BOOK AID  
International

Sabre Foundation

I dedicate this book to my wife Sylvia and our children Alan, Yael, Daniela, and Karyn for their support and sacrifice during this year.

Shlomo Raz

To my sons Marcelo and Andre, because you are the strength of my life, my love, and my inspiration. Thank you for the sacrifices you make to help me fulfill my dreams.

Larissa Rodríguez

# CONTRIBUTORS

**Paul Abrams, MD, FRCS**

Professor, Bristol Urological Institute, Southmead Hospital, Bristol, United Kingdom

*17: Clinical Diagnosis of Overactive Bladder*

**Ilana Beth Addis, MD, MPH**

Assistant Professor, University of Arizona College of Medicine, Associate Director, Female Pelvic Medicine and Reconstructive Surgery, University Physicians Healthcare, Tucson, Arizona

*6: Social Impact of Urinary Incontinence and Pelvic Floor Dysfunction*

**Danita Harrison Akingba, MD**

Fellow, Department of Gynecology, Female Urology, and Pelvic Surgery, Greater Baltimore Medical Center, Baltimore, Maryland

*62: Transabdominal Paravaginal Cystocele Repair*

**Michael E. Albo, MD**

Associate Clinical Professor of Surgery and Urology, University of California–San Diego, San Diego, California; Co-Director of Women's Pelvic Medical Center, University of California–San Diego Hospital, San Diego, California

*29: Selecting the Best Surgical Option for the Treatment of Stress Urinary Incontinence*

**Samih Al-Hayek, MD, MRCS, LMSSA, LRCP, LRCS**

Research Registrar, Bristol Urological Institute, Southmead Hospital, Bristol, United Kingdom

*17: Clinical Diagnosis of Overactive Bladder*

**Cindy Amundsen, MD**

Associate Professor of Obstetrics and Gynecology, Duke University School of Medicine, Durham, North Carolina; Director, Fellowship in Urogynecology and Pelvic Reconstructive Surgery, Department of Obstetrics and Gynecology, Duke University School of Medicine, Durham, North Carolina

*77: Complications of Vaginal Surgery*

**Rodney U. Anderson, MD**

Professor of Urology, Stanford University, Stanford, California

*91: Focal Neuromuscular Therapies for Chronic Pelvic Pain Syndromes in Women*

**Karl-Erik Andersson, MD, PhD**

Wake Forest Institute of Regenerative Medicine, Wake Forest University School of Medicine, Winston-Salem, North Carolina

*4: Pharmacologic Basis of Bladder and Urethral Function and Dysfunction*

**Rodney A. Appell, MD, FACS**

Professor and Chief, Division of Voiding Dysfunction and Female Urology, Baylor College of Medicine, Houston, Texas; Medical Director, Baylor Continence Center, Baylor College of Medicine, Houston, Texas

*33: Vaginal Wall Sling*

**Walter Artibani, MD**

Full Professor of Urology, University of Padova Medical School, Department of Urology, University of Padova Medical School, Padova, Italy

*82: Abdominal Approach for the Treatment of Vesicovaginal Fistula*

**Anthony Atala, MD**

Chair, Department of Urology, Wake Forest Institute for Regenerative Medicine, Winston-Salem, North Carolina

*98: Tissue Engineering for Reconstruction of the Urinary Tract and Treatment of Stress Urinary Incontinence*

**Richard C. Bennett, MD**

Resident, Department of Urology, William Beaumont Hospital, Royal Oak, Michigan

*24: Pudendal Nerve Stimulation*

**Alfred Bent, MD**

Chairman, Department of Gynecology, Female Urology, and Pelvic Surgery, Greater Baltimore Medical Center, Baltimore, Maryland

*62: Transabdominal Paravaginal Cystocele Repair*

**Jerry G. Blaivas, MD**

Clinical Professor of Urology, Weill-Cornell Medical College, New York, New York; Attending Surgeon, New York Presbyterian Hospital, New York, New York; Attending Surgeon, Lenox Hill Hospital, New York, New York

*7: Clinical Evaluation of Lower Urinary Tract Dysfunction; 80: Reconstruction of the Absent or Damaged Urethra*

**David A. Bloom, MD**

Jack Lapides Professor of Urology, Department of Pediatric Urology, University of Michigan, Ann Arbor, Michigan

*1: Developmental Anatomy and Urogenital Abnormalities*

**Timothy Bolton Boone, MD, PhD**

Professor and Chairman, Scott Department of Urology, Baylor College of Medicine, Houston, Texas

*11: Urodynamic Evaluation*

**Sylvia M. Botros, MD**

Assistant Professor, Evanston Northwestern Healthcare, Northwestern University, Feinberg School of Medicine, Evanston, Illinois

*67: Sacrospinous Ligament Suspension for Vaginal Vault Prolapse*

**Alain Bourcier, PT**

Tenon Hospital, Department of Urology, University of Paris, Paris, France; Director, Pelvic Floor Rehabilitation Services, Clinique International Monceau, Paris, France

*19: Behavior Modification and Conservative Management of Overactive Bladder; 28: Pathophysiology of Stress Incontinence*

**Lousine Boyadzhyan, MD**

Resident Physician, Department of Radiology, David Geffen School of Medicine at UCLA, Los Angeles, California

*8: Imaging of the Female Genitourinary Tract; 55: Imaging in the Diagnosis of Pelvic Organ Prolapse*

**C. A. Tony Buffington, DVM, PhD, DACVN**

Professor, Department of Veterinary Clinical Sciences, Ohio State University College of Veterinary Medicine, Columbus, Ohio

**90:** *Neuroendocrine Role in Interstitial Cystitis and Chronic Pelvic Pain in Women*

**Linda Cardozo, MD**

Professor of Urogynaecology, Department of Urogynaecology, King's College Hospital, London, United Kingdom

**5:** *Hormonal Influences on the Female Genital and Lower Urinary Tract*

**Mauro Cervigni, MD**

Professor, Catholic University, Rome, Italy; Chief of Urogynecology, San Carlo-IDI Hospital, Rome, Italy

**66:** *Tension-Free Cystocele Repair Using Prolene Mesh*

**R. Duane Cespedes, MD**

Associate Professor, Department of Urology, University of Texas Health Sciences Center, San Antonio, Texas; Director of Female Urology and Urodynamics, Wilford Hall Medical Center, Lackland AFB, Texas

**97:** *Transvaginal Closure of the Bladder Neck in the Treatment of Urinary Incontinence*

**Christopher R. Chapple, BSc, MD, FRCS, FEBU**

Visiting Professor, Sheffield Hallam University, Sheffield, South Yorkshire, United Kingdom; Consultant Urological Surgeon, Royal Hallamshire Hospital, Sheffield Teaching Hospitals National Health Service Foundation Trust, Sheffield, South Yorkshire, United Kingdom

**27:** *Pathophysiology of Stress Incontinence*

**Chi Chiung Grace Chen, MD**

Fellow, Female Pelvic Medicine/Reconstructive Pelvic Surgery and Minimally Invasive Surgery, Department of Obstetrics and Gynecology, Cleveland Clinic, Cleveland, Ohio

**54:** *Pelvic Organ Prolapse: Clinical Diagnosis and Presentation;*

**73:** *Open Abdominal Sacral Colpopexy*

**Emily E. Cole, MD**

Department of Urology, Vanderbilt University Medical Center, Nashville, Tennessee

**46:** *Radiofrequency for the Management of Genuine Stress Urinary Incontinence*

**Craig V. Comiter, MD**

Associate Professor, Stanford University, Stanford, California

**56:** *Dynamic Magnetic Resonance Imaging in the Diagnosis of Pelvic Organ Prolapse*

**Matthew Cooperberg, MD**

Chief Resident, Department of Urology, University of California–San Francisco, San Francisco, California

**23:** *Posterior Tibial Nerve Stimulation for Pelvic Floor Dysfunction*

**Jaques Corcos, MD**

Professor of Urology, Director of the Urology Department, McGill University, Montreal, Quebec, Canada; Director of the Urology Department, Jewish General Hospital, McGill University, Montreal, Quebec, Canada

**31:** *Urethral Injectables in the Management of Stress Urinary Incontinence*

**Firouz Daneshgari, MD**

Assistant Professor of Surgery, Department of Urology, Case Western Reserve University, Cleveland, Ohio; Director, Center for Female Pelvic Medicine and Reconstructive Surgery, Cleveland Clinic, Cleveland, Ohio

**51:** *Epidemiology of Pelvic Organ Prolapse*

**William de Groat, PhD**

Professor, Department of Pharmacology, University of Pittsburgh, Pittsburgh, Pennsylvania

**3:** *Neuroanatomy and Neurophysiology: Innervation of the Lower Urinary Tract*

**John O. L. DeLancey, MD**

Department of Obstetrics and Gynecology, University of Michigan, Women's Hospital, Ann Arbor, Michigan

**53:** *Functional Anatomy and Pathophysiology of Pelvic Organ Prolapse*

**Donna Y. Deng, MD**

Assistant Professor of Urology, Division of Pelvic Reconstruction, Incontinence, and Neurourology, Department of Urology, University of California–San Francisco, San Francisco, California

**64:** *Transvaginal Paravaginal Repair of High-Grade Cystocele;*

**68:** *Repair of Vaginal Vault Prolapse Using Soft Prolene Mesh;*

**83:** *Rectovaginal Fistula*

**Hans Peter Dietz, MD, PhD**

Associate Professor, Department of Obstetrics and Gynaecology, Western Clinical School, University of Sydney, Nepean Hospital, Penrith, NSW, Australia

**9:** *Pelvic Floor Ultrasound*

**Connie DiMarco, MD**

Urogynecology Department, Sacred Heart Medical Center, McKenzie Willamette Medical Center, Springfield, Ohio

**60:** *Managing the Urethra in Vaginal Prolapse*

**Ananias Diokno, MD**

Department of Urology, William Beaumont Hospital, Royal Oak, Michigan

**93:** *Epidemiology of Incontinence and Voiding Dysfunction in the Elderly*

**Roger Roman Dmochowski, MD**

Professor, Department of Urologic Surgery, Vanderbilt University Medical Center, Nashville, Tennessee

**46:** *Radiofrequency for the Management of Genuine Stress Urinary Incontinence*

**Neil T. Dwyer, MD**

Fellow, Department of Urology, University of Iowa, Iowa City, Iowa

**38:** *Fascia Lata Sling*

**Daniel Eberli, MD**

Wake Forest Institute for Regenerative Medicine, Winston-Salem, North Carolina

**98:** *Tissue Engineering for Reconstruction of the Urinary Tract and Treatment of Stress Urinary Incontinence*

**Karyn Schlunt Eilber, MD**

Director, Comprehensive Center for Continence and Pelvic Reconstruction, Los Angeles, California

**88:** *Benign Cystic Lesions of the Vagina and Vulva*

**Ahmad Elbadawi, MD**

Departments of Pathology and Urology, State University of New York, Syracuse, New York

**2:** *Structural Basis of Voiding Dysfunction*

**Ahmad Elbadawi, MD**

Lecturer in Urology, Alazhar University, Cairo, Egypt; Urology Fellow, Jewish General Hospital, McGill University, Montreal, Quebec, Canada

**31:** *Urethral Injectables in the Management of Stress Urinary Incontinence*

**Raymond T. Foster, Sr., MD, MS, MHSc**

Assistant Professor of Obstetrics and Gynecology, University of Missouri–Columbia, School of Medicine, Columbia, Missouri; Director, Missouri Center for Female Continence and Advanced Pelvic Surgery, Department of Obstetrics, Gynecology, and Women's Health, University of Missouri–Columbia, Columbia Missouri

**70:** *Transvaginal Repair of Apical Prolapse: The Uterosacral Vault Suspension*; **77:** *Complications of Vaginal Surgery*

**Clare J. Fowler, MBBS, MSc, FRCP**

Professor of Neurophysiology, Department of Uro-Neurology, National Hospital of Neurology and Neurosurgery, London, United Kingdom

**10:** *Electrophysiological Evaluation of the Pelvic Floor*

**Joel Funk, MD**

Chief Resident, University of Arizona, Tucson, Arizona

**56:** *Dynamic Magnetic Resonance Imaging in the Diagnosis of Pelvic Organ Prolapse*

**Michelle M. Germain, MD**

Clinical Instructor, Department of Gynecology, Female Urology, and Pelvic Surgery, Greater Baltimore Medical Center, Baltimore, Maryland

**62:** *Transabdominal Paravaginal Cystocele Repair*

**Jason P. Gilleran, MD**

Assistant Professor, Department of Urology, The Ohio State University College of Medicine, Columbus, Ohio

**79:** *Urethrovaginal Fistula*

**David Alan Ginsberg, MD**

Assistant Professor of Clinical Urology, Keck School of Medicine of the University of Southern California, Los Angeles, California; Chief of Urology, Rancho Los Amigos National Rehabilitation Center, Downey, California

**84:** *Ureterovaginal Fistula*

**Roger P. Goldberg, MD, MPH**

Assistant Professor, Northwestern University, Feinberg School of Medicine, Evanston, Illinois

**67:** *Sacrospinous Ligament Suspension for Vaginal Vault Prolapse*

**Irwin Goldstein, MD**

Director, Sexual Medicine, Alvarado Hospital; Clinical Professor of Surgery, University of California, San Diego, California

**50:** *Female Sexual Function and Dysfunction*

**Angelo E. Gousse, MD**

Associate Professor of Urology, Chief of Female Urology and Voiding Dysfunction, University of Miami, Miller School of Medicine, Miami, Florida; Attending Urologist, Jackson Memorial Hospital, Miami, Florida

**15:** *Effect of Pelvic Surgery on Voiding Dysfunction*

**Fred E. Govier, MD**

Clinical Professor of Urology, University of Washington Medical Center, Seattle, Washington; Chief of Surgery, Virginia Mason Medical Center, Seattle, Washington

**59:** *Use of Synthetics and Biomaterials in Vaginal Reconstructive Surgery*

**Asnat Groutz, MD**

Senior Lecturer, The Sackler Faculty of Medicine, Tel Aviv University Tel Aviv, Israel; Urogynecology Unit, Lis Maternity Hospital, Tel Aviv Medical Center, Tel Aviv, Israel

**52:** *Pregnancy, Childbirth, and Pelvic Floor Injury*

**Sender Herschorn, MD, FRCSC**

Professor and Chair, Division of Urology, University of Toronto, Martin Barkin Chair in Urological Research, University of Toronto, Toronto, Ontario, Canada; Attending Urologist, Sunnybrook Health Science Center, Toronto, Ontario, Canada

**57:** *Urodynamics Evaluation of the Prolapse Patient*

**Ken Hsiao, BS, MD**

Assistant Professor of Urology, Indiana School of Medicine, Indianapolis, Indiana; Staff Urologist, John Muir Medical Center, NorCal Urology, Walnut Creek, California

**59:** *Use of Synthetics and Biomaterials in Vaginal Reconstructive Surgery*

**Yvonne Hsu, MD**

Lecturer, University of Michigan, Ann Arbor, Michigan

**53:** *Functional Anatomy and Pathophysiology of Pelvic Organ Prolapse*

**Chad Huckabay, MD**

North Shore Long Island Jewish Health System, Smith Institute of Urology, New Hyde Park, New York

**49:** *Complications of Incontinence Procedures in Women*

**Tracy Hull, MD**

Staff Colorectal Surgeon, Cleveland Clinic Foundation, Cleveland, Ohio

**78:** *Pathophysiology, Diagnosis, and Treatment of Defecatory Dysfunction*

**Nancy Itano, MD**

Assistant Professor and Senior Associate Consultant, Department of Urology, Mayo Clinic, Scottsdale, Arizona

**60:** *Managing the Urethra in Vaginal Prolapse*

**Theodore M. Johnson, II, MD**

Associate Professor of Medicine, Emory University, Atlanta, Georgia; Atlanta Site Director, Atlanta VA GRECC, Atlanta VA Medical Center, Decatur, Georgia

**94:** *Lower Urinary Tract Disorders in the Elderly Female*

**Mickey M. Karram, MD**

Volunteer Professor of Obstetrics and Gynecology, University of Cincinnati, Cincinnati, Ohio; Director of Urogynecology and Reconstructive Pelvic Surgery, Department of Obstetrics and Gynecology, Good Samaritan Hospital, Cincinnati, Ohio  
**71: Vaginal Hysterectomy in the Treatment of Vaginal Prolapse**

**Kathleen Kieran, MD**

Resident, Department of Urology, University of Michigan Health System, Ann Arbor, Michigan  
**1: Developmental Anatomy and Urogenital Abnormalities**

**Adam P. Klausner, MD**

Assistant Professor, Department of Urology, University of Virginia School of Medicine, Charlottesville, Virginia; Assistant Professor, Department of Surgery, Virginia Commonwealth University, Richmond, Virginia  
**18: Pathophysiology of Overactive Bladder**

**Carl George Klutke, MD**

Division of Urologic Surgery, Washington University School of Medicine, St. Louis, Missouri  
**39: Tension-Free Vaginal Tape; 44: Transobturator Approach to Midurethral Sling**

**John J. Klutke, MD**

Assistant Professor of Clinical Gynecology, Department of Obstetrics and Gynecology, Keck School of Medicine, University of Southern California, Los Angeles, California  
**39: Tension-Free Vaginal Tape; 44: Transobturator Approach to Midurethral Sling**

**Kathleen C. Kobashi, MD**

Clinical Associate Professor, Urology, University of Washington, Seattle, Washington; Co-Director, Clinical Fellowship for Voiding Dysfunction and Pelvic Floor Reconstruction, Continence Center at Virginia Mason, Seattle, Washington  
**59: Use of Synthetics and Biomaterials in Vaginal Reconstructive Surgery**

**Karl J. Kreder, MD, FACS**

Professor of Urology, University of Iowa, Iowa City, Iowa  
**38: Fascia Lata Sling**

**Henry Lai, MD**

Fellow, Female Urology and Neurourology, Scott Department of Urology, Baylor College of Medicine, Houston, Texas  
**11: Urodynamic Evaluation**

**Jerilyn M. Latini, MD**

Assistant Professor of Urology, University of Michigan Health System, Ann Arbor, Michigan  
**1: Developmental Anatomy and Urogenital Abnormalities**

**Gary E. Leach, MD**

Director, Tower Urology Institute for Incontinence, Los Angeles, California  
**45: Cadaveric Fascia Using Bone Anchors; 61: Cadaveric Fascial Repair of Cystocele; 75: Posterior Repair Using Cadaveric Fascia**

**Monica Lee, MD**

David Geffen School of Medicine at the University of California–Los Angeles, Los Angeles, California  
**87: Vulvar and Vaginal Pain, Dyspareunia, and Abnormal Vaginal Discharge**

**Gary E. Lemack, MD**

Associate Professor of Urology and Neurology, University of Texas Southwestern Medical Center, Dallas, Texas  
**14: Voiding Dysfunction and Neurological Disorders**

**Malcolm A. Lesavoy, MD**

Department of Plastic Surgery, University of California–Los Angeles, Encino, California  
**99: Reconstruction of Congenital Female Genital Defects**

**Amanda M. Macejko, MD**

Urology Fellow, Northwestern University School of Medicine, Chicago, Illinois  
**86: Urinary Tract Infections in Women**

**Mary Grey Maher, MD**

Urology Center, Yale Medical Center, New Haven, Connecticut  
**41: Distal Urethral Polypropylene Sling; 47: Surgery for Refractory Urinary Incontinence: Spiral Sling**

**Francesca Manassero, MD**

Doctoral Training, Department of Urology, University of Pisa, Pisa, Italy  
**27: Pathophysiology of Stress Incontinence**

**Mariangela Mancini, MD**

Affiliate Professor, Residency in Urology Program, Department of Urology, University of Padova Medical School, Padova, Italy  
**82: Abdominal Approach for the Treatment of Vesicovaginal Fistula**

**Edward J. McGuire, MD**

Professor, Department of Urology, University of Michigan, Ann Arbor, Michigan  
**25: Detrusor Myomectomy; 26: Bladder Augmentation; 36: Autologous Fascial Slings; 48: Mixed Urinary Incontinence**

**Sarah E. Moeller, MS**

University of Minnesota, Minneapolis, Minnesota  
**22: Sacral Neuromodulation Interstim for the Treatment of Overactive Bladder**

**Courtenay K. Moore, MD**

Assistant Professor, Department of Surgery, Cleveland Clinic Lerner College of Medicine, Case Western Reserve University, Cleveland, Ohio; Staff, Female Pelvic Medicine and Reconstructive Surgery, Glickman Urological and Kidney Institute, Cleveland Ohio  
**51: Epidemiology of Pelvic Organ Prolapse**

**Arthur Mourtzinis, MD**

Assistant Professor of Urology, Tufts University Medical School, Boston, Massachusetts; Senior Staff Physician, Institute of Urology, Continence Center, Lahey Clinic Medical Center, Burlington, Massachusetts  
**47: Surgery for Refractory Urinary Incontinence: Spiral Sling**

**M. Louis Moy, MD**

Assistant Professor, Division of Urology, University of Pennsylvania Health System, Philadelphia, Pennsylvania  
**13: Categorization of Voiding Dysfunction; 20: Drug Treatment of Urinary Incontinence in Women**

**Tristi W. Muir, MD**

Assistant Professor, Uniformed Services University of the Health Sciences; Assistant Chief, Female Pelvic Medicine and Reconstructive Pelvic Medicine, Department of Obstetrics and Gynecology, Brooke Army Hospital, Fort Sam Houston, Texas  
**63:** *Anterior Colporrhaphy for Cystocele Repair*; **74:** *Posterior Repair and Pelvic Floor Repair: Segmental Defect Repair*

**Franca Natale, MD**

San Carlo–IDI Hospital, Rome, Italy  
**66:** *Tension-Free Cystocele Repair Using Prolene Mesh*

**Linda Ng, MD**

Assistant Professor of Urology, Boston University School of Medicine, Boston, Massachusetts  
**25:** *Detrusor Myomectomy*; **26:** *Bladder Augmentation*;  
**36:** *Autologous Fascial Slings*

**Victor Nitti, MD**

Associate Professor and Vice Chairman, Department of Urology, New York University School of Medicine, New York, New York  
**49:** *Complications of Incontinence Procedures in Women*

**Peggy A. Norton, MD**

Professor, Department of Obstetrics and Gynecology, and Chief of Urogynecology and Reconstructive Pelvic Surgery, University of Utah School of Medicine, Salt Lake City, Utah  
**58:** *Nonsurgical Treatment of Vaginal Prolapse: Devices for Prolapse and Incontinence*

**Pat D. O'Donnell, MD**

Professor and Chairman, Department of Urology, University of Arkansas for Medical Sciences, Little Rock, Arkansas  
**95:** *Urodynamics Evaluation in the Elderly*

**Joseph G. Ouslander, MD**

Director, Division of Geriatrics and Gerontology, Wesley Woods Geriatric Hospital, Atlanta, Georgia  
**94:** *Lower Urinary Tract Disorders in the Elderly Female*

**Priya Padmanabhan, MD**

Resident, Department of Urology, New York University School of Medicine, New York, New York  
**16:** *Idiopathic Urinary Retention in the Female*

**Maria Fidel Paraiso, MD**

Staff Physician, Department of Obstetrics and Gynecology and the Glickman Urological Institute, Cleveland Clinic, Cleveland, Ohio; Head, Center of Urogynecology and Reconstructive Pelvic Surgery, Cleveland, Ohio; Co-Director, Program of Female Pelvic Medicine and Reconstructive Surgery, Cleveland Clinic Lerner College of Medicine, Case Western Reserve University, Cleveland, Ohio  
**72:** *Laparoscopic Sacral Colpopexy*; **73:** *Open Abdominal Sacral Colpopexy*

**Christopher Kennerly Payne, MD**

Associate Professor of Urology, Director, Female Urology and Neurourology, Stanford University Medical Center, Stanford, California  
**92:** *Painful Bladder Syndrome and Interstitial Cystitis*

**Virgilio G. Petero, Jr., MD**

Urology Research Fellow, William Beaumont Hospital, Royal Oak, Michigan; Clinical Fellow, Division of Immunology and Organ Transplantation, University of Texas, Medical School at Houston, Houston, Texas

**93:** *Epidemiology of Incontinence and Voiding Dysfunction in the Elderly*

**Kenneth M. Peters, MD**

Chairman, Department of Urology, Peter and Florine Ministrelli Distinguished Chair in Urology, William Beaumont Hospital, Royal Oak, Michigan  
**24:** *Pudendal Nerve Stimulation*

**Peter E. Petros, MBBS, PhD, DS, MD, FRCOG, FRANZCOG CU**

Adjunct Professor, Department of Gynaecology, University of Western Australia, Perth, Australia; Consultant Emeritus, Royal Perth Hospital, Perth, Australia  
**40:** *Midurethral to Distal Urethral Slings*; **69:** *Use of IVS Device for Vaginal Vault Prolapse*

**Simon Podnar, MD, DSc**

Associate Professor of Neurology, University of Ljubljana Medical School, Ljubljana, Slovenia; Staff Neurologist and Clinical Neurophysiologist, Institute of Clinical Neurophysiology, University Medical Center, Ljubljana, Slovenia  
**10:** *Electrophysiologic Evaluation of the Pelvic Floor*

**Dimitri U. Pushkar, MD, PhD**

Professor and Head, Department of Urology, Moscow State Medical Stomatological University, Moscow, Russia  
**34:** *Free Vaginal Wall Sling*

**Raymond Robert Rackley, MD**

Co-Head, Section of Voiding Dysfunction and Female Urology; Director, Urothelial Biology Laboratory, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, Ohio  
**21:** *Pharmacologic Neuromodulation*; **43:** *Percutaneous Vaginal Tape Sling Procedure*

**Steven S. Raman, MD**

Associate Professor, Division of Abdominal Imaging and Cross Sectional Interventional Radiology, Department of Radiology, David Geffen School of Medicine at UCLA, Los Angeles, California  
**8:** *Imaging of the Female Genitourinary Tract*; **55:** *Imaging in the Diagnosis of Pelvic Organ Prolapse*

**Andrea J. Rapkin, MD**

Professor, David Geffen School of Medicine, University of California–Los Angeles, Los Angeles, California  
**87:** *Vulvar and Vaginal Disorders: Chronic Pain and Abnormal Discharge*

**Shlomo Raz, MD**

Professor of Urology, Chief of Female Urology, Urodynamics, and Reconstruction, University of California–Los Angeles, School of Medicine, Los Angeles, California  
**47:** *Surgery for Refractory Urinary Incontinence: Spiral Sling*;  
**64:** *Transvaginal Paravaginal Repair of High-Grade Cystocele*;  
**68:** *Repair of Vaginal Vault Prolapse Using Soft Prolene Mesh*;  
**81:** *Vesicovaginal Fistula: Vaginal Approach*; **83:** *Rectovaginal Fistula*

**Dudley Robinson, MRCOG**

Consultant Urogynaecologist, Department of Urogynaecology, King's College Hospital, London, United Kingdom

*5: Hormonal Influences on the Female Genital and Lower Urinary Tract*

**Larissa V. Rodriguez, MD**

Associate Professor of Urology, Division of Female Urology; Co-Director, Division of Pelvic Medicine and Female Urology; Director of Female Urology Research, University of California—Los Angeles, Los Angeles, California

*41: Distal Urethral Polypropylene Sling; 47: Surgery for Refractory Urinary Incontinence: Spiral Sling; 64: Transvaginal Paravaginal Repair of High-Grade Cystocele; 68: Repair of Vaginal Vault Prolapse Using Soft Prolene Mesh; 81: Vesicovaginal Fistula: Vaginal Approach; 83: Rectovaginal Fistula*

**Christopher M. Rooney, MD**

Instructor, Urogynecology and Pelvic Reconstruction, Department of Obstetrics and Gynecology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio

*71: Vaginal Hysterectomy in the Treatment of Vaginal Prolapse*

**Nirit Rosenblum, MD**

Assistant Professor of Urology, New York University School of Medicine, New York, New York

*16: Idiopathic Urinary Retention in the Female; 76: Perineal Hernia and Perineocele*

**Eric Scott Rovner, MD**

Associate Professor of Urology, Department of Urology, Medical University of South Carolina, Charleston, South Carolina

*85: Urethral Diverticula*

**Sarah A. Rueff, MD**

Staff Urologist, Director of the Continence Center, Billings Clinic, Billings, Montana

*45: Cadaveric Fascia Using Bone Anchors; 61: Cadaveric Fascial Repair of Cystocele; 75: Posterior Repair Using Cadaveric Fascia*

**Matthew P. Rutman, MD**

Assistant Professor, Department of Urology, Columbia University Medical Center, New York, New York

*64: Transvaginal Paravaginal Repair of High-Grade Cystocele; 68: Repair of Vaginal Vault Prolapse Using Soft Prolene Mesh; 81: Vesicovaginal Fistula: Vaginal Approach; 83: Rectovaginal Fistula*

**Peter K. Sand, MD**

Professor, Northwestern University, Feinberg School of Medicine, Evanston, Illinois; Evanston Northwestern Healthcare, Evanston, Illinois

*67: Sacrospinous Ligament Suspension for Vaginal Vault Prolapse*

**Jaspreet S. Sandhu, MD**

Urology Fellow, Department of Voiding Dysfunction, Neurourology, and Pelvic Reconstructive Surgery, New York Presbyterian Hospital, Weill-Cornell Medical Center, New York, New York

*7: Clinical Evaluation of Lower Urinary Tract Infection; 80: Reconstruction of the Absent or Damaged Urethra*

**Anthony J. Schaeffer, MD**

Herman L. Kretschmer Professor and Chairman, Department of Urology, Feinberg School of Medicine, Northwestern University; Chairman, Department of Urology, Northeastern Medical Hospital, Chicago, Illinois

*86: Urinary Tract Infections in Women*

**Patrick J. Shenot, MD**

Assistant Professor, Department of Urology, Thomas Jefferson University, Jefferson Medical College, Philadelphia, Pennsylvania

*21: Pharmacologic Neuromodulation*

**Neil D. Sherman, MD**

Assistant Professor, Division of Urology, University of Medicine and Dentistry of New Jersey, Newark, New Jersey

*37: Use of Cadaveric Fascia for Pubovaginal Slings; 65: Cystocele Repair Using Biological Material*

**Steven W. Siegel, MD**

Associate Clinical Professor, Department of Urology, University of Minnesota Medical School, St. Paul, Minnesota; Director, Center for Continence Care, Metropolitan Urologic Specialists, St. Paul, Minnesota

*22: Sacral Neuromodulation Interstim for the Treatment of Overactive Bladder*

**Larry Thomas Sirls, MD, FACS**

Director, Urodynamic Laboratory, William Beaumont Hospital, Royal Oak, Michigan

*12: The Measurement of Urinary Symptoms, Health related Quality of Life and Outcomes of Treatment for Urinary Incontinence*

**Christopher P. Smith, MD**

Assistant Professor, Division of Female Urology and Voiding Dysfunction, Scott Department of Urology, Baylor College of Medicine, Houston, Texas

*11: Urodynamic Evaluation*

**Karen E. Smith, MD**

Kanephe, Hawaii

*48: Mixed Urinary Incontinence*

**David Staskin, MD**

Associate Professor of Urology, Weill-Cornell Medical College, New York, New York; Director, Female Urology and Voiding Dysfunction, New York Presbyterian Hospital, New York, New York

*42: The SPARC Sling System*

**William Donald Steers, MD**

Hovey Dabney Professor and Chair, Department of Urology, University of Virginia School of Medicine, Charlottesville, Virginia

*18: Pathophysiology of Overactive Bladder*

**Marshall L. Stoller, MD**

Professor and Vice-Chair, Department of Urology, University of California—San Francisco, San Francisco, California

*23: Posterior Tibial Nerve Stimulation for Pelvic Floor Dysfunction*

**Lynn Stothers, MD, MHSc, FRCSC**

## PREFACE

*The mere formulation of a problem is far more essential than its solution, which may be merely a matter of mathematical or experimental skills. To raise new questions, new possibilities, to regard old problems from a new angle requires creative imagination and marks real advances in science. Imagination is more important than knowledge. The important thing is not to stop questioning.*

Albert Einstein

During the past 30 years, thanks to the efforts of leading urologists, gynecologists, basic scientists, pharmacologists, neurophysiologists, and geriatricians, we have made unprecedented achievements in female pelvic medicine and reconstruction. These people have worked hard and deserve all the respect and honor they receive. They have done remarkably well in applying new ideas and technologic advances to the field.

Intellectual capital is knowledge, information, and experience that can be used to create better medicine. This collective brainpower is hard to identify and harder still to deploy effectively, but once found and exploited, success is at hand. In this book, we have used this intellectual brainpower of all our collaborators to address simple and complex clinical conditions, with a focus on many medical and surgical specialties.

We have resisted the temptation to offer easy formulas and checklists because the fields of female pelvic medicine and reconstructive surgery are new and continuing to evolve. Although some of the chapters written today may be outdated at the time of publication, we have done our best to provide the most current information available.

The principal contribution of this book is the array of chapters written by leaders in the field that describe the challenges of female pelvic medicine and reconstruction and that offer a framework on which health care professionals can build useful and valuable strategies for treating patients. Although the authors have expressed their own opinions, they also have incorporated the most current scientific and clinical information into accessible formats. They have researched the best evidence for clinical application and have critically appraised that evidence for its validity and usefulness. We thank them all for their great efforts.

We will count this book a success if it inspires many readers to generate ideas far beyond any we have included or we could imagine.

Shlomo Raz and Larissa Rodríguez

## Chapter 1

# DEVELOPMENTAL ANATOMY AND UROGENITAL ABNORMALITIES

*Kathleen Kieran, Jerilyn M. Latini, and David A. Bloom*

Knowledge of the prenatal development of the genitourinary system is essential to understand congenital disorders and normal urinary tract function and anatomy. This chapter summarizes the key milestones in genitourinary tract development at the organ and cellular levels. Many genes appear to play key roles in the molecular signals for development and differentiation of components of the genitourinary system. These genes are temporally and locally expressed during development, and without them, normal development fails.<sup>1</sup> The kidney development database<sup>2</sup> (<http://www.ana.ed.ac.uk/anatomy/database/kidbase>) provides a list of these genes, and updated or revised designations can be found in the international database (<http://www.gene.ucl.ac.uk/nomenclature>).

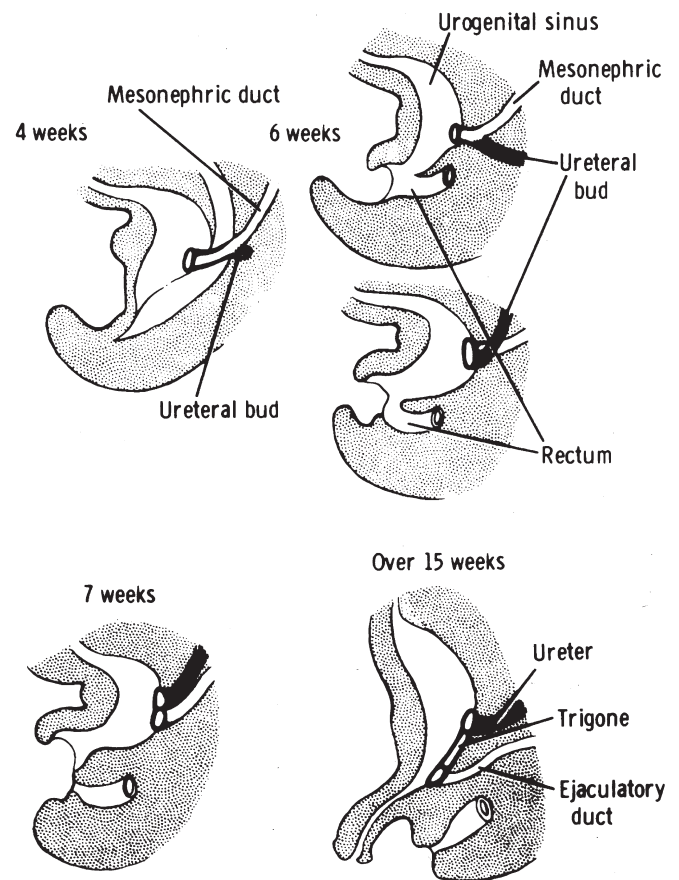

### DEVELOPMENT OF THE GENITOURINARY SYSTEM

The genitourinary system begins to take form from intermediate mesoderm in the third week of gestation. At this point, the embryo is a bilaminar disk composed of external ectoderm and internal endoderm. The longitudinal growth of the embryo begins to exceed its transverse growth, such that the resulting tension induces folding of the cranial and caudal ends toward one another around the umbilical stalk. This folding brings the cloacal membrane (a bilaminar membrane in the caudal portion of the embryo, distal to the allantois) ventrally. The endoderm-lined yolk sac dilates, and the cloaca forms.

The cloaca ultimately is divided into the anterior urogenital sinus and the posterior rectum (Fig. 1-1), although the mechanism is debated. It was once believed that urorectal folds on either side of the midline grew caudomedially to fuse with the cloacal membrane and divide the cloacal membrane into the urogenital sinus and the dorsal rectum by week 7. Subsequent regression of the tail then rotated the urogenital sinus and rectum dorsally. Some investigators<sup>3,4</sup> have suggested that the urorectal septum may not exist or may not fuse with the cloacal membrane.

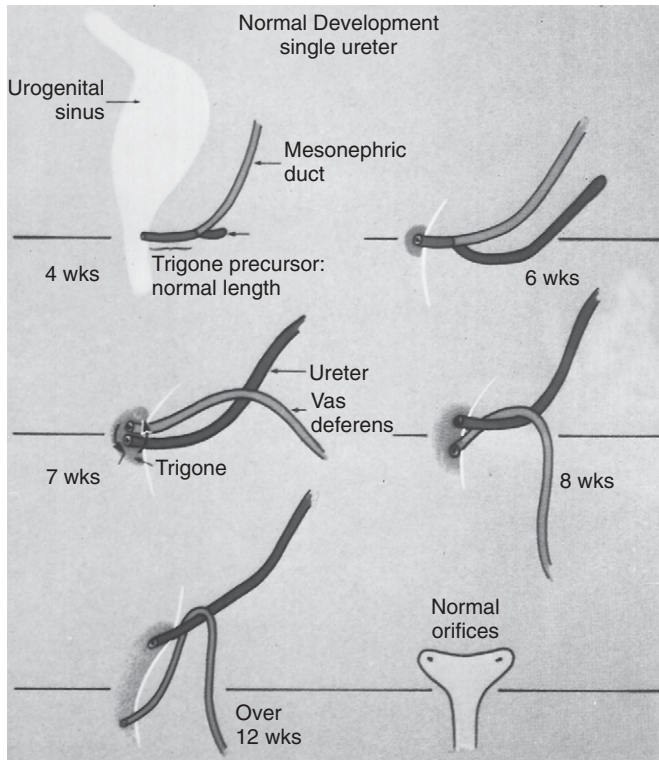

The development of the urinary tracts and portions of the genital system is induced by the mesonephric and paramesonephric (müllerian) ducts. Both ductal systems grow toward the urogenital sinus; the mesonephric ducts grow medially, whereas the müllerian ducts have already fused into a single midline structure. Fusion of the wolffian ducts with the cloaca occurs by the middle of the fourth week (day 24). The junction of the müllerian ducts and the urogenital sinus is a central embryologic location called Müller's tubercle. The mesonephric ducts bend laterally; at this bend, a ureteric bud forms. The portion of the mesonephric duct between the urogenital sinus and the ureteric bud is called the common nephric duct, and by day 33, it is

absorbed into the urogenital sinus, providing an island of mesoderm in the otherwise endoderm-based urogenital sinus (Fig. 1-2). This mesodermal island expands laterally to become the trigone of the bladder. The location of the ureteric bud relative to the urogenital sinus determines whether the ureteral

**Figure 1-1** Development of the lower urinary tract. At 4 weeks, the cloaca is divided by a septum into an anterior urogenital sinus and posterior rectum. The mesonephric duct already joins the anterior portion of the cloaca, and the ureteral bud has started to develop at the bend of the mesonephric duct as it turns forward and medially to join the urogenital sinus. At 6 weeks, the urorectal septum progressively separates the urogenital sinus anteriorly from the rectum posteriorly. By week 7, the separation is complete, and the ureter and the mesonephric duct acquire separate openings in the urogenital sinus. After the 12th week, the ureter starts its upward and lateral movement as the mesonephric duct moves downward and medially. Tissue absorbed in between forms the trigone.

**Figure 1-2** The lower end of the mesonephric duct as it joins the anterior division of the cloaca. Notice that the common nephric duct is progressively absorbed into the urogenital sinus. By week 7, the ureter and the mesonephric duct have separate openings, and rotation takes place. The ureter moves upward and laterally, and the mesonephric duct moves downward and medially, expanding the absorbed tissue to form the trigonal structure.

orifices will be orthotopic; a ureteric bud that originates on a short, common nephric duct will be incorporated sooner into the bladder, with resultant lateral displacement of the ureteral orifices. The intramural ureteral tunnel predisposes to vesico-ureteral reflux. Conversely, ureteric buds that are located a great distance from the urogenital sinus will be incorporated into the urogenital sinus later and may be associated with ectopic drainage into surrounding structures.

The ureteric bud continues to grow cranio-laterally while the mesonephric duct (distal to the bifurcation of the common nephric duct into the mesonephric duct and ureteric bud) grows caudomedially. The ureter undergoes a process of obstruction during the sixth week (37 to 40 days) and then is recanalized from the central portion to the cranial and caudal limits. Incomplete recanalization at either end may account for obstruction at the ureteropelvic junction or at the ureterovesical junction, where a thin transient membrane (i.e., Chwalla's membrane) may fail to dissolve. The cuboidal epithelium of the immature ureter evolves to a lining of transitional cells by 14 weeks.<sup>5</sup>

The urogenital sinus expands caudally to form the bladder and gives rise to the posterior urethra in males or the entire urethra and distal third of the vagina in females. The cranial portion of the urogenital sinus tapers during the third month of gestation so that the allantois forms the urachus and the sacculus bladder remains in place. The intramural bladder wall develops throughout the remainder of gestation, with collagen formation beginning in the lamina propria and with subsequent intercala-

tion between intramural muscle fibers. Intramural muscle fibers form as perivesical splanchnic mesoderm matures after induction by epithelial-mesenchymal interactions. Compliance of the fetal bladder increases over time in human fetuses and in animal models.<sup>6,7</sup> Koo and colleagues<sup>7</sup> showed a decreasing ratio of type 3 to type 1 collagen in the fetal bovine bladder; the changing ratios of perivesical collagen and muscle likely account for at least a portion of this evolution.

### Renal and Ureteral Development

The renal excretory unit is the result of a complex developmental process influenced by reciprocal induction of mesenchyme and the ureteric bud and by many molecular events. The kidney develops in three stages. The first is the pronephros, which arises late in the third week in the cranial portion of the embryo. Pronephric tubules develop cranially and extend caudally, but they degenerate quickly, and the pronephros is obliterated by the start of the fifth week. By day 24, mesonephric ducts are present at the ninth and tenth somites. These ducts grow caudally to the cloacal membrane by day 28, fuse in the midline, and eventually form the bladder. Caudal canalization and then cranial canalization follows. The mesonephros, unlike its predecessor, is able to accomplish limited excretory function for the growing embryo. Mesonephric tubules along the medial nephrogenic cords form and dissolve, sequentially disappearing by the fourth month of development to leave only remnants. Some tubules develop lumens and vesicles and twist into an S shape, in which the lateral portion becomes the mesonephric duct and the medial portion surrounds capillaries originating in the aorta and forms a primitive renal corpuscle. Cranially, the tubules form efferent ductules. The mesonephric ducts give rise to the epididymis and vas deferens, and in females, remnants persist as the paroöphoron and epoöphoron, which are vestigial mesosalpingeal structures.

The metanephros gives rise to the fetal kidney. It forms in the sacral region as the ureteric buds arise from the mesonephric ducts. As the ureteric buds grow cranially, they encounter metanephric mesenchyme on about day 28. After the ureteric bud contacts the mesenchyme, release of many factors culminates in reciprocal induction of growth factors governing the development of the metanephric system. The ureteric bud divides repeatedly between weeks 6 and 32 of development, ultimately giving rise to the collecting system: the collecting ducts, calyces, renal pelvis, and ureter. The metanephric mesenchyme gives rise to the parenchymal portions of the kidney that perform filtration and clearance: the glomeruli, proximal and distal tubules, and loop of Henle. Because of the lengthy period during which branching of the ureteral bud occurs, the growth of the metanephric mesenchyme that will give rise to renal parenchyma is not uniform; nephrons at the juxtamedullary region are formed earlier and mature sooner than nephrons in more peripheral locations. Nephrons undergo four defined stages of development in the human. Stage I occurs when the metanephric mesenchyme is fully discrete from the ureteral bud. Stage II begins when the S-shaped nephron connects with the ureteral bud. In stage III, an ovoid structure emerges, and in stage IV, a round glomerulus is seen. Most nephrons in humans are stage IV at birth, although maturation is completed fully in the early postnatal period.<sup>5</sup>

As the kidneys grow, their location in the embryo becomes progressively more cranial; this is likely caused by active growth of the kidney parenchyma and by increased differential growth of the caudal portion of the embryo. As a result, the kidneys

ascend from their initial pelvic location to the upper retroperitoneum. As renal ascent proceeds, new blood vessels are generated cranially, and the more caudal blood vessels break down. In postnatal patients with renal ectopia, the renal blood supply is typically anomalous because angiogenesis is arrested when renal ascent ceases. The possibility of an aberrant blood supply should be considered in any patient with renal ectopia.

