophagocytosis occur in the spleen and lymph nodes.[5] In the spleen, malpighian corpuscle germinal centers are necrotic. Depletion of lymphocytes occurs in the thymus. In the liver, varying degrees of fatty metamorphosis, focal midzonal necrosis, and hyperplasia of Kupffer cells are present.[5] Non-nucleated cells with vacuolated acidophilic cytoplasm resembling Councilman bodies (apoptotic hepatocytes[51]) are seen in the sinusoids. A mild, proliferative glomerulonephritis is present. Biopsy specimens of the rash

reveal swelling and minimal necrosis of endothelial cells, subcutaneous deposits of fibrinogen, and, in a few cases, dengue antigen in extravascular mononuclear cells and on blood vessel walls.[40,43]

DIAGNOSIS

DENGUE FEVER

A clinical diagnosis can be made by having a high index of suspicion and knowledge of the geographic distribution and ecology of dengue viruses. Activities of the patient during the period preceding the onset of illness may give important clues to the possibility of infection.

The differential diagnosis includes many viral, respiratory, and influenza-like diseases and the early stages of malaria, typhoid fever, scrub typhus, hepatitis, and leptospirosis. Abortive forms of these diseases may never evolve beyond a dengue-like stage. Four arbovirus diseases are dengue-like: chikungunya and o'nyong-nyong fever (togaviruses), West Nile fever (flavivirus), and Oropouche (bunyavirus). Four other diseases are dengue-like but without rash: Colorado tick fever, sandfly fever, Ross River fever, and the mild form of Rift Valley fever. Because of the variation in clinical findings and the multiplicity of possible causative agents, the descriptive term *dengue-like disease* should be used until a specific etiologic diagnosis is provided by the laboratory.

DENGUE HEMORRHAGIC FEVER/DENGUE SHOCK SYNDROME

According to WHO criteria, DHF is a dengue illness accompanied by thrombocytopenia (<100,000/mm^3) and hemoconcentration (hematocrit >20% of the recovery value). Early detection of vascular permeability remains a diagnostic problem; however, the use of strain-gauge plethysmography documents up to 50 percent higher microvascular permeability in DHF/DSS patients than in controls.[4] Pleural or peritoneal effusions observed by ultrasonography or radiography are virtually pathognomonic. DSS is diagnosed when these manifestations are accompanied by hypotension or narrow pulse pressure (≤20 mm Hg). In areas endemic for dengue, hemorrhagic fever should be suspected in children with a febrile illness who exhibit shock and hemoconcentration with thrombocytopenia. Hypoproteinemia, hemorrhagic manifestations, and hepatic enlargement are frequent accompanying findings. Because many rickettsial diseases, meningococcemia, and other severe illnesses caused by a variety of agents may produce a similar clinical picture, the diagnosis should be made only when epidemiologic or serologic evidence suggests the possibility of dengue. Hemorrhagic manifestations have been described in other diseases of viral origin, including the arenavirus hemorrhagic fevers of Argentina, Bolivia, and West Africa (Lassa fever); the tick-borne hemorrhagic fevers of India and the former Soviet Union; hemorrhagic fever with renal syndrome, which occurs across northern Eurasia, specifically from Scandinavia to Korea; and Marburg and Ebola virus infections in central Africa.[54]

LABORATORY STUDIES

An etiologic diagnosis can be made by serologic study of properly collected serum samples, by isolation of the virus, and by identification of viral RNA or the nonstructural protein NS1 in acute-phase sera.[2,52,123] The acute-phase serum or plasma collected for isolation of virus should be stored optimally at –65° C or colder. Serologic diagnosis depends on a fourfold or greater increase in antibody titer by hemagglutination inhibition, complement fixation, radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), or neutralization. IgM capture ELISA has revolutionized dengue serology, and commercial kits are available.[19,52] Primary and sequential (secondary) dengue virus infections result in the production of dengue-reactive IgM antibodies, which appear during the acute phase and disappear within 60 days of infection.[52] Secondary or primary dengue virus infections can be confirmed in a single serum specimen by quantitating IgM-IgG antibody ratios. IgG antibody concentrations are abundant in secondary but minimal in primary dengue virus infection. Dengue NS1 proteins can be detected in blood during the acute illness phase by dengue group–specific antibodies, and these have been formatted into commercial ELISA or rapid immunochromatographic tests.[2a,25a] By combining IgM-capture ELISA and NS1 detection, point-of-care tests may soon be available to diagnose acute dengue infections.

Numerous techniques are available for the recovery and identification of dengue viruses.[101,123] Recommendations for general use have been made by a WHO expert committee.[123] Acute-phase serum, mosquito suspensions, or other materials thought to contain dengue virus may be inoculated into suckling mice, which may be examined for sickness or subtle neurologic signs or challenged at 14 days with a neurovirulent dengue virus. Repeated subpassage markedly increases the neurovirulence of dengue virus. Alternatively, materials may be inoculated into any of several tissue cultures of mammalian or mosquito origin and examined for plaques under agar or methylcellulose overlay, for cytopathic effect or resistance to a challenge cytopathic virus by use of a fluid overlay, or for fluorescence or other markers with the use of an appropriate detection system. Intrathoracic inoculation of *A. albopictus*, *A. aegypti*, or *Toxorhynchites* spp. is a highly sensitive dengue virus recovery system.[89,90]

TREATMENT

DENGUE FEVER

Treatment is supportive. Bed rest is advised during the febrile period. Antipyretics or cold sponging should be used to keep the body temperature below 40° C (104° F). Paracetamol (10-15 mg/kg every 4-6 hours) is the preferred antipyretic agent. Analgesics or mild sedation may be required to control pain. Fluid and electrolyte replacement therapy is required when deficits caused by sweating, fasting, thirsting, vomiting, or diarrhea are present. Because of the risk of Reye syndrome and the dengue hemorrhagic diathesis, aspirin should not be given to reduce fever or to control pain.

DENGUE HEMORRHAGIC FEVER/DENGUE SHOCK SYNDROME

Explicit recommendations for management of DSS have been made by a WHO expert committee.[120] These and earlier recommendations by Cohen and Halstead[18] and recent studies by Dung and colleagues[25] and Wills and associates[122] are the basis of this section.

No specific antiviral treatment exists, but in DHF/DSS, symptomatic and supportive measures are effective.

The major pathophysiologic abnormality seen in DHF/DSS is an acute increase in vascular permeability that leads to leakage of plasma. Plasma volume studies revealed a reduction of more than 20 percent in severe cases. Supporting evidence of plasma leakage (and consequent hypovolemia) includes a rapid, weak pulse; diaphoresis; cool, pale skin of the extremities; decreased urine output; and direct measurement by strain-gauge plethysmography,[4] pleural effusion on chest radiography or ultrasonography, hemoconcentration, and hypoproteinemia. Pleural effusion may not be evident until after fluid resuscitation is started.

In the absence of increased vascular permeability, clinically significant hemoconcentration may result from thirst, dehydration, fever, anorexia, and vomiting. Fluid intake by mouth should be as ample as tolerated. Electrolyte and dextrose solution (as used in diarrheal disease), fruit juice, or both are preferable to plain water. With high fever, a risk of convulsions exists, so antipyretic drugs may be indicated. Salicylates should be avoided because they are known to cause bleeding and acidosis. Acetaminophen is preferable at the following doses: younger than 1 year, 60 mg per dose; 1 to 3 years of age, 60 to 120 mg per dose; 3 to 6 years of age, 120 mg per dose; and 6 to 12 years of age, 240 mg per dose.

Children should be observed closely for early signs of shock. The critical period is the transition from the febrile to the afebrile phase. Frequent hematocrit determinations are essential because they reflect the degree of plasma leakage and the need for administration of intravenous fluid. Hemoconcentration usually precedes changes in blood pressure and pulse. The hematocrit should be determined daily from the third day until the temperature becomes normal for 1 or 2 days.

Oral or parenteral fluid therapy can be administered in an outpatient rehydration unit for correction of dehydration or acidosis or when signs of hemoconcentration are present. The volume of fluid and its composition are similar to the fluids used for the treatment of diarrhea with moderate dehydration. The fluids should consist of the following:

- One third to half of the total fluid as physiologic saline solution.
- Half to two thirds of the remainder as 5 percent glucose in water.
- For acidosis: one fourth of the total fluids should be one-sixth molar sodium bicarbonate.
- Solution for fluid therapy in DHF: lactated Ringer solution, 5 percent glucose in one half normal physiologic saline solution, 5 percent glucose in one half lactated Ringer solution, 5 percent glucose in one third physiologic saline solution.
- Fluids as listed are calculated to be given during a 24-hour period. If the child seems severely dehydrated, half the calculated fluid is given in the first 8 hours and the second half in the next 16 hours. During rapid administration of fluids, watching for signs of cardiac failure is especially important.

Written orders should be explicit about the type of solution and the rate of administration. A rough estimate of flow may be derived from the formula

$$\text{mL/hr} = \text{drops/min} \times 3$$

SHOCK

Patients should be hospitalized and immediately treated when they have any of the following signs and symptoms of shock: restlessness or lethargy, cold extremities and circumoral cyanosis, rapid and feeble pulses, narrowing of pulse pressure (≤20 mm Hg) or hypotension, and sudden rise in hematocrit or continuously elevated hematocrit despite the administration of intravenous fluid.

Shock is a medical emergency. Immediate administration of intravenous fluid to expand plasma volume is essential. In children, shock may develop or subside during the course of a 48-hour period, so close observation 24 hours a day is imperative. Patients with similar degrees of severity should be grouped together. Those with shock require intensive 24-hour care by nurses and physicians. Paramedical workers or parents can assist in provision of oral fluid therapy or in surveillance of the rate of intravenous fluid administration and general status of the patient.

Initial fluid therapy with lactated Ringer or isotonic saline solution (20 mL/kg intravenously) infused as rapidly as possible may be required. Positive pressure may be necessary. In continued or profound shock, plasma expanders (6% dextran 70 or 6% hydroxyethyl starch [MW 200,000]) may be given to replace the initial fluid and administered at a rate of 10 to 15 mL/kg/hr or more until improvement in vital signs is apparent. In most cases, not more than 20 to 30 mL/kg of plasma is needed.

Intravenous fluids (5% dextrose, half-normal lactated Ringer, or half-normal saline solution) are continued, even after improvement in vital signs and a declining hematocrit. The rate of fluid replacement should be adjusted as judged by the rate of plasma loss. Plasma loss may continue for 24 to 48 hours. Microhematocrit determination is a simple and reliable index for estimating plasma leakage. Monitoring of central venous pressure may be necessary in the management of severe cases of shock that are not easily reversible.

Administration of intravenous fluids should be discontinued when the hematocrit drops to approximately 40 percent and the patient's appetite improves. Good urine flow indicates sufficient circulating volume. In general, fluid therapy is not needed beyond 48 hours after termination of the shock. Extravasated plasma is reabsorbed and causes a further drop in hematocrit after the administration of intravenous fluid is stopped; if more fluid is given, hypervolemia, pulmonary edema, or heart failure may result. Of importance is that a drop in hematocrit at this stage is not viewed as a sign of internal hemorrhage. A strong pulse and blood pressure along with a wide pulse pressure and diuresis are good vital signs at this resorption phase. They rule out the likelihood of gastrointestinal hemorrhage, which occurs most frequently during the shock stage.

Hyponatremia and, commonly, metabolic acidosis occur. Electrolyte and blood gas determinations should be performed periodically in severely ill patients as well as in those who do not seem to respond as promptly as expected. These determinations will provide an estimate of the sodium deficit and help determine the presence and degree of acidosis. Acidosis, in particular, may lead to disseminated intravascular coagulation if it is uncorrected. Heparin may be indicated in some of these patients, but extreme caution should be exercised in its use. In general, early volume replacement and early correction of acidosis with sodium bicarbonate result in a favorable outcome, and heparin is not required. Heparin should be reserved for patients with laboratory evidence of consumptive coagulopathy (disseminated intravascular coagulation) or intractable bleeding.

Sedatives are needed in some cases because of marked agitation. Hepatotoxic drugs should be avoided. Chloral hydrate administered orally or rectally is recommended in a dose of 30 to 50 mg/kg as a single hypnotic dose (maximal dose, 1 g). In patients without pulmonary complications, paraldehyde, 0.1 mL/kg intramuscularly (maximal dose, 10 mL), also may be used.

Oxygen therapy should be given to all patients in shock, but an oxygen mask or tent may increase apprehension.

Blood transfusion is indicated only in patients with severe bleeding (e.g., gastrointestinal bleeding, hematemesis, melena). Fresh whole blood is preferable. Blood grouping and matching for prompt treatment should be carried out as a routine precaution for every patient in shock.

In general, steroids do not shorten the duration of disease or improve the prognosis in children receiving careful supportive therapy.[108]

Frequent recording of vital signs and determination of hematocrit are important in evaluating the results of treatment. If patients show any signs of shock, vigorous antishock therapy should be instituted promptly. Patients should be monitored con-

stantly until it is reasonably certain that the danger has passed. In practice, the following should be carried out:

1. Pulse, blood pressure, respiratory rate, and temperature should be taken every 15 to 30 minutes or more often, until the shock resolves.
2. Hematocrit or hemoglobin studies should be performed every 2 hours for the first 6 hours and then every 4 hours thereafter until the patient is stable.
3. An accurate record of intake and output, including the type of fluid given, should be made. The frequency and volume of urine output should be recorded.

Having a pro forma sheet for recording symptoms, signs, and treatment of DHF and DSS cases is useful.

A blinded comparison of four intravenous fluids by Dung and associates[25] provided evidence that the relatively more expensive lactated Ringer solution provides no greater benefit than 0.9 percent saline does. Dextran could contribute to altered hemostasis.[46] Patients with DHF/DSS are resuscitated as though they have diarrhea. A more apt therapeutic analogy may be burn injury or hypovolemia from "third-space" loss in surgery. Of interest would be a trial of small-volume hypertonic saline with or without colloid.[46] The widespread and unstudied use of blood products to treat hemorrhage or simple thrombocytopenia[14] suggests a need for many more careful studies of DHF/DSS resuscitation.[46] In this regard, placebo-controlled or blinded studies are the ideal.[25,108]

EPIDEMIC DENGUE HEMORRHAGIC FEVER

During epidemics, outpatient and inpatient facilities may be overwhelmed. Under these conditions, only children requiring hospital care should be admitted. A recently elevated body temperature and positive tourniquet test result are sufficient to suggest DHF; when possible, a microhematocrit and platelet count should be performed in the outpatient department. Patients with thrombocytopenia and an elevated hematocrit should be sent to a rehydration ward or, if the hematocrit does not fall or rises in the face of fluid therapy, admitted to a hospital. If a patient lives a long distance from the hospital and nearby accommodations are not available, admission for observation may be necessary. Triage can be performed by properly instructed paramedical workers. Competent laboratory assistance is an essential factor.

Cool extremities, skin congestion, circumoral cyanosis, and rapid pulse are signs that suggest the need for hospitalization. Patients should be hospitalized until 2 days after the fever terminates.

REGULATORY MEASURES

Dengue diseases are not subject to international quarantine or surveillance regulations. An intensive and effective voluntary reporting system has been devised by the regional offices of the WHO.

PROGNOSIS

Not all patients suspected of having DHF need to be hospitalized because circulatory failure and shock may develop in only approximately a third of patients. Mild and moderate cases may be treated on an outpatient basis. For the purpose of early recognition of shock, parents should be advised to bring the patient back if evidence of clinical deterioration is noted or such warning signs as restlessness with or without lethargy, severe abdominal pain, cold extremities, and skin congestion occur on or after the third day following the onset of fever.

In most cases, early and effective replacement of lost plasma with plasma, plasma expanders, or fluid and electrolyte solutions (or any combination of these products) results in a favorable outcome. The acute onset of shock and the rapid, often dramatic clinical recovery, together with the fact that no destructive or inflammatory vascular lesions are observed, suggest that the disease is produced by transient functional vascular changes caused by short-acting pharmacologic mediators.

Sequelae in dengue or in DHF have not been studied systematically. Common sequelae of mild and uncomplicated dengue virus infection include bradycardia and ventricular extrasystoles during the convalescent stage, often persisting for several weeks. Profound asthenia with or without mental depression has been described. In patients with DHF/DSS, great care must be taken to reduce use of invasive procedures for managing shock. Nosocomial infections such as gram-negative sepsis can masquerade as DHF/DSS. Overhydration during the shock resuscitation phase may lead to heart failure and a complicated, stormy post-shock stage. Infrequently, residual brain damage occurs, apparently as a result of either prolonged shock or, occasionally, intracranial hemorrhage. Children in whom profound shock develops rapidly with no detectable diastolic pressure or with unobtainable blood pressure, children in shock with delayed admission to the hospital, or children in shock with gastrointestinal hemorrhage have a poor prognosis. Mortality rates may exceed 50 percent in these groups.