### Formation of the Urogenital Sinus and External Genitalia

With dissolution of the tail and further development of the lower abdominal wall, the cloaca returns to a more dorsal position, and mesodermal proliferation in the fifth week forms genital tubercles. These tubercles ultimately fuse in the midline to form the phallus or clitoris. The urogenital sinus remains at the base of the tubercles; the folds of the urogenital sinus ultimately fuse in the male to form the penile urethra and widen in the female to form the vaginal vestibule and the discrete labia minora. The endodermally derived urethral groove develops from the urogenital sinus in the sixth week, and the urethral plate (a deepening of this groove) forms shortly thereafter. Male and female embryos remain morphologically identical until approximately 12 weeks' gestation.

### Abnormalities of the Urogenital Sinus

Bladder exstrophy occurs in approximately 1 of 30,000 births and is seven times more likely in children conceived through in vitro fertilization.<sup>8</sup> This disorder is characterized by early rupture of the cloacal membrane, which is sometimes related to an intrinsic defect in the membrane. It is more common in males than in females by a ratio of approximately 2:1 to 6:1,<sup>9</sup> and it is related to epispadias and to cloacal exstrophy. The latter condition is also associated with early rupture of the cloacal membrane, although it occurs much less commonly (1 in 200,000 to 400,000 births<sup>10</sup>). Although no genes associated with either condition have been definitively identified, the risk of bladder exstrophy is substantially greater with an affected relative (1 in 275) or an affected parent (1 in 70).<sup>9</sup> Mesenchymal ingrowth between the ectodermal and endodermal layers of the cloacal membrane ultimately results in formation of the lower anterior abdominal wall and division of the cloaca into the anterior urogenital sinus and posterior rectum. Both disorders are associated with malformations of other organ systems, including the limbs, lower anterior abdominal wall, pelvic girdle, and in the case of cloacal exstrophy, the hindgut. Management of these conditions remains challenging.

### Gonadal Development

Development of the testes and ovaries is initiated in the fifth week of gestation, when germ cells from the yolk sac migrate to the posterior body wall, inducing formation of the urogenital ridge medial to the mesonephros (Fig. 1-3). Invasion of the adjacent mesenchyme in the sixth week creates a primitive gonad with epithelium and blastema; the latter is formed from loosened epithelial cells. Persistent growth of the germinal epithelium into the adjacent mesenchyme forms cords that ultimately branch many times and form seminiferous tubules.

Initially, all embryos have the potential to become male or female; the development of internal or external genitalia is an event influenced by genetic, endocrine, and paracrine factors.

*SRY*, a gene on the short arm of the Y chromosome, induces formation of the Sertoli and Leydig cells. It also induces secretion of anti-müllerian hormone (AMH), formerly called müllerian-inhibiting substance (MIS), which induces regression of the müllerian system between 8 and 10 weeks' gestation.<sup>5</sup> Remnants of the müllerian system in the male include the prostatic utricle and the appendix testis. AMH has unilateral paracrine activity, and expression is required locally and bilaterally to achieve eradication of müllerian structures. Failure of testicular secretion of AMH or lack of receptive tissue results in persistence of the müllerian structures ipsilaterally as a miniature uterus and fallopian tube, typically associated with an inguinal hernia (i.e., hernia uteri inguinale). In the absence of *SRY* protein and AMH, ovarian follicles form from the maturing cortex at 3 to 4 months.

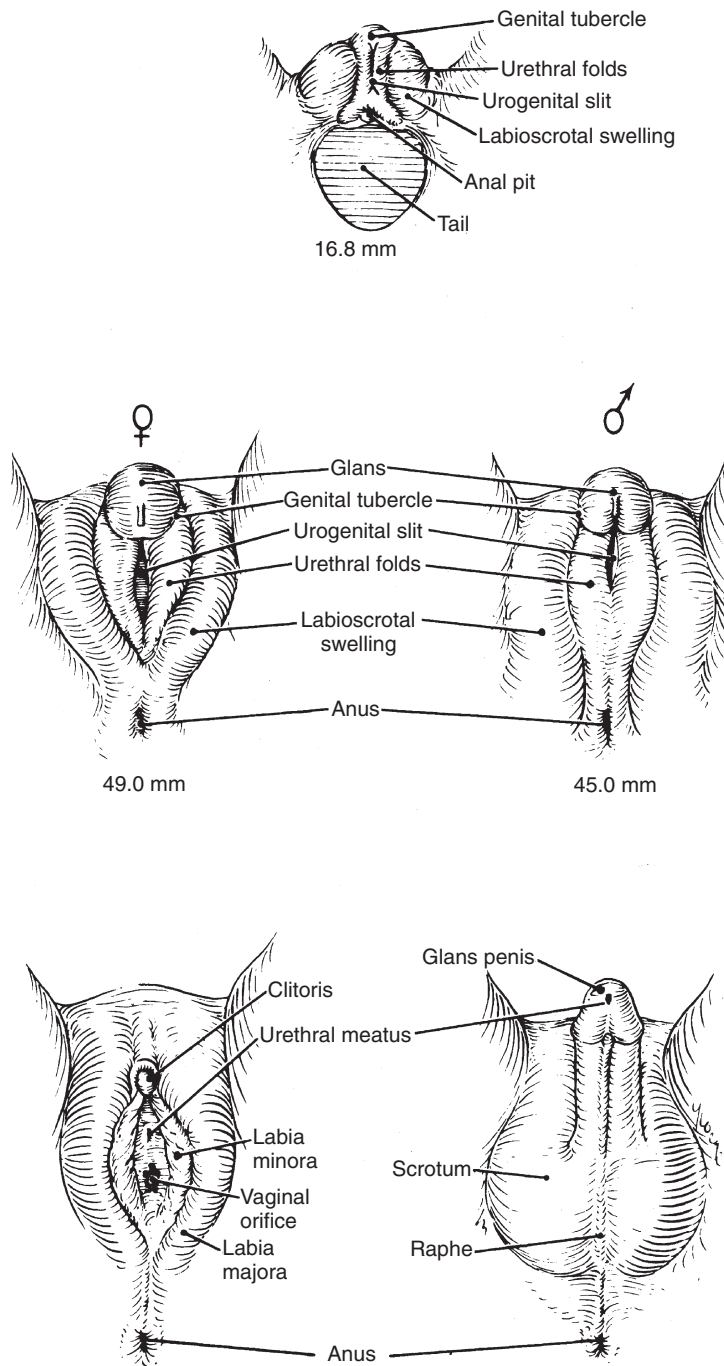

Testosterone, which is secreted by the Leydig cells, and dihydrotestosterone, which is a derivative of testosterone arising from the action of 5 $\alpha$ -reductase, play key roles in the development of the male ductal anatomy and external genitalia. Testosterone induces formation of the vasa deferentia and efferent ductules. Cranially, the mesonephric ducts degenerate, leaving the epididymis and its appendix. The distal mesonephric ducts give rise to the seminal vesicles. Testosterone stimulation and local conversion to dihydrotestosterone induce development of the prostate. Dihydrotestosterone also is locally responsible for fusion of the labioscrotal folds and the phenotypic development of the male external genitalia. Figure 1-4 illustrates the developmental and phenotypic correlates of male and female external genitalia.

Descent of the fetal gonad is a two-step process. During the third month, the embryonic gonad is retroperitoneal and descends caudally so that by the seventh month, it is at the internal inguinal ring. The gubernaculum forms in the seventh week, and the processus vaginalis develops as a peritoneal outpouching. The second phase of scrotal descent occurs during the eighth and ninth months.

The exact mechanism by which the testicle descends into the scrotum is unknown. Theories include contraction of the cremasteric fibers with resultant shortening of the gubernaculum, swelling of the tissue surrounding the inguinal canal such that the canal is widened sufficiently for passage of the testis, and increased intra-abdominal pressure with subsequent passage of the testis through the inguinal canal.<sup>5</sup> The ovarian gubernaculum attaches to the müllerian ducts in the seventh week when fusion of the paramesonephric structures creates the broad ligament from folds of peritoneum. The gubernaculum then divides into two portions. Superiorly, the ovarian ligament connects the uterus and ovary, and inferiorly, the round ligament connects the ovary and the labioscrotal folds.

### Abnormalities in Development of Internal and External Genitalia

Abnormalities in the development of the internal and external genitalia can be divided into those in which only the external genitalia are affected and those in which the internal and external genitalia are affected. Disorders in which the external genitalia are affected are considered ambiguous genitalia ("hermaphroditism") and occur in approximately 1 of 30,000 live births. Male pseudohermaphrodites are genetically 46,XY, with preserved wolffian duct structures and internal testicular tissue but feminized external genitalia.<sup>11,12</sup> Female pseudohermaphrodites (60% to 70% of hermaphrodites) are genetically 46,XX, with preserved müllerian structures and internal ovarian tissue but virilized

**Figure 1-3** The undifferentiated sexual structures early in embryonic life (eighth week) grow and differentiate into female or male forms. The representative segments and their future course (depending on sexual differentiation) are illustrated. (From Tanagho EA: Embryology of the genitourinary system. In Tanagho EA, McAninch JW [eds]: General Urology, 14th ed. Norwalk, CT, Appleton & Lange, 1995.)

external genitalia. True hermaphrodites are rare and have both ovarian and testicular tissue, typically with a 46,XX genotype<sup>11</sup>; there is no consistent appearance of the external genitalia, but about 75% of patients have male external genitalia with hypospadias and variable gonadal descent.<sup>12</sup>

Female pseudohermaphrodites are most commonly the result of 21-hydroxylase deficiency,<sup>11</sup> an autosomal recessive disorder in which insufficiency of this enzyme leads to incomplete synthesis of all products in the steroidogenic pathway in the adrenal gland. The lack of production of the final product yields lack of feedback on the precursors, and intermediate products (many of them androgenic at high doses) accumulate. Less commonly, other enzymes in the steroidogenic pathway are affected; 3 $\beta$ -

hydroxylase deficiency is rare, whereas 11-hydroxylase deficiency is associated with salt retention and hypertension rather than the salt wasting observed with 21-hydroxylase deficiency. The end result is virilization of the external genitalia while the normal female internal genitalia are preserved. Less frequently, extrinsic exposure to androgens can be the cause. In either case, management of the affected patient includes correction of the electrolyte abnormalities and reconstruction of functional phenotypic anomalies.

Male pseudohermaphrodites arise through defects in androgen synthesis or recognition in the developing embryo. Androgen resistance is an X-linked abnormality seen in approximately 1 of 60,000 newborns, in which the testes form and function normally

**Figure 1-4** Development of the male and female external genitalia. Notice that the genital tubercles that develop on the undersurface of the cloacal membrane progressively enlarge and fuse to form the body of the penis in the male and to form the clitoris in the female. Fusion of the urethral folds completes the urethral formation in the male, whereas the folds remain as the labia in the female. The post-tubercle segment of the urogenital sinus opens to become the vaginal vestibule of the female, whereas in the male, it forms part of the urethra, which is completed by the urethral fold fusion.

but the target tissues have a receptor defect that renders them insensitive to androgens.<sup>11,13</sup> AMH is still secreted by the normal testes, and the müllerian ducts degenerate. Wolffian structures are preserved. Many of these patients present at puberty, but patients who are identified soon after birth can be given testosterone or human chorionic gonadotropin to stimulate phallic

growth and determine whether male gender assignment is feasible.<sup>11</sup> Testes should be closely monitored or removed because of the risk of dysgerminoma.

True hermaphroditism is associated with the presence of ovarian and testicular tissue. Lateral hermaphroditism is associated with the presence of an ovary on one side and a testis on the

other. Unilateral hermaphroditism is associated with an ovotestis on one side and a normal gonad on the other. Bilateral hermaphroditism is associated with bilateral ovotestes. Like male pseudohermaphroditism, true hermaphroditism is associated with an increased risk of neoplastic conversion in the testis.<sup>11</sup>

Less common abnormalities of gonadal development include mixed gonadal dysgenesis and pure gonadal dysgenesis. In the former, karyotypes are typically 45,X/46,XY, and patients have a single testis accompanied by a streak ovary. These patients are at increased risk for dysgerminoma. In pure gonadal dysgenesis, ambiguous genitalia are not present; these patients are at increased risk for gonadoblastoma.<sup>11,12</sup>

Because formation of the female reproductive system from the müllerian ducts relies on fusion of primitive structures, abnormalities of fusion are not uncommon. Normal development of the müllerian system relies on elongation of the epithelial tubes lateral to the wolffian ducts, fusion of these ducts after reaching Muller's tubercle, independent recanalization of each side, and resorption of the residual septum in a caudad-to-cephalad fashion. Failure at any of these steps may result in disorders such as unicornuate uterus, persistent vaginal septum with resultant septate vagina, or Mayer-Rokitansky-Küster-Hauser syndrome (1 in 5000).<sup>14</sup> In the latter syndrome, failure of müllerian duct fusion gives rise to vaginal agenesis, although the ovaries and fallopian tubes develop normally. Concomitant renal and genitourinary (15% to 40%) or skeletal (12% to 50%) abnormalities occur.<sup>11,15</sup>

### MOLECULAR CAUSES OF ABNORMAL DEVELOPMENT

During the past decade, significant advances have been made in the identification of the genes and their proteins involved in the normal and abnormal development of the genitourinary tract. Knowledge of the precise molecular events involved in embryogenesis is evolving rapidly, and key genes and proteins crucial to certain steps in genitourinary development are discussed in the following sections.

#### FGF10

Fibroblast growth factor 10 (FGF10) is expressed in the mesenchyme of the genital tubercle; FGF8 is expressed by urethral tissues. Interactions between these structures likely induce growth of the male phallus. The lack of FGF10 expression is theorized to account for the hypospadiac morphology with failure of fusion of the distal urethral plate, although the plate itself appears to develop normally because of the presence of FGF-8.<sup>16,17</sup>

#### GDNF

Glial cell–derived neurotrophic factor (GDNF) is a mesenchyme-derived signaling factor that is a member of the transforming growth factor- $\beta$  (TGF- $\beta$ ) family. It acts as the ligand for the RET receptor and induces growth of the ureteral bud during its interaction with the metanephric mesenchyme. In *GDNF*-knockout animals, development of the pronephros and mesonephros proceeds normally, but metanephric development is stunted by the lack of reciprocal interactions between the mesenchyme and the ureteral bud.<sup>18</sup> Similar defects are seen in *WT1* mutants<sup>19</sup> and

*RET*-deficient mutants, although the latter may have primitive, poorly developed kidneys.<sup>1,19</sup>

#### WNT4

WNT4 (i.e., wingless-type mouse mammary tumor virus [MMTV] integration site family member 4 protein) is expressed in the mesenchyme adjacent to the mesonephric ducts and in the metanephric mesenchyme. *WNT4* mutants have abnormally small, dysplastic kidneys and arrest of development at the level of formation of the renal tubules and renal epithelium from the mesenchyme.<sup>1</sup> It is theorized that WNT4 signals enable organization of the epithelial cells into tubular structures.<sup>19</sup>

#### AMH

Behringer and colleagues<sup>20</sup> found that in *AMH* knockouts, testes were bilaterally descended, but the female reproductive organs remained intact, although they were often hypoplastic. Testes had Leydig cell hyperplasia, but spermatogenesis and semen analyses were normal in the affected animals. In contrast, mice that did not produce AMH but who also had a defect in the androgen receptor had absent wolffian structures and bilaterally undescended testes with maturational arrest in spermatogenesis. AMH is thought to exert its effects through paracrine actions, and it must be present before week 8 of gestation to induce müllerian regression.<sup>18</sup>

Bartlett and coworkers<sup>21</sup> evaluated mice heterozygous for the *AMH* gene. These heterozygotes had poor development of the cremaster-gubernaculum complex; the gubernaculum did develop but remained fibrotic and had poor cremaster development. Testes descended normally in these mice. The investigators concluded that AMH was not the determinant of gubernaculum development or testicular descent but that it did play a key role in cremaster development.

Defects in the type II anti-müllerian hormone receptor gene (*AMHR2*) (formerly referred to as the MIS type II receptor gene) have also been associated with persistent presence of paramesonephric structures. Persistent müllerian duct syndrome (PMDS) is a subtype of male pseudohermaphroditism in which the external genitalia are virilized and are morphologically normal, but paramesonephric structures persist. Hoshiya and associates<sup>22</sup> reported a novel mutation in the *AMHR2* gene caused by abnormal splicing; prior research identified additional abnormalities in the gene caused by base pair mutation in an intron and by deletion of genetic material from an exon.

AMH is a hormone associated with the TGF- $\beta$  family that is expressed in neonates, with a peak level occurring in male infants and in prepubertal girls. In addition to effects on degeneration of the müllerian system, its exact hormonal effects are unknown. However, it was shown to decrease testosterone production by the Leydig cells by a cytochrome P450–dependent mechanism in one study.<sup>23</sup> Testosterone levels were increased in normal controls compared with hypospadiacs, and AMH protein levels were inversely correlated, suggesting that AMH may influence external genital development and induce the hypospadiac phenotype.

AMH expression has been a useful means of differentiating between patients with extrinsic and those with intrinsic virilization. Because AMH is synthesized by the Sertoli cells, elevated AMH levels in male infants with undescended testes suggest the presence of normal or malignant testicular tissue, whereas the absence of AMH is associated with residual ovarian tissue.<sup>24</sup>

### KSP-Cadherin

KSP-cadherin, also designated CHD16 or cadherin 16, is a cell-adhesion molecule expressed solely in the tubular epithelial cells of the kidney and genitourinary tract during prenatal development. Using protein linkage and immunoassays, expression of KSP-cadherin has been localized to the embryonic ureteric bud, wolffian duct, müllerian ducts, and mesonephric and metanephric structures. In adults, expression is limited to the thick ascending loop of Henle, proximal renal tubules, and Bowman's capsules. Shao and colleagues<sup>25</sup> demonstrated that tissue-specific expression of this protein could be established through linkage to a promoter and that a small segment of DNA adjacent to the promoter was adequate for tissue-specific expression. Although the exact function of KSP-cadherin has not been elucidated, its tissue-specific expression during development suggests that it may be involved with organogenesis of the genitourinary system.<sup>25</sup>

### PAX2

*PAX* genes have been linked in previous research to abnormal prenatal development of the renal and visual systems, including Waardenburg's syndrome, aniridia, and alveolar rhabdomyosarcoma. *PAX2* (i.e., paired box gene 2) is localized to chromosome 10. It is expressed in the mesonephric ducts, ureteral bud, and the periureteral mesenchyme, and it is absent in mature nephrons.

Animals heterozygous for the *PAX2* gene had diminished kidney size and disorganized structure, with a thin cortex, decreased number of cortical structures, increased cystic components, and immaturity of mesenchyme-derived tissue.<sup>18</sup> Homozygous *PAX2*-knockout animals manifested renal agenesis associated with failure of wolffian duct formation.<sup>26</sup> These abnormalities are referable to failed branching of the ureteral bud, lack of appropriate differentiation of the metanephric mesenchyme, or failure of reciprocal induction of the mesenchyme and ureteral bud.<sup>26</sup> Sanyanusin and coworkers<sup>27</sup> found similar ultrastructural abnormalities in heterozygotes in a family cohort with a known *PAX2* mutation who were affected by optic nerve colobomas and genitourinary abnormalities, including vesicoureteral reflux and anomalous renal development. Animal models homozygous for *PAX2* mutations failed to develop genitourinary tracts; development of the external genitalia was also abnormal because of limited growth of the mesonephric duct and subsequent failure of the subdivision of the cloaca.<sup>1</sup>

### WT1

Wilms' tumor 1 gene (*WT1*) is one of the most well-known genes in renal development. Located on chromosome 11p, its linkage to the appropriate receptor results in blockage of transcription, and abnormal linkage is associated with development of Wilms' tumors. Clarkson and associates<sup>28</sup> demonstrated that mutations in the *WT1* gene were associated with nephric anomalies and genital anomalies, although the latter were not observed independently of the former. Expression of the *WT1* protein has been localized to the mesonephric tubules and metanephric mesenchyme, and prenatal lack of expression is associated with failure of metanephric development; *WT1*-knockout mice fail to develop caudal mesonephric tubules, which ultimately give rise to renal structures.<sup>18</sup> The local events surrounding *WT1* expression appear

to include suppression of insulin-like growth factor 2 (IGF2) expression in the local mesenchyme, because IGF2 is expressed before *WT1* activity, and IGF2 expression declines in the presence of *WT1*.<sup>19</sup>

*WT1* has been associated with prenatal expression of *PAX2* and *AMH*. *WT1*-knockout mice fail to express *PAX2*, and *WT1* is thought to exert effects on *AMH* expression in the developing embryo. Activity of the *AMH* promoter is known to be under the influence of many substances, including *WT1*, GATA-binding protein 4 (*GATA4*), SRY-box 9 (*SOX9*), and splicing factor 1 (*SF1*). *WT1* expression in the developing embryo parallels that of *AMH* expression while müllerian regression takes place, and *WT1* binds to a specific region of the *AMH* promoter.<sup>29</sup> Abnormalities in the *WT1* gene are associated with development of Wilms' tumor and with less common syndromes such as the Denys-Drash syndrome (i.e., ambiguous genitalia, rudimentary gonads, nephrotic syndrome, and Wilms' tumor) and Frasier syndrome,<sup>29</sup> which is characterized by dysgenetic gonads and renal anomalies with development of the nephrotic syndrome.<sup>30</sup> Abnormalities in sex differentiation of *WT1* mutants are linked to preservation of a triplet of amino acids (KTS: lysine, threonine, and serine); without KTS preservation, there is decreased synthesis of *AMH* and *SRY*. Genetic males with a 46,XY karyotype will be phenotypic females with preservation of müllerian structures.<sup>30</sup>

### HOXA

Homeobox genes have been identified in multiple organisms, from mammals to insects and lower organisms, and they appear to affect structural symmetry during organogenesis. Research has identified homeobox genes as important for the normal development of the genitourinary tract. Cohn<sup>31</sup> reviewed the research that found that homeobox genes were needed for the normal growth and differentiation of the urethral plate and distal genital tubercle. Development of the genital tubercle parallels that of development of the limb buds in the embryo; without *HOXA* genes, growth of the distal genital tubercle remains rudimentary.

Mutations in the homeobox genes have also been associated with abnormal development of the external genitalia, often in the setting of a syndrome of developmental abnormalities. One such novel syndrome is X-linked lissencephaly with abnormal genitalia (XLAG), in which patients have frameshift or point mutations in the *Aristaless*-related homeobox gene (*ARX*).<sup>32</sup> Affected patients present with neural malformations, including agenesis of the corpus callosum, abnormalities of midline structures in the brain, disorganized and incomplete development of the cerebral cortex, and micropenis with bilateral undescended testicles. Some patients also have associated renal phosphate wasting.<sup>33</sup>

The importance of the homeobox genes in regulating normal organogenesis is underscored by duplication of function. *HOXA* and *HOXD* genes have been found to have compensatory activity for mild mutations such that affected embryos may develop without significant congenital abnormalities. However, more severe or extensive mutations in either gene cannot be compensated by the remaining normal gene.<sup>34</sup> Work by Utsch and colleagues<sup>34</sup> found that novel mutations in the homeobox genes associated with the hand-foot-genital syndrome may reflect the limitations of duplicated function in compensatory genes.

## Androgen Receptor

Androgen resistance is associated with decreased growth of the glans and corpora cavernosal structures, but the corpus spongiosum develops normally and may be hypertrophied. This pattern of development suggests that although growth of the corpora cavernosa may be induced by androgens, growth of the corpus spongiosum is androgen independent.<sup>17</sup>

Shapiro and coworkers<sup>35</sup> evaluated an animal model of congenital adrenal hyperplasia by exposing embryos to androgens for different periods. They found that virilization resulting from congenital adrenal hyperplasia could be induced through exogenous androgen exposure between 8 and 13 weeks' gestation. However, even within this time frame, morphologic changes observed after early androgen exposure differed from those induced by later exposure. Exposure to androgens earlier in the critical period was associated with increased virilization, including complete fusion of the labioscrotal folds and clitoromegaly.

## CONCLUSIONS

Development of the genitourinary tract is a complex series of events and interactions over time and space. Common and uncommon errors in these events and interactions result in anomalies and may set the stage for dysfunctions later in life. Understanding the prenatal events involved in the development of the genitourinary tract facilitates comprehension of normal and aberrant postnatal anatomy and informs management of urologic disorders.

# STRUCTURAL BASIS OF VOIDING DYSFUNCTION

*Ahmad Elbadawi*

Functional behavior of the urinary bladder has been investigated for more than a century, but several aspects of the mechanism of voiding and the way it is altered in vesical dysfunction remain unresolved. This can largely be attributed to the complexity of structural organization of the bladder and its outlet and the matching complexity of their functions.<sup>1-7</sup>

The storage (i.e., filling) and expulsion (i.e., voiding) phases of micturition involve essentially opposite functions of the bladder and urethra.<sup>8</sup> The bladder acts as a reservoir for urine during filling and as a pump for expelling its stored urine during voiding. The urethra during bladder filling is closed, sealed, and noncompliant, acting as a sphincter to maintain continence, but it opens, dilates, and becomes compliant during voiding, acting as a conduit for the urinary stream. Efficient urine storage requires a compliant and stable detrusor together with a continent bladder outlet.<sup>5,9</sup> Compliance of the detrusor allows distention of the bladder to capacity, and its stability ensures absence of untimely contractions that could involuntarily force some urine past the closed outlet, resulting in incontinence. Complete emptying of the full bladder<sup>9</sup> depends on optimal contractility of the detrusor so that it can mount a strong, speedy, sustained, and unitary voiding contraction; coordinated opening of the bladder outlet; and maintenance of the opened outlet as a free conduit for an uninterrupted and strong urinary stream.

The anatomy and structure of the bladder and urethra must be optimally suited to the complex dynamic events in the micturition cycle.<sup>6</sup> Important elements in this regard are the inherent physical and biomechanical properties of the tissue components of the vesical and urethral walls and their bearing on organ distensibility and contractility.<sup>8,10-12</sup> Two crucial elements are the topographic and microstructural organization of the musculature of the bladder wall and urethra and the elaborate system of vesicourethral innervation, with complex central cephalospinal control and intricate peripheral pathways.<sup>1-6,13,14</sup>

Various disciplines have contributed through experimental and clinical investigation to our knowledge of bladder function and dysfunction. Gross anatomy was the natural start during the previous century, and it prevailed for many decades. It resulted in some fundamental concepts that have been expanded and refined in the current century as the result of improved methods of dissection, neuroanatomic tracing techniques, and microscopic staining procedures. After the initial era of anatomic investigation, the principal approach to studies on voiding has been the characterization of physiologic and muscular responses of the lower urinary tract, mainly the bladder. It is undeniable that definition and measurement of these responses are important for understanding the overall nature of neuromuscular function of the bladder and urethra. Nonetheless, such an approach cannot define the factors that determine function of the effector

organ (i.e., smooth muscle of detrusor and urethral wall) in regard to the exact mechanism and balance of their contractility, distensibility, and stability during the filling and expulsion phases of micturition. Attempts to define these factors based purely on physiopharmacologic studies are largely inferential and have generated some misconceptions. One such misconception is the idea that the sympathetic autonomic nervous system has little or no role in vesical or urethral function.<sup>15,16</sup> This dogma prevailed through the mid-1960s, until it was invalidated by microscopic proof of sympathetic innervation of the vesicourethral muscularis, which was subsequently confirmed by innumerable physiopharmacologic observations.<sup>1,4,5,7</sup>

Landmarks in our knowledge of muscular anatomy of the lower urinary tract<sup>3,6,17,18</sup> include continuation of the muscularis of the terminal ureters as the vesical “trigone” and beyond into the dorsal wall of the urethra; the nonlayered, interwoven organization of muscle bundles of the detrusor<sup>13</sup>; identification of a vesical sheath around the terminal ureters,<sup>19</sup> which was eventually refined as the concept of dual ureteral sheath<sup>20,21</sup>; and the concept of the rhabdosphincter as an integral striated muscle component of urethral muscularis.<sup>1,3,6,22</sup> Milestones in our knowledge of the innervation and neural control of the bladder and urethra include<sup>1-5</sup> definition in the spinal cord of a sacral parasympathetic and a lumbar sympathetic nucleus for subcephalic bladder control, as well as a sacral cord nucleus supplying peripheral somatomotor innervation of the volitional urinary sphincter<sup>23-26</sup>; multilevel localization of centers of bladder control in the brain, their interconnections, and their spinal neurotract projections<sup>27-30</sup>; description of the topographic organization of peripheral sympathetic and parasympathetic outflows, respectively, through the hypogastric and pelvic nerve or plexus pathways and their differences in different species<sup>23,31,32</sup>; recognition of dual sympathetic and parasympathetic innervation of the bladder and urethra and introduction of the functional concept of bladder body versus bladder base<sup>33,34</sup>; localization of the origin of intrinsic vesicourethral innervation in peripheral ganglia close to and within the organs, including the concept of sympathetic and parasympathetic effector short neurons<sup>35,36</sup>; concepts of infraspinal interaction of sympathetic and parasympathetic pathways within peripheral ganglia (through collaterals and interneurons)<sup>34-39</sup> and the vesicourethral muscularis (through axoaxonal synapses at the effector cell level)<sup>40-42</sup>; recognition of auxiliary autonomic innervation of the rhabdosphincter in animals and humans<sup>22,43-45</sup>; and recognition of neuropeptides as a class of putative neurotransmitters or modulatory cotransmitters in peripheral vesicourethral innervation.<sup>5-7,46,47</sup>

Full knowledge of the structure of an organ is key to the understanding of how it functions. A corollary of this axiom is that alteration of the structure of an organ is reflected in altera-

tion of its function. The axiom and its corollary should be fundamental premises in studies of the bladder in view of its unique function and intimate anatomic relationship to two other organs of different but closely integrated function—the ureter supplying it with urine and the urethra serving as the conduit for its expulsion. Tacit awareness of these premises stimulated research at the biochemical and molecular levels during the past few decades. This research has yielded important information on the biomechanics, energetics, and neuroreceptor attributes of the bladder and urethra. Not unexpectedly, such information has not fully clarified the basis of normal or abnormal smooth muscle function of either organ.

Microscopic study of the vesicourethral muscularis has yet to attain its full potential for determining the true basis of normal and abnormal voiding. Routine tissue histology and histochemistry have provided only limited information about tissue topography and general organization of this system. The notoriously tedious nature of electron microscopy has in part been responsible for its lagging use in investigation of bladder function and dysfunction until recently. Another major stumbling block has been the lack of clear guidelines and precisely defined criteria for such ultrastructural approaches.

In this chapter, the microstructure of the vesicourethral muscularis and its functional correlates are reviewed. Observations on microstructural defects in various forms of voiding dysfunction are presented, and their bearing on the pathophysiology and management of such disorders is discussed. The information presented is derived largely from overlapping studies on bladder ultrastructure in normal experimental animals, experimental voiding dysfunction, and various clinical disorders of micturition.

### ULTRASTRUCTURE OF THE VESICourethRAL MUSCULARIS

Until the previous decade, the urinary bladder had received little attention by students of tissue ultrastructure, unlike organs such as the intestine. The rather simplistic ideas about bladder function and its neural control that prevailed until the mid-1960s probably thwarted interest in serious electron microscopic investigation, or perhaps no one suspected that bladder structure and function were sufficiently complex to justify such investigation.

The few reports on vesical ultrastructure available before the 1980s presented general, vague, or imprecise information and therefore were largely noncontributory. A notable exception was a study on the distribution of intrinsic afferent (sensory) nerves in the cat bladder, including the relative contributions of sympathetic and parasympathetic pathways.<sup>48,49</sup> The observations reported in this study confirmed and supplemented earlier accounts of the cholinergic and adrenergic suburothelial nerves demonstrated histochemically in the cat bladder.<sup>33</sup> The existence of nerve terminals within the urothelium is ultrastructurally indisputable in animals and humans.<sup>1</sup> A proposal for distinguishing suburothelial sensory nerves by electron microscopic counting of axonal synaptic vesicles<sup>50</sup> remains unfulfilled.

Studies on the detrusor and “internal sphincter”<sup>51-53</sup> have provided detailed information about their intrinsic innervation and have shown that their muscle cells have the ultrastructural features of smooth muscle in general.<sup>54-56</sup> Definitions of the various terms and structural parameters have been provided in other reports.<sup>51,56-58</sup>

**Figure 2-1** Muscle cells of a normal detrusor. The sarcolemma (i.e., cell membrane) has alternating thick, dense bands and interposed thin zones with caveolae, with outlying basal laminae (arrowheads). Cells are adjoined by intermediate junctions (thick arrows) and separated by narrow spaces. The nucleus is capped on one side by endoplasmic reticulum and mitochondria (thin arrows). The sarcoplasm is packed with myofilaments and with evenly distributed, cigar-shaped dense bodies and scattered mitochondria (magnification  $\times 13,890$ ). (From Elbadawi A: Functional pathology of urinary bladder muscularis: The new frontier in diagnostic uropathology. *Semin Diagn Pathol* 10:319, 1993.)

### Muscle Cells

Ultrastructurally, each of the grossly recognizable bundles of vesicourethral muscularis in various animals and in humans is composed of incompletely separated and imperfectly outlined compact groups (fascicles) of muscle cells.<sup>51,56,58</sup> The muscle cell profile (Fig. 2-1) has a smooth contour and a polygonal to cylindrical configuration, depending on the plane of sectioning relative to its long axis. Nuclei of typical appearance are centrally located and rarely have nucleoli. Mitoses are ordinarily absent in muscle cells of the adult bladder.<sup>59</sup>

The perimeter of each cell profile is delineated by a continuous cell membrane (i.e., sarcolemma) that displays alternating thick, electron-dense and thinner, less dense zones, with an outlying basal lamina of even thickness and moderate electron density. The thick sarcolemmal zones (i.e., dense bands) are composed of sarcolemma plus subjacent highly dense material in sarcoplasm. The interposed thinner zones consist only of sarcolemma, with strings of caveolae that appear as rows of flask-shaped surface vesicles of uniform size.

The sarcoplasm is packed with evenly distributed myofilaments of uniform orientation and alignment, with evenly dispersed dense bodies of uniform cigar-shaped appearance in cylindrical cell profiles of longitudinally sectioned cells. The myofilaments are slanted at an approximately 10-degree angle from the long cell axis and are anchored to dense bands of sarcolemma. Organelles of typical structure, mainly mitochondria and endoplasmic reticulum, are aggregated in a conical zone capping each nuclear pole (in cylindrical profiles); some mitochondria, cisternae of reticulum, and clusters of ribosomes are also scattered in sarcoplasm, particularly beneath sarcolemmal caveolae.

Individual cells within muscle fascicles are separated by spaces of uniform width (usually <200 nm). The intercellular space contains small amounts of amorphous material similar to basal lamina and a few isolated collagen fibrils that are mainly attached to sarcolemmal dense bands of related muscle cells. Contiguous muscle cells have intermediate-type junctions (e.g., attachment plaques, zonulae adherentes) of typical appearance and length and with 30- to 60-nm separation gaps. Some also have zones (with approximately 15-nm gaps) of simple apposition of sarcolemma.<sup>57,60</sup> Contrary to one report,<sup>61</sup> it is generally accepted that gap junctions (i.e., nexus) are absent or only sparsely encountered in the normal vesicourethral muscularis of animals and humans.<sup>51,53,60,62</sup>

### Intrinsic Nerves

Ultrastructural studies have confirmed dual innervation of the normal bladder and urethra by cholinergic and adrenergic axons and provided morphologic details of the relationships between these axons and muscle cells.<sup>1-5</sup> Nerve elements within the vesicourethral muscularis course in its interstitium as Schwann cell-ensheathed axon bundles. Varicosities of some axons become exposed along their course in these bundles to face smooth muscle cells. The main vehicle of muscular innervation is provided by individual preterminal axons that “break away” from the bundles to establish contact with the muscle cells. Many muscle cells have cholinergic or adrenergic neuroeffector junctions, some have both (diautonomic junctions), and some have neither.<sup>2,4,51</sup> Clefts of neuroeffector junctions (i.e., spaces between axon and muscle cell) typically are 15 to 80 nm wide.

It seems certain that no part of the vesicourethral muscularis has a 1 : 1 nerve-to-muscle ratio,<sup>1,5,59</sup> as inferred in the original histochemical study on vesical innervation.<sup>33</sup> The basis for upholding that impression in one study on the human bladder<sup>53</sup> is questionable.<sup>4,6,59</sup> Synaptic contacts between cholinergic and adrenergic or probable copeptidergic axons (i.e., axoaxonal synapses) have been discovered as a unique feature of intrinsic neuroplexuses of vesicourethral muscularis in animals<sup>40,41</sup> and humans (A Elbadawi, unpublished data).

### Interstitium

Collagen and elastic fibers are the main components of interstitium in the vesicourethral muscularis. Partitions of interstitium surround and separate muscle bundles.<sup>56,58</sup> These partitions extend into each bundle as microsepta that incompletely delineate its component fascicles. Vascular and neural elements supplying the muscularis are contained in interstitium between and within the muscle bundles.

### Microstructural Basis of Vesicourethral Muscular Function

Conceptually, the vesicourethral muscularis comprises three integrated microstructural compartments: one for generating, another for modulating, and a third for coordinating its functional responses.<sup>9,63</sup>

The *generator compartment* consists of smooth muscle cells, which enable the vesicourethral muscularis to respond appropriately to various stimuli, particularly to generate the neurally triggered unitary detrusor contraction of voiding. Several microstructural elements play specific roles in the excitation-contraction coupling mechanism of smooth muscle.<sup>9,52,54-56</sup> Proper composition, organization, and intracellular disposition of myofilaments bearing the contractile proteins actin and myosin ensure generation of an optimal contractile force. A sufficient complement of intact mitochondria provides the enzymes necessary for generating the necessary ATP-dependent energy. Mitochondria and an intact endoplasmic reticulum provide and store intracellular calcium ions ( $\text{Ca}^{2+}$ ), which are necessary for muscle cell contraction. An intact sarcolemma provides anchorage for myofilaments at its dense bands to transmit the contractile force to the cell surface. The function of sarcolemmal caveolae has not yet been established. The close spatial association between caveolae and cisternae of subsarcolemmal endoplasmic reticulum, a site of  $\text{Ca}^{2+}$  binding and storage,<sup>54,64</sup> suggests that they are involved in the mechanism of muscle contraction. There is evidence that caveolae are sites of active ion ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ) transport,  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchange, or passive  $\text{Ca}^{2+}$  binding, all of which are involved in the excitation-contraction coupling mechanism.<sup>65</sup>

The *modulator compartment* comprises intrinsic neuroplexuses and their neuroeffector junctions. Neural influence through the latter involves induction, facilitation, inhibition, or disinhibition of chemical neurotransmission to muscle cells under central cephalospinal and peripheral autonomic ganglionic control.<sup>1,5,9</sup> Intact structure of intrinsic axons is necessary for conduction of neural impulses throughout their course within the detrusor. Structural integrity of neuroeffector junctions, including the predominant small (clear or dense-core) vesicle content of their axonal components, is necessary for chemical neurotransmission to the target muscle cells. Axoaxonal synapses modulate prejunctional, reciprocal cholinergic-adrenergic inhibition of effector neural influence in the normal mammalian vesical muscularis, including that of humans.<sup>9,40,41</sup> From the structural standpoint, the efficacy and net effect of neural influence on this muscularis depend mainly on the distribution and relative density of the various functional types of structurally intact axons (i.e., cholinergic versus adrenergic) and the width and content of junctional clefts of preserved neuroeffector junctions. Alteration of the inherent structure or spatial relationship of axons within the bladder may hinder one normal neurally triggered neural response or another, or it may generate incongruous, uncoordinated, or spurious muscle cell responses.<sup>9</sup>

The *coordinator compartment* is in part muscular and in part interstitial. It is responsible for maintaining spatial topographic organization of muscle cells relative to each other within muscle fascicles and bundles of the detrusor and urethral muscularis. Moreover, it provides the basis for tridimensional distensibility of the bladder, which allows it to be filled to capacity with minimal rise in luminal pressure (i.e., compliance).<sup>11,66</sup> Compliance is determined by the relative proportions of muscular and interstitial elements and by the delicate balance of the rigid and

elastic components of interstitium—collagen and elastin, respectively.<sup>10,66-68</sup>

The main role of the coordinator compartment is to synergize and unify muscle cell responses in the entire detrusor or urethral wall. The most important functional expression of this role is the neurally triggered, coordinated, unitary detrusor contraction that initiates voiding.<sup>1,4,9</sup> Only a fraction of muscle cells of the detrusor are innervated and are directly excitable by neural stimuli, despite its overall dense innervation.<sup>1,4,6</sup> Voiding contraction of the detrusor, which is in essence a synergized, summated, and sustained contraction of its component fascicles and bundles, requires transmittal of contraction from the innervated to all noninnervated muscle cells (i.e., muscle cell coupling).

Cell coupling in smooth muscle is electrical or mechanical.<sup>54,55,69</sup> Electrical coupling *propagates the electrical signal* (i.e., action potential), heralding contraction of a muscle cell through the gap junctions (and to some extent through simple sarcolemmal appositions) of muscle cells; these junctions (or appositions) provide low-resistance pathways that directly “connect” and allow exchange of ions between sarcoplasms of the adjoined muscle cells. A smooth muscle system endowed with an electrical coupling mechanism behaves functionally as a virtual syncytium through which contraction of the component cells can be elicited in near synchrony. The relatively slower mechanical coupling *transmits the force* generated in a contracting muscle cell through intermediate junctions with adjacent cells. Contrary to one review,<sup>61</sup> cell coupling in normal vesicourethral muscularis is achieved by mechanical cell coupling because its muscle cells have intermediate junctions but no or sparse gap junctions.<sup>51,53,60</sup> Active force generated by the contractile apparatus of a muscle cell is discharged to the entire cell surface through insertions of myofilaments into sarcolemmal dense bands, resulting in cell shortening. The tension developed is transmitted through intermediate junctions to adjoined cells, resulting in their deformation and subsequent contraction. Collagen fibrils juxtaposed to the cell surface in the intercellular space contribute to mechanical transmittal of force from the contracting cell to adjacent cells. Summation of minuscule tensions transmitted from cell to cell and from muscle cells to microsepta of interstitium culminates in contraction of entire muscle bundles—and ultimately in contraction of the entire organ in unison—by subsequent force transmittal through partitions of interstitium between the bundles.<sup>60</sup>

Normal contractility of the vesicourethral muscularis in regard to complete emptying of the bladder depends on three factors in addition to the inherent topographic organization and structural integrity of its cells. These are the ability of a contracting muscle cell to shorten (generating a contraction force), mechanical cell coupling to transmit that force, and a vehicle to summate the transmitted force through the muscularis. All three factors have recognizable ultrastructural correlates. Effective cell shortening requires a normal cylindrical configuration of the muscle cell and a normal complement of myofilaments optimally aligned at a narrow angle with sarcolemma. Mechanical cell coupling is largely determined by the geometric spatial disposition of detrusor muscle cells and their structural inter-relationships in regard to their compact arrangement within fascicles, intermediate cell junctions, and narrow interspaces containing few collagen fibrils. Collagen fibers in microsepta and partitions of interstitium, respectively between muscle fascicles and bundles, play a key role in eliciting the summated, unitary voiding contraction.

## ULTRASTRUCTURE OF THE RHABDOSPHINCTER

The feline rhabdosphincter is composed of a mixture of fast- and slow-twitch myofibers, which have the same distinguishable ultrastructure as ordinary somatic mammalian striated muscle.<sup>44</sup> Contrary to one report,<sup>70</sup> the human rhabdosphincter appears to be composed of both types of myofibers (Mathews, Light, Wheeler, et al, unpublished data).

The concept of triple (i.e., somatomotor plus dual parasympathetic-sympathetic autonomic) innervation of the feline rhabdosphincter based on histochemical study<sup>22</sup> was validated by electron microscopy in the cat,<sup>44,71</sup> and its adrenergic autonomic component was also confirmed in humans.<sup>45</sup> Two forms of the nerve-myofiber relationship are present in the feline rhabdosphincter with intact innervation. One has the classic sole plate differentiation of the myofiber facing a cholinergic neuroterminal, which is characteristic of somatomotor neuromuscular junctions at large. In the other, a cholinergic or adrenergic axon terminal is closely apposed to the surface of a myofiber and has a functionally plausible, narrow neuromuscular cleft but no sole plate differentiation. These surface contacts are considered autonomic because their morphology is identical to those of autonomic neuroeffector junctions in the vesicourethral muscularis and other mammalian smooth muscle systems and because they persist, despite disappearance of axons innervating sole plates, after bilateral sacral ventral rhizotomy—the known source of somatomotor innervation through the pudendal nerves (discussed later).<sup>71-73</sup>

## Functional Pathology of the Detrusor

Changes in the three microstructural compartments of the detrusor have been described in various forms of voiding dysfunction. Those described in histologic preparations are largely nonspecific and have been of limited usefulness in regard to correlation with the functional abnormalities.<sup>56,58</sup> The constellations of changes identified ultrastructurally in different dysfunctions tend to predominate in one compartment or another and are distinctive for each dysfunction.<sup>56,58</sup> For this reason, accurate definition of the microstructural correlates of a voiding dysfunction requires study of the smooth muscle, interstitium, and intrinsic neural compartments of the detrusor with equal attention and scrutiny.<sup>9,56</sup>

## NEUROPATHIC VOIDING DYSFUNCTION

Practically all information on the microstructural basis of neuropathic voiding dysfunction has been derived from experimental studies in the cat. These studies have dispelled some traditionally held dogmas and have laid the foundation for a new concept in pathophysiology of the lower motor neuropathic bladder.<sup>74-79</sup> According to this concept, abnormal behavior of such a bladder does not merely reflect its release from cephalospinal neural control but is largely the result of dynamic, profound changes in intrinsic nerves and to some extent muscle cells—the two structural elements that jointly determine that behavior. These neuropathic structural changes can be defined fully and accurately only by electron microscopy,<sup>79</sup> and they readily distinguish a decentralization from a denervation functional type of lower motor neuropathic bladder. The same studies

also validate the concept of triple innervation of the feline rhabdosphincter.<sup>71-73,80</sup>

### The Decentralized Bladder

For decades, belief that postganglionic nerves within the bladder are unchanged after decentralization by parasympathetic preganglionic neurectomy (e.g., sacral roots, pelvic nerve trunks) remained universal and absolute. The underlying logic was that such neurectomy leaves untouched and structurally intact the ganglion cells that provide the intrinsic vesical nerves. Studies on models of the decentralized bladder, however, revealed dynamic structural changes in intrinsic postganglionic nerves of the detrusor: initial degeneration with eventual regeneration.