PREVENTION

Tissue culture–based vaccines for dengue virus types 1, 2, 3, and 4 are immunogenic but not yet licensed for use.[6,7] Numerous multivalent dengue vaccines using a variety of approaches are in various stages of development.[30,50,61,65] At present, prophylaxis depends on the use of insecticides, repellents, protective body clothing, and screens on houses to avoid mosquito bites. Destruction of *A. aegypti* breeding sites also is effective.[16] If water storage is mandatory, a tight-fitting lid or a thin layer of oil may prevent eggs from being deposited or hatching. A larvicide such as temefos (Abate), which is available as a 1 percent sand granule formulation and effective at a concentration of 1 ppm, may be added safely to drinking water.

EPIDEMIC MEASURES

The WHO recommendations are as follows. On the basis of epidemiologic and entomologic information, the size of the area that requires adult mosquito abatement should be determined. With technical-grade malathion or fenitrothion at 438 mL/hectare, two adulticide treatments at a 10-day interval should be made with the use of a vehicle-mounted or portable ultra-low-volume aerosol generator or mist blower.[71,123] Cities of moderate size should stockpile at least one vehicle-mounted aerosol generator, five mist blowers, 10 swing fog machines, and 1000 L of ultra-low-volume insecticide to be prepared to perform adulticide operations over a 20-km^2 area rapidly. With limited funds, such equipment and insecticides can be stockpiled centrally for rapid transportation when required. Priority areas for launching ground applications are those that have a concentration of cases. Special attention should be focused on areas where people congregate during daylight hours, such as hospitals and schools.

During the early stages of epidemics, an ultra-low-volume spray of 4 percent malathion in diesel oil or kerosene may be used to spray all houses within a 100-m radius of the residence of patients with DHF.

ERADICATION AND CONTROL

A. aegypti was eradicated successfully from countries and whole continents with use of the techniques pioneered by the Rockefeller Foundation in its worldwide program to control urban yellow fever.[106] With time, the species successfully re-established itself in much of its former range. An eradication campaign in the United States was abandoned and replaced by a program of disease surveillance and containment of introduced virus.

Mosquito control or eradication programs require the simultaneous use of two approaches: a reduction in breeding sites and the application of larvicides. Alternatively, a significant reduction in population may be effected by closely spaced applications of adulticide.[82]

Source reduction requires public support either by legal sanctions or by voluntary actions (see the following section). Source reduction campaigns should be well organized, supervised, and evaluated. Proper disposal of discarded cans, bottles, tires, and other potential breeding sites not used for storage of drinking or bathing water should be performed. Sides of water storage containers should be scrubbed to remove eggs when the water level is low. Water storage containers for drinking and bathing and flower vases should be emptied completely once weekly. Water containers that cannot be emptied should be treated with Abate 1 percent sand granules at a dosage of 1 ppm (e.g., 10 g of sand to 100 L of water). Treatments should be repeated at intervals of 2 to 3 months.

Vehicle-mounted or portable ultra-low-volume aerosol generators or mist blowers can be used to apply technical-grade malathion or fenitrothion at 438 mL/hectare. Three applications made at 1-week intervals can suppress *A. aegypti* populations for approximately 2 months.

In dengue-endemic countries, little effort has been made to adopt building codes or waste collection methods to reduce the number of mosquito breeding sites.[67] Furthermore, almost no way has been found to use the private sector to implement vector control despite ample evidence of long-term successful programs in the United States.[12,17]

HEALTH EDUCATION

Control of *A. aegypti* has been maintained effectively in some tropical areas through the simple expedient of emptying water containers once a week. During the yellow fever campaigns, strong sanitary laws made the breeding of mosquitoes on premises a crime punishable by fine or jail.[106] In the modern era, Singapore and Cuba have adopted these measures successfully. Health education through mass media or through the schools has been attempted in Burma, Thailand, Malaysia, and Indonesia, but without spectacular success.[24] The goals of health education and community participation approaches are to make the population aware of the identity of the vector of DHF, to describe its biting habits (daytime feeding) and its breeding habits (containers holding clean water), and to motivate people to reduce breeding sources by emptying water from containers on a regular basis.[42] The use of piped water rather than water storage should be encouraged. Studies in Malaysia after the 1973 epidemic of DHF indicated a very low level of functional knowledge among the inhabitants of Kuala Lumpur, Malaysia, about the vector of DHF.[24] Discouragingly, persons who were informed correctly, in most instances, took no action to protect themselves against mosquito breeding in their homes. Extensive effort is being made to apply social science methods to gain the voluntary participation of the population in sustained mosquito control programs.[70]

CHAPTER **188e**

Japanese Encephalitis

Theodore F. Tsai

Japanese encephalitis (JE), a mosquito-borne flaviviral infection, is the leading cause of childhood viral encephalitis in Asia.

HISTORY

JE first was recognized after an outbreak in Japan in 1924 led to 6125 cases of clinical encephalitis. In retrospect, similar summer-autumn outbreaks were recognized as early as 1871 to 1873. In 1933, Hayashi recovered the virus from monkeys and the brain of a patient, and in 1938, Mitamura confirmed its mosquito-borne mode of transmission by isolating the virus from *Culex tritaeniorhychnus*.[29] Inactivated vaccine prepared from infected mouse brain was licensed in Japan in 1956, and its use has led to control of the disease in developed Asian countries.[58] As poliomyelitis has been brought under control in Asia, JE has become the leading viral central nervous system infection on that continent. New cell culture–derived vaccines are now displacing the 50-year-old mouse brain–derived product.

ETIOLOGIC AGENT

JE virus is the prototypic member of an antigenic complex that includes St. Louis, Murray Valley, Kunjin encephalitis, and West Nile viruses. Molecular taxonomic studies based on nucleotide sequences of the E protein gene or the pre-M region have segregated JE strains into five genotypes that can be mapped roughly to regions of epidemic and endemic transmission in temperate Asia and India or Southeast Asia (four types, including one limited to Indonesia). However, the virus exists as a single serotype, and correspondence of genotype to human virulence has not been demonstrated epidemiologically. Sequence analysis has been helpful in tracing the potential origins of epidemic strains and has suggested the emergence of ancestral JE virus within the last 300 years.

Strains isolated from nature exhibit a range of virulence in mice. With repeated cell culture passage, biologically derived neuroattenuated strains have been produced for use as vaccines. Combinations of mutations in genes of the E glycoprotein, nonstructural proteins, and noncoding regions have been identified with attenuation of the live vaccine strain SA 14-14-2.[55] Comparisons of neurovirulent and attenuated viruses and manipulations of infectious clones have identified specific codon changes (resulting in amino acid changes principally in the E protein) that make fully replicative viruses avirulent.

As with other flaviviruses, important biologic functions such as viral neutralization are associated with the E glycoprotein. Canarypox, yellow fever 17D, and vaccinia recombinant viruses containing various JE viral sequences protect mice from challenge, thus demonstrating the biologic importance of specific genes and their mutations.[7,50,55] Some of the recombinants have utility as synthetic antigens in diagnostic assays or as human or animal vaccines.