Occurring beyond and across preganglionic synapses, short-term degeneration of axons duplicates the well-known phenomenon of primary transsynaptic nerve degeneration in the brain<sup>81</sup> and represents the first example of this phenomenon in the peripheral autonomic nervous system.<sup>74</sup> The axonal degeneration results in loss of cholinergic neuroeffector junctions and is associated with transjunctional degeneration of detrusor muscle cells, a previously unknown phenomenon.<sup>76</sup> The term *transjunctional* underscores the fact that muscle cell degeneration occurs at a site two levels of anatomic discontinuity peripheral to the sacral spinal cord nucleus (i.e., the preganglionic synapse in the peripheral ganglia and the neuroeffector junction at the terminal effector tissue level). The initially degenerating axons eventually regenerate. This regeneration expresses yet another previously unrecognized phenomenon because it is not a simple restitution of the original complement of cholinergic axons but is also associated with<sup>75</sup> sprouting of adrenergic (i.e., postganglionic sympathetic) axons with adrenergic hyperinnervation (also documented histochemically<sup>71,82</sup>) and with emergence of peptide-replete axons and axon terminals. Neuroeffector junctions become reestablished by the latter axonal population in addition to the regenerating cholinergic and sprouting adrenergic axons; muscle cell regeneration occurs concomitantly.<sup>76</sup> Ultrastructural profiles of regenerating muscle cells have expanded rough endoplasmic reticulum replete with clustered ribosomes, prominent subsarcolemmal mitochondria, numerous intact paranuclear and subsarcolemmal mitochondria, and frequent nucleoli. It appears that an intact preganglionic sympathetic pathway is necessary for the long-term axonal changes to take place after decentralization because they do not occur when decentralization is combined with hypogastric neurectomy.<sup>78</sup> This fact, together with available pharmacologic evidence,<sup>83</sup> suggests that adrenergic hyperinnervation of the detrusor is an important factor in development of hypertonicity in the lower motor neuropathic bladder.<sup>78</sup>

### The Denervated Bladder

Changes in intrinsic axons and muscle cells of the detrusor also occur after postganglionic neurectomy,<sup>77</sup> which severs the pelvic plexus (i.e., parasympathetic plus sympathetic extrinsic nerves) very close to the bladder. Neurectomy mimics the clinical situation of severe neural deficit after major extirpative pelvic surgery.<sup>84</sup> The resultant short-term degenerative changes in axons and muscle cells are similar to those seen in the decentralized bladder but are more profound in scope and degree. Long-term changes, however, are different, including little cholinergic axonal regeneration, sparse adrenergic innervation, and no appreciable popu-

lation of peptide-rich axons. Similar scarcity of adrenergic nerves has been reported in bladder biopsy specimens from patients who had undergone abdominoperineal resection of the rectum.<sup>85</sup>

### The Denervated Rhabdosphincter

Decentralization of the bladder by bilateral sacral ventral rhizotomy deprives the rhabdosphincter of its somatomotor innervation. The somatomotor-denervated rhabdosphincter loses its population of classic neuromuscular junctions, and the ultrastructure of its sole plates becomes markedly simplified, but the autonomic axon contacts with the myofibers lacking sole plates persist.<sup>71</sup> Eventually, the autonomic junctions become prominent and widespread, and many of the residual simplified sole plates become newly innervated by a cholinergic axon or an adrenergic axon, or both.<sup>72</sup> These changes indicate permanent degeneration of somatomotor nerves and persistence plus long-term “propagation” of autonomic innervation in denervated territories of the rhabdosphincter. Along with the axonal changes, the myofibers display a combination of degeneration and regeneration.<sup>80</sup>

The somatomotor-denervated rhabdosphincter appears to be under exclusive autonomic neural control. The nature of this control has not as yet been investigated, nor have responses to autonomic neural stimuli been demonstrated physiologically or pharmacologically in the normal rhabdosphincter, although they are unequivocal in the cat, and their adrenergic component has been proved in humans. The autonomic component may have a subtle, very specific, or precisely timed function in normal micturition that is difficult to duplicate in an investigative setting, or it may be functionally operative or discernible only in abnormal voiding. Available physiopharmacologic methods of study may or may not be sufficiently sensitive to segregate autonomic responses of the rhabdosphincter from those of the intimately associated urethral smooth muscularis in the normal or the neuropathic rhabdosphincter.

### The Upper Motor Neuropathic Bladder

As described in the brain, the phenomenon of transsynaptic degeneration may be primary, secondary, tertiary, and so on, depending on the number of synaptic relays between the injured neuron and the neuron providing degenerating terminals in the same pathway.<sup>81</sup> Transsynaptic degeneration in the decentralized bladder is primary because, as far as is known, only one relay station (in a peripheral vesicourethral ganglion) is interposed between the interrupted preganglionic neuron (ventral root) and the corresponding postganglionic neuron providing the degenerating terminals within the bladder. It is conceivable that comparable degeneration may follow interruption of central neuraxial pathways as an expression of secondary or tertiary transsynaptic degeneration (i.e., across one or two central plus the peripheral relay stations). Observations in one study on a spinal cord transection model suggest that such degeneration may occur,<sup>86</sup> but it needs to be confirmed by detailed investigation in experimental models and clinical settings. If such confirmation is obtained, an important concept would emerge: functional derangement in the bladder deprived of cephalic control is in part caused by structural changes in vesicourethral muscularis despite preserved anatomic integrity of the sacral cord and infrasacral neural pathways.

## DETRUSOR DYSFUNCTION

### Poorly Contractile Detrusor

Impaired contractility may be the only manifestation of a non-neuropathic detrusor dysfunction (e.g., in the elderly<sup>87,88</sup>), or it may occur as an additional abnormality in an obstructed or unstable detrusor.<sup>89,90</sup> The ultrastructural hallmark of a poorly contractile detrusor is the *degeneration pattern* (Fig. 2-2), characterized by widespread degeneration of muscle cells and intrinsic nerves.<sup>52,58</sup> Degeneration of muscle cells can be recognized ultrastructurally by a spectrum of features that reflect its severity. Mild degeneration results in subtle features such as malalignment of myofilaments with patchy stacking, crisscross or swerving patterns, and uneven crowding or clumping of sarcoplasmic dense bodies. Features of moderate degeneration include disorganization or disruption of myofilaments, disruption of sarcoplasmic dense bodies and mitochondria, distention of cisternae of endoplasmic reticulum with loss of ribosomes, appearance in sarcoplasm of highly electron-dense patches or laminate bodies, and occasionally large deposits of glycogen particles. Severe degeneration is manifested by sequestration, extrusion (i.e., blebbing), vacuolation, or floccular appearance of sarcoplasm; loss or electron-dense homogenization of myofilaments; distortion of the nucleus with irregular clumping of chromatin; and thickening or breaching of sarcolemma with replication of the basal lamina. Severely degenerated cells ultimately become shriveled or disintegrated.

Degeneration in intrinsic nerves can be recognized only ultrastructurally by a constellation of features that include<sup>52,58</sup> depletion of synaptic vesicles, axoplasmic dense bodies, breaching of axolemma, and disruption of mitochondria in axon terminals and varicosities of neuroeffector junctions. Severe degeneration of axons results in their retraction from related muscle cells and ultimately in fragmentation or lysis. Axons ensheathed by Schwann cells may undergo vacuolar or floccular change, with disruption of their axoplasmic content of neurofilaments and neurotubules. Loss of ensheathed axons results in the distinctive appearance of collapsed Schwann cells with redundant and replicated basal laminae.

Features of the degeneration pattern can easily explain impaired contractility of the detrusor.<sup>9,52,58</sup> Degeneration of the intrinsic nerves impedes transmission of neural impulses along axons and neuroeffector transmission to muscle cells at their terminals. Degeneration of muscle cells disrupts their contractile elements, energetic machinery, and  $\text{Ca}^{2+}$  stores, rendering them unable to generate an efficient contraction or any contraction, whether in response to a propagated neural impulse or secondary to mechanical “pull” by a contracting adjacent muscle cell with preserved structure.

### Detrusor Overactivity

Several factors have been implicated in the pathogenesis of detrusor instability (i.e., overactivity). Some of these factors are functional, whereas others revolve around a structural change in the unstable detrusor. A change in density of one functional type of intrinsic nerves or another has been reported in histochemical preparations,<sup>91,92</sup> but the methods used to determine nerve density in these studies are questionable.<sup>8,59,89,93</sup> Electron microscopic studies have revealed that the principal structural change in the

unstable detrusor, whether obstructed or not, is in the interrelationship of its muscle cells.<sup>58,60,63,89</sup>

Reduction of vasoactive intestinal polypeptide (VIP)-reactive nerves in the detrusor with idiopathic instability (i.e., no outlet obstruction or neural deficit) has been described in one histochemical study.<sup>91</sup> Loss of such nerves was suggested as the cause of instability on the premise that it would deprive the detrusor of an inhibitory role of the neuropeptide as a neurotransmitter or neuromodulator.<sup>94,95</sup> Histochemical observations on VIPergic nerves are not sufficient to determine their structural status; only electron microscopy can determine such status, particularly the content and type of axonal synaptic vesicles.<sup>1,9</sup> No correlation between detrusor function and immunohistochemical reactivity of VIP was found in a study of human bladder biopsies.<sup>96</sup> Loss of inhibitory VIP-reactive nerves as the cause of involuntary detrusor contractions is difficult to reconcile with the clinical observation that they are susceptible to neurally mediated inhibition.<sup>97</sup>

In a later study, “increased appreciation of bladder filling” due to “relative abundance” of “presumptive sensory nerves” in the suburothelium was suggested as an explanation for idiopathic instability.<sup>92</sup> Aside from the questionable counting method used, no adjustment for thickness of suburothelium in the specimens studied was mentioned; such thickness varies in different subjects and can easily be altered even by minor pathologic changes in the bladder wall such as mild cystitis, vascular congestion, or edema.<sup>8</sup> Moreover, there is no basis for the postulated association between the number of nerves and the degree of sensory excitability or perception.<sup>8</sup>

Muscle cells of the overactive (unstable) aging detrusor, whether obstructed or not, have some distinctive ultrastructural features, collectively designated the *dysjunction pattern*.<sup>58,60,89</sup> This pattern is characterized by moderately widened spaces between individual muscle cells, scarce intermediate muscle cell junctions, and abundant distinctive protrusion junctions and ultraclose cell abutments (Figs. 2-3 and 2-4) that are not found in the normal detrusor. The only difference between the obstructed and unobstructed overactive detrusor is a superimposed myohypertrophy pattern (discussed later) in the former (see Fig. 2-4). The dysjunction pattern is not associated with any particular change in intrinsic nerves of the overactive detrusor, whether obstructed or not, except degenerative changes when the detrusor is also poorly contractile.

The protrusion junctions and ultraclose abutments of the dysjunction pattern resemble gap junctions in having a very narrow separation cleft ( $\leq 10$  nm) and no sarcolemmal thickening at the contact zone of the adjoined muscle cells. These features suggest that both types of junction serve as a vehicle for electrical muscle cell coupling in the overactive detrusor in lieu of the normal mechanism of mechanical cell coupling that is curtailed by reduction of intermediate cell junctions.<sup>58,60</sup> This introduces a new concept of pathogenesis of detrusor overactivity (instability), whether it is associated with outlet obstruction or not. According to this concept, involuntary detrusor contractions in either setting are elicited by a bipartite myogenic mechanism, consisting of irritable loci and a final common pathway. The irritable locus represents muscle cells with heightened inherent spontaneous activity, with or without increased responsiveness to a “trigger for contraction,” such as stretch or excitatory neural stimuli. The final common pathway is served by muscle cells linked by protrusion junctions and abutments to acquire the functional properties of a syncytium in and around the irritable loci. Limited, small

**Figure 2-2** Degeneration in poor detrusor contractility. **A**, One degenerating muscle cell has sequestered sarcoplasm (*arrows*), and another has a sarcoplasmic bleb intruding on an adjacent cell (*thick arrow*) (magnification  $\times 16,500$ ). **B**, In a degenerating muscle cell, the sarcoplasm has a rarefied appearance, with disrupted myofilaments and clustered, thickened, and confluent dense bodies (*arrows*) (magnification  $\times 27,300$ ). **C**, In a severely degenerated muscle cell (*thick arrow*), the sarcoplasm is completely disrupted and replaced by irregular, large, highly electron-dense patches and multivesiculated bodies; abundant cell debris (*arrows*) is evident in the adjacent interstitium. Notice the profile of a degenerating axon (*open arrow*), with depleted vesicles, disrupted mitochondria, and a highly electron-dense patch (magnification  $\times 14,000$ ). (From Elbadawi A: Pathology and pathophysiology of detrusor in incontinence. *Urol Clin North Am* 22:3, 1995.)

**Figure 2-3** Dysjunction pattern in detrusor overactivity. Muscle cells are separated by mildly widened spaces with depleted, normal intermediate junctions, adjoined by protrusion junctions (arrows) with indiscernible gaps between the cells and an overall appearance of pseudosyncytium at the junctions. The profile of the residual intermediate junction (open arrow) is distinctly different from that of protrusion junction (magnification  $\times 13,500$ ). (From Elbadawi A: Pathology and pathophysiology of detrusor in incontinence. Urol Clin North Am 22:3, 1995.)

contractions originating independently in one or more loci, whether spontaneous or triggered, are propagated electrically through that syncytium to outlying muscle cells, recruiting them to contract in near-synchrony. If the electrical propagation involves a sufficiently large muscle territory, the result would be significant, urodynamically measurable contractions that, by definition, are involuntary. Electrical cell coupling remains partially suppressible by neurally mediated inhibition insofar as its completion, progression, or even initiation is concerned,<sup>60</sup> and it does not hinder the development of neurally triggered, unitary, effective voiding contractions. Preliminary studies indicate the presence of the dysjunction pattern in idiopathic instability in young adults and in the overactive neuropathic (i.e., hyper-reflexic) detrusor.

### Obstructed Detrusor

Until the previous decade, structure of the obstructed detrusor was investigated almost exclusively by routine histologic methods. The only convincing changes reported were in the interstitium,<sup>98-106</sup> which, not surprisingly, failed to explain why or how the obstructed bladder becomes dysfunctional. Changes in intrinsic nerves of the obstructed detrusor were described in a few histochemical studies, but no meaningful correlation was made with its abnormal functional behavior.<sup>107-111</sup> The validity and significance of these neural changes remain debatable.<sup>8,59,89,93</sup>

Ultrastructural studies revealed characteristic changes in the experimentally or clinically obstructed detrusor,<sup>89,112-116</sup> including the rare entity of outlet obstruction in women.<sup>89</sup> Collectively designated the *myohypertrophy pattern*, these changes predominate in muscle cells and interstitium and can explain practically all functional abnormalities in the obstructed detrusor.<sup>89</sup> Additional changes in the obstructed human detrusor have been correlated with specific superimposed, urodynamically defined

A

B

**Figure 2-4** Myohypertrophy plus dysjunction pattern of an overactive (unstable) obstructed detrusor. **A**, The overview shows the widely variable sizes and shapes of muscle cell profiles, markedly widened intercellular spaces containing abundant collagen, depleted intermediate cell junctions, and numerous protrusion junctions (arrows); the open arrow marks a residual intermediate junction (magnification  $\times 4090$ ). **B**, Muscle cell profiles are adjoined as a pseudosyncytium by ultraclose abutments (arrows); sarcolemmas (i.e., cell membranes) are dominated by dense bands (arrowheads) with depleted caveolae in interposed thinner zones (magnification  $\times 11,800$ ). (**A**, Modified from Elbadawi A: Functional pathology of urinary bladder muscularis: The new frontier in diagnostic uropathology. Semin Diagn Pathol 10:348, 1993; **B**, from Elbadawi A: Pathology and pathophysiology of detrusor in incontinence. Urol Clin North Am 22:3, 1995.)

derangements of its function.<sup>52,60,89</sup> Contrary to some reports,<sup>104,105</sup> there is no correlation between the scope and degree of ultrastructural changes in the detrusor and the degree of bladder trabeculation as observed cystoscopically.<sup>58,89</sup>

### Myohypertrophy Pattern

The myohypertrophy pattern has three features (Fig. 2-5): muscle cell hypertrophy, markedly widened spaces between individual muscle cells, and collagenosis.<sup>58,63,89</sup> Characteristically, the extent of cell separation and collagenosis is nonuniform, so that muscle

A

B

**Figure 2-5** Myohypertrophy pattern of an obstructed detrusor. **A**, Bizarre, twisted profile of a hypertrophic muscle cell (magnification  $\times 13,000$ ). **B**, Markedly widened spaces between individual muscle cells containing abundant collagen fibrils and some elastic fibers (arrows) (magnification  $\times 18,600$ ).

fascicles with different degrees of loosened structure exist side by side in the same section or even microscopic field.

Muscle cell hypertrophy (i.e., increased cell size) is the traditional hallmark of obstruction in hollow viscera.<sup>117,118</sup> Because of its nonlayered meshwork organization,<sup>3,6,13</sup> the detrusor does not lend itself to traditional methods for estimating muscle cell size used in the intestine, such as diameter or length of muscle cell profiles, number of muscle cell nuclei per area, or volume density of muscle cells.<sup>59,93,114</sup> This fact casts doubt on the validity of data indicating the presence of hypertrophy of obstructed detrusor in several studies.<sup>99,103,105,119-121</sup>

A hypertrophied muscle cell cannot be recognized qualitatively on light microscopy, but it has a distinctive, easily discernible ultrastructural profile<sup>58,63,89,113,116</sup> characterized by branching of the tapering ends of the cell, deformed or bizarre cell configuration with irregular infoldings or contortions (see Fig. 2-5A), and occasional reflexive intermediate junctions<sup>122</sup> between contortions or branches of the same cell. Branches of hypertrophic muscle cells appear to interlock as a braid in tridimensional perspective.

*Collagenosis* designates the presence of abundant collagen fibrils and fibers in markedly widened spaces between individual muscle cells (see Figs. 2-4A and 2-5B).<sup>58,89</sup> These features cannot be recognized by light microscopy. Abundant collagen fibers also expand microsepta and partitions of interstitium, respectively, between muscle fascicles and bundles. This corresponds to the fibrosis mentioned as the main structural change in earlier studies on the obstructed detrusor. Intercellular collagen is generally associated with deposits of basal lamina-like material and a variable number of elastic fibers. Separation of muscle cells results in shearing of their junctions, which consequently become fewer and unevenly distributed. Muscle cell separation results in loosening of the normally compact arrangement of muscle cells in fascicles and bundles of the detrusor. When such separation is excessive, the fascicular arrangement is lost, and the cells lie individually, wide apart, amid a dominant background of collagen.

### Structural-Functional Correlations

Traditionally, it has been thought that the obstructed detrusor undergoes compensatory muscular hypertrophy and becomes stronger to overcome the obstruction.<sup>123</sup> This dogma is fallacious. The obstructed detrusor is not stronger; it may actually become weaker, and it has a slower velocity (speed) of contraction than the norm, even in the presence of adequate bladder emptying and absence of retained urine.<sup>63,124-127</sup> Theoretically, a hypertrophic smooth muscle cell can generate a stronger contraction than a normal cell. This, however, does not necessarily mean a stronger contraction of the detrusor as a whole. Several ultrastructural features of the myohypertrophy pattern limit the ability of hypertrophic muscle cells to shorten (i.e., contract). Loss of intermediate cell junctions between widely separated muscle cells greatly restricts the main vehicle for mechanical cell coupling, so that the force of contraction of muscle cells would not be transmitted effectively to outlying cells. Such hindrance of force transmittal is accentuated by excessive collagen in the widened intercellular spaces and the expanded interstitium. The net effect of these impediments is an inability of the obstructed detrusor to mount the speedy, strong, coordinated, or sustained contraction necessary for complete emptying of the full bladder.

### Superimposed Structural Changes

Muscle cell degeneration has been described as a constant feature of experimental acute, transient overdilatation of the rabbit detrusor,<sup>113,114</sup> the human detrusor after repeated episodes of acute retention with bladder overdilatation,<sup>128</sup> and the chronically obstructed human detrusor of both genders when its contractility is overtly impaired with considerable residual urine.<sup>89</sup> Degeneration of intrinsic nerves has also been observed ultrastructurally in the rabbit model and in the chronically obstructed, poorly contractile human detrusor. Widespread degenerative changes superimposed on myohypertrophy and collagenosis further weaken an obstructed detrusor.<sup>89</sup> Reduction in density of intrinsic nerves has been reported in some light microscopic histochemical studies on the obstructed human detrusor<sup>107,109,111</sup> and in a pig model intended to reproduce long-term bladder outlet obstruction.<sup>108</sup> Based primarily on such reduction and on in vitro detrusor responses in the pig model, it was proposed that “cholinergic denervation” with subsequent supersensitivity was the cause of obstruction-associated instability.<sup>129</sup> However, the methods used to assess nerve density in the histochemical studies were questionable.<sup>8,59,93</sup> The conclusion in most of these studies

**Figure 2-6** Hyperelastosis in an overdistended obstructed detrusor. Muscle cell profiles are far apart (up to 6  $\mu\text{m}$ ) in the interstitium with abundant collagen and elastic fibers (arrows) (magnification  $\times 10,550$ ). (Modified from Elbadawi A: Functional pathology of urinary bladder muscularis: The new frontier in diagnostic uropathology. *Semin Diagn Pathol* 10:349, 1993.)

that the observed changes were the result of nerve loss (i.e., denervation) was not substantiated by direct evidence of structural nerve damage or degeneration in any. More reservations about the denervation concept of instability were raised in an ultrastructural study of the obstructed human detrusor,<sup>89</sup> which attributed instability in such detrusors to the presence of the same protrusion junctions and abutments (see Fig. 2-5) that are the cardinal feature of the overactive unobstructed bladder (discussed earlier).

A variable number of elastic fibers accompanies deposits of collagen in intercellular spaces (see Figs. 2-4A and 2-5B) and interstitium of the obstructed detrusor.<sup>89,112</sup> Massive deposits of elastic fibers (i.e., *hyperelastosis*) have been observed in the excessively distended detrusor of patients with chronic urinary retention caused by bladder outlet obstruction (Fig. 2-6).<sup>58,89</sup> Such detrusors also have excessive collagenosis, marked expansion of interstitium, and severe muscle cell degeneration, with scattered residual hypertrophic muscle cells. These changes markedly obscure or eliminate orderly organization of detrusor muscular elements as fascicles.<sup>58,89</sup>

Regeneration of muscle cells and intrinsic axons in the detrusor accompanies degeneration of the corresponding elements after obstruction in the experimental rabbit model of acute transient overdistention and is the most prominent change after relief of that obstruction.<sup>113,114</sup> No regenerative changes were observed in the chronically obstructed human detrusor of either gender, even when degeneration of its muscle cells and axons was evident and widespread in association with overt impaired contractility.<sup>58,63,89</sup> Muscle cell regeneration therefore is not a part of the process leading to myohypertrophy in the obstructed detrusor and probably is not a manifestation of hyperplasia in the rabbit model. In this model, muscle cell regeneration and hypertrophy are probably manifestations of structural adaptation, eventually leading to recovery, that follows the initial damage induced by

acute distention of the bladder.<sup>130</sup> Similarly, regeneration of axonal elements in the same model probably represents their eventual structural recovery, as observed earlier in the experimentally decentralized bladder.<sup>75</sup>

### The Aging Detrusor

Knowledge about the microstructure of the aging detrusor is crucial for our understanding of the pathology and pathophysiology of voiding dysfunctions and incontinence in the elderly. It has been shown biochemically that collagen content of the detrusor increases with advancing age in women,<sup>131</sup> resulting in reduction of its contractility.<sup>11,68,126</sup> One report stated that neither the amount of smooth muscle nor the size of its individual cells is altered by age, but the density of cholinergic innervation is markedly reduced by age.<sup>132</sup> The validity of these observations has been questioned in an ultrastructural study of truly aging detrusors.<sup>52,56,58</sup> This study defined the microstructural norm of the aging detrusor, which was obtained from asymptomatic subjects who had no urodynamic evidence of obstruction, detrusor hyperactivity, impaired detrusor contractility, or altered bladder compliance.<sup>52,53</sup> In such a detrusor, muscle cells and axons remain virtually intact except for a few subtle ultrastructural changes. These include moderate widening of spaces between individual muscle cells, modest intercellular deposits of basal lamina, considerable depletion of sarcolemmal caveolae with marked elongation of sarcolemmal dense bands, and normal (often elongated) intermediate cell junctions. These changes may be manifestations of a process of dedifferentiation of detrusor muscle cells associated with aging.<sup>52</sup>

### CONCLUSIONS

Morphologic evaluation of detrusor microstructure can be truly objective and functionally meaningful only if it includes an analysis of its muscular, interstitial, and neural (MIN) microstructural compartments. Most structural parameters that have direct impact on detrusor function can be defined only by electron microscopy. Studies done so far indicate that the data necessary for correlation of detrusor structure and function can be obtained readily and reproducibly from an endoscopic biopsy, which appears to be truly representative of the whole detrusor insofar as the fine structure of its smooth muscle elements is concerned. The parameters sought are basic and have been defined clearly so that they can be studied and evaluated by any pathologist with a knowledge of diagnostic electron microscopy and smooth muscle ultrastructure.<sup>58</sup>

Different forms of human detrusor dysfunction are associated with changes in one or more of the three MIN compartments but at the same time differ in one or more. This fact emphasizes the great potential of study of detrusor microstructure as the means of better understanding the pathophysiology of various voiding dysfunctions and of developing a valuable tool in the clinical diagnosis and management of such disorders. To gain the full benefit of such study, its goal should be to determine for each dysfunction the presence, spectrum, degree, and extent of distribution of the changes seen in each microstructural compartment. Only through pursuit of this approach can the natural history and the outcome of treatment of various voiding dysfunctions be explained, understood, and perhaps predicted with reasonable accuracy. To this end, the material needed for microstructural

study should ideally be obtained at the time of patient presentation, during follow-up of patients managed conservatively, and at various intervals after surgical intervention or other specific therapy aimed at manipulation of bladder behavior. From such information, we can begin to understand the basis for differences in clinical presentation between patients with the same disorder and between different disorders; recognize patterns of the natural course and evolution of different presentations of the same disorder and of different disorders; define structural markers of reversibility or permanence of each disorder; and identify the

structural correlates of successful or ineffective treatment in patients with the same disorder and patient groups with different disorders. As information on the various dysfunctional disorders is gathered and correlated, we can begin to identify trends in the natural evolution and prognosis of each dysfunction and to methodically set appropriate indications, contraindications, and predictive indices for available treatment modalities. Eventually, the stage will be set for the use of detrusor structural morphology as a routine modality in the clinical management of vesical dysfunction.

# NEUROANATOMY AND NEUROPHYSIOLOGY: INNERVATION OF THE LOWER URINARY TRACT

*William C. de Groat*

The storage and periodic elimination of urine depend on the coordinated activity of two functional units in the lower urinary tract: a reservoir, which is the urinary bladder, and an outlet consisting of the bladder neck, the urethra, and the urethral sphincter. Coordination between these organs is mediated by a complex neural control system located in the brain, spinal cord, and peripheral ganglia. Urine storage and release depend on central nervous system pathways. This distinguishes the lower urinary tract from many other visceral structures (e.g., the gastrointestinal tract, cardiovascular system) that maintain a certain level of function even after extrinsic neural input has been eliminated.

The lower urinary tract is unusual in its pattern of activity and organization of neural control mechanisms. For example, the urinary bladder has only two modes of operation: storage and elimination. Many of the neural circuits have switchlike or phasic patterns of activity, unlike the tonic patterns characteristic of the autonomic pathways to cardiovascular organs. Micturition is under voluntary control and depends on learned behavior that develops during maturation of the nervous system, whereas many other visceral functions are regulated involuntarily. Micturition also requires the integration of autonomic and somatic efferent mechanisms to coordinate the activity of visceral organs (i.e., bladder and urethra) with that of urethral striated muscles.

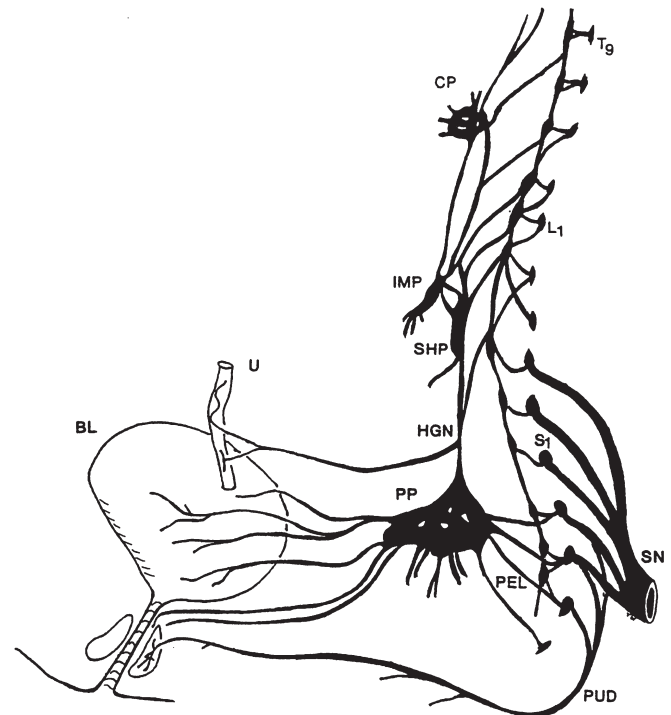

Because of the complexity of the neural mechanisms regulating the lower urinary tract, micturition is sensitive to a wide variety of injuries, diseases, and chemicals that affect the nervous system. Neurologic mechanisms are an important consideration in the diagnosis and treatment of voiding disorders. This chapter reviews the innervation of the urinary bladder and urethra, the organization of the reflex pathways controlling urine storage and elimination, the neurotransmitters involved in micturition reflex pathways, and neurogenic dysfunctions of the lower urinary tract.

## INNERVATION

The innervation of the lower urinary tract is derived from three sets of peripheral nerves: sacral parasympathetic (i.e., pelvic nerves), thoracolumbar sympathetic (i.e., hypogastric nerves and sympathetic chain), and sacral somatic nerves (i.e., primarily pudendal nerves) (Fig. 3-1).<sup>1-5</sup>

### Sacral Parasympathetic Pathways

The sacral parasympathetic nerves, which in humans originate from the S2 to S4 segments of the spinal cord, provide most excitatory input to the bladder. Cholinergic preganglionic neurons located in the intermediolateral region of the sacral spinal cord send axons to ganglionic cells in the pelvic plexus and the bladder wall (see Fig. 3-1). Transmission in bladder ganglia is mediated by a nicotinic cholinergic mechanism. In some

**Figure 3-1** Diagram of the innervation of the female lower urinary tract. **Table 3-1 Receptors for Putative Transmitters in the Lower Urinary Tract**

Tissue	Cholinergic	Adrenergic	Other
Bladder body	+ (M <sub>2</sub> )* + (M <sub>3</sub> )	– (β <sub>2</sub> ) – (β <sub>3</sub> )	+ Purinergic (P2X <sub>1</sub> ) – VIP + Substance P (NK <sub>2</sub> )
Bladder base	+ (M <sub>2</sub> ) + (M <sub>3</sub> )	+ (α <sub>1</sub> )	– VIP + Substance P (NK <sub>2</sub> ) + Purinergic (P2X)
Urothelium	+ (M <sub>2</sub> ) + (M <sub>3</sub> )	+ α + β	+ TRPV1 + TRPM8 + P2X + P2Y + SP + Bradykinin (B <sub>2</sub> )
Urethra	+ (M)	+ (α <sub>1</sub> ) + (α <sub>2</sub> ) – (β)	+ Purinergic (P2X) – VIP – Nitric oxide
Sphincter striated muscle	+ (N)		
Adrenergic nerve terminals	– (M <sub>2</sub> ) + (M <sub>1</sub> )	– (α <sub>2</sub> )	– NPY
Cholinergic nerve terminals	– (M <sub>2</sub> ) + (M <sub>1</sub> )	+ (α <sub>1</sub> )	– NPY
Afferent nerve terminals			+ Purinergic (P2X <sub>2/3</sub> ) + TRPV1
Ganglia	+ (N) + (M <sub>1</sub> )	+ (α <sub>1</sub> ) – (α <sub>2</sub> ) + (β)	– Enkephalinergic (δ) – Purinergic (P <sub>1</sub> ) + Substance P

\*Letters in parentheses indicate receptor type, such as muscarinic (M) and nicotinic (N). Plus and minus signs indicate excitatory and inhibitory effects.

NPY, neuropeptide Y; TRP, transient receptor potential; VIP, vasoactive intestinal polypeptide.

species (e.g., cats, rabbits) ganglionic synapses act like gating circuits, exhibiting marked facilitation during repetitive preganglionic activity and modulation by various transmitter systems, including muscarinic, adrenergic, purinergic, and enkephalinergic (Table 3-1).<sup>6,7</sup> The ganglia can have an important role in regulating neural input to the bladder. Whether bladder ganglia in humans have similar properties is not known. Ganglion cells excite the bladder smooth muscle. Histochemical studies of the ganglia and nerves supplying the human lower urinary tract have shown that many ganglion cells contain choline acetyltransferase, acetylcholinesterase, and the vesicular acetylcholine transporter and therefore are cholinergic. Choline acetyltransferase-, acetylcholinesterase-, and acetylcholine transporter-positive nerves are abundant in all parts of the bladder but are less extensive in the urethra.<sup>1,2,5</sup> Neuropeptide Y and nitric oxide synthase also have been identified in 40% to 95% of intramural ganglia of the human bladder. Several populations of axonal varicosities have been detected close to intramural ganglion cells, including substance P-, vasoactive intestinal polypeptide (VIP)-, and calcitonin gene-related peptide (CGRP)-positive axons, which are presumably collaterals of extrinsic sensory nerves; tyrosine hydroxylase and neuropeptide Y axons, which are likely to be sympathetic axons; and galanin- and neuropeptide Y-containing axons.

Parasympathetic neuroeffector transmission in the bladder is mediated by acetylcholine acting on postjunctional muscarinic receptors.<sup>8-11</sup> M<sub>2</sub> and M<sub>3</sub> muscarinic receptor subtypes are expressed in bladder smooth muscle; however, examination of

subtype-selective muscarinic receptor antagonists and studies of muscarinic receptor-knockout mice have revealed that the M<sub>3</sub> subtype is the principal receptor involved in excitatory transmission.<sup>8-11</sup> Activation of M<sub>3</sub> receptors triggers intracellular Ca<sup>2+</sup> release, whereas activation of M<sub>2</sub> receptors inhibits adenylate cyclase.<sup>10</sup> The latter may contribute to bladder contractions by suppressing adrenergic inhibitory mechanisms that are mediated by β<sub>3</sub>-adrenergic receptors and stimulation of adenylate cyclase.

In bladders of various animals, stimulation of parasympathetic nerves produces a noncholinergic contraction that is resistant to atropine and other muscarinic receptor-blocking agents. Adenosine triphosphate (ATP) (see Table 3-1) has been identified as the excitatory transmitter mediating the noncholinergic contractions.<sup>10-13</sup> ATP excites the bladder smooth muscle by acting on P2X receptors, which are ligand-gated ion channels. Among the seven types of P2X receptors that have been identified in the bladder, P2X<sub>1</sub> is the major subtype expressed in the rat and in human bladder smooth muscle.<sup>12,13</sup> Purinergic agonists also modulate transmission in bladder ganglia.<sup>6,14,15</sup> Although purinergic excitatory transmission is not important in the normal human bladder, it appears to be involved in bladders from patients with pathologic conditions such as detrusor overactivity, chronic urethral outlet obstruction, or interstitial cystitis.<sup>12,16,17</sup>

Parasympathetic pathways to the urethra induce relaxation during voiding.<sup>1,10,11,18-20</sup> In various species, the relaxation is not affected by muscarinic antagonists and therefore is not mediated

by acetylcholine. However, inhibitors of nitric oxide synthase block the relaxation *in vivo* during reflex voiding or block the relaxation of urethral smooth muscle strips induced *in vitro* by electrical stimulation of intramural nerves, indicating that nitric oxide is the inhibitory transmitter involved in relaxation.<sup>1,2,11,18,19</sup> In some species, neurally evoked contractions of the urethra are reduced by muscarinic receptor antagonists or by desensitization of P2X purinergic receptors, indicating that acetylcholine or ATP are involved in excitatory transmission to urethral smooth muscle.<sup>21</sup>

### Thoracolumbar Sympathetic Pathways

Sympathetic preganglionic pathways that arise from the T11 to L2 spinal segments pass to the sympathetic chain ganglia and then to prevertebral ganglia in the superior hypogastric and pelvic plexus and to short adrenergic neurons in the bladder and urethra. Sympathetic postganglionic nerves that release norepinephrine provide excitatory input to smooth muscle of the urethra and bladder base, inhibitory input to smooth muscle in the body of the bladder, and inhibitory and facilitatory input to vesical parasympathetic ganglia.<sup>1,7,11</sup> Radioligand receptor binding studies showed that  $\alpha$ -adrenergic receptors are concentrated in the bladder base and proximal urethra, whereas  $\beta$ -adrenergic receptors are most prominent in the bladder body.<sup>1,10</sup> These observations are consistent with pharmacologic studies showing that sympathetic nerve stimulation or exogenous catecholamines produce  $\beta$ -adrenergic receptor-mediated inhibition of the body and  $\alpha$ -adrenergic receptor-mediated contraction of the base, dome, and urethra. Molecular and contractility studies have shown that  $\beta_3$ -adrenergic receptors elicit inhibition and  $\alpha_1$ -adrenergic receptors elicit contractions in the human bladder.<sup>10</sup> The  $\alpha_{1A}$ -adrenergic receptor subtype is most prominent in the normal bladders, but the  $\alpha_{1D}$ -adrenergic receptor subtype is upregulated in bladders from patients with outlet obstruction, raising the possibility that  $\alpha_1$ -adrenergic receptor excitatory mechanisms in the bladder may contribute to irritative lower urinary tract symptoms in patients with benign prostatic hyperplasia.<sup>10</sup>

### Sacral Somatic Pathways

Somatic efferent pathways to the external urethral sphincter are carried in the pudendal nerve from anterior horn cells in the third and fourth sacral segments. Branches of the pudendal nerve and other sacral somatic nerves also carry efferent impulses to muscles of the pelvic floor and proprioceptive afferent signals from these muscles, as well as sensory information from the urethra.<sup>2,22-24</sup> Analysis of urethral closure mechanisms in the female rat during bladder distention or sneeze-induced stress conditions revealed that the major rise in urethral pressure occurred in the middle urethra and was mediated by efferent pathways in the pudendal nerve to the external urethral sphincter and by pathways in nerves to the iliococcygeus and pubococcygeus muscles, although not by pathways in the sympathetic or parasympathetic nerves.<sup>25</sup>

### Neural Modulation

Postganglionic nerve terminals are sites of “cross-talk” between sympathetic and parasympathetic nerves and possible sites of gating mechanisms.<sup>26-30</sup> For example, in the rat lower urinary

tract, activation of  $M_{2/4}$  (muscarinic) cholinergic receptors on nerve terminals suppresses acetylcholine and norepinephrine release,<sup>30</sup> whereas activation of  $M_1$  cholinergic receptors or  $\alpha_1$ -adrenergic receptors enhances acetylcholine release (see Table 3-1).<sup>26-29</sup> Inhibitory  $M_{2/4}$  mechanisms are dominant at low frequencies of nerve activity and therefore may contribute to urine storage, whereas  $M_1$  facilitatory mechanisms are dominant at high frequencies of nerve stimulation and may contribute to an enhancement of neurally evoked bladder contractions during micturition to induce complete bladder emptying.

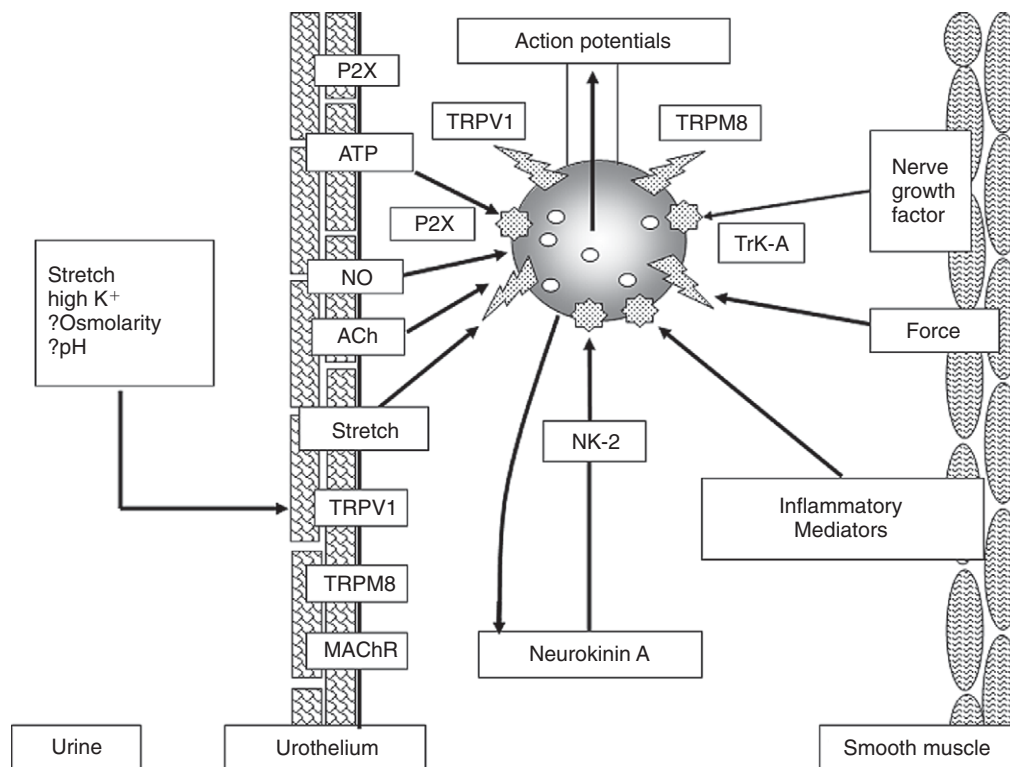

Other putative transmitters that have been identified in efferent pathways to the lower urinary tract of animals and humans may modulate neuroeffector transmission (see Table 3-1).<sup>3,31,32</sup> Neuropeptide Y is present in adrenergic and cholinergic neurons,<sup>32</sup> and when administered exogenously, it acts prejunctionally to suppress the release of norepinephrine and acetylcholine from postganglionic nerve terminals.<sup>21</sup> Although nitric oxide relaxes smooth muscle in the urethra, it is inactive in bladder smooth muscle.<sup>10</sup> However, in the bladder, it may act on afferent nerves to modulate excitability.<sup>10,31</sup> VIP, which is released with acetylcholine, may function as an inhibitory transmitter in the bladder.<sup>10</sup> Efferent control of the bladder and urethra is potentially complex and involves many transmitters and many synaptic gating mechanisms in ganglia and at postganglionic nerve terminals.

### Lumbosacral Afferent Pathways

Afferent activity arising in the bladder is transmitted to the central nervous system by both sets of autonomic nerves.<sup>2,33-37</sup> The afferent nerves most important for initiating micturition are those passing in the pelvic nerves to the sacral spinal cord. These afferents consist of small, myelinated (A) and unmyelinated (C) fibers that convey impulses from tension receptors and nociceptors, respectively, in the bladder wall.<sup>2,3,36</sup> Electrophysiologic studies in the cat have shown that A bladder afferents respond in a graded manner to passive distention and to active contraction of the bladder.<sup>35-37</sup> The intravesical pressure threshold for activation of these afferents ranges from 5 to 15 mm Hg, which is consistent with pressures at which humans report the first sensation of bladder filling during cystometry. The A afferents in the cat show a linear increase in firing with increasing intravesical pressures that extend into the noxious range, suggesting that nociceptive stimuli in the bladder may be encoded in part by high rates of firing in polymodal afferents that also transmit non-noxious information.