ECOLOGY

In its basic transmission cycle, JE virus is transmitted between birds, especially certain egrets and herons, and *Culex* mosqui-

toes.[2,3,72] However, pigs, when present, are the most important source of viral amplification (Fig. 188–9). Pigs maintain a high sustained viremia and may be hosts to thousands of mosquitoes in a single night, thereby providing an abundant source of infected vectors that can transmit the infection further. In the typical setting in rural Asia, the onset of human cases each summer occurs shortly after pigs become infected.[60,72] The importance of pigs to epidemic transmission can be seen in countries such as Bangladesh, Malaysia, and Indonesia, where JE occurs principally in the non-Moslem population, which does not eschew pigs. However, outbreaks of JE have occurred in areas devoid of pigs, where birds, including ducklings, pigeons, sparrows, and possibly other small birds found near human residences, have been the principal amplifying hosts; furthermore, other sylvatic cycles have been proposed.[17,70,72]

C. tritaeniorhychnus is the major mosquito vector in most areas of Asia, although in various regions, related species *(Culex pseudovishnui*, *Culex vishnui*, *Culex gelidus*, *Culex fuscocephalus*, and *Culex bitaeniorhychnus)* are important locally.[2,3] *Culex annulirostris* is the principal vector in northern Australia and the Pacific. Certain anopheline mosquitoes may contribute to the transmission of JE in northeastern India. The primary *Culex* vectors use ground pools and especially rice paddies in their pre-adult stages. Immense numbers are produced from the flooded rice paddies that frequently surround individual residences and villages. With the custom of keeping pigs near or inside houses, all elements of the viral transmission cycle are found close to human activity. The mosquito *C. tritaeniorhychnus* is most active in the evening and night and feeds outdoors. The vector is zoophilic and prefers to feed on large animals rather than on humans.

Domestic animals such as dogs and cattle can be infected, but sufficient viremia does not develop to support further transmission. Because they are attractive to JE vectors, their presence may divert mosquitoes from humans (zooprophylaxis). Clinical illness develops in horses after infection and results in periodic outbreaks and economically significant loss of prize horses. Equine vaccines are administered in China, Mongolia, and Japan to prevent disease. Adult pigs remain asymptomatic after infection; however, sows infected during pregnancy abort or deliver piglets with lethal congenital malformations. Pig vaccines are widely used to prevent these congenital infections.

The overwintering mechanism for JE virus has not been defined clearly, although considerable evidence suggests a carryover of virus in mosquito eggs, with re-establishment of the transmission cycle by vertically infected mosquitoes.[15,72] Viral persistence in local mammalian reservoirs such as bats and reintroduction from external sources by migrating birds or windblown mosquitoes also have been proposed.

EPIDEMIOLOGY

The disease occurs mainly in rural areas, where high levels of virus transmission lead to infection at an early age. Nearly all cases occur in children younger than 10 years, with a slight preponderance in boys.[18] More than 99 percent of infections are subclinical, and cumulative exposure with age leads to seroprevalence rates of 80 percent or more by adulthood.[1,18] In Japan and other developed Asian countries, where children are protected by mass vaccination, adult cases occur principally in adults and especially in the elderly. Waning immunity or other biologic factors associated with aging have been speculated to be risk factors.[35]

Transmission is seasonal: late summer and early fall in temperate regions (July to September) and a longer interval in southern China and Southeast Asia (April to November). The seasonality is more complex in tropical areas, where mosquitoes proliferate after monsoon rains, and two epidemic seasons or year-round transmission is possible in some tropical locations. Although an abundance of mosquitoes usually corresponds to the rainy season, in many locations, vector populations now follow irrigation-controlled schedules of rice field flooding.[57]

JE occurs in nearly every country in Asia (Fig. 188–10), with 30,000 to 50,000 cases reported annually from the region. Trans-

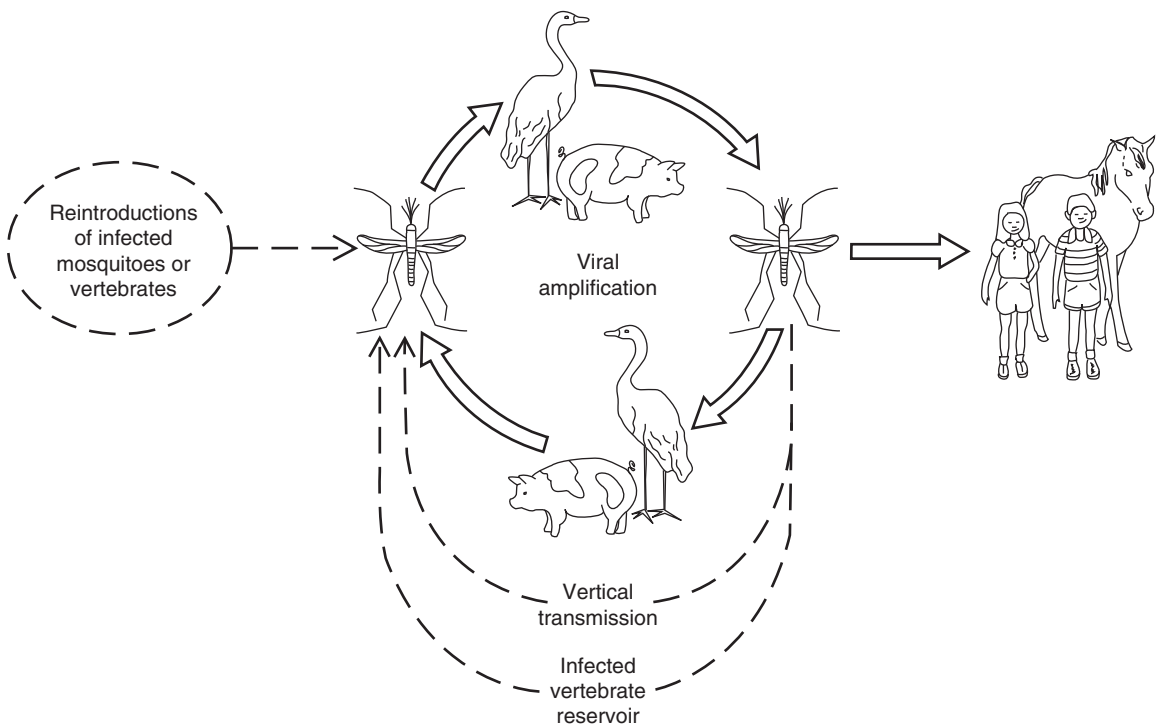

Figure 188–9 Transmission cycle of Japanese encephalitis virus. Speculative portions of the cycle are shown in broken lines.

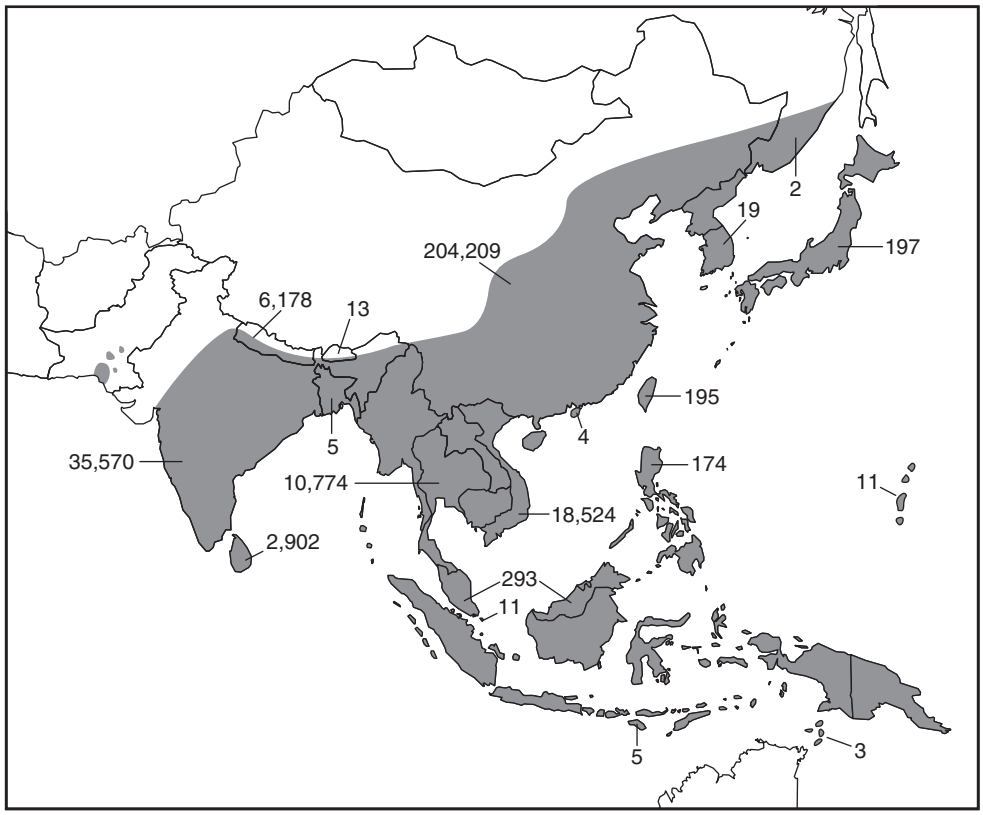

Figure 188–10 Geographic distribution of Japanese encephalitis and reported cases from 1985 to 1994. Torres Strait cases are from 1995.

mission is endemic; annual incidence rates of 1 to 10 per 100,000 population are observed in China and most areas of Southeast Asia, but epidemic attack rates as high as 100 per 100,000 population have been described. Only sporadic cases are reported from Indonesia, Malaysia, and the Philippines, whereas periodic, often sizable outbreaks typify transmission in India. Rare outbreaks have occurred in Oceania, on Guam and Saipan in 1949 and 1989, respectively, and in far northern Australia in 1995 and 1998.[22,59] These outbreaks appeared to have occurred after introduction of the virus by migrating birds or other mechanisms, coupled with unusual conditions of human activity or weather patterns. Establishment of JE virus on the Australian mainland appears to have been limited by the zooprophylactic intervention of alternate hosts, as well as by immunity in the vertebrate host population as a result of infection by other flaviviruses.[85] Few cases are reported from countries where vaccination rates are high (e.g., Japan, Korea, Taiwan) and where development through urbanization, decreased land under cultivation, and improved standard of living have reduced human exposure. The use of agricultural pesticides and centralized pig rearing also may have contributed to a decline in infected vectors in these countries. The significant reduction in human cases belies the persistence of enzootic viral transmission in rural areas of these countries, however.[1,41]

Although economic development has paralleled a decline in JE in some countries, in other areas, development in the form of deforestation, construction of dams, and irrigation schemes has led to increases in transmission of JE virus or its emergence in areas where the disease had not occurred previously. Examples include development projects in the Terai in southern Nepal and the Mahaweli Valley in Sri Lanka, where JE and malaria have become hyperendemic after large-scale programs of deforestation and agricultural development.[60]

Travelers to areas where JE is endemic may be at risk for acquiring the illness.[78] However, risk in the general traveling public is low; approximately 50 cases have been reported in travelers and expatriots from North America, Europe, and Australia in the past 20 years, many of them in military personnel and their family members. The risk has been estimated to be in the range of 1 per 15,000 to 1 per 150,000 person-months of exposure. This low rate can be understood by factoring the probability of development of an illness after a single mosquito bite: only certain vector species transmit the virus, typically less than 3 percent of vector mosquitoes are infected, and only one in several hundred infections leads to clinical illness. Because the principal vector species are found in rural areas and they feed mainly outdoors and in the evening and night, the risk is low in the great majority of travelers who can avoid these circumstances of exposure.

CLINICAL MANIFESTATIONS

Only one in several hundred infections leads to clinical illness, and the overwhelming majority of infections are inapparent or manifested as mild self-limited illnesses. Patients who come to medical attention may have aseptic meningitis or encephalitis, and 5 to 25 percent die. After an incubation period of 4 to 14 days, the earliest symptoms are lethargy, nausea or abdominal pain, headache, and feverishness (Fig. 188–11). During a period of 2 to 3 days, lethargy increases and the child may exhibit uncharacteristic patterns of behavior and motor abnormalities.[34,40,43,69,80] In other cases, a long prodrome of a week or more may occur, with periods of confusion or agitation and unsteadiness. A sudden convulsion is frequently the initial symptom. Unusual manifestations, such as acute psychosis and Guillain-Barré syndrome, also have been reported; the latter may lead to

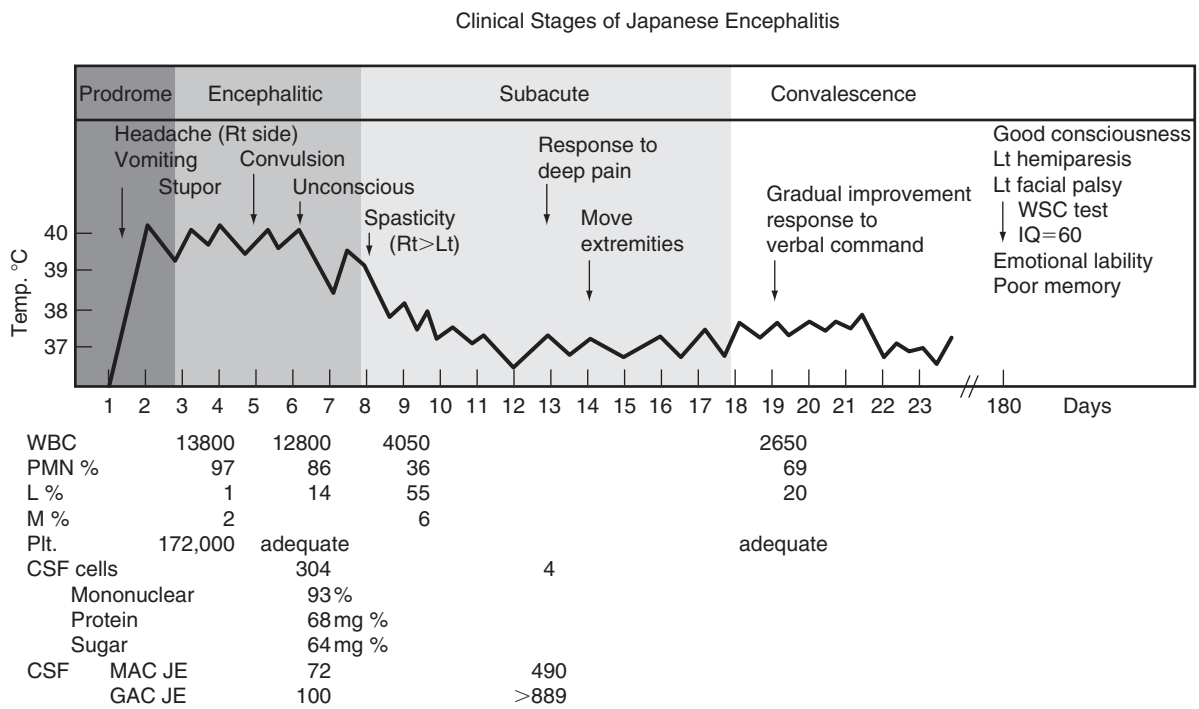

Figure 188–11 Clinical stages of a typical Japanese encephalitis case.

a misdiagnosis of acute poliomyelitis in areas of Asia where that disease has not been eradicated.[68]

The principal physical findings are high fever and obvious alterations in consciousness ranging from mild mental clouding, frank disorientation and delirium, to coma. Some children exhibit bizarre behavior, including shouting, spitting, and other personality changes. Mutism is an initial feature in some cases. Signs of meningeal irritation can be elicited in a third to two thirds of cases. Cranial nerve palsies, mainly disconjugate gaze and central facial paralysis, are observed in a third of cases. Muscle weakness, either flaccid or spastic, is a usual symptom. Weakness may be generalized or in many cases is asymmetric, with hemiparesis or an unusual distribution of flaccid and spastic paralysis. Muscle tone generally is increased, with hyperreflexia and ankle clonus; the Babinski sign and other abnormal reflexes are variable. Some patients exhibit erratic flailing movements. Tremor, rigidity, expressionless facies, or thick slurred speech may be initial features, but more frequently, choreoathetosis and other extrapyramidal signs become evident in the second week of illness.[33,64] Focal or generalized convulsions develop in 50 to 75 percent of patients.[48] Papilledema is seen in 10 percent of cases, and patients occasionally may be hypertensive. Patients with fulminant infections often die during the first 5 days of illness.

In most other cases, fever abates during the next week, and neurologic function gradually improves during the course of several weeks. Further recovery of motor function occurs during the next several months to years, although in other cases neurologic abnormalities may not appear until months after hospital discharge. In more than a third of patients, coma and respiratory failure necessitate institution of ventilatory support. During this prolonged period of recovery from coma and paralysis, stasis ulcers, urinary tract infections, pneumonia, and bacteremia are frequent complications and may be secondary causes of death. A biphasic pattern of illness has been described in anecdotal cases, with a recurrence of motor and behavioral abnormalities 2 to 5 weeks after initial improvement accompanied by larger and more numerous associated magnetic resonance imaging lesions.[63]

Routine laboratory studies initially show a peripheral leukocytosis, often with a left shift and a total leukocyte count as high as 30,000/mm^3. Opening pressures on lumbar puncture usually are normal or slightly elevated. Cerebrospinal fluid (CSF) pleocytosis ranges from fewer than 10 cells to several thousand, with a median of several hundred per cubic millimeter. Lymphocytic pleocytosis is a typical finding, but some patients have an initial predominance of polymorphonuclear cells. CSF glucose and protein levels are generally normal (80% of cases); when elevated, protein levels rarely exceed 100 mg/dL.