High-threshold C-fiber afferents have also been detected in the cat bladder.<sup>34</sup> Under normal conditions, most of these afferents do not respond to bladder distention and therefore have been designated silent C fibers, but many can be activated by chemical irritation of the bladder mucosa<sup>3,34</sup> or cold temperatures (Fig. 3-2).<sup>38</sup> After chemical irritation, C-fiber afferents exhibit spontaneous firing with the bladder empty and increased firing during bladder distention.<sup>34</sup> Activation of C-fiber afferents by chemical irritation facilitates the micturition reflex and decreases bladder capacity.<sup>2,3,39-41</sup> Administration of capsaicin, a neurotoxin that desensitizes C-fiber afferents, blocks this facilitation but does not block micturition reflexes in normal animals, indicating that C-fiber afferent pathways are not essential for normal voiding.<sup>2,42,43</sup>

In the rat, A-fiber and C-fiber bladder afferents are not distinguishable on the basis of stimulus modality; both types of afferents consist of mechanosensitive and chemosensitive popu-

**Figure 3-2** The diagram shows the receptors in the urothelium and in sensory nerve endings in the bladder mucosa and the putative chemical mediators that are released by the urothelium, nerves, or smooth muscle that can modulate the excitability of sensory nerves. Urothelial cells and sensory nerves express common receptors (i.e., P2X, TRPV1, and TRPM8). Distention of the bladder activates stretch receptors and triggers the release of urothelial transmitters such as adenosine triphosphate (ATP), acetylcholine (ACh), and nitric oxide (NO) that may interact with adjacent nerves. Receptors in afferent nerves or the urothelium can respond to changes in pH, osmolality, high potassium ion ( $K^+$ ) concentration, chemicals in the urine, or inflammatory mediators released in the bladder wall. Neuropeptides (e.g., neurokinin A) released from sensory nerves in response to distention or chemical stimulation can act on NK-2 autoreceptors to sensitize the mechanosensitive nerve endings. The smooth muscle can generate a force that may influence some mucosal endings. Nerve growth factor released from muscle or urothelium can exert an acute and chronic influence on the excitability of sensory nerves through an action on tyrosine kinase A (Trk-A) receptors. MACHR, muscarinic acetylcholine receptor; TRPM8, menthol/cold receptor; TRPV1, transient receptor potential vanilloid receptor 1, sensitive to capsaicin.

lations.<sup>44-47</sup> C-fiber afferents that respond only to bladder filling have also been identified in the rat bladder and appear to be volume receptors possibly sensitive to stretch of the mucosa.<sup>2,44</sup> C-fiber afferents are sensitive to the neurotoxins capsaicin and resiniferatoxin and to other substances, such as tachykinins, nitric oxide, ATP, prostaglandins, and neurotrophic factors, released in the bladder by afferent nerves, urothelial cells, and inflammatory cells (see Fig. 3-2).<sup>2,3,41,45,48-54</sup> These substances can sensitize the afferent nerves and change their response to mechanical stimuli.

Mechanosensitive afferents from the bladder and urethra have been identified in sympathetic nerves passing to the lumbar spinal cord.<sup>55</sup> These afferent pathways consist of myelinated and unmyelinated axons that respond to similar stimulus modalities as afferents in the pelvic nerve. The function of sympathetic nerve afferents in the control of micturition is uncertain; however, based on clinical observations, it is clear that in humans they carry nociceptive information from the lower urinary tract.

Afferent pathways from the urethra, which induce the sensations of temperature, pain, and passage of urine, travel in the pudendal nerve to the lumbosacral spinal cord.<sup>2,3</sup> Afferents from the female sex organs, including the clitoris, vagina, and part of the innervation of the uterine cervix, also travel in the pudendal

nerve.<sup>56,57</sup> These afferents and pudendal nerve afferents from the striated sphincter muscles have a modulatory influence on micturition.<sup>3,24</sup>

The properties of lumbosacral dorsal root ganglion cells innervating the bladder, urethra, and external urethral sphincter in the rat have been studied with patch-clamp recording techniques in combination with axonal tracing methods to identify the different populations of neurons.<sup>58-65</sup> Based on responsiveness to capsaicin, it is estimated that approximately 70% of bladder afferent neurons in the rat are the C-fiber type. These neurons exhibit high-threshold, tetrodotoxin-resistant sodium channels and action potentials and phasic firing (one to two spikes) in response to prolonged depolarizing current pulses.<sup>58,60,61</sup> Approximately 90% of the bladder C-fiber afferent neurons also are excited by ATP, which induces depolarization and firing of afferent neurons by activating  $P2X_3$  or  $P2X_{2/3}$  receptors.<sup>65</sup> These neurons express isolectin-B4 binding, which is commonly used as a marker for ATP-responsive sensory neurons.<sup>60</sup> A-fiber afferent neurons are resistant to capsaicin and ATP and exhibit low-threshold, tetrodotoxin-sensitive sodium channels and action potentials and tonic firing (multiple spikes) to depolarizing current pulses. C-fiber bladder afferent neurons also express a slowly decaying A-type  $K^+$  channel that controls spike threshold

and firing frequency.<sup>58,62</sup> Suppression of this  $K^+$  channel induces hyperexcitability of bladder afferent nerves.<sup>58</sup> These properties of dorsal root ganglion cells are consistent with the different properties of A-fiber and C-fiber afferent receptors in the bladder.

Immunohistochemical studies have shown that a large percentage of bladder afferent neurons contain peptides: CGRP, VIP, substance P, pituitary adenylate cyclase-activating polypeptide (PACAP), corticotropin-releasing factor (CRF), and enkephalins.<sup>66,67</sup> In the bladder, these peptides are common in nerves in the submucosal and subepithelial layers and around blood vessels. The neurotoxin capsaicin, when applied locally to the bladder in experimental animals, releases peptides from peripheral afferent terminals and produces inflammatory responses, including plasma extravasation and vasodilatation.<sup>41</sup> Afferent peptides can also modulate transmission in bladder ganglia.<sup>6</sup> These findings suggest that the neuropeptides may be important neurotransmitters in afferent pathways in the lower urinary tract.

### *Urothelial-Afferent Interactions*

Studies have revealed that the urothelium, which has been traditionally viewed as a passive barrier at the bladder luminal surface,<sup>2,68,69</sup> has specialized sensory and signaling properties that allows urothelial cells to respond to their chemical and physical environment and to engage in reciprocal chemical communication with neighboring nerves in the bladder wall (see Fig. 3-2).<sup>68-80</sup> These properties include expression of nicotinic, muscarinic, tachykinin, adrenergic, purinergic, and capsaicin (TRPV1) receptors<sup>70-76,80-83</sup>; responsiveness to transmitters released from sensory nerves; close physical association with afferent nerves<sup>74,84,85</sup>; and an ability to release chemical mediators such as ATP, acetylcholine, and nitric oxide that can regulate the activity of adjacent nerves and thereby trigger local vascular changes or reflex bladder contractions.<sup>71,75,77,82,86</sup> The role of ATP in urothelial-afferent communication has attracted considerable attention because bladder or urethral distention releases ATP from the urothelium,<sup>72,77,87,88</sup> and intravesical administration of ATP induces bladder hyperactivity,<sup>86,88</sup> an effect blocked by administration of P2X purinergic receptor antagonists that suppress the excitatory action of ATP on bladder afferent neurons.<sup>65,86,88</sup> Mice in which the P2X<sub>3</sub> receptor was knocked out exhibited hypoactive bladder activity and inefficient voiding,<sup>76,88</sup> suggesting that activation of P2X<sub>3</sub> receptors on bladder afferent nerves by ATP released from the urothelium was essential for normal bladder function. It has also been reported that urothelial cells obtained from patients or cats with a chronic, painful bladder condition (i.e., interstitial cystitis) released significantly larger amounts of ATP in response to mechanical stretching than urothelial cells from normal patients.<sup>72,89</sup> The release of other substances, including nitric oxide<sup>90</sup> and a nonapeptide glycoprotein called APF,<sup>91-93</sup> is also increased in feline interstitial cystitis and human interstitial cystitis, respectively. This raises the possibility that enhanced signaling between the urothelium and afferent nerves is involved in the triggering of painful bladder sensations (see Fig. 3-2).

Communication between the urothelium and afferent nerves may also involve another cell type, the myofibroblast.<sup>94-96</sup> These cells, which stain intensely for vimentin and gap junction protein connexin 43, have been identified immediately below the urothelium in human and guinea pig bladders. Electron microscopic studies have revealed that the cells make close appositions with unmyelinated suburothelial nerve endings.<sup>95</sup> Exogenous ATP can induce  $Ca^{+2}$ -activated chloride currents in myofibroblasts by

stimulation of P2Y receptors.<sup>96</sup> It has been suggested that stretch-induced ATP released from urothelial cells may act on myofibroblasts, which modulate the excitability of adjacent afferent nerves.

## ANATOMY OF CENTRAL NERVOUS PATHWAYS

### Efferent Neurons

Preganglionic neurons in the lumbosacral parasympathetic nucleus have been identified in the intermediolateral region of the spinal cord in several species.<sup>3,97</sup> In the cat, the sacral parasympathetic nucleus is divided into two groups of cells: a dorsal band and a lateral band. Neurons innervating the urinary bladder are located in the lateral band. These neurons have an extensive network of axon collaterals<sup>98</sup> that is involved in a recurrent inhibitory mechanism<sup>99</sup> that regulates reflex bladder activity. The neurons send dendrites to discrete regions of the spinal cord, including the lateral and dorsal lateral funiculus, lamina I on the lateral edge of the dorsal horn, the dorsal gray commissure, and the gray matter and lateral funiculus ventral to the autonomic nucleus (Fig. 3-3).<sup>97</sup> It has been suggested that the dendrites in the lateral funiculus receive inputs from descending pathways from the brain, whereas the other dendrites receive segmental inputs from interneurons or primary afferents. Lumbar sympathetic preganglionic neurons and motor neurons in Onuf's nucleus that innervate the external urethral sphincter have similar dendritic distributions (see Fig. 3-3).<sup>100-102</sup>

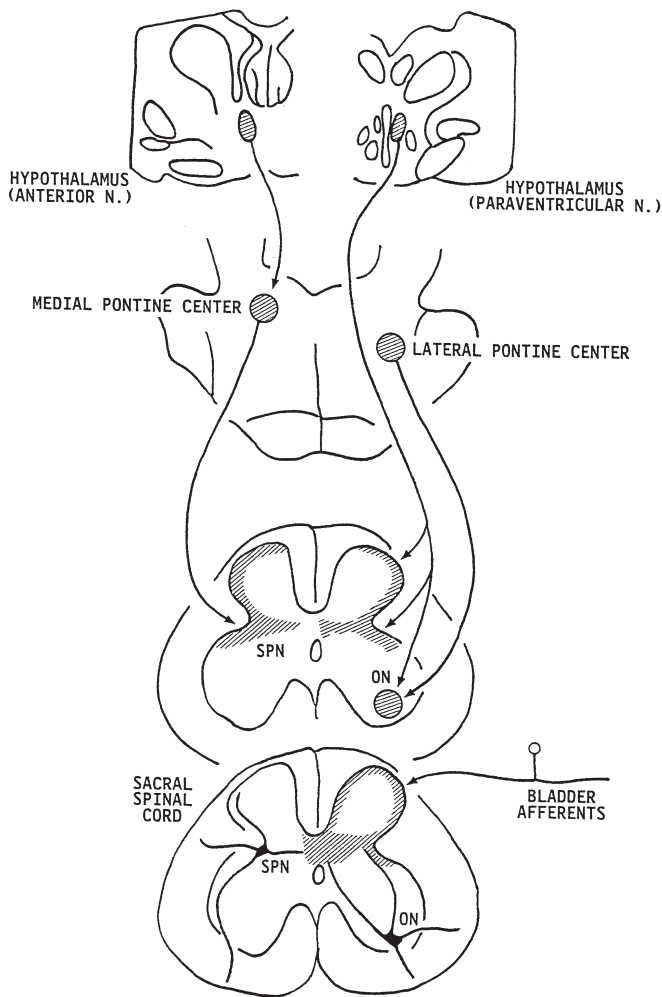

### Afferent Projections

Afferent pathways from the lower urinary tract project to discrete regions of the dorsal horn that contain the soma or dendrites of efferent neurons innervating the lower urinary tract. Pelvic nerve afferent pathways from the urinary bladder of the cat<sup>103,104</sup> and the rat<sup>105</sup> project into Lissauer's tract at the apex of the dorsal horn and then pass rostrocaudally, giving off collaterals that extend laterally and medially through the superficial layer of the dorsal horn (lamina I) into the deeper layers (laminae V to VII and X) at the base of the dorsal horn (Fig. 3-4A and see Fig. 3-3). The lateral pathway, which is the most prominent projection, terminates in the region of the sacral parasympathetic nucleus and also sends some axons to the dorsal commissure (see Figs. 3-3 and 3-4A).

Pudendal nerve afferent pathways from the external urethral sphincter of the cat have central terminations that overlap in part with those of bladder afferents in lateral laminae, I, V to VII, and X.<sup>100,101</sup> Afferents from the female sexual organs also terminate in these areas.<sup>56,57</sup> The overlap of the central projections of bladder afferents and the afferents in the pudendal nerve to the sex organs and urethra is of interest, because activation of the latter afferents can markedly influence bladder function.<sup>106-109</sup>

### Spinal Interneurons

The spinal neurons involved in processing afferent input from the lower urinary tract and the sex organs have been identified by physiologic and anatomic tracing techniques.<sup>110-115</sup> Interneurons that fire in response to bladder distention or mechanical stimulation of the vagina or uterine cervix have been detected in lateral intermediate gray matter near the sacral para-

**Figure 3-3** Neural connections between the brain and the sacral spinal cord that may be involved in the regulation of the lower urinary tract in the cat. Lower section of the spinal cord shows the location and morphology of a preganglionic neuron in the sacral parasympathetic nucleus (SPN), a sphincter motoneuron in Onuf's nucleus (ON), and the sites of central termination of afferent projections from the urinary bladder. Upper section of the spinal cord shows the sites of termination of descending pathways arising in the pontine micturition center (medial), the pontine sphincter or urine storage center (lateral), and the paraventricular nuclei of the hypothalamus. Section through the pons shows the projection for anterior hypothalamic nuclei to the pontine micturition center. (From de Groat WC: Neural control of urinary bladder and sexual organs. In Bannister R, Mathias, CJ [eds]: *Autonomic Failure*, 3rd ed. Oxford, Oxford University Press, 1992, p 129.)

sympathetic nucleus and in the region of the dorsal commissure (lamina X).<sup>2,108</sup> Commonly, stimulation of sex organ afferents inhibits neurons activated by bladder distention, which is consistent with the inhibitory effect of these afferents on bladder reflexes.<sup>108,109</sup>

Spinal interneurons have also been identified by the expression of the immediate-early gene *FOS* (see Fig. 3-4B)<sup>110-112</sup> and by transneuronal transport of pseudorabies virus from the bladder (see Fig. 3-4C).<sup>40,113-115</sup> The protein product of the *FOS* gene can be detected immunocytochemically in the nuclei of neurons within 30 to 60 minutes after synaptic activation. In the rat,

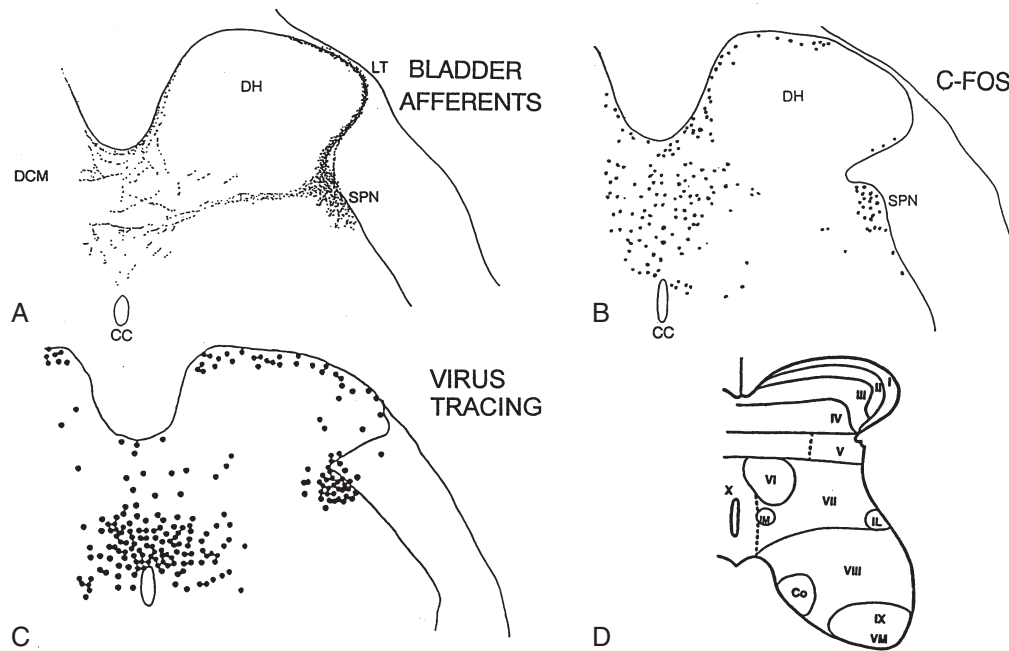

noxious or non-noxious stimulation of the bladder and urethra and electrical stimulation of the pelvic or pudendal nerves increased the levels of FOS protein, primarily in the dorsal commissure and in the area of the sacral parasympathetic nucleus (see Fig. 3-4B), the major sites of termination of afferents from the lower urinary tract. Neurons in these same regions are labeled by the pseudorabies virus (see Fig. 3-4C), which passes transsynaptically in a sequential manner from postganglionic to preganglionic efferent neurons and then to segmental interneurons and eventually to neurons in the brain (Fig. 3-5) (discussed later).<sup>113-115</sup> Interneurons in the dorsal commissure region also project to the sphincter motor nucleus.<sup>116,117</sup> These results indicate that interneurons in restricted regions of the intermediate gray matter and dorsal commissure play a major role in coordinating the different aspects of lower urinary tract function.

Patch-clamp recordings from parasympathetic preganglionic neurons in the rat spinal slice preparations have revealed that interneurons located immediately dorsal and medial to the parasympathetic nucleus make direct monosynaptic connections with the preganglionic neurons (PGNs).<sup>118-120</sup> Microstimulation of interneurons in both locations elicits glutamatergic, *N*-methyl-D-aspartic acid (NMDA), and non-NMDA excitatory postsynaptic currents in PGNs. Stimulation of a subpopulation of medial interneurons elicits GABAergic and glycinergic inhibitory postsynaptic currents.<sup>118</sup> In this way, local interneurons likely play an important role in excitatory and inhibitory reflex pathways controlling the preganglionic outflow to the lower urinary tract. Glutamatergic excitatory inputs have also been elicited by stimulation of the projections from lamina X and the lateral funiculus.<sup>121,122</sup>

### Pathways in the Brain

The neurons in the brain that control the lower urinary tract have been studied with a variety of anatomic tracing techniques in several species. In the rat, transneuronal virus tracing methods<sup>113-115</sup> have identified many populations of central neurons that are involved in the control of the bladder, urethra, and urethral sphincter, including the Barrington nucleus, the pontine micturition center (PMC); the medullary raphe nucleus, which contains serotonergic neurons; the locus ceruleus, which contains noradrenergic neurons; the periaqueductal gray (PAG); and the A5 noradrenergic cell group (see Fig. 3-5). Several regions in the hypothalamus and the cerebral cortex also exhibited virus-infected cells. Neurons in the cortex were located primarily in the medial frontal cortex.

Other anatomic studies in which anterograde tracer substances were injected into brain areas and then identified in terminals in the spinal cord are consistent with the virus-tracing data. Tracer injected into the paraventricular nucleus of the hypothalamus labeled terminals in the sacral parasympathetic nucleus and the sphincter motor nucleus (see Fig. 3-3).<sup>123-125</sup> Neurons in the anterior hypothalamus project to the PMC, and neurons in the PMC project primarily to the sacral parasympathetic nucleus and the lateral edge of the dorsal horn and the dorsal commissure, areas containing dendritic projections from the preganglionic neurons, sphincter motoneurons, and afferent inputs from the bladder. Conversely, projections from neurons in the lateral pons terminate rather selectively in the sphincter motor nucleus (i.e., Onuf's nucleus) (see Fig. 3-3).<sup>125</sup> The sites of termination of descending projections from the PMC are optimally located to regulate reflex mechanisms at the spinal level.

**Figure 3-4** The distribution of bladder afferent projections to the L6 spinal cord of the rat (**A**) is shown, with the distribution of Fos-positive cells in the L6 spinal segment after chemical irritation of the lower urinary tract of the rat (**B**) and the distribution of interneurons in the L6 spinal cord labeled by transneuronal transport of pseudorabies virus injected into the urinary bladder (**C**). Afferents labeled by lectin wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) injected into the urinary bladder. Fos immunoreactivity is present in the nuclei of cells. CC central canal; DH, dorsal horn; SPN, sacral parasympathetic nucleus. D, Laminar organization of the cat spinal cord.

**Table 3-2 Reflexes to the Lower Urinary Tract**

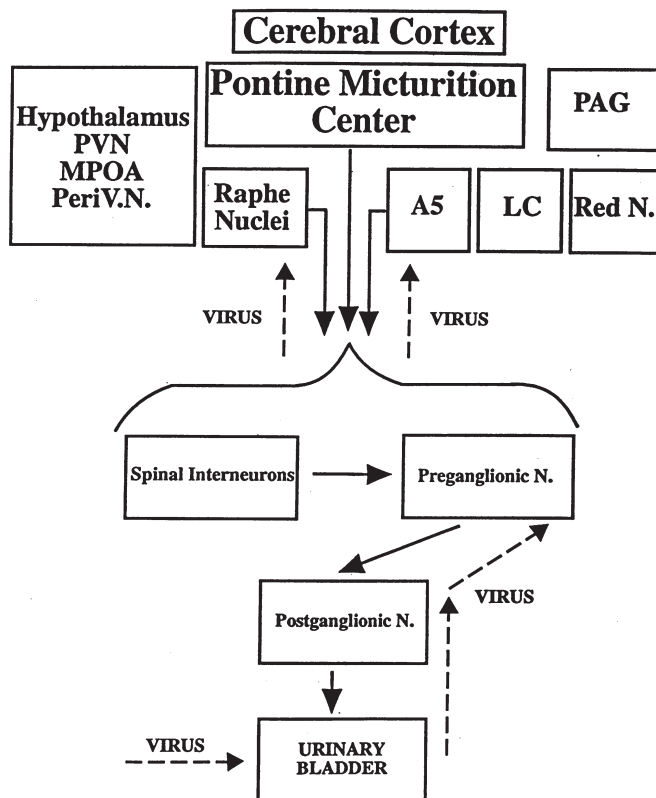

Afferent Pathway	Efferent Pathway	Central Pathway
Urine storage: low-level vesical afferent activity (pelvic nerve)	External sphincter contraction (somatic nerves) Internal sphincter contraction (sympathetic nerves) Detrusor inhibition (sympathetic nerves) Ganglionic inhibition (sympathetic nerves) Sacral parasympathetic outflow, inactive	Spinal reflexes
Micturition: high-level vesical afferent activity (pelvic nerve)	Inhibition of external sphincter activity Inhibition of sympathetic outflow Activation of parasympathetic outflow to the bladder	Spinobulbospinal reflexes

### REFLEX MECHANISMS CONTROLLING THE LOWER URINARY TRACT

The central pathways controlling lower urinary tract function are organized as simple on-off switching circuits that maintain a reciprocal relationship between the urinary bladder and the urethral outlet. The principal reflex components of these switching circuits are listed in Table 3-2 and are illustrated in Figure 3-6. Intravesical pressure measurements during bladder filling in humans and animals reveal that bladder pressure is maintained at a low and relatively constant level when bladder volume is below the threshold for inducing voiding (Fig. 3-7A). Accommodation of the bladder to increasing volumes of urine is primarily a passive phenomenon that depends on the intrinsic properties of the vesical smooth muscle and the quiescence of the parasympathetic efferent pathway.<sup>2-4</sup> In some species, urine storage is also facilitated by sympathetic reflexes that mediate

inhibition of bladder activity and closure of the urethral outlet (see Table 3-2 and Fig. 3-6).<sup>126,127</sup> During bladder filling, the activity on the sphincter electromyogram also increases (see Fig. 3-7), reflecting an increase in efferent firing in the pudendal nerve and an increase in outlet resistance that contributes to the maintenance of urinary continence.<sup>24</sup>

The storage phase of the urinary bladder can be switched to the voiding phase involuntarily (by reflex) or voluntarily (see Fig. 3-7B). The former is readily demonstrated in the human infant (see Fig. 3-7A) and in the anesthetized animal when the volume of urine exceeds the micturition threshold. At this point, increased afferent firing from tension receptors in the bladder reverses the pattern of efferent outflow, producing firing in the sacral parasympathetic pathways and inhibition of sympathetic and somatic pathways. The expulsion phase consists of an initial relaxation of the urethral sphincter (see Fig. 3-7A) followed in a few seconds by a contraction of the bladder, an increase in bladder pressure,

**Figure 3-5** Structures in the brain and spinal cord of the adult and neonatal rat were labeled after injection of pseudorabies virus into the urinary bladder or the urethra. Virus is transported transneuronally in a retrograde direction (*dashed arrows*). Normal synaptic connections are indicated by *solid arrows*. At long survival times, the virus can be detected in neurons at specific sites in the spinal cord and brain, extending to the pontine micturition center in the pons (i.e., Barrington's nucleus) and to the cerebral cortex. Other sites in the brain labeled by the virus are the paraventricular nucleus (PVN), medial preoptic area (MPOA), and periventricular nucleus (Peri.V.N.) of the hypothalamus; periaqueductal gray (PAG); locus ceruleus (LC) and subceruleus; red nucleus (Red N.); medullary raphe nuclei; and the noradrenergic cell group (A5).

and flow of urine. Secondary reflexes elicited by the flow of urine through the urethra facilitate bladder emptying.<sup>4</sup>

These reflexes require the integrated action of neuronal populations at various levels of the neuraxis (Fig. 3-8 and see Fig. 3-6). Certain reflexes, such as those mediating the excitatory input to the sphincters and the sympathetic inhibitory input to the bladder, are organized at the spinal level (see Fig. 3-6A), whereas the parasympathetic input to the detrusor has a more complicated central organization involving spinal and spinobulbospinal pathways (see Fig. 3-6B).

### Storage Reflexes

#### *Sympathetic Pathways*

Studies in animals indicate that sympathetic input to the lower urinary tract is tonically active during bladder filling.<sup>3</sup> Surgical or pharmacologic blockade of the sympathetic pathways can reduce urethral resistance, bladder capacity, and bladder wall compliance and increase the frequency and amplitude of bladder con-

tractions. Sympathetic firing is initiated at least in part by a sacrolumbar intersegmental spinal reflex pathway triggered by vesical afferent activity in the pelvic nerves (see Table 3-2 and Fig. 3-6A).<sup>126,127</sup> This vesicosympathetic reflex represents a negative-feedback mechanism whereby an increase in bladder pressure triggers an increase in inhibitory input to the bladder, allowing the bladder to accommodate larger volumes of urine. The reflex pathway is inhibited during micturition, and the inhibition is abolished by transection of the spinal cord at the thoracic level, indicating that it originates at a supraspinal site, possibly the PMC (see Fig. 3-6B).<sup>127</sup>

#### *Somatic Efferent Pathways to the Urethral Sphincter*

Reflex control of the striated urethral sphincter is similar to control of sympathetic pathways to the lower urinary tract (see Fig. 3-6A). During bladder filling, pudendal motor neurons are activated by vesical afferent input, whereas during micturition, motor neurons are reciprocally inhibited. Inhibition depends in part on supraspinal mechanisms, because in animals with chronic spinal lesions and in paraplegic patients, it is weak or absent. In paraplegics, the uninhibited spinal vesicosphincter excitatory reflex pathway commonly initiates a striated sphincter contraction in concert with a contraction of the bladder (i.e., bladder-sphincter dyssynergia) (see Fig. 3-7C). This reflex interferes with bladder emptying.

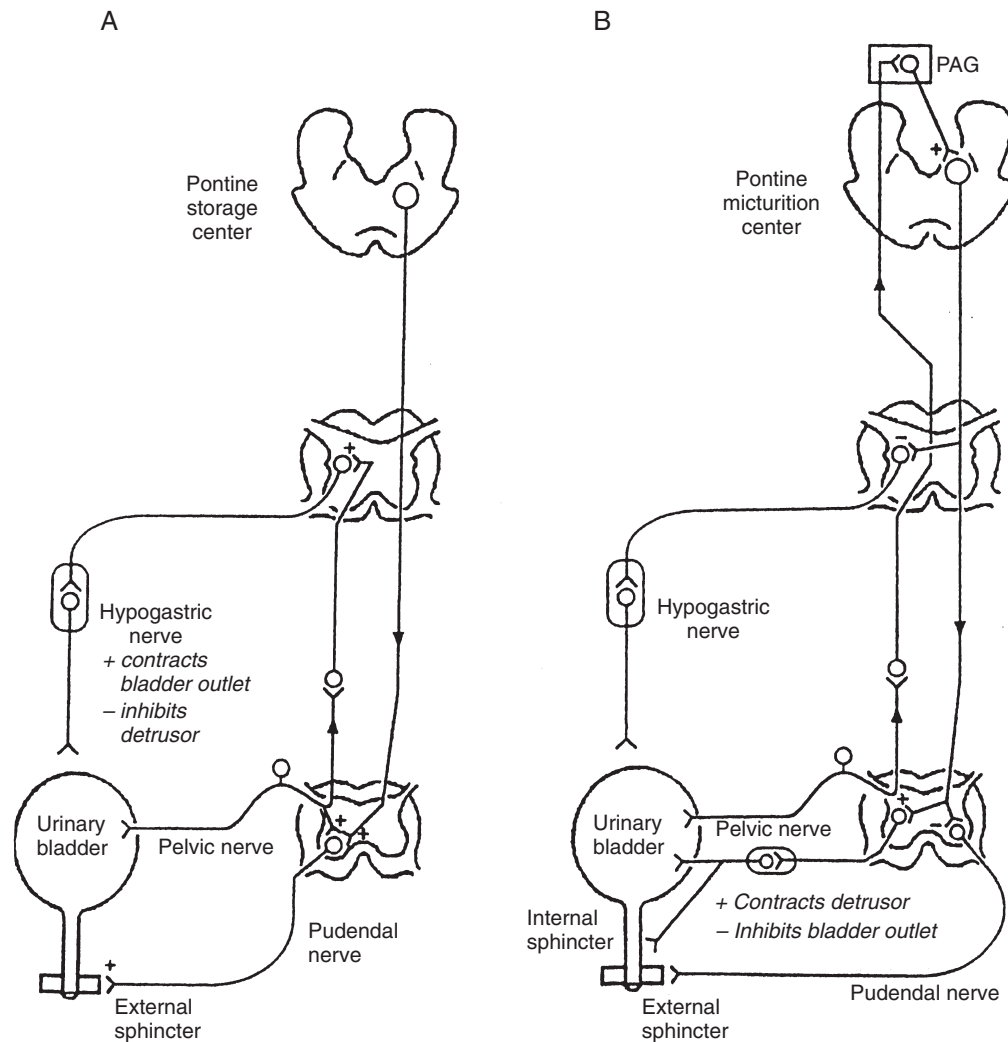

Supraspinal control of sphincter motor neurons has been studied with electrophysiologic techniques in animals. Electrical stimulation of the lateral funiculus of the spinal cord or stimulation of various areas of the brain evokes excitatory postsynaptic potentials and firing in sphincter motor neurons and an increase in sphincter electromyographic activity in the cat.<sup>128-132</sup> Stimulation of the lateral pontine reticular formation, an area that has been designated the urine storage center, elicits an increase in sphincter electromyographic activity and inhibits bladder activity.<sup>124,133</sup> Stimulation of dorsal medial pontine sites (e.g., PMC) excites the bladder and inhibits sphincter electromyographic activity at latencies of 40 to 50 ms.<sup>124,132,133</sup> These findings indicate that the spinal reflex pathways that mediate urine storage are strongly modulated by descending input from the brain.

### Voiding Reflexes

#### *Spinobulbospinal Micturition Reflex Pathway*

Micturition is mediated by activation of the sacral parasympathetic efferent pathway to the bladder and reciprocal inhibition of the somatic pathway to the urethral sphincter (see Table 3-2 and Fig. 3-6B). Studies in animals using brain-lesioning techniques have revealed that neurons in the brainstem at the level of the inferior colliculus play an essential role in the control of the parasympathetic component of micturition (Fig. 3-9 and see Fig. 3-8).<sup>131,134-138</sup> Removal of areas of the brain above the inferior colliculus by intercollicular decerebration usually facilitates micturition by eliminating inhibitory inputs from more rostral areas of the brain (see Fig. 3-8).<sup>3,4,134,135</sup> However, transection at any point below the colliculi abolishes micturition. Bilateral lesions in the rostral pons abolish micturition, whereas electrical stimulation at these sites triggers bladder contractions and micturition.<sup>136,138</sup> These observations led to the concept of a spinobulbospinal micturition reflex pathway that passes through a center in the rostral brainstem, the PMC (see Figs. 3-6B and 3-9). This pathway functions as an on-off switch (see Fig. 3-6)

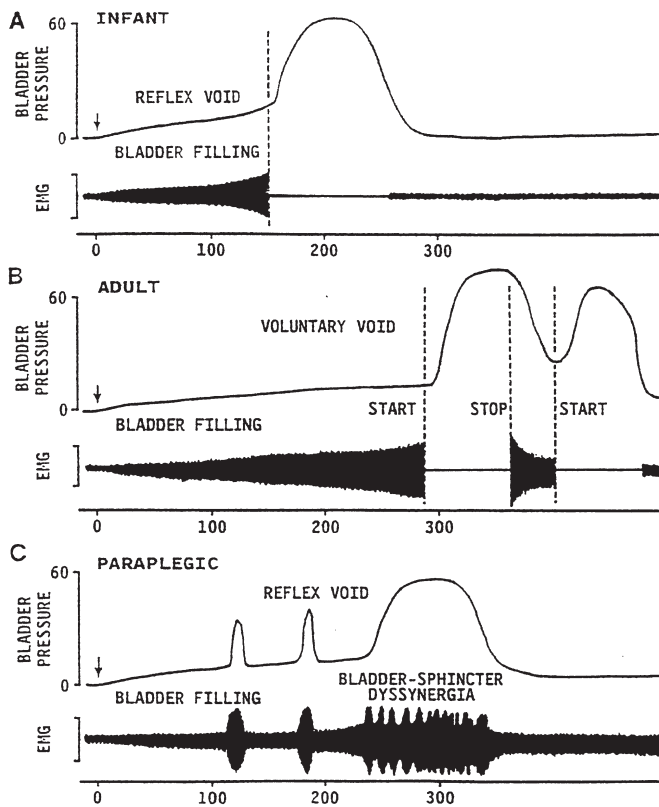

**Figure 3-6** Neural circuits controlling continence and micturition. **A**, Urine storage reflexes. During the storage of urine, distention of the bladder produces low-level vesical afferent firing, which stimulates sympathetic outflow to the bladder outlet (i.e., base and urethra) and pudendal outflow to the external urethral sphincter. These responses occur by spinal reflex pathways and represent guarding reflexes, which promote continence. Sympathetic firing also inhibits the detrusor muscle and modulates transmission in the bladder ganglia. A region in the rostral pons (i.e., pontine storage center) increases external urethral sphincter activity. **B**, Voiding reflexes. During elimination of urine, intense bladder afferent firing activates spinobulbospinal reflex pathways passing through the pontine micturition center, which stimulates the parasympathetic outflow to the bladder and internal sphincter smooth muscle and inhibits the sympathetic and pudendal outflow to the urethral outlet. Ascending afferent input from the spinal cord may pass through relay neurons in the periaqueductal gray (PAG) before reaching the pontine micturition center.

that is activated by a critical level of afferent activity arising from tension receptors in the bladder.<sup>136</sup> This switch is modulated by inhibitory and excitatory influences from areas of the brain rostral to the pons (i.e., diencephalon and cerebral cortex) and from other areas of the brainstem (Fig. 3-10 and see Figs. 3-8 and 3-9).<sup>134,135</sup>

### Pontine Micturition Center

Physiologic and pharmacologic experiments have provided substantial support for the concept that neuronal circuitry in the PMC functions as a switch in the micturition reflex pathway. The switch seems to regulate bladder capacity and coordinate the activity of the bladder and external urethral sphincter.<sup>2,3,131,138</sup> Electrical or chemical stimulation in the PMC of the rat, cat, or dog induces suppression of urethral sphincter electromyographic

activity, firing of sacral preganglionic neurons, bladder contractions, and release of urine.<sup>3,124,131,136,138</sup> Microinjections of putative inhibitory transmitters into the PMC of the cat can increase the volume threshold for inducing micturition and, in high doses, completely block reflex voiding, indicating that synapses in this region are important for regulating the set point for reflex voiding and are an essential link in the reflex pathway.<sup>131</sup> The PMC receives inputs indirectly through relay stations in the PAG or directly from spinal tract neurons (see Fig. 3-10) located in lateral laminae I, V, and VII of the sacral spinal cord.<sup>112,116,139-141</sup> Neurons in the latter areas of the spinal cord receive dense projections from bladder afferent pathways<sup>104,105,110</sup> (see Figs. 3-3 and 3-4) and respond to distention or contraction of the bladder.<sup>108,110</sup> Brain imaging studies in humans using positron emission tomography (PET) or functional magnetic resonance imaging (fMRI) have

**Figure 3-7** Combined cystometrograms and sphincter electromyograms (EMGs) comparing reflex voiding responses in an infant (**A**) and in a paraplegic patient (**C**) with a voluntary voiding response in an adult (**B**). The abscissa in all recordings represents bladder volume (mL), and the ordinates represent bladder pressure (cm H<sub>2</sub>O) and electrical activity of the EMG recording. On the left side of each trace, the arrows indicate the start of a slow infusion of fluid into the bladder (i.e., bladder filling). Vertical dashed lines indicate the start of sphincter relaxation, which precedes by a few seconds the bladder contraction in **A** and **B**. In **B**, notice that a voluntary cessation of voiding (i.e., stop) is associated with an initial increase in the sphincter electromyographic pattern, followed by a reciprocal relaxation of the bladder. A resumption of voiding is associated with sphincter relaxation and a delayed increase in bladder pressure. In the paraplegic patient (**C**), the reciprocal relationship between bladder and sphincter is abolished. During bladder filling, transient uninhibited bladder contractions occur in association with sphincter activity. Further filling leads to more prolonged and simultaneous contractions of the bladder and sphincter (i.e., bladder-sphincter dyssynergia). Loss of the reciprocal relationship between the bladder and sphincter in paraplegic patients interferes with bladder emptying. (From de Groat WC, Steers WD: Autonomic regulation of the urinary bladder and sex organs. In Loewy AD, Spyer KM [eds]: Central Regulation of Autonomic Functions. Oxford, Oxford University Press, 1990, p 310.)

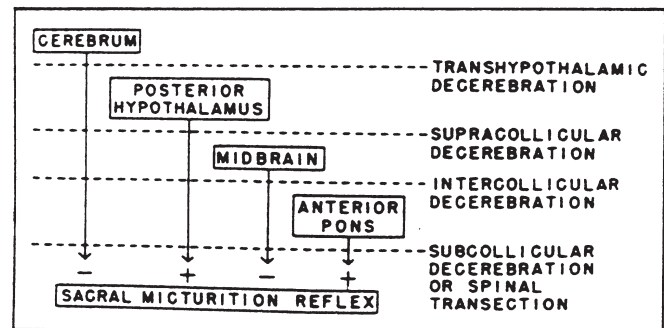

identified increased neuronal activity in the PMC and PAG during voiding (see Fig. 3-9).<sup>142-144</sup>

### Spinal Micturition Pathway

Reflex mechanisms in the spinal cord can also mediate bladder contractions and voiding.<sup>2,3,42,43,137</sup> In most species, these mechanisms are weak or absent in adults with an intact nervous system; however, they are prominent in neonates<sup>145</sup> or in mature animals after spinal cord injury above the lumbosacral level.<sup>146,147</sup> In the

**A**

**B**

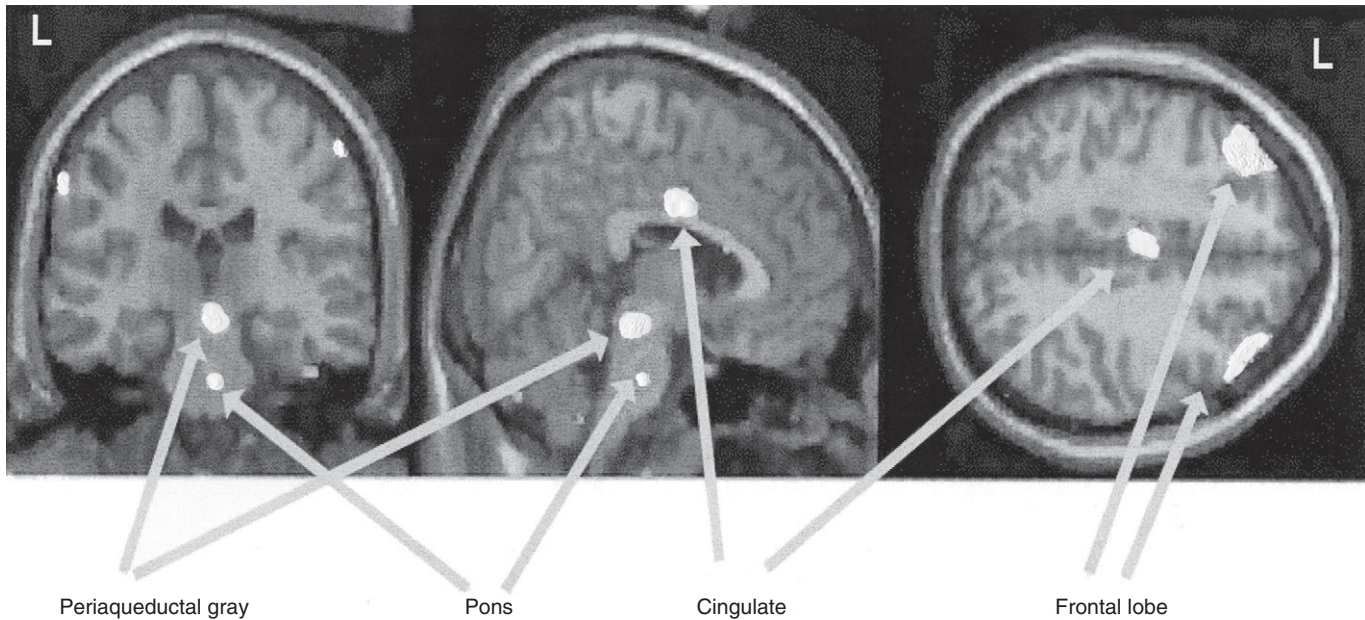

**Figure 3-8** **A**, Sagittal section of the cat brain shows various levels of brain transections made in the study of the supraspinal control of micturition. IC, inferior colliculi; M, midbrain; P, pons; SC superior colliculi. **B**, The net facilitatory and inhibitory actions of various levels of the brain are identified by the transection procedures shown in **A**. (Data from Tang PC: Levels of the brain stem and diencephalon controlling the micturition reflex. *J Neurophysiol* 18:583, 1955; Tang PC, Ruch TC: Localization of brain stem and diencephalic areas controlling the micturition reflex. *J Comp Neurol* 106:213, 1956.)

cat, the spinal micturition reflex is mediated by C-fiber afferents (see Fig. 3-10), whereas the spinobulbospinal reflex in normal animals is triggered by A fiber afferent input from tension receptors in the urinary bladder.<sup>43,136,137</sup> Somatic afferent pathways, particularly afferents with receptors in the perineum, can also induce voiding reflexes.<sup>108,145,146</sup> Spinal pathways mediate involuntary or automatic micturition, whereas the spinobulbospinal pathways are involved in voluntary micturition.

### Suprapontine Control of Micturition

Experiments in animals and clinical studies in humans indicate that various sites in the brain in addition to those directly involved in the micturition reflex pathway influence lower urinary tract function. Reviews of the clinical and animal literature concerning the regulation of micturition by the brain have been published.<sup>2-4,125</sup>

Axonal-tracing studies in rats using transsynaptic transport of pseudorabies virus have revealed the presence of direct connections from neurons in many brain areas to the reflex circuitry that regulates bladder function.<sup>113-115</sup> As illustrated in Figure 3-5, after injection of the virus into the bladder wall, preganglionic neurons and interneurons in the spinal cord are labeled at short transport times; at longer transport times, neurons in various areas of the brain, including the PMC, paraventricular and medial

**Figure 3-9** Increases in brain activity with increasing volume. Activations are shown superimposed on three orthogonal sections of normalized brain. Increases in brain activity with increases in bladder volume are seen in the periaqueductal gray, pons, cingulate, and frontal lobes (SPM *t*,  $P < .05$  uncorrected). (Modified from Athwal BS, Berkley KJ, Hussain I, et al: Brain responses to changes in bladder volume and urge to void in healthy men. *Brain* 124:369, 2001.)

preoptic nuclei of the hypothalamus, cerebral cortex, red nucleus, and PAG and raphe nuclei in the brainstem, are labeled by the virus. The possible functions of these neurons in the regulation of lower urinary tract function have been revealed by lesion and electrophysiologic studies in animals<sup>134,135</sup> and imaging studies in humans.