Electroencephalograms typically show diffuse theta to delta wave slowing, whereas spike and seizure discharges are relatively uncommon findings. Computed tomograms show diffuse white matter edema and nonenhancing low-density areas, mainly in the thalamus, basal ganglia, and pons. Temporal lobe involvement affects principally the hippocampus, aiding in the differential diagnosis of herpes from encephalitis.[21] Thalamic lesions frequently are associated with unilateral or bilateral hemorrhage. A thalamic location of involvement is consistent with the electroencephalogram's pattern of slowing. Magnetic resonance imaging, particularly diffusion-weighted imaging, shows a similar distribution of abnormalities on T2 studies, with lesions of high or mixed signal intensity in the thalamus, midbrain, basal ganglia, substantia nigra, cerebellum, pons, and spinal cord.[21,33,34,65] JE-associated abnormalities have been reported to appear more frequently in the ipsilateral hemisphere affected by neurocysticercosis-related changes.[79] Electromyograms show a neurogenic pattern consistent with anterior horn cell involvement. Central motor conduction times are prolonged, indicative of diffuse subcortical damage.

PATHOLOGY

Pathologic changes are found in the lungs and viscera in addition to the brain.[20,25,31,32,42,76] On gross examination, the brain appears swollen, and the meninges may be congested. Punctate hemorrhages may be visible macroscopically. Microscopic examination discloses a moderate inflammatory response in the meninges. Foci of neuronal degeneration with parenchymal and perivascular inflammatory responses are found principally in the thalamus

and brain stem as well as in the hippocampus, temporal cortex, cerebellum, and spinal cord. Areas of neuronophagia may be surrounded by microglial nodules, but sharply defined round areas of softening or necrolysis without an inflammatory response also are seen. Purkinje cells and cerebellar glial shrubs also may be lost.

PATHOPHYSIOLOGY

After virus is introduced by a mosquito bite, replication locally and within regional lymphatic tissue leads to a secondary amplified viremia and infection of various organs and the brain. Neuroinvasion is thought to occur through cerebral capillaries; infection crosses from the vascular side of the endothelial cell to the perivascular space, with subsequent neuronal infection.[20] Neurons show evidence of viral antigen in the cell body, axons, and dendrites, suggesting a mechanism of viral spread within the brain from cell to cell.[32] CSF levels of catecholamines and their metabolites are acutely lowered.[33] Infiltrating T cells elicit a broad inflammatory response, with B and T cells and macrophages found in perivascular cuffs and macrophages and T cells in the parenchyma.[9,20,33,87] Neuronophagia proceeds with the formation of microglial nodules and the eventual disappearance of neurons, leaving ghost-like remnants with antigen accumulated within macrophages.

The rapidity of the neutralizing antibody response is thought to be a principal determinant of outcome.[4,32,54,56,58] Most fatal cases occurring within approximately 5 days after the onset of illness have no detectable CSF antibody response while virus is recoverable from the CSF, a finding indicative of unimpeded viral replication. In experimentally infected animals, passive immunization reduces mortality, even when it is given 4 to 5 days after inoculation.[54] However, other studies have found that antigen persists in neurons for extensive periods in the presence of intrathecal antibody and immune complexes, thus suggesting a failure of antibody-mediated viral clearance.[14] A role for immunopathologic mechanisms, including the development of antineurofilament antibodies, has been proposed as an alternative correlate of outcome.[13] CSF interleukin-8 levels remain elevated for a longer interval in patients with severe prolonged illness.

Why most JE virus infections are subclinical or lead to no signs of infection in the central nervous system is unclear. Epidemiologic observations indicate an elevated risk for JE in the elderly and increased severity in young children, but the biologic basis for this increased susceptibility has not been defined. Cross-reactive flaviviral immunity as a result of previous dengue virus infection may modulate the severity of JE in some cases.[16] Pathologic observations have shown a higher prevalence of neurocysticercosis in fatal JE cases than in deaths from other causes, which suggests that physical or physiologic disruption of the brain architecture by infection or other mechanisms could facilitate neuroinvasion (see earlier).[11,33,42,44,45] Experimental dual infection of animals with JE virus and other agents supports this hypothesis. In experimental animals, other host factors associated with a risk of acquiring illness and having a poor outcome include a specific gene defining resistance, age, levels of sex hormones, and cold and stress responses.

COMPLICATIONS

The principal complication is secondary bacterial infection occurring in the acute and subacute phases of illness. Stress-induced gastrointestinal hemorrhage and hyponatremia caused by inappropriate antidiuretic hormone secretion also can occur. Concurrent malaria and other parasitic or bacterial infections may complicate management. Although JE occurs in areas of Asia where human immunodeficiency virus (HIV) infection may be prevalent, reports of their interaction have been limited, with no conclusion on differences in outcome.

Cases of clinical relapse with seizures, coma, and weakness, several occurring 6 to 9 months after recovery from the acute illness, have been reported. These patients and other asymptomatic recovered patients had evidence of persistent JE virus infection in peripheral blood mononuclear cells.[77] A study of 253 patients found laboratory evidence of subacute central nervous system infection in 5 percent of cases, with persistent intrathecal production of JE virus–specific IgM beyond 50 to 180 days or CSF containing JE virus antigen or virus more than 3 weeks after recovery.[67] Further studies are needed to confirm and to characterize the persistence of JE virus and its clinical significance.

JE acquired during the first two trimesters of pregnancy may lead to fetal infection and miscarriage. JE virus has been isolated from products of conception in a few cases. Infections acquired during the third trimester have not been associated with adverse outcomes to the pregnancy.[8,47] Whether congenital JE virus infections are associated with sublethal malformations in humans or whether congenital infections follow subclinical JE virus infection remains unknown. The virus is an important abortifacient in pigs and produces central nervous system and other lethal in utero malformations.

LABORATORY DIAGNOSIS

A specific diagnosis can be confirmed serologically by identifying JE virus–specific IgM antibody in serum or CSF by enzyme-linked immunosorbent assay (ELISA) or by demonstrating fourfold titer changes in neutralization, hemagglutination-inhibition, complement-fixation, or immunofluorescent antibodies between acute- and convalescent-phase serum samples. Serologic cross-reactions with dengue virus and other flaviviruses are a common problem that sometimes can be resolved with cross-neutralization. Some laboratories have established empiric ELISA absorbance cutoffs that can differentiate dengue and JE virus infection.[30] IgM can be detected in serum or CSF (or in both) in nearly all cases by 1 week after the onset of illness. ELISA kits as well as rapid, point-of-care immunoblot assays are available commercially.[66] Patients who are moribund or severely ill on admission may be seronegative and are most likely to yield viral isolates from CSF.[5] Real-time polymerase chain reaction and T7 promoter–based assays have proved to be sensitive in related West Nile and St. Louis encephalitis cases and can distinguish the two infections in areas of South Asia, where the viruses circulate.[78] Immunofluorescent staining of CSF mononuclear cells can provide a specific diagnosis within several hours after a lumbar puncture is performed, but this procedure has a reported sensitivity of only 60 percent.[46]

JE virus occasionally can be isolated from the blood of patients in the pre-neuroinvasive phase of illness, usually no later than 6 to 7 days after onset. Virus can be recovered from brain biopsy and autopsy material by intracerebral inoculation of baby mice and various cell cultures, such as primary chick or duck embryo cells, and in Vero, LLCMK-2, C6-36, and AP-61 cell lines.

DIFFERENTIAL DIAGNOSIS

In rural Asia, the principal considerations include tuberculous and pyogenic meningitis; typhoid fever manifested as tremors and ataxia; cerebral malaria; dengue virus infection with encephalopathy; and herpes simplex, measles, enterovirus (especially EV71), HIV, and other causes of viral encephalitis.[10,80] West Nile virus (and its Kunjin subtype) and Murray Valley encephalitis virus overlap JE virus in their distributions in Asia and Australia,

have similar clinical findings, and because of their antigenic relatedness pose a laboratory diagnostic challenge as well. Nipah virus, a newly described bat-associated paramyxovirus that led to large outbreaks of encephalitis in Malaysia in persons exposed to infected pigs, occurs in the same rural circumstances as does JE virus and may have similar clinical features. The absence of thalamic and basal ganglia involvement and multiple white matter lesions on T2-weighted magnetic resonance imaging scans are important differentiating features. Outbreaks of encephalitis caused by Chandipura virus, a sandfly- and mosquito-borne rhabdovirus, have been confused with JE in South Asia, where both viruses circulate.[6] In areas of Asia where poliomyelitis still has not been eradicated, JE should be included among the possible causes of acute flaccid paralysis. In a series from Lucknow, India, in which 394 children 6 months to 12 years of age with an acute encephalopathic illness underwent virologic studies, 23 percent had JE. Similarly, JE and dengue accounted for 35 percent of defined viral encephalitis cases in Thailand.[10] Meningitis or encephalitis develops in some scrub typhus patients; rash, adenopathy, and an eschar, if present, are helpful diagnostic signs. Acute encephalitis with convulsions is encountered in two thirds of patients with neurocysticercosis, which may be detected by brain imaging. Neurocysticercosis itself may increase the risk for acquiring JE (see the section on pathophysiology). In some developing countries, because aspirin continues to be used in febrile children, individual cases and even outbreaks of Reye syndrome have been mistaken initially as JE.

Noninfectious causes of acute encephalopathy to be considered include heat stroke, vascular occlusion and intracranial hemorrhage, acute electrolyte disturbances, lead encephalopathy and other poisonings (especially caused by insect repellents), and inherited metabolic disorders.

TREATMENT

No specific antiviral therapy is available. A few patients have been treated with interferon alfa, but its efficacy has not been evaluated in wider trials.[23,24] Supportive care and control of intracranial pressure are critical for a good outcome. Mannitol is used routinely in many areas of Asia, but early high-dose dexamethasone therapy was shown to have no clinical efficacy in a prospective controlled clinical trial.[27] Corticosteroids also have been given, without apparent benefit, in the late stages of illness as empiric therapy for late neurologic changes that were presumed to have an immunopathologic basis.[16] Other supportive measures, including control of fever and convulsions, attention to fluid balance, respiratory support, and prevention and treatment of secondary infections, have contributed to increased survival and improved outcomes. Small interfering and hairpin RNA molecules are being investigated as therapeutic agents.[39]

PROGNOSIS

The case-fatality ratio varies from 10 to 35 percent, depending on the accessibility and quality of supportive care. Younger children (<10 years) are more likely to die of the infection and to have more serious neurologic complications acutely and as sequelae. Gross neurologic impairment, such as paralysis, weakness, abnormal muscle tone, seizures, ataxia, and extrapyramidal movement disorders, are found in approximately a third to a half of recovered patients several months to a year after onset.[37,38,51,75] Electroencephalographic abnormalities have been detected in more than 50 percent of surviving children 1 year after recovery. Behavioral disorders and subnormal performance on psychological testing may be found in as many as 75 percent of surviving patients 5 years after onset. Thus, in areas where the disease is prevalent, JE may account for substantial disability in the resident population.

PREVENTION

In areas of Asia where JE is endemic, universal childhood immunization is recommended. Three JE vaccines are used, the most widely distributed of which is an inactivated vaccine produced from infected mouse brain. Vaccine effectiveness of 98.5 percent after administration of three doses has been reported, with partial protection provided after two doses.[26,58,88] The others, a killed primary hamster kidney cell–derived vaccine and a live vaccine made from the attenuated SA 14-14-2 strain, are produced exclusively in the People's Republic of China.[55]

Inactivated JE vaccine derived from mouse brains had been the only product distributed in the United States and internationally for use in travelers.[12,19,26,36,39] However, production by the principal Japanese manufacturer has been discontinued, and supplies in the United States are expected to be depleted in 2009. A novel inactivated cell culture–derived vaccine is now available, however, only for adults 17 years of age and older. Pediatric clinical trials are in progress, and an expanded indication for children from 1 year of age and older is expected by 2011. Two doses of the Vero cell–derived vaccine provides protective neutralizing antibody levels in more than 95% of subjects and higher antibody titers than three doses of the mouse brain–derived vaccine. Neutralizing antibodies persist at protective levels for at least 1 year, but the booster interval has not yet been defined. The vaccine is associated with significantly fewer local adverse reactions than the mouse brain vaccine.

Until the pediatric indication is approved, and while supplies are available, children younger than 17 years of age must receive the mouse brain vaccine. The dose for children 1 to 3 years of age is 0.5 mL, given on days 0, 7, and 30 or 14; the vaccine is not approved for use in children younger than 1 year. Children vertically infected with HIV in Asia have demonstrated a diminished response to vaccination.[71]

Local reactions and mild systemic reactions such as fever, headache, and myalgia occur in 10 to 25 percent of vaccinees who receive the mouse brain vaccine.[28] Allergic reactions consisting of generalized urticaria and facial and peripheral angioedema have been a cause for concern because of the potential for respiratory obstruction and anaphylaxis and because the onset of reactions may be delayed for 12 to 72 hours after vaccine administration.[62] Among Japanese vaccinees, immediate reactions (within 1 hour of vaccination) have been associated strongly with IgE specifically reactive to gelatin (a vaccine stabilizer), whereas children with delayed reactions exhibited gelatin-specific IgG.[73,74] Gelatin hypersensitivity may not underlie all cases with these adverse events. However, an allergic history, including atopy, is a risk factor.[53,62] In addition to antihistamines, parenteral corticosteroid therapy often has been needed. Allergic side effects are estimated to occur in 0.5 percent of vaccinees, a sufficiently high rate of a potentially serious adverse event that the vaccine has not been recommended as a routine immunization for travel to Asia.[28,62] In addition, anecdotal cases of temporally associated acute disseminated encephalomyelitis have been reported, with a frequency as high as 1 in 50 to 1 in 75,000 vaccinees.[61]

Current recommendations specify that the vaccine be reserved for expatriates, for persons spending 30 days or more in an endemic area during the transmission season, and for persons with briefer itineraries if they have a high risk of exposure (Table 188–3). The course of immunization should be completed 7 to 10 days before the onset of travel.[28] Production of this mouse brain–derived vaccine was discontinued in 2006, and vaccination of U.S. travelers now relies on a limited stockpile. An inactivated Vero cell culture–derived vaccine that is as immunogenic after