Lesion studies in humans<sup>148</sup> and animals<sup>149</sup> indicate that voluntary control of micturition depends on connections between the frontal cortex and forebrain structures, such as the anterior cingulate gyrus, hypothalamus, amygdala, bed nucleus of the stria terminalis, and septal nuclei, in which electrical stimulation elicits excitatory bladder effects.<sup>149,150</sup> Lesions to these areas of cortex resulting from tumors, aneurysms, or cerebrovascular disease appear to remove inhibitory control over the anterior hypothalamic area, which normally provides excitatory input to micturition centers in the brainstem (see Fig. 3-8).<sup>4,148</sup>

The literature on the hypothalamic influences on lower urinary tract function is extensive.<sup>2-4</sup> Electrical stimulation of the anterior or lateral hypothalamus of animals activates the sacral parasympathetic excitatory pathway to the bladder and induces bladder contractions and voiding. In the cat, the effects of hypothalamic stimulation are probably mediated by actions in the brainstem and direct projections to the spinal cord. Axonal tracing studies in cats have shown that hypothalamic areas have diverse projections to areas of the brainstem that have an important role in the control of bladder function. For example, the anterior hypothalamic area projects directly through the medial forebrain bundle to the PMC (see Fig. 3-3). The lateral hypothalamic area projects to the parabrachial nucleus,<sup>151</sup> which reportedly has facilitatory effects on micturition.<sup>4</sup> The anterior, medial, and paraventricular areas of the hypothalamus project to the central gray matter and medullary raphe nuclei. Electrical stimulation of the latter areas and adjacent reticular formation (i.e., nucleus reticularis gigantocellularis) has been shown to exert prominent modulatory

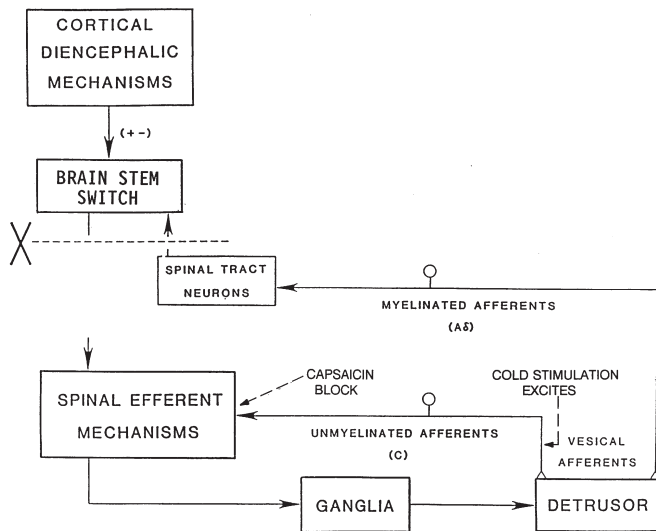

effects on bladder and urethral sphincter activity.<sup>3,4</sup> Medial and posterior hypothalamic areas, including the paraventricular nucleus, have direct projections to the sacral parasympathetic nucleus, the sphincter motor nucleus (i.e., Onuf's nucleus), and certain sites in the spinal cord where bladder afferents terminate (i.e., laminae I and X) (see Fig. 3-3).<sup>123</sup> Hypothalamic control may be mediated by direct inputs to pontine and sacral micturition centers or by indirect mechanisms through other brainstem regions.

The influence of the hypothalamus on bladder function may be modulated by afferent input from the bladder. Tracing studies in rats have identified a spinohypothalamic pathway arising from neurons in the region of the sacral parasympathetic nucleus.<sup>112,153</sup> FOS protein studies have shown that a large percentage of these neurons (60%) receive afferent input from the lower urinary tract.<sup>112</sup> This spinohypothalamic pathway may provide one route by which changes in bladder pressure modulate the firing of hypothalamic neurons.<sup>154</sup> This pathway also provides the anatomic substrate for putative spinohypothalamospinal and spinohypothalamopontine loops that may provide important modulatory control over micturition.

In the rat, the prefrontal cortex is considered a visceromotor area, whereas the insular cortex is considered a viscerosensory area. In rats subjected to infarction of the middle cerebral artery on one side, a prominent decrease in bladder capacity was seen, implying that there is tonic cortical inhibition of bladder function.<sup>155-157</sup> However, several types of synaptic changes related to inhibitory and facilitatory mechanisms involving glutamatergic and dopaminergic pathways were observed, attesting to the complexity of cortical influences on bladder control.<sup>155-157</sup>

Medullary centers have been implicated in inhibitory and facilitatory modulation of the micturition reflex pathway. The two most prominent modulatory mechanisms are mediated by descending bulbospinal projections from the nucleus gigantocel-

**Figure 3-10** Organization of the parasympathetic excitatory reflex pathway to the detrusor muscle. The scheme of micturition reflex pathways is based on electrophysiologic studies in cats. In animals with an intact spinal cord, micturition is initiated by a supraspinal reflex pathway passing through a center in the brainstem. The pathway is triggered by myelinated afferents (A fibers), which are connected to the tension receptors in the bladder wall. Injury to the spinal cord above the sacral segments interrupts the connections between the brain and spinal autonomic centers and initially blocks micturition. However, over a period of several weeks after cord injury, a spinal reflex mechanism emerges, which is triggered by unmyelinated vesical afferents (C fibers); the A-fiber afferent inputs are ineffective. The C-fiber reflex pathway is usually weak or undetectable in animals with an intact nervous system. Stimulation of the C-fiber bladder afferents by instillation of ice water into the bladder (i.e., cold stimulation) activates voiding responses in patients with spinal cord injury. Capsaicin (20 to 30 mg SC) blocks the C-fiber reflex in chronic spinal cats, but it does not block micturition reflexes in intact cats. Intravesical capsaicin also suppresses detrusor hyperreflexia and cold-evoked reflexes in patients with neurogenic bladder dysfunction. (Adapted from de Groat WC, Kawatani M, Hisamitsu T, et al: Mechanisms underlying the recovery of urinary bladder function following spinal cord injury. *J Auton Nerv Syst* 30[Suppl]:S71, 1990.)

lularis reticularis (NGR) and the caudal raphe nuclei (see Fig. 3-5).<sup>158-160</sup> Electrical stimulation in the NGR inhibits bladder motility, reduces reflex firing in the pelvic nerve efferent pathways,<sup>3,4</sup> and elicits excitatory postsynaptic potentials and inhibitory postsynaptic potentials in sphincter motoneurons.<sup>128</sup> Electrical or chemical stimulation of the nucleus raphe magnus (NRM), which is the origin of descending serotonergic projections to the spinal cord, inhibits reflex bladder contractions and reflex firing in the sacral efferent pathways to the bladder of the cat.<sup>158,159</sup> Stimulation of the NRM also inhibits the firing of spinal dorsal horn neurons activated by afferents in the pelvic nerve.<sup>160</sup> Descending raphe spinal pathways may modulate bladder sensory mechanisms in the spinal cord, and this may account for the inhibitory effect of raphe stimulation on bladder reflexes. In the rat and cat, raphe neurons are activated by bladder distention.<sup>160,161</sup> This raises the possibility that afferent input from the bladder may trigger a reflex loop, resulting in activation of a raphe-spinal inhibitory pathway that may suppress the micturition reflex pathway at the spinal level.

PET studies in humans have revealed that two cortical areas, the right dorsolateral prefrontal cortex and the anterior cingulate gyrus (see Fig. 3-9), are active (i.e., exhibited increased blood flow) during voiding.<sup>116,143,162-164</sup> The hypothalamus, including the preoptic area, and the pons and the PAG (see Fig. 3-9) also showed activity in concert with bladder filling or voluntary micturition. It is noteworthy that the active areas were predominantly on the right side of the brain, which is consistent with reports that urge incontinence is correlated with lesions in the right hemisphere. Other PET studies that examined the changes in brain activity during filling of the bladder revealed that increased activity occurred in the PAG, the midline pons, the mid-cingulate gyrus, and bilaterally in the frontal lobes (see Fig. 3-9).<sup>144,164</sup> The results support the notion that the PAG receives information about bladder fullness and then relays this information to other brain areas involved in the control of bladder storage. A PET study was also conducted in adult female volunteers to identify brain structures involved in voluntary control of pelvic floor muscles.<sup>142</sup> The results revealed that the superomedial precentral gyrus, the most medial portion of the motor cortex, is activated during pelvic floor contraction. The right anterior cingulate gyrus also was activated during sustained pelvic floor straining.

Functional brain imaging has provided the opportunity to study cortical activation in response to different types of sensation arising from the bladder. Recognition of bladder fullness appears to be associated with activation of a network of brain regions that is distinct from that related to the perception of urinary urgency, which is associated with a decrease in activity in the hypothalamus, activation bilaterally in the premotor regions and the cingulate regions, but no activity in the PAG.<sup>164</sup> Activation of the primary somatosensory cortex was not seen with changes in bladder volume or the urge to void, but sensorimotor activity was observed during voiding in the presence of a catheter.<sup>163</sup> A difference was also seen between natural bladder filling to capacity and filling with ice water in that there was no overlap between the areas activated in these two conditions; there was marked somatosensory cortex activity but no PAG activity when filling with ice water.<sup>165</sup>

## NEUROTRANSMITTERS IN MICTURITION REFLEX PATHWAYS

### Excitatory Transmitters

Glutamic acid plays an essential role as an excitatory transmitter in the central pathways controlling the lower urinary tract of the rat.<sup>2,3</sup> It is involved at the level of the lumbosacral spinal cord in processing afferent input from the bladder,<sup>166,167</sup> at interneuronal synapses on parasympathetic preganglionic neurons,<sup>119,120,122</sup> and in the descending pathway from the PMC to the sacral parasympathetic nucleus (SPN).<sup>168,169</sup> Intrathecal or intravenous administration of NMDA or  $\alpha$ -amino-3-hydroxy-5-methylisooxazole-4-propionic acid (AMPA) receptor antagonists in urethane-anesthetized rats depressed reflex bladder contractions and electromyographic activity of the external urethral sphincter in animals with an intact spinal cord and in chronic spinal-injured animals with the cord transected at the midthoracic level.<sup>170-172</sup> These results indicate that spinal reflex pathways controlling bladder and sphincter function use NMDA and AMPA glutamatergic transmitter mechanisms. Glutamate also functions as an

excitatory transmitter in the micturition reflex pathways in the brain.<sup>2,3</sup> Administration of glutamatergic agonists into the region of the PMC in cats and rats elicits voiding or increased frequency and amplitude of bladder contractions,<sup>3,131,159,173</sup> whereas injection of agonists at other brainstem nuclei known to have inhibitory functions in micturition elicits inhibitory effects.<sup>159,173</sup> Intracerebroventricular injection of AMPA or NMDA receptor antagonists blocks reflex bladder contractions in anesthetized rats, indicating that glutamatergic transmission in the brain is essential for voiding function.<sup>174</sup>

Substance P is a transmitter in central neurons and in primary afferent neurons innervating the lower urinary tract.<sup>31,41</sup> Studies in various species (e.g., cats, rats, guinea pigs, mice) have shown that substance P or a related tachykinin released from primary afferent terminals and acting on NK<sub>1</sub> receptors in the spinal cord has an excitatory role in the micturition reflex pathways.<sup>175-179</sup> Substance P is thought to act by facilitating the action or enhancing the release of glutamic acid in the spinal cord. Intrathecal or intravenous administration of NK<sub>1</sub> antagonists increased bladder capacity and decreased voiding frequency in animals with normal bladders and in animals with chemically irritated bladders or with neurogenic detrusor overactivity.<sup>175-179</sup> NK<sub>2</sub> receptors also appear to play a role in the generation of chemically induced bladder hyperactivity but not normal bladder activity.<sup>180</sup> NK<sub>1</sub> receptors are upregulated in the spinal cord by chronic irritation of the bladder,<sup>180</sup> and destruction of NK<sub>1</sub> receptor-expressing neurons in the spinal cord of rats by the saporin toxin conjugated with an NK<sub>1</sub> receptor agonist reduces the bladder hyperactivity elicited by intravesical infusion of capsaicin.<sup>181</sup>

Neuronal nitric oxide synthase has been identified in afferent neurons innervating the bladder and in preganglionic neurons in the sacral parasympathetic nucleus.<sup>182-184</sup> Stimulation of bladder afferent nerves with capsaicin releases nitric oxide, and chronic irritation of the bladder, as well as exposure to capsaicin, increases the expression of neuronal nitric oxide synthase in dorsal root ganglion cells.<sup>182,183</sup> Bladder hyperactivity induced by intravesical irritants or capsaicin can be suppressed by intrathecal injection of nitric oxide synthase inhibitors, indicating that nitric oxide release in the spinal cord facilitates the micturition reflex pathway.<sup>185-178</sup>

Injection of ATP or  $\alpha\beta$ -methylene ATP into the PMC or PAG of the rat increased bladder pressure and elicited a discharge in efferent axons in the pelvic nerve.<sup>173</sup> The effects of the agonists were blocked by pretreatment with the purinergic receptor antagonist suramin, indicating that P2X receptors can mediate excitatory effects in the brainstem pathways underlying micturition.<sup>173</sup>

### Inhibitory Transmitters

Several types of transmitters, including inhibitory amino acids (e.g.,  $\gamma$ -aminobutyric acid [GABA], glycine) and opioid peptides (e.g., enkephalins) can inhibit the micturition reflex when they are applied to the central nervous system.<sup>2,3,31</sup> In anesthetized animals, GABA and enkephalins exert a tonic inhibitory control in the PMC and regulate bladder capacity. The inhibitory effects are mediated by GABA<sub>A</sub> and  $\mu$  opioid receptors, respectively.<sup>3,31,131,188-191</sup> Administration of GABA<sub>A</sub> or opioid receptor antagonists into the PMC reduced the micturition volume threshold, indicating that the set point for reflex voiding is regulated by inhibitory mechanisms in the brain. The amino acids

and enkephalins also have inhibitory actions in the spinal cord.<sup>188,189</sup> GABA and glycine are co-released from inhibitory interneurons at synapses on preganglionic neurons.<sup>118</sup> Glycine has also been identified as a transmitter in inhibitory pathways to sphincter motoneurons.<sup>192</sup> Baclofen, a GABA<sub>B</sub> agonist that mimics the inhibitory effect of GABA, has been used clinically by intrathecal administration in patients with hyperactive bladders to suppress bladder activity and promote urine storage.<sup>193</sup>

### Transmitters with Mixed Excitatory and Inhibitory Actions

Some transmitters have inhibitory and excitatory effects, depending on the type of receptor activated. For example, dopaminergic pathways in the brain exert inhibitory or facilitatory effects on the micturition reflex through D<sub>1</sub>-like (D<sub>1</sub> and D<sub>5</sub> receptor subtypes) and D<sub>2</sub>-like (D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub> receptor subtypes) dopaminergic receptors, respectively.<sup>194-199</sup> In anesthetized cats, activation of dopaminergic neurons in the substantia nigra inhibits reflex bladder contractions through D<sub>1</sub>-like receptors. In awake rats, a D<sub>1</sub>-dopamine receptor antagonist (SCH 23390) facilitated the micturition reflex, suggesting that D<sub>1</sub>-receptor-mediated suppression of the bladder activity is tonically active in the normal, awake state.<sup>195,198</sup> Activation of central D<sub>2</sub>-like dopaminergic receptors with quinpirole or bromocriptine facilitates the micturition reflex pathway in rats, cats, and monkeys.<sup>195,197,198</sup> D<sub>2</sub>-like receptor-mediated facilitation of the micturition reflex may involve actions on brainstem and spinal cord because microinjection of dopamine to the PMC reduced bladder capacity and facilitated the micturition reflex in cats,<sup>2</sup> and intrathecal application of quinpirole induced bladder hyperactivity in normal rats and rats with 6-hydroxydopamine-lesioned nigrostriatal pathways.<sup>199</sup>

The monoamines, 5-hydroxytryptamine (5-HT) and norepinephrine, which are present in dense collections of nerve terminals in the lumbosacral spinal autonomic nuclei and in the sphincter motor nucleus,<sup>3,200-202</sup> have a complex role in the regulation of lower urinary tract function. The 5-HT-containing terminals are part of an extensive bulbospinal projection system that arises in the medullary raphe nuclei. Pharmacologic studies in animals indicate that this system may promote urine storage by exciting sympathetic and sphincter efferent pathways and by inhibiting parasympathetic excitatory outflow to the bladder.<sup>200</sup> Many receptors, including 5-HT<sub>1A</sub>, 5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptors, are involved in these effects.<sup>200-205</sup>

Bulbospinal noradrenergic pathways acting by means of  $\alpha$ -adrenergic receptors exert excitatory and inhibitory influences on the lower urinary tract in the rat. Intrathecal administration of an  $\alpha_1$ -adrenergic receptor antagonist (doxazosin) decreased the amplitude of bladder contractions,<sup>205,206</sup> an effect that was more prominent in animals with chronic outlet obstruction.<sup>205</sup> Doxazosin also suppressed small amplitude nonvoiding contractions in spontaneously hypertensive rats.<sup>207</sup> However, doxazosin increased the frequency of isovolumetric contractions, indicating the presence of a tonic adrenergic inhibitory mechanism.<sup>205</sup> Intrathecal injection of the  $\alpha_1$ -agonist phenylephrine elicited facilitatory and inhibitory effects on micturition.<sup>208,209</sup> Sphincter function is also modulated by the spinal noradrenergic pathways. Striated sphincter reflexes in cats, humans, and rats are inhibited by  $\alpha_2$ -adrenergic receptor agonists such as clonidine.<sup>210</sup> Sympathetic and somatic pathways to the lower urinary tract in cats are

suppressed by  $\alpha_1$ -adrenergic receptor antagonists such as prazosin.<sup>211</sup> These data indicate the existence of  $\alpha_1$ -adrenergic receptor-mediated tonic facilitation of sphincter function and a putative  $\alpha_2$ -adrenergic receptor inhibitory mechanism in the spinal cord. Duloxetine, a serotonin-norepinephrine reuptake inhibitor that has been developed for the treatment of stress urinary incontinence, appears to act in part by enhancing serotonergic and noradrenergic facilitatory control of motoneurons innervating the external urethral sphincter.<sup>212,213</sup>

Activation of cholinergic mechanisms in the rat central nervous system with nicotinic or muscarinic receptor agonists can modulate bladder activity. Nicotinic agonists administered intracerebroventricularly suppress voiding in awake or anesthetized rats,<sup>214</sup> whereas activation of muscarinic receptors in the brain or spinal cord with oxotremorine stimulates bladder activity during bladder filling but suppresses voluntary voiding.<sup>215-217</sup> Pirenzepine, an  $M_1$ -selective blocking agent, antagonized the inhibitory effect of oxotremorine, indicating that inhibition is mediated by  $M_1$  receptors.<sup>218</sup> Atropine blocked the inhibitory and excitatory effects of oxotremorine.<sup>215</sup> Intracerebroventricular administration of atropine alone increased bladder capacity and reduced voiding efficiency, indicating that muscarinic excitatory mechanisms in the brain are tonically active.

Intrathecal administration of various neuropeptides, including VIP, PACAP, and CRF, can influence voiding function. VIP, which is contained in C-fiber bladder afferent neurons,<sup>67</sup> inhibited bladder activity when administered intrathecally to normal cats but excited the bladder when administered to chronically spinal cord-injured cats.<sup>42</sup> These findings raised the possibility that changes in VIP synaptic mechanisms might contribute to the emergence of C-fiber afferent-mediated micturition reflexes in the chronically spinal cord-injured cat (discussed later). PACAP, another member of the secretin/glucagon/VIP peptide family, also facilitates the micturition reflex by actions on the spinal cord.<sup>219</sup> Patch-clamp studies revealed that PACAP has a direct excitatory action on parasympathetic PGNs, in part due to blockade of  $K^+$  channels,<sup>220</sup> and has an indirect action on PGNs mediated by activation of excitatory interneurons.

CRF is contained in neurons in the rat PMC and in axons projecting from the PMC to parasympathetic nucleus in the lumbosacral spinal cord.<sup>221</sup> Initial studies revealed that intrathecal administration of exogenous CRF inhibited micturition and decreased the magnitude of bladder contractions induced by stimulation of the PMC.<sup>222,223</sup> A CRF antagonist blocked the effects of CRF and enhanced the response to PMC stimulation, indicating that endogenous CRF is released by PMC stimulation and exerts an inhibitory effect on the descending limb of the micturition reflex pathway.<sup>223</sup> However, later studies have shown that low doses of CRF have an excitatory effect on micturition, suggesting that CRF also has a facilitatory role in the central control of voiding.<sup>224</sup>

## ALTERATIONS IN BLADDER REFLEX PATHWAYS AFTER NEURAL INJURY OR DISEASE

### Parkinson's Disease

Degeneration of dopamine-containing neurons in patients with idiopathic Parkinson's disease is often associated with

detrusor overactivity.<sup>2,31</sup> Animal models for Parkinson's disease have been developed by administering neurotoxins (MPTP in monkeys<sup>196-197</sup> and 6-hydroxy-dopamine in rats<sup>199</sup>) that destroy dopamine-containing neurons. Animals treated with the neurotoxins show motor symptoms typical of Parkinson's disease, and they have hyperactive bladders. Pharmacologic studies in MPTP-treated monkeys have revealed that bladder hyperactivity was caused by the loss of dopaminergic inhibition mediated by  $D_1$ -dopaminergic receptors.<sup>196,197</sup> The bladder hyperactivity was suppressed by stimulation of  $D_1$  receptors with SKF 38393 or pergolide.

### Stroke

The transmitter mechanisms involved in bladder dysfunction after stroke have been studied in rats after permanent occlusion of the middle cerebral artery (MCAO) on one side.<sup>155,156,198,225</sup> MCAO produces a dramatic and persistent reduction in bladder capacity in conscious rats. NMDA-glutamatergic mechanisms play a role in this bladder dysfunction because the bladder hyperactivity can be prevented by pretreatment with MK-801, an NMDA receptor antagonist, before MCAO or can be transiently reduced by MK-801 administered after MCAO.<sup>156,198</sup> The bladder hyperactivity appears to occur in two phases that depend on activation of NMDA-glutamatergic receptors. An initiation phase that occurs at the time of infarction seems to function like long-term potentiation to induce a persistent facilitation of micturition, the second phase. The maintained bladder overactivity after infarction is associated with changes in gene expression and RNA synthesis in the PMC induced by glutamatergic synaptic mechanisms.<sup>226,227</sup>  $D_2$  receptors are also involved in the bladder hyperactivity induced by MCAO.<sup>156,198</sup>  $D_2$ -receptor antagonists do not alter voiding function in normal rats but suppress the detrusor overactivity after MCAO, indicating that  $D_2$  facilitatory mechanisms are upregulated after cerebral infarction.

### Spinal Cord Injury

Electrophysiologic studies in animals have shown that the micturition reflex pathways in neurally intact animals and in those with chronic spinal injuries are markedly different.<sup>42,43,136,137</sup> The most prominent change occurs in the afferent limb of the micturition reflex, which in cats with chronic spinal injuries consists of unmyelinated (C-fiber) axons.<sup>42,43</sup> However, in cats with an intact spinal cord, myelinated (A) afferents activate the micturition reflex (see Fig. 3-10).<sup>136,137</sup> This change in the afferent limb was demonstrated by electrophysiologic recording and by administering capsaicin,<sup>42,43</sup> a neurotoxin known to disrupt the function of C-fiber afferents.<sup>41</sup> In normal cats, capsaicin did not block reflex contractions of the bladder or the A-fiber-evoked bladder reflex. However, in cats with chronic spinal injury, capsaicin completely blocked the rhythmic bladder contractions induced by bladder distention and the C-fiber-evoked reflex firing recorded on bladder postganglionic nerves.<sup>42,43</sup>

The emergence of the C-fiber-evoked reflex in animals with chronic spinal injuries is consistent with the emergence of other types of reflexes in paraplegic humans. For example, introduction of cold water into the bladder of paraplegic patients induces reflex voiding.<sup>228,229</sup> However, cold stimulation has no effect in normal patients. Studies in cats indicate that cold temperatures activate C-fiber afferents (see Fig. 3-10).<sup>38</sup> The positive cold

response in paraplegic humans may also reflect emergence of C-fiber–evoked bladder reflexes.

### Mechanisms Involved in the Emergence of C-Fiber Afferent–Evoked Bladder Reflexes

The cold water test is positive in infants,<sup>230</sup> patients with multiple sclerosis or Parkinson’s disease, and elderly patients with hyperactive bladders.<sup>229</sup> The presence of the cold reflex in neonates, its disappearance with maturation of the nervous system, and its reemergence under conditions in which higher brain functions are disrupted suggests that it may reflect a primitive involuntary voiding reflex organized at the spinal level. Direct evidence of the contribution of C-fiber bladder afferents to bladder hyperactivity and involuntary voiding has been obtained in clinical studies in which capsaicin or resiniferatoxin, C-fiber afferent neurotoxins,<sup>231–233</sup> were administered intravesically to multiple sclerosis patients with hyperreflexic bladders.<sup>233,234</sup> In these patients, capsaicin increased bladder capacity and reduced the frequency of incontinence. These observations suggest that capsaicin-sensitive C-fiber bladder afferents may be involved in several pathologic conditions associated with bladder hyperactivity.

The emergence of C-fiber bladder reflexes is probably mediated by several mechanisms, including changes in central synaptic connections and alterations in the properties of the peripheral afferent receptors that lead to sensitization of the “silent” C fibers and the unmasking of responses to mechanical stimuli.<sup>147,234,235</sup> In rats, bladder afferent neurons undergo morphologic (i.e., neuronal hypertrophy)<sup>236</sup> and physiologic changes (i.e., upregulation of TTX-sensitive Na<sup>+</sup> channels and downregulation of TTR-resistant Na<sup>+</sup> channels) after spinal cord injury.<sup>59</sup> It has been speculated that this neuroplasticity is mediated by the actions of neurotrophic factors released within the spinal cord or the urinary bladder.<sup>234,235</sup> Nerve growth factor (NGF) has been implicated as a chemical mediator of pathology-induced changes in C-fiber afferent nerve excitability and reflex bladder activity (see Fig. 3-2). Chronic administration of NGF into the bladder of rats induced bladder hyperactivity and increased the firing frequency of dissociated bladder afferent neurons,<sup>237</sup> and the production of neurotrophic factors, including NGF, increased in the bladder after spinal cord injury.<sup>238,239</sup> Conversely, intrathecal application of NGF antibodies, which neutralized NGF in the spinal cord, suppressed detrusor hyperreflexia and detrusor-sphincter dys-synergia in spinal cord–injured rats.<sup>240,241</sup> Intrathecal administration of NGF antibodies reportedly blocked autonomic dysreflexia in paraplegic rats.<sup>242</sup> NGF and its receptors represent new targets for the pharmacotherapy of voiding dysfunction after spinal cord injury.

Spinal cord injury alters the urothelium<sup>243,244</sup> and efferent pathways<sup>245</sup> in the bladder. Within 2 hours after spinal cord

injury in rats, the apical cell layer of the urothelium is disrupted, and the urea and water permeability of the urothelial layer is increased. These changes were suppressed by a ganglionic blocking agent and therefore thought to be mediated by autonomic nerves.<sup>243</sup> In chronically spinal cord–injured rats, the resting release of ATP from the urothelium measured in the bladder lumen was ninefold higher than in spinal cord–intact rats.<sup>244</sup> Release of ATP evoked by hypo-osmotic stimulation was also increased. Instillation of botulinum toxin A into the bladder lumen reduced the evoked but not the resting release of ATP. Botulinum toxin A also reduced the stretch-induced release of ATP from cultured urothelial cells.<sup>246</sup> These data, coupled with the report that detrusor hyperactivity in the spinal cord–injured rat is reduced by a selective P2X<sub>2/3</sub> purinergic receptor antagonist,<sup>247</sup> indicate that enhanced purinergic signaling between the urothelium and afferent nerves contributes to neurogenic detrusor overactivity after spinal cord injury. The beneficial effects of intravesical injections of botulinum toxin A in patients with neurogenic bladder dysfunction<sup>248–249</sup> may be mediated by effects on the urothelium and afferent nerves and by effects on the efferent pathways to the bladder smooth muscle.

In chronically spinal cord–injured rats, facilitation of acetylcholine and norepinephrine release by prejunctional muscarinic receptors occurs at lower frequencies, leading to an enhancement of neurally evoked smooth muscle contractions.<sup>245</sup> It was concluded that the hyperreflexic bladder after spinal cord injury in part may reflect modulation of presynaptic mechanisms at bladder postganglionic nerve terminals. The depressant effect of botulinum toxin A on acetylcholine and norepinephrine release in the lower urinary tract<sup>250</sup> is likely to reverse this type of plasticity and promote urine storage in patients with neurogenic bladder dysfunction. More detailed discussions of plasticity in bladder reflex pathways after neural injury can be found in published reviews.<sup>147,239</sup>

### CONCLUSIONS

The lower urinary tract has two main functions: storage and periodic elimination of urine. These functions are regulated by a complex neural control system located in the brain and spinal cord. This control system performs like a simple switching circuit to maintain a reciprocal relationship between the reservoir (i.e., bladder) and the outlet components (i.e., urethra and urethral sphincter) of the urinary tract. The switching circuit is modulated by several neurotransmitter systems and is therefore sensitive to a variety of drugs and neurologic diseases. A more complete understanding of the neurohumoral mechanisms involved in bladder and urethral control will no doubt facilitate the development of new diagnostic methods and therapies for lower urinary tract dysfunction.

# PHARMACOLOGIC BASIS OF BLADDER AND URETHRAL FUNCTION AND DYSFUNCTION

*Karl-Erik Andersson*

The main functions of the bladder and urethra are to collect and store urine at low intravesical pressure and to expel the urine at convenient times. This means that normal voiding is under voluntary control. Urinary continence and voiding depend on the bladder and the urethra working as a functional unit. This is achieved by a complex interplay between the central and peripheral nervous systems and local regulatory factors.<sup>1</sup> Malfunction at various levels may result in micturition disorders, which roughly can be classified as disturbances of storage or emptying. Failure to store urine may lead to various forms of incontinence; the most common forms are urgency and stress incontinence. There are gender differences in these types of bladder dysfunction, which may be related to differences in anatomy and structure of the lower urinary tract.

Because pharmacologic treatment of urinary incontinence (i.e., urgency and stress incontinence) and lower urinary tract symptoms is a main option, several drugs with different modes and sites of action have been tried.<sup>2-5</sup> To optimize treatment, knowledge about the mechanisms of micturition and of the targets for treatment is necessary. This chapter reviews the normal autonomic control of the lower urinary tract and of the pharmacologic basis for some of the principles used for treatment of urinary incontinence and lower urinary tract symptoms.

### AUTONOMIC RECEPTOR FUNCTIONS IN THE BLADDER

Contraction and relaxation of detrusor and urethral smooth muscle are mediated mainly through stimulation of autonomic receptors for the main transmitters, acetylcholine and noradrenaline. However, the occurrence of nonadrenergic, noncholinergic (NANC) neurotransmission is well recognized, although, particularly in humans, its physiologic importance remains to be established.<sup>6</sup>

#### Muscarinic Receptors

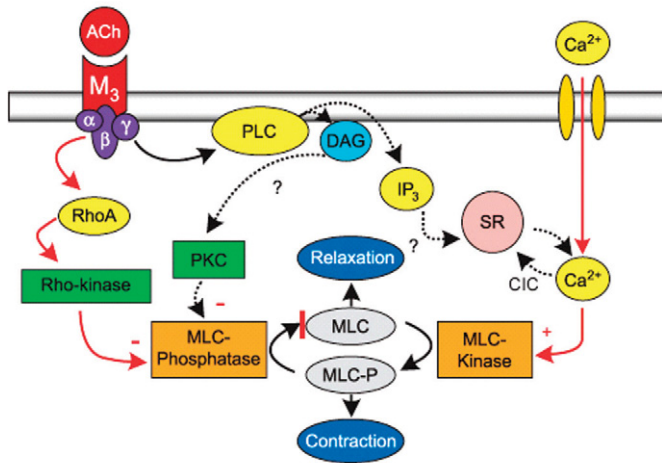

Muscarinic receptors comprise five subtypes, encoded by five distinct genes.<sup>7</sup> The five gene products correspond to pharmacologically defined receptors, and  $M_1$  through  $M_5$  are used to describe the molecular and pharmacologic subtypes. In the human bladder, the mRNAs for all muscarinic receptor subtypes have been demonstrated,<sup>8</sup> with a predominance of mRNAs encoding  $M_2$  and  $M_3$  receptors.<sup>8,9</sup> These receptors are functionally coupled to G proteins, but the signal transduction systems vary.<sup>10-12</sup>

Detrusor smooth muscle contains muscarinic receptors of mainly the  $M_2$  and  $M_3$  subtypes, with a predominance (70% to

80%) of  $M_2$  receptors.<sup>10-13</sup> The  $M_3$  receptors are the most important for detrusor contraction. It is generally believed that  $M_3$  receptors are coupled to release of inositol 1,4,5-triphosphate ( $IP_3$ ) and calcium release from the sarcoplasmic reticulum and that  $M_2$  receptors are linked to inhibition of adenylyl cyclase. This may not be the case in the detrusor.<sup>14</sup> Jezior and colleagues<sup>15</sup> suggested that muscarinic receptor activation of detrusor muscle includes nonselective cation channels and activation of Rho kinase. Supporting a role of Rho kinase in the regulation of rat detrusor contraction and tone, Wibberley and coworkers<sup>16</sup> found that Rho kinase inhibitors (e.g., Y-27632, HA 1077) inhibited contractions evoked by carbachol without affecting the contraction response to KCl. They also demonstrated high levels of Rho kinase isoforms (I and II) in the bladder. Schneider and associates<sup>13</sup> concluded that carbachol-induced contraction of human urinary bladder is mediated by  $M_3$  receptors and largely depends on  $Ca^{2+}$  entry through nifedipine-sensitive channels and activation of the Rho kinase pathway. The main pathway for muscarinic receptor activation of the detrusor by means of  $M_3$  receptors may be calcium influx through L-type calcium channels and increased sensitivity to calcium of the contractile machinery produced by inhibition of myosin light chain phosphatase through activation of Rho kinase (Fig. 4-1).<sup>14</sup>

The functional role for the  $M_2$  receptors has not been clarified, but it has been suggested that  $M_2$  receptors may oppose sympathetically mediated smooth muscle relaxation, mediated by  $\beta$ -adrenergic receptors.<sup>17</sup>  $M_2$ -receptor stimulation may also activate nonspecific cation channels<sup>18</sup> and inhibit  $K_{ATP}$  channels through activation of protein kinase C.<sup>19,20</sup> In certain disease states,  $M_2$  receptors may contribute to contraction of the bladder. In the denervated rat bladder,  $M_2$  receptors or a combination of  $M_2$  and  $M_3$  mediated contractile responses, and the two receptor types seemed to act in a facilitatory manner to mediate contraction.<sup>21-23</sup> In obstructed, hypertrophied rat bladders, there was an increase in total and  $M_2$  receptor density, whereas there was a reduction in  $M_3$  receptor density.<sup>24</sup> The functional significance of this change for voiding function has not been established. Pontari and colleagues<sup>25</sup> analyzed bladder muscle specimens from patients with neurogenic bladder dysfunction to determine whether the muscarinic receptor subtype mediating contraction shifts from  $M_3$  to the  $M_2$  receptor subtype, as found in the denervated, hypertrophied rat bladder. They concluded that whereas normal detrusor contractions are mediated by the  $M_3$  receptor subtype, in patients with neurogenic bladder dysfunction, contractions also can be mediated by the  $M_2$  receptors.

Muscarinic receptors may also be located on the presynaptic nerve terminals and participate in the regulation of transmitter release. The inhibitory prejunctional muscarinic receptors have been classified as  $M_4$  in the human bladder.<sup>26</sup> Prejunctional facili-

**Figure 4-1** Transmitter signal pathways involved in activation of detrusor contraction by means of muscarinic M<sub>3</sub> receptors. ACh, acetylcholine; CIC, calcium-induced calcium release; DAG, diacylglycerol; IP<sub>3</sub>, inositol 1,4,5-trisphosphate; MLC, myosin light chain; PLC, phospholipase C; PKC, protein kinase C; RhoA, protein encoded by *RAS* homolog gene family member A; SR, sarcoplasmic reticulum. There seem to be differences between species in the contribution of the different pathways in contractile activation. In the human detrusor, Ca<sup>2+</sup> influx is of major importance.

tatory muscarinic receptors appear to be the M<sub>1</sub> subtype.<sup>27</sup> The muscarinic facilitatory mechanism seems to be upregulated in overactive bladders from chronic spinal cord transected rats. Facilitation in these preparations is primarily mediated by M<sub>3</sub> receptors.<sup>27,28</sup>

Muscarinic receptors have been demonstrated on the urothelium or suburothelium, but their functional importance has not been clarified.<sup>12,29</sup> It has been suggested that they may be involved in the release of an unknown inhibitory factor.<sup>12</sup>

It is well documented<sup>2,3</sup> that antimuscarinic agents are effective for treatment of overactive bladder, which suggests that muscarinic receptors may be involved in its pathogenesis. Contraction of the bladder, whether voluntary or involuntary, involves stimulation of the muscarinic receptors on the detrusor by acetylcholine released from activated cholinergic nerves. However, antimuscarinic agents at clinically recommended doses have little effect on voiding contractions and may act mainly during the bladder storage phase,<sup>30</sup> during which there is normally no parasympathetic outflow from the spinal cord.<sup>31</sup> Supporting this, antimuscarinic agents have been shown to reduce bladder tone during storage and to increase cystometric bladder capacity. A basal release of acetylcholine from non-neuronal (urothelial) and neuronal sources has been demonstrated in isolated human detrusor muscle.<sup>32</sup> It has been suggested that this release, which is increased by stretching the muscle and in the aging bladder, contributes to detrusor overactivity and overactive bladder by eventually increasing bladder afferent activity during storage.<sup>33</sup> This may occur because of a direct effect on suburothelial afferents or stimulation of contraction of detrusor muscle cells, which already have an increased myogenic activity in the overactive detrusor.<sup>34</sup> Enhanced myogenic contractions can generate an enhanced afferent signal, contributing to urge or initiation of the micturition reflex.

## Alpha-Adrenoceptors

α-Adrenoceptors may have effects on different locations in the bladder: the detrusor smooth muscle, the detrusor vasculature, the afferent and efferent nerve terminal, and intramural ganglia. The importance of the α<sub>1</sub>-adrenoceptors in the human detrusor in the generation of lower urinary tract symptoms has not been established. Most investigators agree on that there is a low-level expression of these receptors.<sup>35,36</sup> In studies of the human detrusor, Malloy and coworkers<sup>36</sup> found that two thirds of the α-adrenoceptor mRNAs expressed were α<sub>1D</sub>, there was no α<sub>1B</sub>, and one third was α<sub>1A</sub>. In the rat detrusor, the α<sub>1</sub>-adrenoceptor distribution was different: the α<sub>1A</sub>-adrenoceptor was the predominant form, one third was the α<sub>1D</sub>-adrenoceptor, and there was very little of the α<sub>1B</sub>-adrenoceptor form. This was consistent in the different parts of the detrusor.<sup>37</sup>

A change of subtype distribution may be produced by outflow obstruction. Hampel and associates<sup>37</sup> reported that there was a change in the obstructed bladder from α<sub>1A</sub>-adrenoceptor to α<sub>1D</sub>-adrenoceptor mRNA predominance. In humans, there is an α<sub>1D</sub>-adrenoceptor predominance in the normal detrusor, which means that a change in a similar direction, as in the rat, would be of minor importance provided that the number of receptors did not increase. Studies by Nomiya and colleagues<sup>38</sup> confirmed the low-level expression of α-adrenoceptor mRNA in normal human detrusor, and they further demonstrated that there was no upregulation of any of the adrenergic receptors with obstruction. In functional experiments, they found a small response to phenylephrine at high drug concentrations with no difference between normal and obstructed bladders. In the obstructed human bladder, there seems to be no evidence for α-adrenoceptor upregulation or change in subtype. This finding was challenged by Bouchelouche and coworkers,<sup>39</sup> who found an increased response to α<sub>1</sub>-adrenoceptor stimulation in obstructed bladders. Whether this would mean that the α<sub>1D</sub>-adrenoceptors in the detrusor muscle are responsible for detrusor overactivity or overactive bladder is unclear. Based on available evidence, however, it does not seem likely that in the detrusor muscle these receptors should be an important treatment target, although α<sub>1D</sub>-adrenoceptors located elsewhere in the bladder may be important.

In the bladder, the function of the detrusor muscle depends on the vasculature and on perfusion. Hypoxia induced by partial outlet obstruction is believed to play a major role in the hypertrophic and degenerative effects of partial outlet obstruction. Das and associates<sup>40</sup> investigated in rats whether doxazosin affected blood flow to the bladder and reduced the level of bladder dysfunction induced by partial outlet obstruction. They found that 4 weeks of treatment with doxazosin increased bladder blood flow in control and obstructed rats. Doxazosin treatment also reduced the severity of the detrusor response to partial outlet obstruction. Doxazosin may reduce the increase in bladder weight in obstructed animals, which may be one of the mechanisms that contributes to a positive effect on detrusor overactivity caused by the obstruction.

## Beta-Adrenoceptors

In the human detrusor, the most important β-adrenoceptor for bladder relaxation is the β<sub>3</sub>-adrenoceptor.<sup>41</sup> This partly explains why the clinical effects of selective β<sub>2</sub>-adrenoceptor agonists in

detrusor overactivity have been controversial and largely inconclusive.<sup>2,3</sup> However, the  $\beta_2$ -adrenoceptor agonist clenbuterol inhibited electrically evoked contractions in human “unstable” but not normal bladder,<sup>42</sup> which is in agreement with previous experiences in patients, suggesting that clenbuterol and other  $\beta_2$ -adrenoceptor agonists such as terbutaline may inhibit detrusor overactivity.<sup>43,44</sup>

The  $\beta_3$ -adrenoceptor seems to be an interesting target for drugs aimed for treatment of overactive bladder. Selective  $\beta_3$ -adrenoceptor agonists have relaxant effects on detrusor muscle *in vitro* and have been effective in animal models of detrusor overactivity.<sup>45-47</sup> However, no proof of concept studies seems to have been performed in humans showing that this is an effective principle to treat overactive bladder.

### Purinergic Receptors

In most animal species, bladder contraction induced by stimulation of nerves consists of an atropine-sensitive component and a component mediated by NANC mechanisms.<sup>48</sup> NANC-mediated contractions have been reported to occur in normal human detrusor,<sup>48</sup> even if not representing more than a few percent of the total contraction in response to nerve stimulation. However, a significant degree of NANC-mediated contraction may exist in morphologically or functionally changed human bladders, and it has been reported to occur in several disorders associated with lower urinary tract symptoms, such as bladder hypertrophy,<sup>49-51</sup> idiopathic detrusor overactivity,<sup>51,52</sup> interstitial cystitis,<sup>53</sup> and neurogenic damage<sup>54</sup> and in the aging bladder.<sup>55</sup> In these disorders, the NANC component of the nerve-induced response may be responsible for up to 40% to 50% of the total bladder contraction.

There is good evidence that the transmitter responsible for the NANC component is adenosine triphosphate (ATP)<sup>56</sup> acting on P2X receptors found in the detrusor smooth muscle membranes of rats<sup>57</sup> and humans.<sup>58</sup> The P2X<sub>1</sub> receptor subtype predominated in both species. Changes in P2X receptor subtypes in bladders from patients with idiopathic detrusor overactivity have been reported.<sup>52,59</sup> O'Reilly and colleagues<sup>52</sup> were unable to detect a purinergic component of nerve-mediated contractions in control (normal) bladder preparations, but they found a significant component in overactive bladder specimens, in which the purinergic component was approximately 50%. They concluded that this abnormal purinergic transmission in the bladder might explain symptoms in these patients. ATP was a more potent contractile agonist in bladder preparations from patients with overactive and obstructive bladders than in specimens from normal bladders,<sup>60</sup> a finding that was suggested to contribute to detrusor overactivity.

O'Reilly and coworkers<sup>61</sup> confirmed that the P2X<sub>1</sub> receptor was the predominant purinoceptor subtype in the human male bladder. They also found that the amount of P2X<sub>1</sub> receptor per smooth muscle cell was greater in the obstructed than in control bladders. This suggests an increase in purinergic function in the overactive bladder arising from bladder outlet obstruction.

It has not been established whether abnormalities in the purinergic transmission in the bladder can explain overactive bladder symptoms in idiopathic detrusor overactivity in women and in men with bladder outlet obstruction. If this is the case, abnormal purinergic activation of the detrusor may explain why antimuscarinic treatment fails in a number of patients.

### Vanilloid Receptors

Appropriate bladder function depends on an intact afferent signaling from the bladder to the central nervous system. This signaling conveys information about bladder filling and the status of the tissue (e.g., presence of infectious agents). The afferent nerves consist of small, slowly conducting, myelinated A $\delta$  fibers and slowly conducting, unmyelinated C fibers. The former are excited by mechanoreceptors and convey information about bladder filling, whereas C fibers mediate painful sensations recognized by chemoreceptors. By means of capsaicin, a subpopulation of primary afferent neurons innervating the bladder and urethra (i.e., capsaicin-sensitive nerves) has been identified. It is believed that capsaicin exerts its effects by acting on specific vanilloid receptors on these nerves.<sup>62</sup> Capsaicin exerts a biphasic effect; initial excitation is followed by a long-lasting blockade, which renders sensitive primary afferents (C fibers) resistant to activation by natural stimuli. In sufficiently high concentrations, capsaicin is believed to cause desensitization, initially by releasing and emptying the stores of neuropeptides and then by blocking further release.<sup>63</sup> Resiniferatoxin, an analogue of capsaicin, is approximately 1000 times more potent for desensitization than capsaicin,<sup>64</sup> but it is only a few hundred times more potent for excitation.<sup>65</sup> Capsaicin and resiniferatoxin also may have effects on A $\delta$  fibers. It is also possible that capsaicin at high concentrations (mM) has additional, nonspecific effects.<sup>66</sup>

Capsaicin and resiniferatoxin have been used successfully to treat bladder function disturbances.<sup>2,3</sup> They are known to bind to the TRPV1 (VR1) receptor, a nonselective cation channel, on the peripheral terminals of nociceptive neurons, but the role of vanilloid receptors in normal bladder function and in the pathogenesis in detrusor overactivity and autonomic dysreflexia has not been established.