TABLE 188—3 Risk of Japanese Encephalitis by Country, Region, and Season

Country	Affected Areas or Jurisdictions	Transmission Season	Comments
Bangladesh	Few data, probably widespread	Possibly July-December, as in northern India	Outbreak reported from Tangail district, Dacca division; sporadic cases in Rajshahi division
Bhutan	No data	No data, presumed to be similar to Nepal	Not applicable
Brunei	Presumed to be enzootic as in Malaysia	Presumed year-round transmission	Muslim population does not raise pigs
Cambodia	Endemic—hyperendemic countrywide	Presumed to be May-October	Highly prevalent in rural areas near Phnom Penh; confirmed cases in large epidemics October-December, 1993-1998
Democratic Republic of Korea	Presumed to be countrywide in rural areas <800 m	July-October	Epidemics in 1970s; few recent data
Hong Kong	Rare cases in new territories	April-October	Vaccine not routinely recommended India
India	Reported cases from all states except Arunachal, Dadra, Daman, Diu, Gujarat, Himachal, Jammu, Kashmir, Lakshadweep, Meghalaya, Nagar Haveli, Orissa, Punjab, Rajasthan, and Sikkim	*South India:* May-October in Goa; October-January in Tamil Nadu; August-December in Karnataka; second peak April-June in Mandya district *Andhra Pradesh*: September-December *North India*: July-December	Outbreaks in West Bengal, Bihar, Karnataka, Tamil Nadu, Andhra Pradesh, Kerala, Assam, Uttar Pradesh, Manipure, and Goa Urban cases reported, e.g., Lucknow
Indonesia	Kalimantan, Bali, Nusa Tenggara, Sulawesi, Mollucas, West Irian Java, and Lombok	Probably year-round risk; varies by island; peak risks associated with rainfall, rice cultivation, and presence of pigs Peak periods of risk: November-March; June-July in some years	Endemic on Bali; sporadic cases recognized elsewhere Vaccine not recommended if travel to urban areas only
Japan*	Rare—sporadic cases on all islands except Hokkaido	June-September, except Ryukyu Islands (Okinawa): April-October	Vaccine not routinely recommended for travel to Tokyo and other major cities; enzootic transmission without human cases observed on Hokkaido
Laos	Presumed to be endemic—hyperendemic countrywide	Presumed to be May-October	No data available
Malaysia	Sporadic—endemic in all states of Peninsula, Sarawak, and probably Sabah	November-January peak on Peninsula	Most cases from Penang, Perak, Salangor, Johore, and Sarawak; differentiate from Nipah encephalitis
Myanmar	Presumed to be endemic—hyperendemic countrywide	Presumed to be May-October	Repeated outbreaks in Shan State in Chiang Mai Valley
Nepal	Hyperendemic in southern lowlands (Terai); sporadic cases in Katmandu valley	July-December	Vaccine not recommended for travelers to high-altitude areas only
Pakistan	May be transmitted in central deltas	Presumed to be June-January	Cases reported near Karachi; endemic areas overlap those for West Nile virus
Papua New Guinea	Sporadic cases from d'Entrecasteaux islands, Gulf, Milne Bay, South Highland, West Sepik, and Western provinces	Unknown	Vaccine not routinely recommended
People's Republic of China	Cases in all provinces except Xizang (Tibet), Xinjiang, and Qinghai	Northern China: May-September Southern China: April-October (Guangshi, Gwangdong, Southern Fujian, Yunnan, Szechuan, Guizhou, Hunan, and Jiangsi provinces)	Vaccine not routinely recommended for travelers to urban areas only
Philippines	Presumed to be endemic on all islands	Uncertain, speculations based on locations and agro-ecosystems: West Luzon, Mindoro, Negro Palawan: April-November Elsewhere: year-round; greatest risk April-January	Outbreaks described in Nueva Ecija, Luzon, and Manila
Republic of Korea	Rare sporadic cases	July-October	Last major outbreaks in 1982-1983
Russia	Far eastern maritime areas south of Khabarovsk	Peak period July-September	Sporadic transmission in both rural and sylvatic cycles
Singapore	Rare cases; last in 1992	Year-round transmission no longer detected	Vaccine not routinely recommended Local transmission on adjacent islands
Sri Lanka	Endemic in all but mountainous areas; periodically epidemic in northern and central provinces	October-January; secondary peak of enzootic transmission May-June	Outbreaks in central (Anuradhapura) and northwestern provinces
Taiwan*	Endemic, sporadic cases; island-wide	April-October; June peak	Cases reported in and around Taipei
Thailand	Hyperendemic in north; sporadic—endemic in south Reduced incidence due to vaccination	May-October	Annual outbreaks in Chiang Valley; sporadic cases in Bangkok suburbs
Vietnam	Endemic, hyperendemic in all provinces	May-October	Highest rates in and near Hanoi
Western Pacific and Australia	Epidemics reported in Guam, Saipan (northern Mariana Islands), and Torres Strait Islands and Cape York (Australia)	September-January in the Pacific; February-April in northern Australia	Enzootic cycle may not be sustainable; epidemics only follow introduction of virus

**Local Japanese encephalitis incidence rates may not reflect risks to nonimmune visitors accurately because of high immunization rates in local populations. Humans are incidental to the transmission cycle. High levels of viral transmission may occur in the absence of human disease.*

Note: *Assessments are based on publications, surveillance reports, and personal correspondence. Extrapolations have been made from available data. Transmission patterns may change. From Tsai, T. F., and Yu, Y. X.: Japanese vaccines.* In *Plotkin, S., and Orenstein, W. (eds.): Vaccines, 3rd ed. Philadelphia, W. B. Saunders, 1999, p. 700.*

just two doses is being evaluated and should be available in the United States and in Europe before the mouse brain vaccine is exhausted.

The live attenuated SA 14-14-2 vaccine now is used in certain states in India and in epidemic zones of Sri Lanka and Nepal. Although the recommended schedule of immunization is three doses given at 1, 2, and 6 years of age, studies of case-control effectiveness suggest that two doses could have the protective effect of 98 percent.[55] The effectiveness of a single dose is uncertain; one case-control study disclosed an effectiveness of 85 percent, but with wide confidence intervals. The methodology of two other case-control studies has been questioned. The acute and long-term safety of the live vaccine has been a concern.

Inactivated equine vaccines are used widely in some Asian countries, and a DNA equine vaccine recently has been shown to be highly efficacious.[7] A recombinant live attenuated vaccine for human use is being developed.[50]

Avoidance of outdoor activities during the evening hours, staying in screened or air-conditioned quarters, and sleeping under a bed net will reduce the risk of exposure to vector mosquitoes. Wearing long-sleeved shirts and long pants and using mosquito repellents on clothing and exposed skin are recommended for outdoor activities.

The production of vector mosquitoes in rice fields has been controlled by scheduled changes in water levels, application of larvicides and larval predators, and nontargeted effects of agricultural pesticides.

CHAPTER **188f**

MURRAY VALLEY ENCEPHALITIS

John G. Aaskov

Outbreaks of an acute, severe encephalitic illness, clinically similar to Japanese and St. Louis encephalitis, occurred in rural areas of southeastern Australia in 1917, 1918, 1922, 1925, 1951, and 1974[1,9,16,17] and in north and northwestern Australia in 1981, 1993, and 2000.[8,13,37] They are thought to represent a single entity for which various names (Australian X disease, Murray Valley encephalitis, Australian encephalitis) have been used. Approximately 420 cases were reported in these 9 outbreaks, and sporadic cases have occurred in most years since 1978 in which outbreaks have not occurred.[37]

Case-fatality rates, as high as 70 percent in the early years,[9,11] declined to 20 percent in the 1974 outbreak and have remained at about this level since then.[5,10,13] However, significant residual neurologic disability occurs in as many as 50 percent of survivors.[10,13]

The presence of this disease in Papua New Guinea was confirmed in 1956.[22] The causative virus was transmitted to experimental animals as early as 1918,[6,11] although those strains could not be maintained. The definitive isolation and characterization of Murray Valley encephalitis virus in 1951[21] led to epidemiologic studies that suggested its survival in bird-mosquito cycles in northern Australia but not in the area of epidemic occurrence in southern Australia.[1]

Murray Valley encephalitis is caused by Murray Valley encephalitis virus. In an effort to dissociate a disease from a specific locality, the term *Australian encephalitis* was proposed by residents of Murray Valley for the disease caused by Murray Valley encephalitis virus. Some researchers subsequently have attempted to expand the term *Australian encephalitis* to include encephalitis caused by any Australian arbovirus. Because the term *Australian encephalitis* has no scientific validity and is ambiguous, it should not be used.

ETIOLOGIC AGENT

Murray Valley encephalitis virus was isolated post mortem from the brains of patients in 1951[21] and 1974[26] and shown to be related antigenically to Japanese encephalitis virus.[21,26]

A partial nucleotide sequence of Murray Valley encephalitis virus[14] confirmed the previous classification of this virus, on serologic grounds, as being a member of the Japanese encephalitis, St. Louis encephalitis, West Nile fever subgroup of flaviviruses.[34] Distinguishing Australian strains of Murray Valley encephalitis virus from those isolated in Papua New Guinea has been possible on the basis of limited nucleotide sequencing.[12,27]

TRANSMISSION AND EPIDEMIOLOGY

The mosquito *Culex annulirostris* is thought to be the major vector of Murray Valley encephalitis virus,[17,18,29] although other mosquitoes, such as *Aedes normanensis*, *Aedes tremulus*, and *Culex quinquefasciatus*, also may play a significant role in transmission of the virus.[7]

Murray Valley encephalitis virus is thought to survive in cycles of infection between birds and mosquitoes in northern Australia and Papua New Guinea,[1] where regular infection of humans and other animals is indicated by seroconversion in the summer-autumn "wet" season[15] as well as by clinical disease.[7,37] Recent studies also suggest that the virus might survive, after vertical transmission, in desiccation-resistant eggs of *A. tremulus* mosquitoes.[7] Epidemics that occurred in more populous areas of southeastern Australia are thought to have followed the introduction of virus when abnormal spring rainfall allowed chains of bird-mosquito transmission to occur through northern Australia.[2] However, several studies also have suggested that interepidemic survival of virus occurs in southern Australia.[23]