Birder and associates<sup>67</sup> investigated bladder function in conscious mice lacking the TRPV1 receptor. TRPV1 receptor-knockout mice seem to have increased voiding frequency compared with wild-type mice. The TRPV1 knockouts also had an increased frequency of nonvoiding bladder contractions. *In vitro*, stretch-induced ATP release was decreased in bladders from TRPV1-knockout mice, and hypo-osmolality-induced ATP released from cultured urothelial cells was reduced.<sup>67</sup> The investigators suggested that TRPV1 receptors participate in normal bladder function, are essential for normal mechanically evoked purinergic signaling by the urothelium, and are involved in ATP release. Experimental and clinical evidence that capsaicin-sensitive afferents may be involved also in idiopathic detrusor overactivity has been presented.<sup>68,69</sup>

### ION CHANNELS

In the detrusor, the two most thoroughly investigated classes of ion channels are calcium channels and potassium channels.<sup>6</sup>

#### Calcium Channels

Calcium is a key component for cell function in many cells. In smooth muscle, increased intracellular calcium concentrations activate the contractile mechanisms, and in nerve terminals, calcium influx in response to action potentials is an important mechanism for neurotransmitter release. Calcium channels can

be divided into at least four different subtypes: L, N, P, and Q channels. The calcium channels present in smooth muscles are L-type (dihydropyridine-sensitive) calcium channels and seem to be involved in contraction of the human bladder irrespective of the mode of activation.<sup>70</sup> A decrease of the membrane potential (i.e., depolarization) increases the open probability for calcium channels, thereby increasing the calcium influx. The channels depend on the membrane potential and are called voltage-operated calcium channels. Elevated intracellular calcium levels are also believed to initiate release of calcium from intracellular stores—calcium-induced calcium release.<sup>71,72</sup> Regulation of the intracellular calcium concentration in smooth muscle cells is a conceivable way to modulate bladder contraction. Dihydropyridines (e.g., nifedipine) have a potent inhibitory effect on isolated detrusor muscle. Inhibitory effects have also been demonstrated on experimentally induced contractions under *in vivo* conditions in rats and clinically in patients with detrusor overactivity.<sup>48</sup> However, therapeutically, there is no evidence that calcium antagonists have any useful effects in the treatment of overactive bladder or detrusor overactivity.<sup>2,3</sup>

### Potassium Channels

Potassium channels represent another mechanism for modulating the excitability of smooth muscle cells. Under normal conditions, the resting membrane potential in smooth muscle cells is determined predominantly by the membrane conductivity for potassium ions. Increased potassium conductivity lowers the membrane potential by increasing the potassium efflux. This increases the threshold for opening of voltage-operated calcium channels and initiation of contraction. There are several different types of K<sup>+</sup> channels, and at least two subtypes have been found in the human detrusor, ATP-sensitive K<sup>+</sup> channels (K<sub>ATP</sub>) and large-conductance calcium-activated K<sup>+</sup> channels (BK<sub>Ca</sub>). Studies on isolated human detrusor muscle and on bladder tissue from several animal species have demonstrated that K<sup>+</sup>-channel openers reduce spontaneous contractions and contractions induced by carbachol and electrical stimulation.<sup>6</sup> However, the lack of selectivity of the available K<sup>+</sup>-channel openers for the bladder versus the vasculature has limited the use of these drugs. No effects of cromakalim or pinacidil on the bladder were found in studies on patients with spinal cord lesions or detrusor overactivity secondary to outflow obstruction.<sup>73,74</sup> Some new K<sup>+</sup>-channel openers have been developed and claimed to have selectivity for the bladder.<sup>6</sup> However, there is no evidence that K<sup>+</sup>-channel openers are an option for treatment of overactive bladder or detrusor overactivity.<sup>2,3</sup>

### AFFERENT SIGNALING FROM THE UROTHELIUM OR SUBUROTHELIUM

Evidence suggests that the urothelium or suburothelium may serve as a mechanosensor that, by producing nitric oxide, ATP, and other mediators, can control the activity in afferent nerves and thereby the initiation of the micturition reflex.<sup>75</sup> Low pH, high K<sup>+</sup> concentration, increased osmolality, and low temperatures can influence afferent nerves, possibly through effects on the vanilloid receptor (i.e., capsaicin-gated ion channel [TRPV1]), which is expressed in afferent nerve terminals and in the epithelial cells that line the bladder lumen.<sup>67,76</sup> A network of interstitial cells, extensively linked by connexin43 (Cx43)—containing gap

junctions, was found to be located beneath the urothelium in the human bladder by Sui and colleagues.<sup>77,78</sup> This interstitial cellular network was suggested to operate as a functional syncytium, integrating signals and responses in the bladder wall. The firing of suburothelial afferent nerves, conveying sensations and regulating the threshold for bladder activation, may be modified by inhibitory (e.g., nitric oxide) and stimulatory (e.g., ATP, tachykinins, prostanoids) mediators. ATP, generated by the urothelium, has been suggested as an important mediator of urothelial signaling.<sup>56,75</sup> Supporting such a view, intravesical ATP induces detrusor overactivity in conscious rats.<sup>79</sup> Mice lacking the P2X<sub>3</sub> receptor were shown to have hypoactive bladders.<sup>80,81</sup>

There seem to be other, unidentified factors in the urothelium that may influence bladder function.<sup>82-89</sup> Fovaeus and coworkers<sup>85</sup> found that a previously unrecognized nonadrenergic, non-nitroergic, nonprostanoid inhibitory mediator is released from the rat urinary bladder by muscarinic receptor stimulation. However, it was not clear whether this factor came from the detrusor muscle or from the detrusor and the urothelium. Hawthorn and associates<sup>86</sup> presented data suggesting the presence of a diffusible, urothelium-derived inhibitory factor, which could not be identified but appeared to be neither nitric oxide, a cyclooxygenase product, a catecholamine, adenosine,  $\gamma$ -aminobutyric acid (GABA), nor any substance sensitive to apamin. The identity and possible physiologic role of the unknown factors remain to be established and should offer an interesting field for further research. These mechanisms can be involved in the pathophysiology of overactive bladder and may be useful targets for pharmacologic intervention.

### URETHRAL FUNCTION AND STRESS URINARY INCONTINENCE

Many factors are involved in the pathogenesis of stress urinary incontinence (SUI). Some, such as weak urethral support, vaginal prolapse, and severe vesical neck or urethral dysfunction,<sup>90</sup> cannot be treated pharmacologically. Women with SUI have lower resting urethral pressures than age-matched, continent women,<sup>91,92</sup> and the aim of treatment often is to increase intraurethral pressure.

Factors that may contribute to urethral closure include urethral smooth and striated muscle tone and the passive properties of the urethral lamina propria, in particular the vascular suburothelial layer. The relative contribution to intraurethral pressure of these factors remains a subject of debate. In one study, the contributions to the total intraurethral pressure of the striated muscle component in the urethra and pelvic floor, the urethral vascular bed, and the smooth musculature and connective tissues in urethra and periurethral tissues were found to be one third each.<sup>93</sup>

Many factors have been suggested to contribute to urethral relaxation and to urethral closure, including urethral smooth muscle tone and the properties of the urethral lamina propria. There is ample pharmacologic evidence that a substantial part of urethral tone is mediated through stimulation of  $\alpha$ -adrenoceptors in the urethral smooth muscle by released noradrenaline.<sup>48</sup> Nitric oxide has emerged as an important mediator of urethral smooth muscle relaxation, but the roles of other transmitters cannot be excluded.<sup>94-96</sup> However, central nervous control of the smooth and striated urethral muscle is important for the maintenance of continence.<sup>97-99</sup> The nucleus Onuf is the

### Sacral Spinal Cord

**Figure 4-2** The striated urethral sphincter is innervated by the pudendal nerve, which contains the axons of motor neurons whose cell bodies are located in Onuf's nucleus. Glutamate exerts tonic excitatory effects on these motor neurons, and this effect is enhanced by noradrenaline (NA) and serotonin (5-HT), acting on  $\alpha_1$ -adrenoceptors and 5-HT<sub>2</sub> receptors, respectively. By inhibition of the reuptake of noradrenaline and serotonin, the contractile activity in the striated sphincter can be increased. ACh, acetylcholine; DC, dorsal commissure; DH, dorsal horn; LF, lateral funiculus; + Nic, nicotinic receptors; VH, ventral horn.

spinal target of reuptake inhibitors of serotonin (5-hydroxytryptamine) and noradrenaline, which may increase the tone of the striated sphincter (Fig. 4-2).

### Innervation

The urethra of males and females receives sympathetic (adrenergic), parasympathetic (cholinergic), and sensory innervation. The pelvic nerve conveys parasympathetic fibers to the urethra, and activity in these fibers results in an inhibitory effect on urethral smooth muscle, which relaxes the outflow region. Most of the sympathetic innervation of the bladder and urethra originates from the intermediolateral nuclei in the thoracolumbar region (T10 to L2) of the spinal cord. The axons travel through the inferior mesenteric ganglia and the hypogastric nerve or pass through the paravertebral chain and enter the pelvic nerve. Sympathetic signals are conveyed in the hypogastric and the pelvic nerves.<sup>100</sup>

Adrenergic and cholinergic nerves contain transmitters and transmitter-generating enzymes other than noradrenaline and acetylcholine. These agents, some of which have not been identified, are responsible for the NANC efferent neurotransmission, which can be demonstrated in urethral smooth muscle (discussed later).

Most of the sensory innervation of the urethra reaches the spinal cord through the pelvic nerve and dorsal root ganglia. Some afferents travel in the hypogastric nerve. The sensory nerves of the striated muscle in the rhabdosphincter travel in the pudendal nerve to the sacral region of the spinal cord.<sup>100</sup> These sensory nerves are usually identified by their content of peptides such as calcitonin gene-related peptide and tachykinins.

### Adrenergic Nerves

There are well-known anatomic differences between the male and female urethra, which are reflected in the innervation. In the

human male, the smooth muscle surrounding the preprostatic part of the urethra is richly innervated by cholinergic and adrenergic nerves.<sup>101</sup> This part is believed to serve as a sexual sphincter, contracting during ejaculation and preventing retrograde transport of sperm. The role of this structure in maintaining continence is unclear, but it probably is not essential.

In the human female, there is no anatomic urethral smooth muscle sphincter, and the muscle bundles run obliquely or longitudinally along the length of the urethra. In the whole human female urethra and in the human male urethra below the preprostatic part, there is a scarce supply of adrenergic nerves.<sup>101,102</sup> Fine varicose terminals can be seen running longitudinally and transversely along the bundles of smooth muscle cells. Adrenergic terminals can also be found around blood vessels. Colocalization studies in animals have revealed that adrenergic nerves, identified by immunohistochemistry (i.e., using tyrosine hydroxylase), also contain neuropeptide Y.<sup>103</sup> Chemical sympathectomy (i.e., using 6-OH-dopamine) in rats resulted in a complete disappearance of tyrosine hydroxylase-immunoreactive nerves, whereas nitric oxide synthase (NOS)-containing nerve fibers did not appear to be affected by the treatment.<sup>104</sup> This result suggests that NOS is not contained within adrenergic nerves.

### Cholinergic Nerves

Urethral smooth muscle receives a rich cholinergic innervation. Most probably, the cholinergic nerves cause relaxation of the outflow region at the start of micturition by releasing nitric oxide and other relaxant transmitters, but otherwise, their functional role is largely unknown. The cholinergic nerves of the bladder produce detrusor contraction, and disturbances in the coordination of the contractant effects on the bladder and the relaxation of the outflow region may lead to the detrusor-sphincter dys-synergia, often seen in suprasacral spinal cord injuries.

In the pig urethra, colocalization studies revealed that acetylcholine esterase-positive and some NOS-immunoreactive nerves had profiles that were similar. These nerves also contained neuropeptide Y and vasoactive intestinal polypeptide (VIP) immunoreactivity. NOS-containing nerves were present in a density lower than that of the acetylcholine esterase-positive nerves but higher than the density of any peptidergic nerves.<sup>105</sup> Coexistence of acetylcholine and NOS was also demonstrated in the rat major pelvic ganglion.<sup>106</sup> In the rat urethra, colocalization studies confirmed that NOS and VIP are contained within a population of cholinergic nerves. The distribution of immunoreactivities to neuronal NOS, heme oxygenases, and VIP was assessed by Werkström and colleagues.<sup>107</sup> Heme oxygenase-2 immunoreactivity was found in all nerve cell bodies of intramural ganglia, localized between smooth muscle bundles in the detrusor, bladder base, and proximal urethra. About 70% of the ganglionic cell bodies were also NOS immunoreactive, whereas a minor amount was VIP immunoreactive.

## AUTONOMIC RECEPTOR FUNCTIONS

### Alpha-Adrenoceptors

In males, up to about 50% of the intraurethral pressure is maintained by stimulation of  $\alpha$ -adrenoceptors, as judged from results obtained with  $\alpha$ -adrenoceptor antagonists and epidural anesthesia in urodynamic studies.<sup>108,109</sup> In human urethral smooth

muscle, functional and receptor binding studies have suggested that the  $\alpha_1$ -adrenoceptor subtype is the predominating postjunctional  $\alpha$ -adrenoceptor.<sup>48,110</sup> Most *in vitro* investigations of human urethral  $\alpha$ -adrenoceptors have been carried out in the male, and the results support the existence of a sphincter structure in the male proximal urethra, which cannot be found in the female. Other marked differences between sexes in the distribution of  $\alpha_1$ - and  $\alpha_2$ -adrenoceptors (as can be found in animals such as rabbits) or in the distribution of  $\alpha_1$ -adrenoceptor subtypes do not seem to occur.<sup>111</sup> Taki and coworkers<sup>112</sup> separated the entire length of the isolated female human urethra into seven parts, from the external meatus to the bladder neck, and examined regional differences in contractile responses to various agents, including noradrenaline ( $\alpha_1$  and  $\alpha_2$ ) and clonidine ( $\alpha_2$ ). Noradrenaline, but not clonidine, produced concentration-dependent contractions in all parts, with a peak response in the middle to proximal urethra. They found a similarity in patterns between noradrenaline-induced contraction and the urethral pressure profile in the human urethra.

Among the three high-affinity  $\alpha_1$ -adrenoceptor subtypes identified in molecular cloning and functional studies ( $\alpha_{1A}$ ,  $\alpha_{1B}$ ,  $\alpha_{1D}$ ),  $\alpha_{1A}$  seems to predominate in the human lower urinary tract. However, the receptor with low affinity for prazosin ( $\alpha_{1L}$ -adrenoceptor), which has not been cloned and may represent a functional phenotype of the  $\alpha_{1A}$ -adrenoceptor,<sup>113</sup> was found to be prominent in the human male urethra.<sup>114</sup> In the human female urethra, the expression and distribution of  $\alpha_1$ -adrenoceptor subtypes were determined by *in situ* hybridization and quantitative autoradiography. mRNA for the  $\alpha_{1A}$ -adrenoceptor subtype was predominant, and autoradiography confirmed the predominance of the  $\alpha_{1A}$ -adrenoceptor.

The studies previously cited suggest that the sympathetic innervation helps to maintain urethral smooth muscle tone through  $\alpha_1$ -adrenoceptor receptor stimulation. If urethral  $\alpha_1$ -adrenoceptors are contributing to the lower urinary tract symptoms, which can occur also in women,<sup>115-117</sup> an effect of  $\alpha_1$ -adrenoceptor antagonists should be expected in women with these symptoms. This was found to be the case in some studies, but it was not confirmed in a randomized, placebo-controlled pilot study,<sup>118</sup> which showed that terazosin was not effective for the treatment of prostatism-like symptoms in aging women.

Urethral  $\alpha_2$ -adrenoceptors are able to control the release of noradrenaline from adrenergic nerves, as shown in *in vitro* studies.<sup>48</sup> In the rabbit urethra incubated with [<sup>3</sup>H]noradrenaline, electrical stimulation of nerves caused a release of [<sup>3</sup>H], which was decreased by noradrenaline and clonidine and increased by the  $\alpha_2$ -adrenoceptor antagonist rauwolscine. Clonidine was shown to reduce intraurethral pressure in humans,<sup>119</sup> an effect that may be attributed partly to a peripheral effect on adrenergic nerve terminals. More likely, this effect was exerted on the central nervous system, with a resulting decrease in peripheral sympathetic nervous activity. The subtype of prejunctional  $\alpha_2$ -adrenoceptor involved in [<sup>3</sup>H]noradrenaline secretion in the isolated guinea pig urethra was suggested to be of the  $\alpha_{2A}$ -adrenoceptor subtype.<sup>120</sup>

### Beta-Adrenoceptors

Both  $\alpha$ - and  $\beta$ -adrenoceptors can be demonstrated in isolated urethral smooth muscle from animals and humans.<sup>48</sup> In humans, the  $\beta$ -adrenoceptors in the bladder neck were suggested to be of the  $\beta_2$ -adrenoceptor subtype, as shown by receptor binding

studies using subtype-selective antagonists.<sup>121</sup> However, the predominating  $\beta$ -adrenoceptor in the human bladder seems to be the  $\beta_3$ -adrenoceptor subtype,<sup>122-124</sup> and in the striated urethral sphincter,  $\beta_3$ -adrenoceptors can be found.<sup>125</sup> The role of this subtype in urethral function does not seem to have been explored.

### Muscarinic Receptors

The number of muscarinic receptor binding sites in the rabbit urethra was lower than in the bladder.<sup>126</sup> Muscarinic receptor agonists contract isolated urethral smooth muscle from several species, including humans, but these responses seem to be mediated mainly by the longitudinal muscle layer.<sup>48</sup> Taki and associates,<sup>112</sup> investigating the whole length of the female human urethra, found that acetylcholine contracted only the proximal part and the bladder neck. If this contractile activation is exerted in the longitudinal direction, it should be expected that the urethra is shortened and that the urethral pressure decreases. Experimentally, *in vitro* resistance to flow in the urethra was increased only by high concentrations of acetylcholine.<sup>127,128</sup> In humans, tolerable doses of the muscarinic receptor agonist bethanechol<sup>129</sup> and the muscarinic receptor antagonist emeprone<sup>130</sup> had little effect on intraurethral pressure.

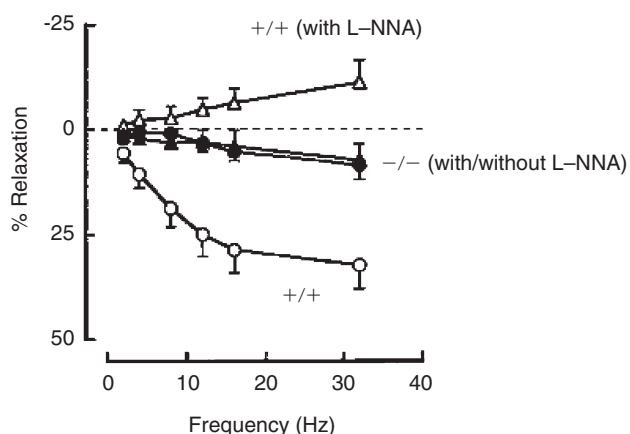

Prejunctional muscarinic receptors may influence the release of noradrenaline and acetylcholine in the bladder neck and urethra. In urethral tissue from rabbits and humans, carbachol decreased and scopolamine increased in a concentration-dependent manner the release of [<sup>3</sup>H]noradrenaline from adrenergic terminals and of [<sup>3</sup>H]choline from cholinergic nerve terminals.<sup>131</sup> This means that released acetylcholine can inhibit noradrenaline release, thereby decreasing urethral tone and intraurethral pressure. The muscarinic receptor subtypes involved in contractile effects on smooth muscle or controlling transmitter release in the urethra have not been established. This may have clinical ramifications, because subtype-selective antimuscarinic drugs ( $M_3$ ) have been introduced as a treatment for detrusor overactivity.

### NONADRENERGIC, NONCHOLINERGIC RELAXANT MECHANISMS

The normal pattern of voiding in humans is characterized by an initial drop in urethral pressure, followed by an increase in intravesical pressure.<sup>48,132</sup> The mechanism of this relaxant effect has not been established, but several factors may contribute. One possibility is that the fall in intraurethral pressure is caused by stimulation of muscarinic receptors on noradrenergic nerves, diminishing noradrenaline release and thereby tone in the proximal urethra. Another is that contraction of longitudinal urethral smooth muscle in the proximal urethra, produced by released acetylcholine, causes shortening and widening of the urethra, with a concomitant decrease in intraurethral pressure. A third possibility is that a NANC mechanism mediates this response.<sup>48</sup>

### Nitric Oxide

Nitric oxide is an important inhibitory neurotransmitter in the lower urinary tract.<sup>133,134</sup> Nitric oxide-mediated responses in smooth muscle preparations are most often linked to an increase in cyclic guanine monophosphate (cGMP) formation. This has

**Figure 4-3** Frequency-response curves in response to electrical field stimulation in urethral preparations from mice lacking cyclic cAMP-dependent protein kinase (cGKI<sup>-/-</sup>, solid symbols) and wild-type controls (cGKI<sup>+/+</sup>, open symbols) before (circles) and after (triangles) treatment with the nitric oxide synthase inhibitor, L-NOARG.

been demonstrated in the rabbit urethra.<sup>135-137</sup> The cGMP analogue 8-Br-cGMP was able to induce relaxation of rabbit urethra, further supporting the view of cGMP as a mediator of relaxation in this tissue. cGMP-dependent protein kinase (cGK) phosphorylates  $K_{Ca}$  channels and increases their open probability, leading to hyperpolarization.<sup>138</sup> cGMP may affect sequestering of intracellular  $Ca^{2+}$ , stimulate  $Ca^{2+}$  extrusion pumps, and decrease the sensitivity of the contractile proteins to  $Ca^{2+}$ .<sup>139</sup> The latter may occur without changing the membrane potential. In this way, cGMP may be able to induce relaxation in different ways in different tissues. The role of nitric oxide for urethral relaxation was further investigated in mice lacking cGK type I.<sup>140</sup> In urethral preparations of cGKI<sup>+/+</sup> mice, electrical field stimulation elicited frequency-dependent relaxations. The relaxations were abolished by the NOS inhibitor L-NOARG, and instead, a contractile response to stimulation was generally found (Fig. 4-3). In cGKI<sup>-/-</sup> urethral strips, the response to electrical field stimulation was practically abolished, but a small relaxation generally appeared at high stimulation frequencies (16 to 32 Hz). This relaxant response was not inhibited by L-NOARG, suggesting the occurrence of additional relaxant transmitters.

The rich occurrence of NOS-immunoreactive nerve fibers supports the current view of nitric oxide as the main inhibitory NANC mediator in rabbit urethra.<sup>133</sup> Waldeck and colleagues<sup>141</sup> demonstrated spindle-shaped cyclic GMP-immunoreactive cells, distinct from the smooth muscle cells, forming a network around and between the smooth muscle bundles. These results confirmed the findings of Smet and coworkers,<sup>142</sup> who found similar cyclic GMP-immunoreactive cells in the guinea pig and human bladder and urethra. The function of these interstitial cells has not been established, but they have been suggested to be pacemaker cells involved in the regulation of urethral tone.<sup>143-145</sup> Based on results obtained in freshly dispersed rabbit urethral interstitial cells, Sergeant and associates<sup>145</sup> suggested that in the urethra, stimulation of  $\alpha_1$ -adrenoceptors releases  $Ca^{2+}$  from an  $IP_3$ -sensitive store. This produces a  $Ca^{2+}$ -activated  $Cl^-$  current, which elevates the slow-wave frequency in the cells. This may underlie the mechanism responsible for increased urethral tone during nerve stimulation.

### Other Nonadrenergic, Noncholinergic Transmitters or Modulators

Additional systems involving ATP, carbon monoxide, and other, unknown mediators have been observed in the urethra. Other agents shown to influence urethral function include neuropeptides, prostanoids, and serotonin.<sup>1</sup> Neuropeptides such as VIP, neuropeptide Y, and endothelins have been suggested to be involved in contraction and relaxation of urethral smooth muscle and, as in the bladder, in afferent signaling, but to a large extent, their functional roles remain to be established.<sup>1</sup>

### EFFECTS OF SEX HORMONES ON THE LOWER URINARY TRACT

#### Estrogen and Progesterone

Lower urinary tract innervation, receptor density and distribution, and contractile function may change significantly during periods of marked changes in female hormone levels, such as puberty, pregnancy, and menopause.<sup>48</sup> The lower urinary tract in animals and humans expresses estrogen receptors.<sup>146,147</sup> However, in human bladders, estrogen receptors were found only in squamous epithelia (i.e., trigone and proximal and distal urethra). No estrogen receptors were found in transitional urothelium or detrusor muscle, and there was no variation with estrogen status.<sup>146</sup> In the urethra, the expression is greater, but it is still inconsistent.<sup>146</sup> In animals, estrogen- $\alpha$  and estrogen- $\beta$  receptors have been demonstrated in the epithelium, detrusor muscle, and rhabdosphincter, but many of the rapid estrogen-induced changes have been postulated not to be receptor mediated.<sup>147</sup>

The effects of estrogen on lower urinary tract structure and function and on the autonomic nervous control have been examined in many animal studies,<sup>48,148-153</sup> often with conflicting results. In particular, there has been disagreement on how estrogens affect muscarinic receptor functions. Levin and colleagues<sup>154</sup> found that estrogen treatment (i.e., estradiol) of immature female rabbits induced a marked increase in the detrusor response to stimulation of  $\alpha$ -adrenoceptors and muscarinic receptors and to ATP, and they found that in the bladder body and midsection, there was a significant increase in the number of  $\alpha$ -adrenoceptors and muscarinic receptors. Shapiro<sup>155</sup> reported that treatment of mature female rabbits with estradiol led to a significant decrease in muscarinic receptor density. This observation was confirmed by Batra and Andersson, who found that the decrease in muscarinic receptor number had little effect on the responses to carbachol and electrical stimulation.<sup>156</sup> Elliott and coworkers<sup>157</sup> found a decreased sensitivity to acetylcholine, carbachol, and electrical stimulation, but not to  $K^+$  in isolated detrusor tissue from female rats treated with estradiol. Addition of diethylstilbestrol further reduced these responses, an effect previously investigated by the same group and attributed to a reduction of calcium influx into the detrusor cells.<sup>157</sup> Selective  $\beta_3$ -adrenoceptor agonists relaxed the detrusor muscle of female rats with low estrogen levels,<sup>158</sup> which was suggested to have potential clinical implications.

In nonanesthetized mice lacking estrogen- $\alpha$ , estrogen- $\beta$ , or both receptor subtypes, in vitro contractility and cystometric values were no different from those in wild-type controls. However, mice lacking estrogen- $\alpha$  receptors did not respond to intravesical capsaicin instillation, suggesting a role of estrogen receptors in afferent signaling in the bladder.<sup>159</sup> In the urethra,

estrogens may increase the smooth muscle sensitivity to  $\alpha$ -adrenoceptor stimulation and improve the function of the vasculature and connective tissue of the lamina propria.<sup>48</sup>

Taken together, these results suggest that estrogens, at least in animals, can influence lower urinary tract structure and function and modify the responses of the detrusor to autonomic nervous influences. The results are not always consistent, and some of the discrepancies may be attributed to differences in experimental approaches. Even if an estrogen effect on afferent signaling in humans seems possible, available data do not allow conclusions to be drawn that consistently are applicable to treatment (e.g., of urine storage disorders).

Little is known about the effects of progesterone on bladder function, and the functional importance of the progesterone receptors that have been demonstrated in the lower urinary tract has not been established.<sup>160,161</sup> In vitro administration of progesterone reduced the response of bladder strips to electrical field stimulation and KCl.<sup>162</sup> In contrast, long-term in vivo treatment with progesterone increased the maximal response of rabbit bladder preparations to electrical field stimulation and increased the sensitivity to muscarinic receptor stimulation compared with ovariectomized controls.<sup>163</sup> In contrast, Tong and associates<sup>164</sup> found that in vivo treatment with progesterone decreased the maximal response of rat bladder strips to acetylcholine and that there was a decrease in muscarinic receptor density. As for estrogens, available information does not allow conclusions to be drawn that are applicable to treatment of lower urinary tract disorders.

## Pregnancy

Urinary incontinence (particularly stress incontinence) is common during pregnancy and has been attributed in part to changes in bladder and urethral function.<sup>165</sup> In rats, pregnancy was reported to increase bladder weight and capacity, decrease the responses to muscarinic and  $\alpha$ -adrenoceptor stimulation, and increase the response to ATP.<sup>164</sup> In the presence of bethanechol, bladder strips from pregnant rabbits generated 50% less tension in response to calcium than those from nonpregnant rabbits.<sup>166</sup> The isolated whole bladder from pregnant animals responded to low-frequency stimulation and to ATP with a greater increase in intravesical pressure than did preparations from virgin rabbits, whereas the response to bethanechol was greater in the virgin rabbits.<sup>167</sup> Receptor binding studies in bladder tissue from pregnant animals revealed a significantly reduced muscarinic receptor density (50%), corresponding to the decrease in response to bethanechol of the whole bladder. The results were interpreted to mean that pregnancy induced an increase in the purinergic component and a decrease in the cholinergic component of the urinary bladder response to field stimulation.<sup>167</sup> A reduction of the muscarinic receptor density in the pregnant rabbit bladder was confirmed by other investigators.<sup>168</sup> To what extent the receptor and functional changes demonstrated in the pregnant bladder from different species can explain the voiding disturbances found in pregnant women remains to be established.

# HORMONAL INFLUENCES ON THE FEMALE GENITAL AND LOWER URINARY TRACTS

*Dudley Robinson and Linda Cardozo*

The female genital tract and lower urinary tract share a common embryologic origin, arising from the urogenital sinus. Both are sensitive to the effects of female sex steroid hormones. Estrogen has an important role in the function of the lower urinary tract throughout adult life, and estrogen and progesterone receptors have been demonstrated in the vagina, urethra, bladder, and pelvic floor musculature.<sup>1-4</sup> This role is supported by the fact that estrogen deficiency occurring after menopause is known to cause atrophic changes within the urogenital tract<sup>5</sup> and is associated with urinary symptoms such as frequency, urgency, nocturia, incontinence, and recurrent infection. These effects may also coexist with symptoms of vaginal atrophy such as dyspareunia, itching, burning, and dryness. This chapter reviews the roles of estrogen and progesterone in lower urinary tract function and assesses the role of estrogens in the management of lower urinary tract dysfunction.

### ESTROGEN RECEPTORS AND HORMONAL FACTORS

The effects of the steroid hormone 17 $\beta$ -estradiol are mediated by ligand-activated transcription factors known as estrogen receptors. They are glycoproteins that share common features with androgen and progesterone receptors, and they can be divided into several functional domains.<sup>6</sup> The classic estrogen receptor (ER $\alpha$ ) was first discovered by Elwood Jensen in 1958 and cloned from uterine tissue in 1986,<sup>7</sup> although it was not until 1996 that the second estrogen receptor (ER $\beta$ ) was identified.<sup>8</sup> The precise role of the two different receptors remains to be elucidated, although estrogen receptor- $\alpha$  appears to play a major role in the regulation of reproduction, whereas estrogen receptor- $\beta$  has a more minor role.<sup>9</sup>

Estrogen receptors have been demonstrated throughout the lower urinary tract and are expressed in the squamous epithelium of the proximal and distal urethra, vagina, and trigone of the bladder<sup>3,10</sup> although not in the dome of the bladder, reflecting its different embryologic origin. The pubococcygeus and the musculature of the pelvic floor also are estrogen sensitive,<sup>11</sup> although estrogen receptors have not yet been identified in the levator ani muscles.<sup>12</sup>

The distribution of estrogen receptors throughout the urogenital tract has been studied, and ER $\alpha$  and ER $\beta$  receptors have been found in the vaginal walls and uterosacral ligaments of premenopausal women, although the latter were absent in the vaginal walls of postmenopausal women.<sup>13</sup> The ER $\alpha$  receptors are localized in the urethral sphincter, and when sensitized by estrogens, they are thought to help maintain muscular tone.<sup>14</sup>

In addition to estrogen receptors, androgen and progesterone receptors are expressed in the lower urinary tract, although their

role is less clear. Progesterone receptors are expressed inconsistently, and they have been reported in the bladder, trigone, and vagina. Their presence may depend on estrogen status.<sup>5</sup> Androgen receptors are present in the bladder and urethra, although their role has not yet been defined.<sup>15</sup> Estrogen receptors have also been identified in mast cells in women with interstitial cystitis<sup>16,17</sup> and in the male lower urinary tract.<sup>18</sup>

The incidence of both estrogen and progesterone expression has been examined throughout the lower urinary tract in 90 women undergoing gynecologic surgery; 33 were premenopausal, 26 were postmenopausal without hormone replacement therapy (HRT), and 31 were postmenopausal and taking HRT.<sup>19</sup> Biopsies were taken from the bladder dome, trigone, proximal urethra, distal urethra, vagina, and vesicovaginal fascia adjacent to the bladder neck. Estrogen receptors were consistently expressed in the squamous epithelia, but they were absent in the urothelial tissues of the lower urinary tract of all women, irrespective of estrogen status. Progesterone receptor expression, however, showed more variability because it was mostly subepithelial and was significantly lower in postmenopausal women not taking estrogen replacement therapy.

### HORMONAL INFLUENCES ON LOWER URINARY TRACT SYMPTOMS

To maintain continence, the urethral pressure must remain higher than the intravesical pressure at all times, except during micturition.<sup>20</sup> Estrogens play an important role in the continence mechanism, with bladder and urethral function becoming less efficient with age.<sup>21</sup> Elderly women have been found to have a reduced flow rate, increased urinary residuals, higher filling pressures, reduced bladder capacity, and lower maximum voiding pressures.<sup>22</sup> Estrogens may affect continence by increasing urethral resistance, raising the sensory threshold of the bladder or by increasing  $\alpha$ -adrenoreceptor sensitivity in the urethral smooth muscle.<sup>23,24</sup> Exogenous estrogens have been shown to increase the number of intermediate and superficial cells in the vagina of postmenopausal women.<sup>25</sup> These changes have also been demonstrated in the bladder and urethra.<sup>26</sup>

A prospective, observational study was performed to assess cell proliferation rates throughout the tissues of the lower urinary tract.<sup>27</sup> Fifty-nine women were studied; 23 were premenopausal, 20 were postmenopausal and not taking HRT and 20 were postmenopausal and taking HRT. Biopsies were taken from the bladder dome, trigone, proximal urethra, distal urethra, vagina, and vesicovaginal fascia adjacent to the bladder neck. The squamous epithelium of estrogen-replete women was shown to exhibit

greater levels of cellular proliferation than in those women who were estrogen deficient.

Cyclic variations in the levels of estrogen and progesterone during the menstrual cycle lead to changes in urodynamic variables and lower urinary tract symptoms, with 37% of women noticing a deterioration in symptoms before menstruation.<sup>28</sup> Measurement of the urethral pressure profile in nulliparous premenopausal women shows there is an increase in functional urethral length midcycle and early in the luteal phase, corresponding to an increase in plasma estradiol.<sup>29</sup> Progestogens have been associated with an increase in irritating bladder symptoms<sup>30,31</sup> and urinary incontinence in women taking combined HRT.<sup>32</sup> The incidence of detrusor overactivity in the luteal phase of the menstrual cycle may be associated with raised plasma progesterone levels after ovulation, and progesterone has been shown to antagonize the inhibitory effect of estradiol on rat detrusor contractions.<sup>33</sup> This may help to explain the increased prevalence of detrusor overactivity found in pregnancy.<sup>34</sup>

The role of estrogen therapy in the management of women with fecal incontinence has been investigated in a prospective, observational study using symptom questionnaires and anorectal physiologic testing before and after 6 months of estrogen replacement therapy. At follow-up, 25% of women were asymptomatic, and another 65% were improved in terms of flatus control, urgency, and fecal staining. Anal resting pressures and voluntary squeeze increments were significantly increased after estrogen therapy, although there were no changes in pudendal nerve terminal latency. The investigators concluded that estrogen replacement therapy may have a beneficial effect, although larger studies are needed to confirm these findings.<sup>35</sup>

### HORMONAL INFLUENCES ON URINARY TRACT INFECTION

Urinary tract infection is a common cause of urinary symptoms in women of all ages. This is a particular problem in the elderly, with a reported incidence of 20% in the community and more than 50% among institutionalized patients.<sup>36,37</sup> Pathophysiologic changes such as impairment of bladder emptying, poor perineal hygiene, and fecal and urinary incontinence may partly account for the high prevalence observed. Changes in the vaginal flora due to estrogen depletion lead to colonization with gram-negative bacilli, which cause locally irritating symptoms and act as uropathogens. These microbiologic changes may be reversed with estrogen replacement after menopause, offering a rationale for treatment and prophylaxis.

### HORMONAL INFLUENCES ON LOWER URINARY TRACT FUNCTION

#### Neurologic Control

Sex hormones are known to influence the central neurologic control of micturition, although their exact role in the micturition pathway has yet to be elucidated. Estrogen receptors have been demonstrated in the cerebral cortex, limbic system, hippocampus, and cerebellum,<sup>38,39</sup> and androgen receptors have been demonstrated in the pontine micturition center and the preoptic area of the hypothalamus.<sup>40</sup>

### Bladder Function

Estrogen receptors, although absent in the transitional epithelium at the dome of the bladder, are present in the areas of the trigone that have undergone squamous metaplasia.<sup>10</sup> Estrogen is known to have a direct effect on detrusor function through modifications in muscarinic receptors<sup>41,42</sup> and by inhibition of movement of extracellular calcium ions into muscle cells.<sup>43</sup> Consequently, estradiol has been shown to reduce the amplitude and frequency of spontaneous rhythmic detrusor contractions,<sup>44</sup> and there is evidence that it may increase the sensory threshold of the bladder in some women.<sup>45</sup>

### Urethral Function

Estrogen receptors have been demonstrated in the squamous epithelium of the proximal and distal urethra,<sup>10</sup> and estrogen has been shown to improve the maturation index of urethral squamous epithelium.<sup>46</sup> It has been suggested that estrogen increases urethral closure pressure and improves pressure transmission to the proximal urethra, both promoting continence.<sup>47-50</sup> Estrogens have been shown to cause vasodilatation in the systemic and cerebral circulation, and these changes are also seen in the urethra.<sup>51-53</sup>

The vascular pulsations seen on urethral pressure profilometry resulting from blood flow in the urethral submucosa and urethral sphincter have been shown to increase in size after estrogen administration,<sup>54</sup> and the effect is lost after estrogen withdrawal at menopause. The urethral vascular bed is thought to account for about one third of the urethral closure pressure, and estrogen replacement therapy in postmenopausal women with stress incontinence has been shown to increase the number of periurethral vessels.<sup>55</sup>

### Collagen Metabolism

Estrogens affect collagen synthesis, and they have a direct effect on collagen metabolism in the lower genital tract.<sup>56</sup> Changes found in women with urogenital atrophy may represent an alteration in systemic collagenase activity,<sup>57</sup> and urodynamic stress incontinence and urogenital prolapse have been associated with a reduction in vaginal and periurethral collagen levels.<sup>58-60</sup> There is a reduction in skin collagen content after menopause,<sup>61</sup> and the rectus muscle fascia becomes less elastic with increasing age, resulting in a lower energy requirement to cause irreversible damage.<sup>62</sup> Changes in collagen content have also been identified, the hydroxyproline content in connective tissue from women with stress incontinence being 40% lower than in continent controls.<sup>63</sup>

### LOWER URINARY TRACT SYMPTOMS

#### Urinary Incontinence

The prevalence of urinary incontinence increases with age, affecting 15% to 35% of community-dwelling women older than 60 years,<sup>64</sup> and other studies have reported a prevalence of 49% among women older than 65 years.<sup>65</sup> Rates of 50% have been reported in elderly nursing home residents.<sup>66</sup> A cross-sectional population prevalence survey of 146 women between the ages of 15 and 97 years found that 46% experienced symptoms of pelvic floor dysfunction, defined as stress or urge incontinence, flatus

or fecal incontinence, symptomatic prolapse, or previous pelvic floor surgery.<sup>67</sup>

Little work has been done to examine the incidence of urinary incontinence. However, a study in New Zealand of women older than 65 years found 10% of the originally continent developed urinary incontinence in the 3-year study period.<sup>68</sup>

Epidemiologic studies have implicated estrogen deficiency in the cause of lower urinary tract symptoms, with 70% of women relating the onset of urinary incontinence to their final menstrual period.<sup>5</sup> Lower urinary tract symptoms are common in postmenopausal women attending a menopause clinic, with 20% complaining of severe urgency and almost 50% complaining of stress incontinence.<sup>69</sup> Urge incontinence in particular is more prevalent after menopause, and the prevalence appears to rise with increasing years of estrogen deficiency.<sup>70</sup> There is, however, conflicting evidence regarding the role of estrogen withdrawal at the time of menopause. Some studies have shown a peak incidence in perimenopausal women,<sup>71,72</sup> and other evidence suggests that many women develop incontinence at least 10 years before the cessation of menstruation, with significantly more premenopausal women than postmenopausal women being affected.<sup>73</sup>

### Urogenital Atrophy

Urogenital atrophy is a manifestation of estrogen withdrawal after menopause, and symptoms may appear for the first time more than 10 years after the last menstrual period.<sup>74</sup> Increasing life expectancy has led to an increasingly elderly population, and with the average age of the menopause being 50 years,<sup>76</sup> it is now common for women to spend one third of their lives in the estrogen-deficient postmenopausal state.<sup>75</sup>

Postmenopausal women comprise 15% of the population in industrialized countries, with a predicted growth rate of 1.5% over the next 20 years. Overall, in the developed world, 8% of the total population is estimated to have urogenital symptoms.<sup>77</sup> This represents 200 million women in the United States alone.

It has been estimated that 10% to 40% of all postmenopausal women are symptomatic,<sup>78</sup> although only 25% are thought to seek medical help. Two out of three women report vaginal symptoms associated with urogenital atrophy by the age of 75 years.<sup>79</sup> However, the prevalence of symptomatic urogenital atrophy is difficult to estimate, because many women accept the changes as being an inevitable consequence of the aging process and do not seek help, leading to considerable underreporting.

In a study assessing the prevalence of urogenital symptoms in 2157 Dutch women,<sup>80</sup> 27% complained of vaginal dryness, soreness, and dyspareunia, and the prevalence of urinary symptoms such as leakage and recurrent infections was 36%. When considering severity, almost 50% reported moderate to severe discomfort, although only a third had received medical intervention. Women who had had a hysterectomy reported moderate to severe complaints more often than those who had not.

The prevalence of urogenital atrophy and urogenital prolapse was examined in a population of 285 women attending a menopause clinic.<sup>81</sup> Overall, 51% of women had anterior vaginal wall prolapse, 27% had posterior vaginal prolapse, and 20% had apical prolapse. In this same group, 34% of women had urogenital atrophy, and 40% complained of dyspareunia. Although urogenital atrophy and symptoms of dyspareunia were related to menopausal age, the prevalence of prolapse showed no association.

Although urogenital atrophy is an inevitable consequence of menopause, women may not always be symptomatic. In one study, 69 women attending a gynecology clinic were asked to fill out a symptom questionnaire before examination and undergoing vaginal cytology.<sup>82</sup> Urogenital symptoms were found to be relatively low and were poorly correlated with age and physical examination findings, although not with vaginal cytologic maturation index. Women who were taking estrogen replacement therapy had higher symptom scores and physical examination scores.

From this evidence, it appears that urogenital atrophy is a universal consequence of menopause, although elderly women often may be minimally symptomatic. Treatment therefore should not be the only indication for replacement therapy.

## MANAGEMENT OF LOWER URINARY DYSFUNCTION

### Estrogens in the Management of Incontinence

Estrogen preparations have been used for many years in the treatment of urinary incontinence,<sup>83,84</sup> although their precise role remains controversial. Many of the studies performed have been uncontrolled, observational series examining the use of a wide range of different preparations, doses, and routes of administration. The inconsistent use of progestogens to provide endometrial protection is another confounding factor, making interpretation of the results difficult.

To clarify the situation, a meta-analysis was conducted by the Hormones and Urogenital Therapy (HUT) Committee.<sup>85</sup> Of 166 articles identified that were published in English between 1969 and 1992, only 6 were controlled trials, and 17 were uncontrolled series. Meta-analysis found an overall significant effect of estrogen therapy on subjective improvement in all patients and for patients with urodynamic stress incontinence alone. Subjective improvement rates with estrogen therapy in randomized, controlled trials ranged from 64% to 75%, although placebo groups also reported an improvement of 10% to 56%. In uncontrolled series, subjective improvement rates were 8% to 89%, with patients with urodynamic stress incontinence showing improvement rates of 34% to 73%. However, when assessing objective fluid loss, there was no significant effect. Maximum urethral closure pressure was found to increase significantly with estrogen therapy, although this outcome was influenced by a single study showing a large effect.<sup>86</sup>

Another meta-analysis performed in Italy analyzed the results of randomized, controlled clinical trials on the efficacy of estrogen treatment in postmenopausal women with urinary incontinence.<sup>87</sup> A search of the literature (1965-1996) revealed 72 articles, of which only four were considered to meet the meta-analysis criteria. There was a statistically significant difference in subjective outcome between estrogen and placebo, although there was no such difference in objective or urodynamic outcome. The investigators concluded that this difference could be relevant, although the studies may have lacked objective sensitivity to detect this effect.

The role of estrogen replacement therapy in the prevention of ischemic heart disease was assessed in a 4-year, randomized trial, the Heart and Estrogen/Progestin Replacement Study (HERS),<sup>88</sup> involving 2763 postmenopausal women younger than 80 years with intact uteri and ischemic heart disease. In the study, 55% of women reported at least one episode of urinary incontinence

**Table 5-1 Randomized, Controlled Trials Assessing the Use of Estrogens in the Management of Urinary Incontinence**

Study	Year	Type of Incontinence	Estrogen	Route
Henalla et al <sup>88</sup>	1989	Stress	Conjugated estrogen	Vaginal
Hilton et al <sup>100</sup>	1990	Stress	Conjugated estrogen	Vaginal
Beisland et al <sup>99</sup>	1984	Stress	Estriol	Vaginal
Judge <sup>126</sup>	1969	Mixed	Quinestradiol	Oral
Kinn and Lindskog <sup>127</sup>	1988	Stress	Estriol	Oral
Samsioe et al <sup>103</sup>	1985	Mixed	Estriol	Oral
Walter et al <sup>95</sup>	1978	Urge	Estradiol and estriol	Oral
Walter et al <sup>128</sup>	1990	Stress	Estriol	Oral
Wilson et al <sup>94</sup>	1987	Stress	Piperazine estrone sulfate	Oral

each week, and they were randomly assigned to oral conjugated estrogen plus medroxyprogesterone acetate or to placebo daily. Incontinence improved in 26% of women assigned to placebo and in 21% receiving HRT, and 27% of the placebo group complained of worsening symptoms, compared with 39% in the HRT group ( $P = .001$ ). The incidence of incontinent episodes per week increased an average of 0.7 in the HRT group and decreased by 0.1 in the placebo group ( $P < .001$ ). Overall, combined HRT was associated with worsening stress and urge urinary incontinence, although there was no significant difference in daytime frequency, nocturia, or number of urinary tract infections.

These findings were confirmed in the Nurse's Health Study, which followed 39,436 postmenopausal women between 50 and 75 years old over a 4-year period. The risk of incontinence was found to be elevated for those women taking HRT compared with those who had never taken HRT. There was an increase in risk for women taking oral estrogen (RR = 1.54; 95% CI: 1.44 to 1.65), transdermal estrogen (RR = 1.68; 95% CI: 1.41 to 2.00), oral estrogen and progesterone (RR = 1.34; 95% CI: 1.24 to 1.34), and transdermal estrogen and progesterone (RR = 1.46; 95% CI: 1.16 to 1.84). Although there remained a small risk after the cessation of HRT (RR = 1.14; 95% CI: 1.06 to 1.23), by 10 years, the risk was identical to that for women who had never taken HRT (RR = 1.02; 95% CI: 0.91 to 1.41).<sup>89</sup>

The effects of oral estrogens and progestogens on the lower urinary tract were assessed in 32 female nursing home residents<sup>90</sup> with an average age of 88 years. Subjects were randomized to oral estrogen and progesterone or to placebo for 6 months. At follow-up, there was no difference in severity of incontinence, prevalence of bacteriuria, or the results of vaginal cultures, although there was an improvement in atrophic vaginitis in the placebo group.

A meta-analysis of the effect of estrogen therapy on the lower urinary tract was performed by the Cochrane group.<sup>91</sup> Overall, 28 trials were identified that included 2926 women. In the 15 trials comparing estrogen with placebo, there was a higher subjective impression of improvement rate in women taking estrogen, and this was the case for all types of incontinence (RR for cure = 1.61; 95% CI: 1.04 to 2.49). When subjective cure and improvement were taken together, there was a statistically higher cure and improvement rate for urge (57% versus 28%) and stress (43% versus 27%) incontinence. In women with urge incontinence, the chance of improvement was 25% higher than in women with stress incontinence, and overall, about 50% of women treated with estrogen were cured or improved, compared

with 25% on placebo. The investigators conclude that estrogens can improve or cure incontinence and that the effect may be most useful in women complaining of urge incontinence.

### Estrogens in the Management of Stress Incontinence

In addition to the studies included in the HUT meta-analysis, several investigators have also assessed the role of estrogen therapy in the management of urodynamic stress incontinence only (Table 5-1). Oral estrogens have been reported to increase the maximum urethral pressures and to lead to symptomatic improvement in 65% to 70% of women,<sup>92,93</sup> although other work has not confirmed this finding.<sup>94,95</sup> Two placebo-controlled studies examined the use of oral estrogens in the treatment of urodynamic stress incontinence in postmenopausal women. Neither conjugated equine estrogens plus medroxyprogesterone<sup>96</sup> nor unopposed estradiol valerate<sup>97</sup> showed a significant difference in subjective or objective outcomes. A review of 8 controlled and 14 uncontrolled, prospective trials concluded that estrogen therapy was not an efficacious treatment for stress incontinence but that it could be useful for symptoms of urgency and frequency.<sup>98</sup>

From the available evidence, estrogen does not appear to be an effective treatment for stress incontinence, although it may have a synergistic role in combination therapy. Two placebo-controlled studies examined the use of oral and vaginal estrogens with the  $\alpha$ -adrenergic agonist phenylpropanolamine, used separately and in combination. Both studies found that combination therapy was superior to either drug given alone; although there was subjective improvement in all groups,<sup>99</sup> there was objective improvement only in the combination therapy group.<sup>100</sup> This may offer an alternative conservative treatment for women who have mild urodynamic stress incontinence; however, because of its pressor effects, phenylpropanolamine has been withdrawn in the United States.<sup>101</sup>

One meta-analysis has helped determine the role of estrogen replacement in women with stress incontinence.<sup>102</sup> Of the papers reviewed, 14 were nonrandomized studies, 6 were randomized trials (of which 4 were placebo controlled), and 2 were meta-analyses. There was symptomatic or clinical improvement identified only in the nonrandomized studies, whereas there was no such effect found in the randomized trials. The study authors concluded that the evidence does not support the use of estrogen replacement alone in the management of stress incontinence.

### Estrogens in the Management of Urge Incontinence

Estrogens have been used in the treatment of urinary urgency and urge incontinence for many years, although there have been few controlled trials to confirm their efficacy (see Table 5-1). A double-blind, placebo-controlled, crossover study using oral estriol in 34 postmenopausal women produced subjective improvement in 8 women with mixed incontinence and in 12 with urge incontinence.<sup>103</sup> However, a double-blind, multicenter study of the use of estriol (3 mg/day) in postmenopausal women complaining of urgency has failed to confirm these findings,<sup>104</sup> showing subjective and objective improvement but not significantly better than placebo. Estriol is a naturally occurring, weak estrogen that has little effect on the endometrium and does not prevent osteoporosis, although it has been used in the treatment of urogenital atrophy. Consequently, it is possible that the dosage or route of administration in this study was not appropriate in the treatment of urinary symptoms, and higher systemic levels may be required.

The use of sustained release 17 $\beta$ -estradiol vaginal tablets (Vagifem, Novo Nordisk) (Fig. 5-1) has been examined in postmenopausal women with urgency and urge incontinence or a urodynamic diagnosis of sensory urgency or detrusor overactivity. These vaginal tablets were well absorbed from the vagina and induced maturation of the vaginal epithelium within 14 days.<sup>105</sup> However, after a 6-month course of treatment, the only significant difference between active and placebo groups was an improvement in the symptom of urgency in women with a urodynamic diagnosis of sensory urgency.<sup>106</sup> Another double-blind, randomized, placebo-controlled trial of 17 $\beta$ -estradiol vaginal

tablets showed lower urinary tract symptoms of frequency, urgency, and urge and stress incontinence to be significantly improved, although no objective urodynamic assessment was performed.<sup>107</sup> In both of these studies, the subjective improvement in symptoms may represent local estrogenic effects reversing urogenital atrophy rather than a direct effect on bladder function.

A randomized, parallel-group, controlled trial compared the estradiol-releasing vaginal ring (Estring, Pharmacia, Uppsala, Sweden) with estriol vaginal pessaries in the treatment of postmenopausal women with bothersome lower urinary tract symptoms.<sup>108</sup> Low-dose, vaginally administered estradiol and estriol were found to be equally efficacious in alleviating lower urinary tract symptoms of urge incontinence (58% versus 58%), stress incontinence (53% versus 59%), and nocturia (51% versus 54%), although the vaginal ring was found to have greater patient acceptability.

To clarify the role of estrogen therapy in the management of women with urge incontinence, a meta-analysis of the use of estrogen in women with symptoms of overactive bladder was conducted by the HUT Committee.<sup>109</sup> In a review of 10 randomized, placebo-controlled trials, estrogen was found to be superior to placebo when considering symptoms of urge incontinence, frequency, and nocturia, and vaginal estrogen administration was found to be superior for symptoms of urgency. In those taking estrogens, there was also a significant increase in first sensation and bladder capacity compared with those taking placebo.

### Estrogens in the Management of Recurrent Urinary Tract Infection

Estrogen therapy has been shown to increase vaginal pH and reverse the microbiologic changes that occur in the vagina after menopause.<sup>110</sup> Initial small, uncontrolled studies using oral or vaginal estrogens in the treatment of recurrent urinary tract infection appeared to give promising results,<sup>111,112</sup> although unfortunately this has not been supported by larger, randomized trials. Several studies have examined the use of oral and vaginal estrogens, and they have had mixed results (Table 5-2).

Kjaergaard and colleagues<sup>113</sup> compared vaginal estriol tablets with placebo in 21 postmenopausal women over a 5-month period and found no significant difference between the two groups. However, a subsequent randomized, double-blind, placebo-controlled study assessing the use of estriol vaginal cream in 93 postmenopausal women during an 8-month period did reveal a significant effect.<sup>114</sup>

Kirkengen randomized 40 postmenopausal women to receive placebo or oral estriol and found that although both groups initially had a significantly decreased incidence of recurrent infections, estriol was shown after 12 weeks to be significantly more effective.<sup>115</sup> These findings were not confirmed subsequently in a trial of 72 postmenopausal women with recurrent urinary tract infections randomized to oral estriol or placebo. After a 6-month treatment period and another 6-month follow-up, estriol was found to be no more effective than placebo.<sup>116</sup>

A randomized, open, parallel-group study assessing the use of an estradiol-releasing silicone vaginal ring (Estring) in postmenopausal women with recurrent infections showed the cumulative likelihood of remaining infection free was 45% in the active group and 20% in the placebo group.<sup>117</sup> Estring was also shown to decrease the number of recurrences per year and to prolong the interval between infection episodes.

**Table 5-2 Randomized, Controlled Trials Assessing the Use of Estrogens in the Management of Recurrent Lower Urinary Tract Infections**

Study	Study Group	Type of Estrogen	Route of Delivery	Duration of Therapy	Results
Kjaergaard et al, 1990 <sup>113</sup>	21 Postmenopausal women with recurrent cystitis 10 active group 11 placebo	Estradiol	Vaginal tablets	5 months	Number of positive cultures not statistically different between the two groups
Kirkengen et al, 1992 <sup>115</sup>	40 Postmenopausal women with recurrent UTIs 20 active group 20 placebo	Estriol	Oral	12 weeks	Both estriol and placebo significantly reduced the incidence of UTIs ( $P < .05$ ). After 12 weeks, estriol was significantly more effective than placebo ( $P < .05$ ).
Raz and Stamm, 1993 <sup>114</sup>	93 Postmenopausal women with recurrent UTIs 50 active group 43 placebo	Estriol	Vaginal cream	8 months	Significant reduction in the incidence of UTIs in the group given estriol compared with placebo ( $P < .001$ )
Cardozo et al, 1998 <sup>116</sup>	72 Postmenopausal women with recurrent UTIs 36 active group 36 placebo	Estriol	Oral	6-month treatment period with another 6 months of follow-up	Reduction in urinary symptoms and incidence of UTIs in both groups; estriol no better than placebo
Eriksen, 1999 <sup>117</sup>	108 Women with recurrent UTIs 53 active group 55 no treatment	Estradiol	Estring	36 weeks for the active group; 36 weeks or until first recurrence for the controls	Cumulative likelihood of remaining free of infection was 45% in active group and 20% in control group ( $P = .008$ )

UTI, urinary tract infection.

### Estrogens in the Management of Urogenital Atrophy

Symptoms of urogenital atrophy do not occur until the levels of endogenous estrogen are lower than those required to promote endometrial proliferation.<sup>118</sup> Consequently, it is possible to use a low dose of estrogen replacement therapy to alleviate urogenital symptoms while avoiding the risk of endometrial proliferation and removing the necessity of providing endometrial protection with progestogens.<sup>119</sup> The dose of estradiol commonly used in systemic estrogen replacement is usually 25 µg to 100 µg, although studies investigating the use of estrogens in the management of urogenital symptoms have shown that 8 µg to 10 µg of vaginal estradiol are effective.<sup>120</sup> Only 10% to 30% of the dose used to treat vasomotor symptoms may be effective in the management of urogenital symptoms. Because 10% to 25% of women receiving systemic HRT still experience the symptoms of urogenital atrophy,<sup>121</sup> low-dose local preparations may have an additional beneficial effect.

The HUT Committee<sup>122</sup> reviewed estrogen therapy in the management of urogenital atrophy. Ten randomized trials and 54 uncontrolled series conducted between 1969 and 1995 assessed 24 treatment regimens. Meta-analysis of 10 placebo-controlled trials confirmed the significant effect of estrogens in the management of urogenital atrophy (Table 5-3).

The route of administration was assessed, and oral, vaginal, and parenteral (i.e., transcutaneous patches and subcutaneous implants) were compared. Overall, the vaginal route of adminis-

tration correlated with better symptom relief, greater improvement in cytologic findings, and higher serum estradiol levels.

Estradiol was found to be the most effective type of estrogen preparation in reducing patient symptoms. Conjugated estrogens produced the most cytologic change and the greatest increase in serum levels of estradiol and estrone.

The effect of different dosages was examined. Low-dose vaginal estradiol was found to be the most efficacious according to symptom relief, although oral estriol was also effective. Estriol had no effect on the serum levels of estradiol or estrone, and vaginal estriol had a minimal effect. Vaginal estradiol was found to have a small effect on serum estrogen levels, although not as great as systemic preparations. These findings indicate that estrogen is efficacious in the treatment of urogenital atrophy and that low-dose vaginal preparations are as effective as systemic therapy.

The use of a low-dose, estradiol-releasing silicone vaginal ring (Estring) continuously releasing estradiol (5 to 10 µg/24 hr) was investigated in postmenopausal women with symptomatic urogenital atrophy.<sup>111</sup> There was a significant effect on symptoms of vaginal dryness, pruritus vulvae, dyspareunia, and urinary urgency, with improvement reported for more than 90% of women in an uncontrolled study. Patient acceptability was high, and although the maturation of vaginal epithelium was significantly improved, there was no effect on endometrial proliferation.

**Table 5-3 Randomized, Controlled Trials Assessing the Use of Estrogens in the Management of Urogenital Atrophy**

Study	Year	Estrogen	Route
Bellatoni et al <sup>129</sup>	1991	Estradiol	Transdermal
Campbell et al <sup>130</sup>	1977	Conjugated estrogen	Oral
Campbell et al <sup>130</sup>	1977	Conjugated estrogen	Oral
Eriksen and Rasmussen <sup>107</sup>	1992	Estradiol	Pessary
Felding et al <sup>131</sup>	1992	Estradiol	Pessary
Foidart et al <sup>132</sup>	1991	Estriol	Vaginal cream
Laufer et al <sup>133</sup>	1983	Estradiol	Transdermal
Mettler and Olsen <sup>119</sup>	1991	Estradiol	Pessary
Molander et al <sup>134</sup>	1990	Estriol	Oral
Raz and Stamm <sup>114</sup>	1993	Estriol	Vaginal cream
Van der Linden et al <sup>135</sup>	1993	Estriol	Oral

These findings were supported by a 1-year multicenter study of Estring in postmenopausal women with urogenital atrophy, which found subjective and objective improvement in 90% of patients up to 1 year. However, there was a 20% withdrawal rate, with 7% of women reporting vaginal irritation, two having vaginal ulceration, and three complaining of vaginal bleeding, although there were no cases of endometrial proliferation.<sup>123</sup> Long-term safety was confirmed by a 10-year review of the use of the estradiol ring delivery system, which found its safety, efficacy, and acceptability to be comparable to other forms of vaginal administration.<sup>124</sup> A comparative study of safety and efficacy of Estring with conjugated equine estrogen vaginal cream in 194 postmenopausal women complaining of urogenital atrophy found no significant difference in vaginal dryness, dyspareunia, and resolution of atrophic signs between the two treatment groups. There was similar improvement in the vaginal mucosal maturation index and a reduction in pH in both groups, with the vaginal ring found to be preferable to the cream.<sup>125</sup>

## CONCLUSIONS

Estrogens have important physiologic effects on the female lower genital tract throughout adult life, leading to symptomatic, his-

tologic, and functional changes. Urogenital atrophy occurs with estrogen withdrawal after menopause, manifesting with vaginal and urinary symptoms. The use of estrogen replacement therapy has been examined in the management of lower urinary tract symptoms and in the treatment of urogenital atrophy, although only recently has it been subjected to randomized, placebo-controlled trials and meta-analyses.

Estrogen therapy alone has been shown to have little effect in the management of urodynamic stress incontinence, but when used in combination with  $\alpha$ -adrenergic agonists, it may lead to an improvement in urinary leakage. For the overactive bladder symptoms of urinary urgency, frequency, and urge incontinence, estrogen therapy may be of benefit, although it may cause reversal of urogenital atrophy rather than having a direct effect on the lower urinary tract. The role of estrogen replacement therapy in the management of women with recurrent lower urinary tract infections remains to be determined, but there is some evidence that vaginal administration may be efficacious. Low-dose vaginal estrogens have been shown to have a role in the treatment of urogenital atrophy in postmenopausal women and appear to be as effective as systemic preparations.

# SOCIAL IMPACT OF URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION

*Ilana Beth Addis*

Urinary incontinence is a common condition in women that in the past was considered an inevitable result of aging. As a result, little attention was paid to women who complained of the condition. They were expected to suffer silently, and because they were concerned about leakage, they often became housebound. Urinary incontinence is defined by the International Continence Society as an “involuntary loss of urine which is objectively demonstrable and a social or hygienic problem.”<sup>1</sup> With more focus placed on the problems of aging, specifically of aging women, we now know that urinary incontinence has many, wide-ranging effects on a woman’s daily activities, social interactions, and personal perceptions of wellness. Women with urinary incontinence, especially urgency, have a lower sense of general well-being compared with similar-aged women without this problem. Urinary incontinence does not have to be endured by every aging woman. It is often curable, and it is certainly manageable by a multitude of therapies.

Normal support of the vagina and pelvic organs is provided by an interaction between the levator ani muscle and the connective tissue supports constituting the pelvic diaphragm. When muscular function in the pelvis is normal, the pelvic organs are held over the levator plate and away from the genital hiatus, with increased intra-abdominal pressure pushing the pelvic organs into the hollow of the sacrum. The purpose of the connective tissue is to provide stabilization of the pelvic organs in relation to the pelvic muscles and to provide temporary support when the pelvic muscles are relaxed. *Pelvic floor dysfunction* is a term that is applied to a wide variety of clinical conditions, including urinary incontinence, pelvic organ prolapse, sensory abnormalities of the lower urinary tract, defecatory dysfunction, sexual dysfunction, and chronic pain syndromes. The most common conditions are urinary and fecal incontinence and pelvic organ prolapse. The pathophysiology of pelvic floor disorders includes a combination of genetic predisposition and acquired dysfunction of the muscular and connective tissue support systems.

This chapter provides a review of the epidemiology of urinary incontinence and pelvic floor dysfunction. In it, I discuss the prevalence, incidence, and risk factors of urinary incontinence and pelvic organ prolapse. The social, psychologic, sexual, and economic effects of female urinary incontinence and pelvic floor dysfunction also are addressed.

## URINARY INCONTINENCE

### Defining Urinary Incontinence

It is difficult to discuss urinary incontinence without discussing the definition of urinary incontinence. Various definitions have been used, depending on the goals of the definer, and according

to the International Continence Society, the definition of urinary incontinence has changed in the past 25 years. In 1979, urinary incontinence was “the involuntary loss of urine that is a social or hygienic problem and is objectively demonstrable.”<sup>2</sup> By 2002, urinary incontinence became “the complaint of any involuntary leakage of urine” with further description of frequency, severity, risk factors, social and hygienic impact, and effect on quality of life.<sup>1</sup> These changes were made to promote treatments based on symptoms, to facilitate comparison of results in research, and to help with effective communication between researchers. The most recent definition does not require incontinence to be demonstrable; rather, a complaint of urinary incontinence is enough to support a diagnosis of urinary incontinence, allowing for the fact that each woman’s perception of her incontinence is different.

### Incidence and Prevalence

Despite approved definitions of urinary incontinence, every study uses a slightly different definition. For example, in four studies published in 2000, the prevalence of incontinence ranged from 11% to 72%.<sup>3-6</sup> This wide range probably reflects the different populations studied and the differences in definitions of urinary incontinence that were used in each study. One review found that a study with a broad definition of urinary incontinence, such as any loss of urine in a 12-month period, had a higher prevalence rate than one defining urinary incontinence over a shorter period, such as the number of episodes in the past month.<sup>7</sup> When the definition of urinary incontinence in a study becomes even more specific, the result is that the prevalence numbers decrease. For example, in one study, incontinence was assessed by asking a series of detailed questions modified from epidemiologic studies, as opposed to asking just one or two questions. The result of this more detailed ascertainment was a slightly lower number of women with incontinence in the population than identified in previous studies, with only 21% of women over the age of 70 complaining of at least weekly urinary incontinence.<sup>8</sup> These differences speak loudly to the need for standardized definitions of urinary incontinence to achieve a more precise assessment of the scope of the problem.

Three types of incontinence are usually assessed in survey questionnaires. *Urge urinary incontinence* is urine loss associated with an overwhelming urge to void associated with rushing to the bathroom and not making it there in time. These women wear a pad to go out and often limit their social schedule. *Stress urinary incontinence* is loss of urine caused by increased physical activity, coughing, sneezing, or laughing. These women have limited their physical activity because of their incontinence. *Mixed urinary incontinence* incorporates aspects of stress and

urge incontinence in a woman's complaints. Mixed incontinence is often difficult to assess until certain therapies have been attempted. For example, a woman with stress and urge symptoms may be so significantly improved with behavioral modification, pelvic floor exercises, and medication for urgency that she does not notice her stress incontinence. Most studies report a higher rate of stress and mixed incontinence compared with urge incontinence.<sup>9,10</sup> An analysis of the world literature reports that stress incontinence is predominant at 49%, followed by mixed incontinence at 29% and urge incontinence at 22%.<sup>11</sup>

The various prevalence numbers for different varieties of incontinence also result from the inconsistent ages of populations studied and from the diverse populations evaluated. Each study has a new group of women with differences in age, ethnicity, and history such that it is difficult to generalize the results of the study to any other population. Incorrect estimates can also result from bias in data collection and underreporting due to embarrassment. In simple population surveys, most adult women report that they occasionally leak drops of urine with physical exercise, and up to 46% of community-dwelling women complain about some degree of urinary incontinence.<sup>12,13</sup> These numbers underscore the magnitude of this issue and the importance of reporting valid data.

### Risk Factors

Women who exercise report more urinary incontinence. Studies by Nygaard and associates<sup>14,15</sup> found that as many as 30% of women complain of urinary leakage during physical activity. The highest rate (38%) was reported in runners. The same researchers demonstrated that even among young, nulliparous women, up to 28% report incontinence with exercise.<sup>14,15</sup> Another study found that up to 80% of elite trampolinists reported involuntary urine leakage.<sup>16</sup> Although this is an extreme example, it does make the point that high-impact sports lead to more urinary incontinence in women.

As our population ages, the prevalence of urinary incontinence will increase. According to the United States Bureau of Census, the number of postmenopausal women in the population will increase from 23% of the total population in 1995 to 33% in 2050, and the proportion of women older than 85 years will triple in the same period.<sup>17</sup> In women with incontinence, the rate of stress incontinence peaks between 45 and 49 years of age and then begins to slowly decrease with further aging.<sup>3</sup> This decrease in stress urinary incontinence may reflect the decrease in activity that usually occurs with aging, leading to a concomitant decrease in urinary incontinence. Although there is a decrease in stress urinary incontinence, the prevalence of any incontinence increases with age in a linear fashion from 3% to 34.7% in young women to 25% to 59.5% in women older than 60 years. This statistic highlights the increase in urge urinary incontinence and the prevalence of that problem later in life.

More than 70% of women living in nursing homes report urinary incontinence.<sup>18-20</sup> Urinary incontinence reported by nursing home residents often has causes other than detrusor overactivity or hypermobility of the urethra. These women can have problems with chronic disease, decreased mobility, and medications that cause urinary incontinence.

Urinary incontinence is two to three times more common in women than in men. There is a very low prevalence of urinary incontinence in men younger than 60 years, whereas incontinence in women steadily increases starting at a much younger

age. Men are very unlikely to report stress incontinence, severe incontinence, or irritative bladder symptoms. The anatomic differences between men and women and the risk factors that women face, such as childbirth and hysterectomy, cause them to have more problems with stress urinary incontinence. Men are, however, much more likely to report voiding difficulties due to prostate problems as they age and their prostates enlarge.<sup>21</sup>

Several studies have shown an association between childbirth and urinary incontinence.<sup>22-24</sup> Stress incontinence shows the strongest correlation with parity, whereas there is little correlation between parity and urgency incontinence; rather, aging is more strongly associated with this problem. Vaginal birth may directly damage the pelvic muscles and connective tissues that are necessary for pelvic floor support and for functioning of the urethra. Vaginal birth also leads to a loss of pelvic muscle strength in the immediate postpartum period that gradually returns, something not seen after cesarean section. Studies have also shown that there is an increased risk of urinary incontinence after surgical vaginal delivery compared with cesarean section that lasts for at least 3 years.<sup>25</sup> The debate over whether cesarean section prevents urinary incontinence is ongoing, with arguments from both sides and many physicians caught in the middle.

It had been thought that menopause was a risk factor for lower urinary tract symptoms and urinary incontinence. Atrophic vaginitis of menopause is associated with a multitude of symptoms, including vaginal dryness, burning, and irritation; urinary urgency and frequency; stress urinary incontinence; and recurrent urinary tract infections. The atrophy caused by estrogen deficiency is in part responsible for sensory urogenital symptoms and for the decreased resistance to infection seen in menopausal women. The value of estrogen replacement in this situation, however, is debatable. In two randomized, controlled trials of estrogen and progestin or estrogen alone versus placebo in menopausal women, there was no difference in urinary tract infection rates in the patients who received hormone therapy.<sup>26,27</sup> In another trial, low-dose estriol reduced the frequency of urinary tract infections in menopausal women.<sup>28</sup> Another study showed that intravaginal estriol reduced the risk of recurrent urinary tract infections.<sup>29</sup> Hormone therapy for urinary incontinence has been evaluated in many randomized, controlled trials. In the Heart and Estrogen/Progestin Replacement Study (HERS), no difference was found in incontinence improvement between the hormone therapy group and the placebo group, and hormone therapy seemed to exacerbate incontinence more than the placebo group.<sup>30</sup> Another randomized trial also demonstrated no difference between the estrogen group and the placebo group for improvement of stress urinary incontinence.<sup>31</sup> In a trial of estrogen for urgency incontinence, there was no difference between the hormone group and the placebo group.<sup>32</sup> The conclusion can be made that frequent urinary tract infection in menopausal women can be treated with intravaginal estrogen if there is an element of atrophy involved with the bladder infection.

Obesity and hysterectomy have been thought to be risk factors for urinary incontinence, although much of the evidence is conflicting. Obesity is more common in women with urinary incontinence than in continent women. It is possible that obese women have higher intra-abdominal pressures that overwhelm the continence mechanism. Weight loss has been shown to improve incontinence that is primarily stress related.<sup>33-38</sup> Hysterectomy has been associated with incontinence in some observational studies, but in others, there was no difference between women

who had had a hysterectomy and those who had not had surgery.<sup>24,39,40</sup>

### Psychosocial Impact

Approximately 31% to 38% of community-dwelling, middle-aged and older women have urinary incontinence, making it a very common chronic health condition among women of many ages.<sup>41,42</sup> The International Continence Society defines urinary incontinence as “a condition in which involuntary loss of urine is a social or hygienic problem.” By this definition, every woman with urinary incontinence has some social distress.<sup>12,43,44</sup> Because many women believe that urinary incontinence is a normal consequence of childbirth and aging, they avoid seeking therapy.<sup>45</sup> The burden of urinary incontinence reflects experiences from many aspects of life. Urinary incontinence can affect physical, psychosocial, and economic well-being. Women with urinary incontinence can experience psychologic distress, social isolation and loneliness, increased falls, and increased health care use.<sup>46-50</sup> The monetary costs of urinary incontinence have been estimated at \$3565 per incontinent person.<sup>51</sup>

Many studies suggest an association between urinary incontinence and depression and anxiety,<sup>52-54</sup> whereas some suggest only a weak association between urinary incontinence and psychological well-being.<sup>48</sup> There seem to be ethnic differences in distress about urinary incontinence. African American women with urinary incontinence have higher rates of psychological distress than those without urinary incontinence, whereas there is a much weaker association between urinary incontinence and psychological distress among white women.<sup>46</sup> This difference in reactions may reflect the fact that urinary incontinence is less common in African American women and therefore is seen as more of a problem. Despite the apparent bother of urinary incontinence, many women do not discuss this problem with their physicians. The reasons include embarrassment, feelings that incontinence is a natural part of aging, and a belief that there is nothing to help the problem.

Almost 75% of women with stress urinary incontinence are at least slightly bothered by their symptoms, and about 29% moderately to extremely bothered by their incontinence. The frequency and duration of symptoms and the existence of comorbid conditions are associated with increased annoyance by stress urinary incontinence. Fifty-four percent of women who are bothered by their symptoms feel that their symptoms have at least a moderate impact on certain aspects of their lives, including physical activity, self-confidence, daily activities, and social activities.<sup>10</sup> Urinary incontinence does not just affect older women in the psychosocial realm. One study demonstrated that urinary stress incontinence negatively affected the quality of life, work performance, and sexual activity of young and middle-aged women. Urinary incontinence in this group of women caused distress for them emotionally, physically, and socially.<sup>55</sup>

Some forms of urinary incontinence have a more detrimental social impact than others.<sup>56</sup> Urge urinary incontinence has a greater effect on quality of life than stress incontinence.<sup>57-60</sup> In a study of primarily urge urinary incontinence, the women reported generalized anxiety and concern about location of the bathroom. They also reported concern about dating and sexual activity. Women younger than 70 years reported feeling unattractive and having more feelings of low self-esteem.<sup>61</sup>

Loss of urinary control affects the social, psychological, domestic, occupational, physical, and sexual lives of 15% to 30%

of women of all ages.<sup>62</sup> Women who perceive urinary incontinence as a disease and those with a higher degree of quality-of-life impact are more likely to seek medical help.<sup>63</sup> Quality-of-life issues seem to be more important than objective outcome measures for most patients.<sup>64</sup> One study demonstrated that the perceived degree of urinary incontinence significantly affected quality of life. Women who perceive their symptoms as being moderate or severe have a significantly lower quality of life.<sup>65</sup> This response was entirely independent of the severity of symptoms determined by objective measures such as a diary or urodynamic testing.

In assessing the economic impacts of urinary incontinence, many studies focus on the cost of caring for elderly incontinent people in nursing homes. This type of data is easier to obtain than that from patients in a community setting.<sup>66</sup> When estimating costs of urinary incontinence, direct and indirect expenses should be included. Direct costs are the resources used to diagnose, treat, care for, and rehabilitate incontinent patients. Indirect costs include lost productivity, missed days of work, time spent by caregivers, and the consequences of incontinence from problems such as skin breakdown or falls and its impact on death rates.<sup>67</sup> A study conducted in 2005 found that although admissions and inpatient stays for urinary incontinence decreased from 1994 to 2000, outpatient visits more than doubled for the same period. While inpatient surgery rates decreased during this time, rates of outpatient surgery were more than doubled. Medical expenditures for urinary incontinence also greatly increased during the 1990s, doubling from 1992 to 1998 for Medicare beneficiaries.<sup>68</sup> Urinary incontinence increases the risk of hospitalization by more than 30% and is believed to be a significant factor for institutionalization among the elderly.<sup>69</sup> One study shows that urinary incontinence doubles the risk of admissions to nursing homes, independent of age and the presence of other diseases.<sup>50</sup>

## PELVIC ORGAN PROLAPSE

### Definition and Prevalence

Pelvic organ prolapse can be defined as any descent of the uterus or anterior or posterior vagina into the potential space of the vagina. With this definition, 30% to 40% of older women have had some degree of prolapse.<sup>70,71</sup> A newer definition uses the stages of prolapse proposed by the International Continence Society using the pelvic organ prolapse quantification system. This definition is translated into a 0 to 4 staging system. Stage 1 is minor vaginal descensus, and stages 2 and above are believed to be more clinically relevant degrees of prolapse. Prevalence estimates for pelvic organ prolapse range from 2% to 50%, depending on the severity of the prolapse and the definition that is used.<sup>72</sup> In a group of women from the Women’s Health Initiative Study, 65.5% had prolapse of stage 2 or above. Risk factors for significant pelvic organ prolapse include a history of hysterectomy, lower education level, and a greater number of vaginal deliveries.<sup>73</sup>

Women with prolapse can be asymptomatic with regard to bladder, bowel, and sexual dysfunction, or they can have various complaints. Some of the symptoms associated with advanced prolapse are urgency, frequency, and voiding difficulties. It is difficult to tell whether other symptoms, such as sexual dysfunction, have any relation to severity of prolapse or are multifactorial, with one aspect of the sexual dysfunction being related to

prolapse.<sup>74-77</sup> Pelvic organ prolapse is the most common indication for hysterectomy in women older than 55 years.<sup>78</sup> In the United States, rates of surgery for pelvic organ prolapse vary by age, race, and region of the country. Approximately 200,000 women underwent surgery for pelvic organ prolapse between 1979 and 1997, making prolapse one of the most common surgical indications in women.<sup>73,79</sup> The lifetime risk for undergoing surgery for prolapse or incontinence is 11%.<sup>80</sup> Surgery for prolapse, because it is so common, likely has its own impact on quality of life when immediate and long-term postoperative recovery is taken into account.

As with urinary incontinence, pelvic organ prolapse reduces the quality of life.<sup>81</sup> One study found that surgery for pelvic organ prolapse or urinary incontinence improved the quality of life for women who received this treatment.<sup>82</sup> Research shows that conservative therapy also greatly improves the quality of life of these women.<sup>83,84</sup> The use of nonsurgical therapy, such as biofeedback and pelvic floor rehabilitation, for urinary incontinence and pelvic organ prolapse can greatly help with very little risk to the patient.

### PSYCHOSOCIAL IMPACT OF URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION IN CLINICAL PRACTICE

It is difficult to interpret the research on the social implications of urinary incontinence and pelvic floor dysfunction and apply this information to current clinical practice. The experience of each woman is different, and the actuality of incontinence should

be separated from the woman's experience of the problem. The lived experience of incontinence is very dissimilar for different groups of women and for women of different ages.<sup>41,85</sup>

Incontinent women do share some burdens. Many do not report their incontinence to their health care provider and may live for years without medical treatment. Only one of four eventually seeks help from her physician. Reasons for not discussing this problem with a physician include social embarrassment, fear of surgery, belief that urinary incontinence is a natural part of aging, and lack of knowledge or information about the condition and its management.<sup>7</sup> In the past, urinary incontinence has been marginalized by physicians, and patients have been dissatisfied with their interactions with health care professionals, making them wary of presenting for treatment or returning for worsening of symptoms.<sup>86</sup> Only recently has innovative therapy been introduced for urinary incontinence and pelvic floor dysfunction, so that women now have a choice of treatment options.

A sensitive approach to the subject of urine leakage is required while taking a woman's history and performing the physical examination. It is sometimes helpful to have a woman complete her pelvic floor history form and voiding diary before her initial visit to help her feel more at ease with the subject. Women often are able to describe the problem in more detail when given adequate time to think about it. Continuing public information and patient education allow women to recognize incontinence as a treatable symptom and encourage them to seek solutions for this problem. The complaint of urinary incontinence should be addressed at every annual visit and should then be taken as seriously as any other health problem.

# CLINICAL EVALUATION OF LOWER URINARY TRACT SYMPTOMS

*Jerry G. Blaivas and Jaspreet Sandha*

Diagnostic evaluation of voiding dysfunction in women commences with a focused but detailed history and physical examination. Various diagnostic tests and instruments are used to determine the nature and severity of the symptoms. These may be divided into subjective, semi-objective, and objective instruments. Subjective information is obtained from the patient's history. Semi-objective data are obtained from self-reported diaries, pad tests, and validated questionnaires. Objective data are obtained by physical examination, laboratory tests, radiologic studies, ultrasound imaging, urodynamic studies, and cystoscopy. The collection of subjective, semi-objective, and objective data should continue during and after treatment to determine outcomes.

The spectrum of voiding dysfunction ranges from mild stress urinary incontinence to severe neurologic disease resulting in upper tract deterioration. Because the patient's symptoms are not necessarily proportional to the degree of bladder or renal involvement, a systematic approach should be taken in assessing all aspects of voiding dysfunction.

## LOWER URINARY TRACT SYMPTOMS

### Standardization

What follows is based on the International Continence Society (ICS) Standardization Report, except where specifically stated to be otherwise.<sup>1</sup> The ICS divides lower urinary tract symptoms into three groups: storage, voiding, and postmicturition. However, the ICS also recognizes a number of pain syndromes that are poorly defined and cannot be easily classified. Storage symptoms include daytime frequency, urgency, incontinence, nocturia, and pain. Voiding symptoms are experienced during the voiding phase and include slow stream, splitting or spraying of the stream, intermittent stream, hesitancy, straining to void, and terminal dribble. Postmicturition symptoms are experienced immediately after micturition and include a feeling of incomplete emptying, postmicturition dribble, or pain.

### Storage Symptoms

*Urinary frequency* (i.e., pollakisuria) is defined as eight or more voids per 24 hours. *Urinary urgency* is defined by the ICS as “the complaint of a sudden, compelling desire to pass urine, which is difficult to defer.” We think this definition is too restrictive. Many patients feel a “compelling desire to void” that is not sudden, and others feel uncomfortable, annoying feelings in their bladder that make them think they should void frequently, but the desire is really not compelling. There are currently no single other words or phrases to capture these symptoms.

*Urinary incontinence* is the involuntary loss of urine. It denotes a symptom, a sign, and a condition. It indicates the patient's (or caregiver's) statement of involuntary urine loss. The sign is the objective demonstration of urine loss. The condition is the pathophysiology underlying incontinence as demonstrated by clinical, cystoscopic, or urodynamic techniques. The symptoms of incontinence include stress, urge, mixed, unaware, continuous, and nocturnal enuresis.<sup>1,2</sup>

*Stress urinary incontinence* is the complaint of involuntary leakage on effort or exertion or on sneezing or coughing, and *urge incontinence* is the complaint of involuntary leakage accompanied by or immediately preceded by urgency. *Mixed urinary incontinence* is the complaint of involuntary leakage associated with urgency and with exertion, effort, sneezing, or coughing. *Enuresis* means any involuntary loss of urine, and *nocturnal enuresis* is the complaint of loss of urine occurring during sleep. *Continuous urinary incontinence* is the complaint of continuous leakage. *Other types of urinary incontinence* may be situational, such as the report of incontinence during sexual intercourse or giggle incontinence.

## CAUSES OF URINARY INCONTINENCE

Urinary incontinence can be further divided into urethral and extraurethral incontinence. Extraurethral causes of incontinence include an ectopic ureter opening into the vagina and urinary fistula. Urethral incontinence is caused by bladder abnormalities, sphincter abnormalities, or combinations of both. Cognitive abnormalities and physical immobility, although not the proximate causes of incontinence, are important cofactors that should be taken into account for the diagnosis and treatment. For example, a woman with mild urgency and severe Parkinson's disease may develop disabling incontinence because it takes her too long to get to the bathroom.

The conditions causing urinary incontinence may be presumed or definite.<sup>2</sup> Definite conditions are documented by urodynamic or other objective techniques. Presumed conditions are documented clinically. For example, a neurologically normal woman who complains of urge incontinence despite a normal cystometrogram is considered to have presumed detrusor overactivity provided that sphincter abnormalities and overflow incontinence have been excluded. If the cystometrogram documents involuntary detrusor contractions, the diagnosis is definite detrusor overactivity.

### Urethral Incontinence

Bladder abnormalities causing urinary incontinence include detrusor overactivity and low bladder compliance. *Detrusor*

**Table 7-1 Detrusor Overactivity: Causes and Associated Conditions**

Idiopathic detrusor overactivity
Non-neurogenic detrusor overactivity
Bladder outlet obstruction
Sphincteric incontinence
Postoperative (anti-incontinence, prolapse)
Bladder infection
Bladder tumor
Bladder stones
Foreign body
Neurogenic detrusor overactivity
Supraspinal neurologic lesions
Stroke
Parkinson's disease
Hydrocephalus
Brain tumor
Traumatic brain injury
Multiple sclerosis
Suprasacral spinal lesions
Spinal cord injury
Spinal cord tumor
Multiple sclerosis
Myelodysplasia
Transverse myelitis

*overactivity* is a generic term for involuntary detrusor contractions, defined by the ICS as a “urodynamic observation characterized by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked.” The ICS subdivides detrusor overactivity into idiopathic (i.e., non-neurogenic) and neurogenic detrusor overactivity. We have modified this classification as follows:

*Idiopathic detrusor overactivity* denotes involuntary detrusor contractions that are not associated with neurologic disorders or other conditions known to be associated with involuntary detrusor contractions.

*Neurogenic detrusor overactivity* denotes involuntary detrusor contractions that are caused by neurologic conditions.

*Non-neurogenic detrusor overactivity* denotes involuntary detrusor contractions that are associated with conditions thought to be related to detrusor overactivity, such as urethral obstruction and stress incontinence.<sup>3,28,29</sup> The causes of detrusor overactivity are depicted in Table 7-1.

*Low bladder compliance* denotes an abnormal (decreased) volume-pressure relationship during bladder filling. Low bladder compliance is recognized by a steep rise in detrusor pressure during bladder filling. Causes of low bladder compliance are provided in Table 7-2.

### Sphincter Abnormalities Causing Urinary Incontinence

It has long been thought that sphincter abnormalities that cause urinary incontinence were of two generic types—urethral hypermobility and intrinsic sphincter deficiency—and many clinicians still adhere to this concept.<sup>4-6</sup> According to this classification, urethral hypermobility is characterized by rotational descent of the vesical neck and proximal urethra during increases in abdominal pressure.<sup>4-11</sup> If the urethra opens concomitantly, stress urinary

**Table 7-2 Causes of Low Bladder Compliance**

Neurogenic causes
Myelodysplasia
Shy-Drager syndrome
Suprasacral spinal cord injury or lesion
Radical hysterectomy
Abdominoperineal resection
Non-neurogenic causes (i.e., increased collagen)
Chronic indwelling catheter
Bladder outlet obstruction
Chronic cystitis (e.g., radiation, tuberculous, bilharzial)

incontinence ensues. The basic abnormality causing urethral hypermobility is a weakness of the pelvic floor. Intrinsic sphincteric deficiency denotes an intrinsic malfunction of the urethral sphincter itself.<sup>4,12</sup> Clinically, intrinsic sphincter deficiency manifests by a low leak point pressure and is most commonly seen in three circumstances: after surgery on the urethra, vagina, or bladder neck; as a consequence of a neurologic lesion that involves the nerves to the vesical neck and proximal urethra; and in the elderly.<sup>4,12,13</sup> It had also been accepted that urethral hypermobility and intrinsic sphincter deficiency often coexist in the same patient.<sup>14</sup>

The validity of the concept of urethral hypermobility as a sole cause of urinary incontinence has been challenged, and several investigators have shown that there is no relationship between vesical leak point pressure and urethral mobility.<sup>15,16</sup> For that reason, we no longer use the term *intrinsic sphincter deficiency*, but instead characterize sphincteric incontinence by two parameters, vesical leak point pressure and urethral mobility, as measured by the Q-tip test.<sup>7,17</sup>

### Overflow Incontinence

Overflow incontinence is the leakage of urine associated with incomplete bladder emptying caused by impaired detrusor contractility or bladder outlet obstruction. The pathophysiology of overflow incontinence has not been studied very well. Conceptually, the leakage must be caused by an overactive detrusor or a relative sphincter deficiency.

### SYMPTOMS, SIGNS, AND CONDITIONS CAUSING INCONTINENCE

The symptoms of incontinence are elicited by the patient's history, questionnaires, voiding diaries, and pad test. Symptoms can and should be reproduced during urodynamic studies. The signs are assessed by examination and urodynamic studies. The conditions are the underlying pathophysiologies. Table 7-3 lists symptoms and conditions that cause urinary incontinence.

Urge incontinence has the following characteristics:

*Symptom:* The symptom of urge incontinence is the complaint of the involuntary loss of urine immediately preceded by urgency.

*Sign:* The sign of urge incontinence is the observation of involuntary urine loss from the urethra synchronous with an uncontrollable urge to void. Urodynamically, the sign is the presence of detrusor overactivity incon-

**Table 7-3 Storage Symptoms and the Conditions That Cause Urinary Incontinence**

Symptom	Conditions
Urinary frequency	Polyuria Sensory urgency Detrusor overactivity Low bladder compliance Acquired behavior (e.g., defensive voiding)
Urgency or urge incontinence	Sensory urgency Detrusor overactivity Low bladder compliance
Stress incontinence	Urethral hypermobility Intrinsic sphincter deficiency Stress hyperreflexia
Unaware incontinence*	Detrusor overactivity Sphincter weakness Extra-urethral incontinence
Continuous leakage	Sphincter weakness Extra-urethral incontinence
Nocturnal enuresis	Detrusor overactivity Sphincter weakness Extra-urethral incontinence
Postvoid dribble	Urethral diverticulum Urethral obstruction Vaginal voiding
Extra-urethral incontinence	Urinary fistula Ectopic ureter

\*Not part of International Continence Society (ICS) definitions.

tinence (i.e., incontinence due to an involuntary detrusor contraction).

*Condition:* The condition of urge incontinence is caused by detrusor overactivity.

Stress incontinence has the following characteristics:

*Symptom:* The symptom of stress incontinence is the complaint of involuntary loss of urine during coughing, sneezing, or physical exertion, such as sport activities or sudden changes of position.

*Sign:* The sign of stress incontinence is the observation of loss of urine from the urethra synchronous with coughing, sneezing, or physical exertion.

*Condition:* The condition of stress incontinence may be caused by an underactive sphincter or detrusor overactivity, presumably caused by an increase in abdominal pressure. This is called *stress hyperreflexia*, but it is not part of the ICS lexicon.

Unconscious incontinence has the following characteristics:

*Symptom:* The symptom of unconscious incontinence is the involuntary loss of urine that is unaccompanied by urge or stress. The patient may be aware of the incontinent episode by feeling wetness or by other associated symptoms such as the onset of autonomic dysreflexia with spinal cord injury.

*Sign:* The sign of unconscious incontinence is the observation of loss of urine without patient awareness of urge or stress.

*Condition:* The condition of unconscious incontinence may be caused by detrusor overactivity, sphincter abnormalities, overflow, or extraurethral incontinence.

Continuous leakage has the following characteristics:

*Symptom:* The symptom of continuous leakage is the complaint of a continuous, involuntary loss of urine.

*Sign:* The sign of continuous leakage is the observation of a continuous urinary loss.

*Condition:* The condition of continuous leakage may be caused by sphincter abnormalities or extraurethral incontinence.

Nocturnal enuresis has the following characteristics:

*Symptom:* The symptom of nocturnal enuresis is the complaint of urinary loss that occurs only during sleep.

*Sign:* The sign of nocturnal enuresis is the observation of urinary loss during sleep.

*Condition:* The condition of nocturnal enuresis may be caused by a sphincter abnormality, detrusor overactivity, or extra-urethral incontinence.

A precise diagnosis of urinary incontinence is best attained when it is witnessed by the examiner. In most instances, it makes little difference whether the urinary loss is visualized during physical examination with a full bladder (i.e., Marshall or Bonney test), at cystoscopy, cystometry, or by x-ray imaging. Regardless of the method of observation, when urinary loss is visualized from the urethral meatus, the observations and measurements of the astute clinician usually can pinpoint the underlying abnormality and direct appropriate treatment.

### Voiding Symptoms

Voiding symptoms are experienced during the voiding phase and include slow stream, splitting or spraying of the urine stream, intermittent stream (i.e., stopping and starting during micturition), hesitancy (i.e., difficulty in initiating micturition, resulting in a delay in the onset of voiding after the individual is ready to pass urine), straining to void, and terminal dribble (i.e., prolonged final part of micturition when the flow has slowed to a trickle or dribble). The conditions underlying these symptoms include urethral obstruction, impaired or absent detrusor contractility, detrusor–external sphincter dyssynergia, and voiding at low bladder volumes. Pain during voiding may be caused by urinary tract infection, urethral stricture, urethral diverticulum, foreign body, or stone.

### Pain

During storage, suprapubic or retropubic pain that increases with bladder filling and subsides immediately after voiding is most likely caused by the bladder; if the pain persists after voiding, the source is more difficult to assess. The relationship between other sites of pain is confounding, and a cause-and-effect relationship usually can only be inferred for the urethra, vulva (in and around the external genitalia), vaginal (internally, above the introitus), and perineum (between the posterior fourchette and the anus). The term *pelvic pain* is used when patients describe a pain “down there” but cannot pinpoint its location.

*Painful bladder syndrome* is the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and nighttime frequency, in the absence of proven urinary infection or other obvious pathology. We think

interstitial cystitis should be considered in this category because, in contradistinction to the National Institutes of Health consensus recommendations,<sup>18</sup> there are no diagnostic cystoscopic or histologic features that can be used to distinguish these two terms. Interstitial cystitis has connotations of incurability and chronicity—allusions that are not necessarily warranted in many of the patients burdened by such a diagnosis. The differential diagnosis includes pelvic floor myalgia, endometriosis, chronic cystitis (e.g., radiation, tuberculous, bilharzial), low bladder compliance, urethral diverticulum, bladder cancer, bladder stones, and a foreign body.

*Urethral pain syndrome* is recurrent episodic urethral pain that usually occurs on voiding, often with daytime frequency and nocturia. The differential diagnosis includes urethritis (unspecified), vaginitis, pelvic floor myalgia, urethral diverticulum, urethral stricture, and tumor.

*Vulvar pain syndrome* (i.e., vulvodynia) is the occurrence of persistent or recurrent episodic vulval pain. The differential diagnosis includes pelvic organ prolapse, vaginitis, and tumor.

*Vaginal pain syndrome* is the occurrence of persistent or recurrent episodic vaginal pain that is associated with symptoms suggesting urinary tract or sexual dysfunction. The differential diagnosis includes vaginitis, prolapse, urethral diverticulum, endometriosis, pelvic floor myalgia, and tumor.

*Perineal pain syndrome* is the occurrence of persistent or recurrent episodic perineal pain, which is related to the micturition cycle or associated with symptoms suggesting urinary tract or sexual dysfunction. The differential diagnosis includes pelvic organ prolapse, endometriosis, pelvic floor myalgia, urethral diverticulum, and tumor.

In addition to the specific symptoms listed previously, several clinical symptoms and syndromes warrant special mention. For most of the pain symptoms, the cause remains speculative. The ICS suggests that these terms be used when “there is no proven infection or other obvious pathology.”<sup>21</sup> We disagree. We find these terms useful to describe symptoms just as one would use the word *headache* to describe pain in the head from any source, even migraine, brain tumor, or stroke. Moreover, some experts believe that all of these pain syndromes can be the result of a kind of pelvic floor myalgia that results from muscular spasm associated with emotional stress or an acquired behavior resulting from prior painful experiences that could be as simple as bacterial cystitis.

### Detrusor Sphincter Dyssynergia

Detrusor–external sphincter dyssynergia is a condition characterized by involuntary sphincter contractions during involuntary detrusor contractions. It is seen exclusively in patients with neurologic disorders that interrupt the normal spinal neuronal circuits of micturition (between the pontine and sacral micturition centers).<sup>20,21</sup> It is essentially a urodynamic diagnosis characterized by increased sphincter electromyographic activity during an involuntary detrusor contraction and narrowing of the distal third of the urethra on voiding cystourethrography.<sup>21</sup> Detrusor–external sphincter dyssynergia is a serious condition that, untreated, leads to urinary retention, ureteral obstruction, vesicoureteral reflux, stones, infection, upper tract deterioration, and renal failure. It should not be confused with acquired voiding dysfunction.

### Acquired Voiding Dysfunction

Acquired voiding dysfunction (i.e., learned voiding dysfunction, dysfunctional voiding, or Hinman’s syndrome) is often confused

with detrusor–external sphincter dyssynergia because the urodynamic findings are similar.<sup>22,25–28</sup> In detrusor–external sphincter dyssynergia, the increased electromyographic activity (when detected by needle electrodes placed directly in the urethral or periurethral striated muscles) precedes the onset of the involuntary detrusor contraction.<sup>21</sup> In acquired voiding dysfunction, there is a period of electromyographic silence that precedes the involuntary detrusor contraction, followed by increased electromyographic activity during the contraction (i.e., the acquired dysfunction). In childhood, acquired voiding dysfunction (i.e., Hinman’s syndrome) is postulated to be caused by improper toilet training, resulting in prolonged times between voiding, or “holding urine” to prevent urinary loss, resulting in increased sphincter tone while voiding. It can also be associated with constipation, recurrent urinary tract infection, low bladder compliance, hydronephrosis, and vesicourethral reflux. In children and adults, it can be caused by recurrent painful experiences associated with voiding, such as cystitis and local trauma.

### Overactive Bladder

Overactive bladder is defined by the ICS as “urgency, with or without urge incontinence, usually with frequency and nocturia . . . if there is no proven infection or other etiology.”<sup>21</sup> From a practical standpoint, we believe that this definition is much too restrictive, and in contradistinction to the ICS definition consider overactive bladder to be a symptom complex caused by one or more of the following conditions: detrusor overactivity, sensory urgency, and low bladder compliance. *Sensory urgency* is a term (abandoned by the ICS) that refers to an uncomfortable need to void that is unassociated with detrusor overactivity. Common conditions causing or associated with overactive bladder are diverse and include urinary tract infection, urethral obstruction, pelvic organ prolapse, sphincteric incontinence, urethral diverticulum, bladder stones or a foreign body, and bladder cancer. In women with overactive bladder, diagnostic evaluation should be directed at early detection of these conditions, because in many instances, the symptoms are reversible if the underlying cause is successfully treated.

### Pelvic Prolapse

Prolapse refers to a protrusion of the bladder (i.e., cystocele), urethra (i.e., urethrocele), rectum (i.e., rectocele), intestine (i.e., enterocele), or uterus (i.e., uterine prolapse) past the ordinary anatomic confines of the affected organ. Women with pelvic prolapse may be asymptomatic, or they may complain of concomitant voiding, bowel, or other pelvic symptoms. The severity of symptoms may not correlate at all with the degree of prolapse. A large prolapse can cause extrinsic urethral or ureteral obstruction with resultant hydronephrosis and recurrent urinary tract infection due to incomplete emptying. Prolapse may mask sphincteric incontinence, which becomes evident only after the prolapse is reduced manually or by a pessary or surgery.<sup>29</sup> Failure to take this into account can result in a high rate of incontinence after prolapse surgery. The ICS has described an objective, validated system for quantifying pelvic organ prolapse (POPQ).<sup>30</sup> The POPQ describes the topographic position of six vaginal sites and gives information regarding perineal descent and the change in axis of the levator plate based on increases in the genital hiatus and perineal body measurements. Table 7-4 and Figure 7-1 depict the ICS POP quantification and staging system.

**Table 7-4 International Continence Society Pelvic Organ Prolapse Quantification and Staging System**

Stage	Description
0	No prolapse is demonstrated.
1	The most distal portion of the prolapse is greater than 1 cm above the level of the hymen.
2	The most distal portion of the prolapse is less than 1 cm above or below the level of the hymen.
3	The most distal portion of the prolapse is greater than 1 cm below the level of the hymen but protrudes no more than 2 cm less than the total vaginal length.
4	There is complete eversion of the total length of the lower genital tract. The distal portion of the prolapse protrudes by at least 2 cm less than the total vaginal length.

From Bump et al.<sup>30</sup>

Prolapse is caused by loss of vaginal wall support and weakness in suspensory ligaments. Enterocoele may be further classified as congenital, acquired, pulsion, and traction. Congenital enteroceles result from an incomplete closure of the rectovaginal septum. Acquired enteroceles occur after bladder suspension procedures that cause widening of the pouch of Douglas or cul-de-sac, and traction enteroceles are associated with uterine prolapse. Pulsion enteroceles occur after hysterectomy, and they are associated with weakness of the vaginal vault. Another term for pulsion enterocele is a *true enterocele*, because it is filled with bowel, whereas a traction enterocele may contain only the cul-de-sac.<sup>30-33</sup>

## EVALUATION OF LOWER URINARY TRACT DYSFUNCTION

### Subjective Data

#### History

The history begins with a detailed account of the precise nature of the patient's symptoms. Each symptom should be characterized and quantified as accurately as possible by anamnesis, questionnaire, bladder diary, and for incontinence, a pad test. When more than one symptom is present, the patient's assessment of the relative severity of each should be considered. The examiner should not rely on any one of these tools, but rather use each as a test of the other.

The patient should be asked how often she urinates during the day and night, how long she can comfortably go between urinations, and how long micturition can be postponed after she gets the urge. It should be determined why she voids as often as she does. Is it because of a severe urge, or is it merely out of convenience or an attempt to prevent incontinence? The severity of incontinence should be graded. Does stress incontinence occur during coughing, sneezing, or rising from a sitting to standing position or only during heavy physical exercise? If the incontinence is associated with stress, is urine lost only for an instant during the stress, or is there uncontrollable voiding? Is the incontinence positional? Does it ever occur in the lying or sitting positions? Is there a sense of urgency first? Does urge incontinence

**Figure 7-1** Pelvic organ prolapse grading system. The Aa point is located in the midline of the anterior vaginal wall 3 cm proximal to the external urethral meatus. The Ba point represents the most distal (i.e., most dependent) position of any part of the upper anterior vaginal wall from the vaginal cuff or anterior vaginal fornix to point Aa. By definition, point Ba is at  $-8$  cm in the absence of prolapse. The C point represents the most distal (i.e., most dependent) edge of the cervix or the leading edge of the vaginal cuff (i.e., hysterectomy scar) after total hysterectomy. Point D represents the location of the posterior fornix (or pouch of Douglas) in a woman who still has a cervix. It represents the level of uterosacral ligament attachment to the proximal posterior cervix. It is included as a point of measurement to differentiate suspensory failure of the uterosacral-cardinal ligament complex from cervical elongation. When the location of point C is significantly more positive than the location of point D, it indicates cervical elongation that may be symmetric or eccentric. Point D is omitted in the absence of the cervix. Point Bp represents the most distal (i.e., most dependent) position of any part of the upper posterior vaginal wall from the vaginal cuff or posterior vaginal fornix to point Ap. By definition, point Bp is at  $-3$  cm in the absence of prolapse. Point Ap is located in the midline of the posterior vaginal wall 3 cm proximal to the hymen. By definition, the range of position of point Ap relative to the hymen is  $-3$  to  $+3$  cm. The genital hiatus (GH) is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body (PB) is measured from the posterior margin of the genital hiatus to the mid-anal opening. The total vaginal length (TVL) is the greatest depth of the vagina (in centimeters) when point C or D is reduced to its full normal position. (Modified from Bump RC, Mattiasson A, Bo K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10, 1996.)

occur? Is the patient aware of the act of incontinence, or does she just find herself wet (i.e., unconscious incontinence)? Is there continuous, involuntary loss of urine? Does the patient lose a few drops or saturate her outer clothing? Does she have postvoid dribbling or enuresis? Are protective pads worn? Do they become saturated? How often are they changed? Is there difficulty initiating the stream requiring pushing or straining to start? Is the stream weak or interrupted? Is there postvoid dribbling? Has the patient ever been in urinary retention?

The symptoms of prolapse do not necessarily correlate with the degree of prolapse. The patient may notice or feel the protrusion or feel like she is “sitting on a ball.” There may be a pressure sensation in the vagina, rectum, or groin. She may feel perineal wetness or bleeding from vaginal ulceration, or she may perceive a sensation of pelvic insecurity.<sup>31</sup> There may be a sacral backache that resolves when the patient is lying down.

Prolapse may manifest with a spectrum of lower urinary tract symptoms ranging from urinary retention to overt stress incontinence. Between the two ends of this spectrum fall symptoms of urgency, frequency, straining to void, and a dribbling stream. Most women with prolapse are less symptomatic when supine during the night, with the prolapse reduced. Some patients enhance voiding by applying pressure on the anterior wall of the vagina. When a pessary is inserted, a previously continent woman may develop stress incontinence, a condition called *occult stress incontinence*. A history of stress incontinence that spontaneously subsides suggests occult stress urinary incontinence. Rarely, in severe prolapse, the intestines can become irreducible or even strangulated, which is a surgical emergency. Unmonitored pessaries can erode into the bladder, urethra, bowel, or uterus.

Symptoms caused by a rectocele include the sensation of an inability to evacuate stool from the rectum or the need to apply digital pressure on the posterior vaginal wall to evacuate. Constipation usually is not caused by a rectocele, although the patient may misinterpret her symptoms as constipation. Blood in the stool or changes in the caliber of the stools should prompt colon and rectal examination to rule out neoplasm.<sup>29-33</sup>

### Medical History

The patient should be specifically queried about neurologic conditions that are known to affect bladder and sphincteric function, such as multiple sclerosis, spinal cord injury, lumbar disk disease, myelodysplasia, diabetes, stroke, Parkinson’s disease, or multi-system atrophy. If she does not have a previously diagnosed neurologic disease, it is important to ask about double vision, muscular weakness, paralysis or poor coordination, tremor, numbness, and tingling. A history of vaginal surgery or previous surgical repair of incontinence should suggest the possibility of sphincteric injury. Abdominoperineal resection of the rectum or radical hysterectomy may be associated with neurologic injury to the bladder and sphincter, resulting in sphincteric incontinence, urinary retention (due to detrusor areflexia), or hydronephrosis (due to low bladder compliance). Radiation therapy may cause a small-capacity, low-compliance bladder or radiation cystitis.

Medications are a rare cause of urinary incontinence.  $\alpha$ -Adrenergic antagonists may cause stress incontinence.  $\alpha$ -Adrenergic agonists such as histamine and tricyclic antidepressants may cause bladder outlet obstruction, urinary retention, and overflow incontinence. Parasympathomimetics such as bethanechol may cause involuntary detrusor contractions and bladder pain.

### Bladder Questionnaire

Questionnaires can expedite the retrieval of all information. In the past decade, there has been a plethora of questionnaires, but no single one has met with widespread approval.<sup>34,35</sup> However, even well-constructed questionnaires with highly significant validation cannot supplant the medical history. Each should supplement the other, and final judgment about the nature of symptoms should be attained by resolving conflicts in the questionnaire,

bladder diary, pad tests, and anamnestic responses. We have fashioned two questionnaires for our practice; one is directed toward bladder symptoms, and the other addresses the medical history, medications, and allergies. These questionnaires are sent to the patient before the office visit. The patient has the opportunity to ponder the questions and to acquire information, such as the names of medications and dates of previous operations, before the office visit.

## Semi-objective Data

### Bladder Diary

To document the nature and severity of urinary symptoms, we find a bladder diary indispensable. The reproducibility of the diary has been confirmed.<sup>23,36-42</sup> The particular information recorded in the diary depends on the patient’s symptoms, but all diaries should include at least the time and amount of each micturition. From such a diary, the following information can be calculated: the total 24-hour urinary output, number of voids, longest intervoiding interval, largest single voided volume, diurnal distribution, and diuresis. Depending on the patient’s complaints, notations about the characterization, time, and severity of incontinence; the need to push or strain to void; and associated pain or urgency can be compiled. The ICS has advised that the inclusion of a frequency-volume chart is an essential component of the patient’s clinical assessment.<sup>8</sup>

### Pad Tests

A number of pad tests have been described, but none has met with widespread approval. The reliability of 24-hour pad tests has been reasonably well established, but most 1- and 2-hour tests have considerable test-retest variability.<sup>23-24,43-47</sup> Despite these shortcomings, the pad test is exceedingly useful, but it must be put in perspective with the patient’s symptoms. The most direct way of doing this is to ask the patient whether the pad test was representative of her usual symptoms; if not, it should be repeated. The relationship between pad loss and degree of incontinence has been described by a number of studies. A rate of less than 8 g/24 hours is considered normal (e.g., sweat, secretions), and more than 20 g/24 hours is considered to be moderate to severe incontinence.<sup>24,45</sup>

## Objective Data

### Physical Examination

The physical examination begins by observing the patient’s gait and demeanor as she first enters the office. A slight limp or lack of coordination, an abnormal speech pattern, facial asymmetry, or other abnormalities may be subtle signs of a neurologic condition.

The abdomen and flanks should be examined for masses, hernias, and a distended bladder. A pelvic examination is performed with the bladder comfortably full and the patient in the lithotomy position; in patients with prolapse and incontinence it usually should be repeated with the patient standing or sitting. The patient is asked to cough or strain to reproduce symptoms of incontinence. The degree of hypermobility may be assessed by examination with a full bladder and by the Q-tip test. However, examination alone is insufficient for accurate assessment. The Q-tip test is performed by inserting a well-lubricated, sterile, cotton-tipped applicator gently into the urethra while the patient

is in lithotomy position. During a Valsalva maneuver or while coughing, the arc of the end of the Q-tip may be estimated or measured from the resting position with a goniometer or approximated by the examiner in terms of degrees from the 0 axis (i.e., position of the applicator at rest). Some examiners use a shortened, red-rubber catheter to obtain a residual volume and then check for mobility during stress. Mobility of the end of the instrument from the resting position to more than 30 degrees with straining indicates urethral hypermobility.<sup>7,17</sup>

Pelvic organ prolapse is best evaluated according to the POPQ protocol as depicted in Table 7-4 and Figure 7-1.<sup>30</sup> The anterior vaginal wall is inspected by applying gentle pressure on the posterior vaginal wall with the posterior blade from a split speculum or with examining fingers. The blade, if metal, should be warmed with water and inserted into the vagina toward the posterior wall. While the patient is straining, the presence of anterior vaginal wall and cervical or uterine mobility are assessed. The design of some examination and urodynamics tables allows the perineum to be visualized and examined while the patient is sitting. In many instances, prolapse and incontinence are appreciated only in one or the other position. Moreover, in some patients, incontinence can be reproduced only with the cystocele reduced. The cervix is normally mobile, but descent to within 1 cm of the hymenal ring is considered grade 1 prolapse.

After examination of the anterior vaginal wall and cervix or uterus, the speculum blade is rotated, and the anterior vagina is gently retracted. The posterior vaginal wall and vault are examined for the presence of an enterocele and rectocele. As the speculum is slowly withdrawn, a transverse groove separating an enterocele from a rectocele below may be visible, and a finger inserted into the rectum can “tent up” a rectocele but not an enterocele.<sup>38</sup>

The sacral dermatomes are evaluated by assessing anal sphincter tone and control, perianal sensation, and the bulbocavernosus reflex. With a finger in the rectum, the patient is asked to squeeze as if she were in the middle of urinating and trying to stop. A lax or weakened anal sphincter and the inability to voluntarily contract and relax may be signs of neurologic damage. The bulbocavernosus reflex is checked by suddenly squeezing the clitoris and feeling (or seeing) the anal sphincter and perineal muscles contract. Alternatively, the reflex may be initiated by suddenly pulling the balloon of the Foley catheter against the vesical neck. The absence of this reflex in men is almost always associated with a neurologic lesion, but the reflex is not detectable in up to 30% of otherwise normal women.<sup>19</sup>

If the patient complains of prolapse or incontinence that is not demonstrated in the lithotomy or sitting position, she is asked to cough and strain while standing. She should be positioned standing in front of the examiner with one foot elevated on a short standing stool. An enterocele is palpable between the forefinger (in the rectum) and the thumb (in the vagina). The perineal body and vaginal rectal septum are examined by palpating the septum through the vagina and rectum.

If a patient has been fitted with a pessary, the pessary should ideally be removed on the day before the office visit; if not, it should be removed and the patient examined. If she states that the prolapse is not at its maximum descent, she should be asked to return later in the day (after she feels the prolapse has fallen down again). The vagina should be examined for any erosions or pudendal nerve injury from an ill-fitted pessary.

The diagnosis of urinary fistula depends on a high index of suspicion, and it should be suspected if there is new onset of

incontinence after pelvic surgery or childbirth or after pelvic irradiation for gynecologic malignancy. In most instances, vesicovaginal and urethrovaginal fistulas are apparent on examination of the patient with a full bladder or at the time of cystoscopy, but ectopic ureter and ureterovaginal or vesicouterine fistula are usually not apparent on examination. If a vesicovaginal fistula is suspected but not seen on examination, it almost always is apparent at cystoscopy. If detection defies these simple steps, the bladder can be filled with saline or water to which a dye such as indigo carmine has been added. The vagina should then be inspected for signs of urinary leakage with the urethra occluded with a Foley balloon catheter or with the surgeon's examining finger to prevent urethral leakage. Cystoscopy and pelvic examination are essential to evaluate the extent of the anatomic defect, the possibility of unrecognized secondary fistulas, the pliability of local tissue, the need for securing bulk-ensuring tissue pedicle flaps, the need for concomitant pelvic reconstructive surgery, and the timing of surgery. At the time of cystoscopy, retrograde pyelography may be performed when indicated, and the integrity of the urethral sphincter should be tested while the bladder is full.

To confirm the presence of an ectopic ureter or of a ureterovaginal or vesicouterine fistula, intravenous pyelography, retrograde pyelography, cystography, and hysterosalpingography may be necessary. In doubtful cases, Pyridium may be given orally and the patient instructed to wear a tampon and pads. If the Pyridium stains the tampon but not the pad, a vaginal fistula should be excluded. Urinary incontinence is not always caused by what appears to be the most overt lesion. For example, neither a urethrovaginal fistula nor a destroyed distal urethra should cause urinary incontinence unless the proximal urethra and vesical neck are also damaged. A careful, stepwise evaluation should be carried out in all patients to delineate the pathophysiology underlying incontinence. Other causes of urinary incontinence commonly seen in these patients include a previously undiagnosed vesicovaginal or ureterovaginal fistula, detrusor overactivity, low bladder compliance, and sphincteric abnormalities.

### *Routine Urologic Assessment*

Routine laboratory studies include urinalysis, urine culture, and, in selected patients, renal function tests. Positive urine cultures should be treated with culture-specific antibiotics, but patients with persistent bacteriuria or recurrent infections may require invasive testing while on antibiotics. Hematuria should be evaluated by upper tract imaging (i.e., computed tomography with intravenous contrast or intravenous pyelography) and cystourethroscopy.

### *Urodynamic Study*

The main purpose of urodynamic investigation is to determine the precise cause of the patient's voiding dysfunction, and to this end, it is important that the symptoms be reproduced during the examination. Urodynamic technique varies from “eyeball urodynamics” to sophisticated multichannel, synchronous video, pressure-flow, and electromyographic studies. Using synchronous, multichannel video urodynamics offers the most comprehensive, artifact-free means of arriving at a precise diagnosis, and we perform these techniques routinely when urodynamics are indicated. When multichannel studies are not routinely performed, they should be considered under the following circumstances:

1. When simpler diagnostic tests have been inconclusive
2. When the patient complains of incontinence, but it cannot be demonstrated clinically
3. In patients who have previously undergone corrective surgery for incontinence
4. In patients who have previously undergone radical pelvic surgery, such as abdominoperineal resection of the rectum or radical hysterectomy
5. In patients with known or suspected neurologic disorders that may interfere with bladder or sphincter function (e.g., myelodysplasia, spinal cord injury, multiple sclerosis, herniated disk, cerebrovascular accident, Parkinson's disease, multisystem atrophy).

Laboratory urodynamics are discussed in Chapter 11. The use of eyeball urodynamics is discussed here.

### Eyeball Urodynamics

Eyeball urodynamics are performed with the patient in the lithotomy position. The patient should already have completed a bladder diary and, if incontinent, a pad test. The examiner should know the patient's history and symptoms. She should be asked to void (and uroflow measured, if available). After voiding, she should be asked whether that void was typical and if she felt that she emptied her bladder; if not, the data should not be considered with that perspective. A regional neurologic examination, including the assessment of perineal sensation, anal tone and control, and bulbocavernosus reflex,<sup>47</sup> is performed. A Foley catheter or (preferably) a cystoscope is inserted, and postvoid residual urine is measured. A fluid reservoir (i.e., 60-mL catheter tip syringe with its barrel removed or irrigation bag or bottle) is connected, and water or saline is then infused into the bladder by gravity. The syringe, bag, or bottle is lowered, and the meniscus is observed at the height that fluid inflow stops. The height (in centimeters) of the meniscus above the symphysis pubis is the resting intravesical pressure. The bladder is filled, and in contradistinction to the recommendations of the ICS, the patient is told to neither void nor try to inhibit micturition; rather, she is instructed to report her sensations to the examiner. When she

perceives the urge to void, she is asked if that is the usual feeling that she experiences when she needs to urinate. Changes in intravesical pressure are apparent as a slowing down in the rate of fall or a rise in the level of the fluid meniscus. A change in pressure may be caused by a detrusor contraction, an increase in abdominal pressure, or low bladder wall compliance. As soon as a change in pressure occurs, the examiner should attempt to determine the cause. Visual inspection usually belies abdominal straining, but in doubtful cases, the abdomen should be palpated. In most instances, the cause of the rise in intravesical pressure is obvious, but when in doubt, formal cystometry with rectal pressure monitoring is necessary.

Any sudden rise in pressure that is accompanied by an urge to void or by incontinence is an involuntary detrusor contraction. In some instances, the cause of the patient's incontinence is easily discernable because she voids uncontrollably around the catheter during an involuntary detrusor contraction. If involuntary detrusor contractions do not occur, the bladder is filled until a normal urge to void is experienced. The bladder is left full, and the catheter is removed. The presence or absence of gravitational urinary loss is noted. The patient is asked to cough and bear down with gradually increasing force to determine the ease with which incontinence is produced, and the vagina is inspected for signs of prolapse.

Incontinence that occurs during stress is not always caused by sphincter abnormalities. In some patients, the stress initiates a reflex detrusor contraction. This condition has been called *stress hyperreflexia*. It is important to determine whether the leakage is accompanied by descent of the bladder base and urethra. It should be further noticed whether the leakage stops as soon as the stress is over or the patient continues to void uncontrollably. In the former case, the patient has stress incontinence; in the latter, it is stress hyperreflexia.

If the patient complains of urinary incontinence, but it has not been demonstrated, the examination should be repeated in the standing position as described previously. Under ordinary circumstances, no patient should undergo invasive or irreversible treatment until the cause of the incontinence has been clearly demonstrated.

# IMAGING OF THE FEMALE GENITOURINARY TRACT

*Steven S. Raman and Lousine Boyadzhyan*

### REVIEW OF IMAGING MODALITIES

#### Projectional Radiography

In uro radiology, the role of projectional radiography, once an integral part of diagnosis, has been steadily diminishing as cross-sectional techniques have become more advanced (Fig. 8-1). X-ray-based images are now routinely captured on digital media instead of film, enabling rapid storage on a central server with multiple display options, including a picture archiving and retrieval system (PACS), or for distribution on the Internet. However, the principles of x-ray-based diagnosis have not changed. An image is formed when diagnostic-range x-ray energy interacts with the electron cloud of different human tissues (i.e., bone, soft tissue [water], fat, and air). The different electron densities of these tissues allow various degrees of x-ray beam penetration, resulting in differences in exposure (i.e., shades of gray) on the receptor film or digital media. Most naturally occurring electron-dense structures, such as calcified bone or dental enamel, attenuate x-ray energy strongly and by convention appear white on the conventional or digital receptor. Conversely, the least electron-dense substances, such as gas, allow almost 99% of x-ray energy to penetrate the tissue and reach the receptor, and by convention, these images are black. Between these two extremes are the shades of gray, which represent the summation of various three-dimensional (3D) electron densities on a two-dimensional (2D) receptor. Perception and interpretation of projectional images is highly operator dependent and requires a large degree of experience for proper interpretation.

Because it is easy to visualize structures at extremes of the spectrum of beam penetrance, calcified structures such as most urologic stones (i.e., white) or gas (i.e., black) can be seen well. However, most solid and fluid-filled organs are essentially of water density and are distinguished on radiographs by the relative contrast provided by relatively radiolucent fat.

A patterned approach to the abdominal radiograph is useful for instruction. On most radiographs, the lower poles of the kidneys are apparent with a laterally divergent axis that usually parallels the psoas muscles when visualized. Renal calculi are usually seen as ovoid or toothlike opacities overlying the kidneys or proximal ureters. They are more difficult to detect over the distal ureter because contrast is reduced by overlying bony pelvis. Gas projecting over the bladder is usually seen after recent Foley catheterization, but it may be caused by infections and fistulas. Bony abnormalities should not be overlooked because they can represent metastatic disease or suggest a neurogenic bladder, especially in patients with spinal abnormalities.<sup>1</sup>

To address the problem of poor soft tissue attenuation differences and to image gross pathologic conditions, various radio-

graphic contrast agents (usually iodinated agents with high electron density especially suited for x-ray interaction) were introduced into the field of uro radiology. The first introduction of retrograde urothelial injection agents in the 1920s was followed by the development of intravascular contrast agents, giving rise to intravenous urography, a mainstay of uro radiology for renal and ureteral evaluation for almost 50 years (Figs. 8-2 and 8-3).<sup>2</sup> A large variety of catheter-injected uro radiologic studies were developed for niche applications, including urethrograms, cystograms, pyelograms, loopograms, nephrostograms, and suprapubic cystograms.

#### Fluoroscopy

Fluoroscopy is the dynamic counterpart of static projectional radiography because it displays real-time images of a particular process under investigation. During fluoroscopic studies, a low dose of continuous x-ray beams passes through the patient to an image intensifier to generate images on a high-resolution television monitor.<sup>3</sup> The examiner can obtain a series of individual snapshots (i.e., frames per second) of the process, so-called spot films, or a real-time movie such as evaluation of dynamic processes for storage and review. However, fluoroscopic imaging is best performed with iodinated contrast material for genitourinary applications. Fluoroscopy is most useful for vascular applications, but it may be used for real-time evaluation of ureteral peristalsis; bladder filling and emptying, especially during voiding (i.e., voiding cystourethrography [VCUG]); and guiding a variety of genitourinary interventions, such as nephrostomy tube placement.

#### Cystography and Voiding Cystoureterography

Cystography can be done in a static fashion or as VCUG. During static cystography, contrast material is instilled into the bladder through a Foley catheter, and various views of the full bladder are taken along with postdrainage views. This examination is usually indicated in cases of suspected bladder rupture, low-pressure vesicoureteral reflux, or a vesical fistula. It can also be useful in the assessment of intravesical filling defects, bladder diverticula, or lower urinary tract congenital anomalies. In an update to conventional cystography, the study may be modified and performed as a computed tomography (CT)-based examination for almost all indications, especially in the setting of trauma.

VCUG is performed as an adjunct to a cystogram to determine the morphology of the bladder and urethra, especially if high-pressure vesicoureteral reflux and related complications are suspected. The bladder is filled, as in static cystography, followed by fluoroscopy and/or a video recording of the voiding process once the catheter is removed.<sup>1</sup>

A

B

**Figure 8-1** Endometriosis implants in the colon are seen on a plain film (A) as filling defects, which were later confirmed with transabdominal ultrasound (B).

### *Video Urodynamics*

In video urodynamics (VUDs), multichannel urodynamic measurements are combined with concomitant fluoroscopic VCUG to determine whether morphologic findings with regard to bladder function and its outlet correlate with physiologic measurements. It is therefore possible to go beyond the level of a simple VCUG or cystometry by obtaining simultaneous measurements of abdominal and vesical pressures under fluoroscopic guidance. In addition to revealing a great deal about dynamics of the bladder and its outlet, VUDs has led to greater diagnostic and therapeutic efficacy. With modern advent of digital recording, the examiner can manipulate the data with various software packages with incorporation of other clinical information and statistical calculations to maximize the yield even further. Some of the most common indications for VUDs in women are various

A

B

**Figure 8-2** Tubular ectasia in the kidney is shown by traditional intravenous pyelogram (A) and computed tomography (B).

kinds of incontinence; bladder outlet obstruction, as can be seen in urethral obstruction; neuropathic bladder due to a variety of neurologic disorders; geriatric incontinence; urinary diversion; and unidiversion.<sup>4</sup>

The main problem with VUDs is that it often may not reproduce the presenting symptoms of the patient because it is

**Figure 8-3** Papillary necrosis is shown by traditional intravenous pyelogram (A) and maximum intensity projection (MIP), from CTP urogram computed tomography (B). Note that they defect in the renal papilla in the liver poles are more easily seen on the MIP CT image.

nonphysiologic in nature and is performed in surroundings unfamiliar to the patient. The presence of severe grades of cystoceles, rectoceles, enteroceles, and uterine prolapse can lead to a rather unreliable interpretation of the examination results. In such clinical scenarios, it is especially important to repeat the study in a variety of positions to assess the severity of the pelvic floor pathology present in a given patient. Despite these limitations, VUDs is still highly recommended in patients with postoperative incontinence and in neuropathic and refractory cases.<sup>4</sup>

#### *Intravenous Urography and Pyelography*

The traditional intravenous urogram (IVU), which is used to evaluate the kidneys, kidney function, and ureteral excretion and function, has undergone a radical transformation over the past 10 years, with increasing resolution and performance of CT, magnetic resonance imaging (MRI), and ultrasound (see Figs. 8-2 and 8-3). Evaluation of the kidneys is best performed with contrast-enhanced CT or MRI (Figs. 8-4 and 8-5). Evaluation of the ureters also may be performed with CT or MRI, although a fluoroscopic or radiographic examination, if performed properly, may be adequate, especially when detecting urothelial malignancies. Advances in competing technologies have limited or severely restricted the clinical application of the IVU. The intravenous urogram is no longer indicated for many upper tract indications, such as renal mass evaluation and evaluation of acute renal colic, and is best reserved for evaluation of hollow parts of the urinary system, such as follow-up of patients with transitional cell carcinoma.<sup>1</sup>

**Figure 8-4** Oblique coronal virtually rendered image shows detailed renal and vascular anatomy. Notice the small renal vein draining into the gonadal vein in the lower abdomen.

**Figure 8-5** Coronal maximum intensity projection (MIP) image generated with a 64-detector CT scanner in nephrographic (A) and excretory (B) phase demonstrates a cystic structure. It contains a stone adjacent to the fornix of the lower pole calyx on the left kidney, which displays delayed-contrast filling, suggesting a calyceal diverticulum.

### Retrograde Pyelography

Retrograde pyelography allows morphologic evaluation of the collecting system and ureters. It involves retrograde injection of contrast material directly into the ureters after their cystoscopic cannulation to visualize the collecting system and the ureter without reliance on renal contrast excretion. It also is possible to biopsy suspected urothelial lesions in the course of the examination. Some of the most common indications for retrograde pyelography are further evaluation of congenital anomalies, urinary obstruction, and possible filling defects detected during other studies. However, because this is a rather invasive diagnostic study associated with several potential complications, it usually is not used as an initial diagnostic procedure.<sup>1</sup>

### Urethrography

Although most commonly used in male patients, urethrography occasionally is used in female patients by injecting contrast material into the urethra directly. This examination can be especially useful in cases of urethral fistulas and suspected urethral diverticula that failed to opacify during voiding studies, as described in the preceding section.

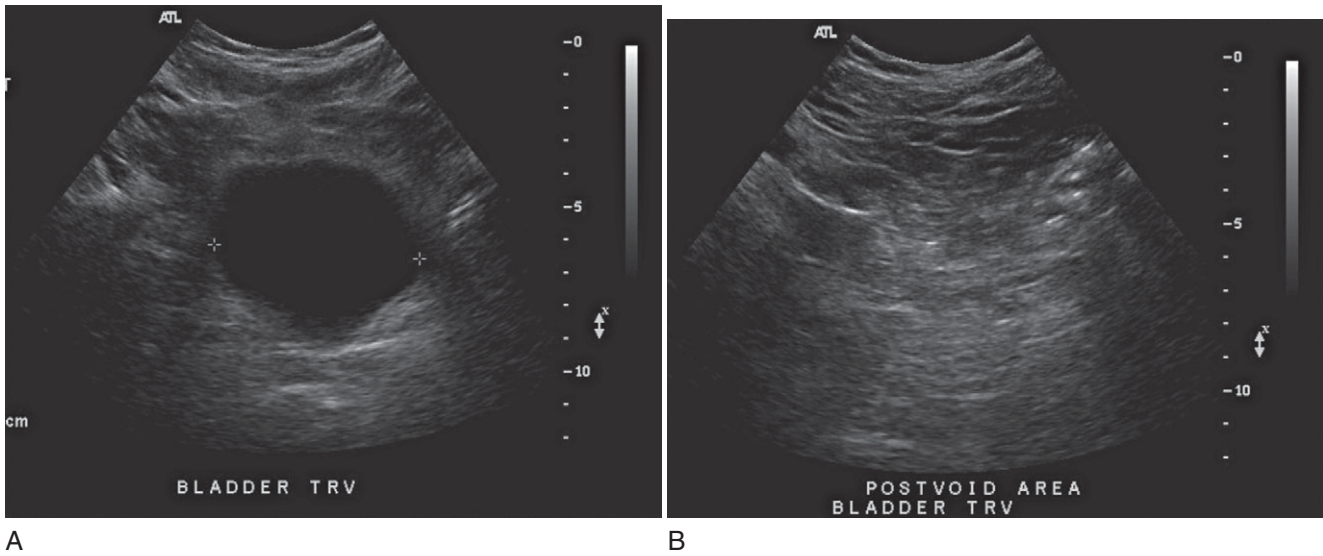

### Ultrasonography

In sonography, also referred to as ultrasound or ultrasonography, sound waves with frequencies in the range of 2 to 20 MHz are

generated by an array of piezoelectric crystals in a hand-held transducer. These tightly focused, high-frequency sound waves are propagated through human tissues and reflected back at tissue interfaces to the transducer's crystals, subsequently producing a diagnostic medical image.<sup>3</sup> The choice of imaging frequencies is determined by the size and composition of the tissue involved. Higher frequencies (>7 MHz) usually lead to improved spatial resolution at the expense of depth of imaging, whereas lower frequencies (2 to 5 MHz) enable imaging of deeper tissues with lower spatial resolution. The chief advantages of sonography are its lack of ionizing radiation, its real-time imaging capability, its 2D and 3D imaging capability, and its ability to depict flow direction and velocity in blood vessels and tissues.<sup>4</sup> Disadvantages of sonography are its operator dependence and its inability to image through hollow viscera or bone. In urology, ultrasound is the initial test of choice for adult and pediatric renal and bladder imaging. A wide variety of pathologies, such as congenital anomalies, hydronephrosis, and vascular disorders, may be diagnosed. In bladder applications, it may be used to determine residual postvoid urine volume and to delineate the urethrovesical anatomy (Figs. 8-6 and 8-7).<sup>5</sup>

Sonography is integral to diagnosis in obstetrics and gynecology (Figs. 8-8 and 8-9; see Fig. 8-1). The reproductive organs may be evaluated by means of transabdominal, transvaginal, or transrectal approaches, as appropriate. Transvaginal and transrectal sonography enable high-resolution imaging of the uterus, adnexa, bladder, and pelvic side wall. For endometrial abnormalities,

**Figure 8-6** Transverse views of the bladder on ultrasound show prevoid (A) and postvoid (B) bladder volume of urine.

**Figure 8-7** Color Doppler ultrasound of the bladder shows the urinary jet, which indicates urine flow from the right ureter in the bladder.

especially in the setting of vaginal bleeding, saline infusion hysterosonography, which involves catheterizing the endometrium and infusing saline during imaging, has become the initial test of choice in the evaluation of endometrial and subendometrial disorders such as polyps, fibroids, and cancer (see Fig. 8-9).<sup>6,7</sup> Endoanal ultrasonography enables high-resolution visualization of the anal sphincter muscles in patients with incontinence, as well as delineation of fistulas, abscesses, and anal malignancies.<sup>5</sup>

### Computed Tomography

Introduction of CT revolutionized evaluation of the retroperitoneum and disorders of the upper urinary tract, essentially replacing most indications for the intravenous urogram (see Figs. 8-2 to 8-5). Although many systems have been devised, on most CT scanners, a thin narrowly collimated beam of x-rays from a

A

**Figure 8-8** Sagittal views of the uterus in a female patient with menorrhagia were obtained from transabdominal (A) and transvaginal (B) approaches. In B, notice some endometrial displacement, which led to additional studies in this patient (see Fig. 8-9).

**Figure 8-9** Series of transvaginal studies in a female patient presenting for a gynecologic evaluation of menometrorrhagia. Color (A) and power Doppler (B) images show a displaced endometrium with a heterogeneous structure demarcated (C), which has Doppler flow to it. After infusion of saline (D), an intracavitary solid mass can be seen protruding into the endometrial cavity. The mass was shown to be a submucosal myoma during surgery.

generator rotates around a patient's body on a ring in a continuous circular arc. A panel of electronic x-ray detectors lies directly opposite the x-ray tube on the ring and converts the x-ray beams exiting the patient's body into electronic signals, which are converted by a computer to display the density of each point (i.e., voxel) of the region being scanned, eventually generating a cross-sectional image. Helical multidetector CT (MDCT) scanners are configured to scan a volume of the body continuously. With MDCT, the principal advantages compared with conventional "step and shoot" CT are rapid, near-isotropic voxel ( $x = y = z$ ) data acquisition with greater radiation dose efficiency. With isotropic voxels and sophisticated software, multiplanar and 3D imaging has become routine. Many postprocessing techniques exist, and two of the most useful are known as multiplanar reformation (MPR) and volume rendering (VR). These display techniques that are especially important for determining renal vascular anatomy, determining the relation of tumors to collecting system and vessels, and detecting fine filling defects on excretory CT urography. In the realm of female urology, CT has become a well-established imaging modality for conditions such as congenital anomalies, tumors, acute and chronic inflammatory diseases, and abscesses.

### Magnetic Resonance Imaging

MRI provides unparalleled tissue contrast and multiplanar, high-resolution imaging of urologic and pelvic floor structures without ionizing radiation. With MRI, a variety of tissues, such as muscle, fat, fluid, blood, blood vessels, and bone marrow, may be delineated with exceptional clarity (Figs. 8-10 to 8-12).<sup>8</sup> In MRI, the water protons in the human body are magnetized by a main magnetic field ranging between 1 and 3 Tesla. Using a variety of supplemental magnetic fields, a region of interest may be selected, and based on subtle magnetic field perturbations of water protons and their various relaxation times, diagnostic images are obtained. Tissues such as fat and fluid are differentiated based on their different relaxation properties by a variety of excitation algorithms known as MR sequences. One of the most useful in urology and pelvic floor imaging is the half-Fourier acquisition turbo spin-echo (HASTE) or single-shot fast spin-echo (SSFSE) T2-weighted sequence. This is a rapid, cost-effective, and noninvasive sequence that allows a multiplanar survey of the entire abdomen and pelvis within less than 1 minute. It may also be used to provide a dynamic study of the pelvic floor during relaxation and straining, providing superb anatomic detail survey of

**Figure 8-10** Sagittal magnetic resonance image shows the detailed anatomy of a post-hysterectomy patient.

**Figure 8-11** Vaginal coil magnetic resonance imaging provides a detailed view of the urethral mucosa.

the extent of suspected pelvic floor relaxation and pelvic organ prolapse. It is very likely that it will replace ultrasound for evaluating women, even those with pelvic pain.<sup>9</sup>

Like CT, MRI may be performed with the use of contrast agents; gadolinium-diethylenetriamine penta-acetic acid (Gd-DTPA), which is a water-soluble, inert agent excreted primarily through the kidneys. Advantages compared with iodinated agents include a much lower incidence of dose-related and idiosyncratic reactions. T1-weighted, gradient-echo MR sequences in combination with a small dose of gadolinium contrast enables a comprehensive evaluation of the kidneys and ureters, similar to CT and CT urography, without ionizing radiation or iodinated contrast risk. T2-weighted sequences enable differentiation of cysts, tumors, and normal tissue parenchyma.

A

B

**Figure 8-12** Magnetic resonance imaging used in staging cervical cancer. The tumor is shown to protrude into the vaginal fornix (A, arrows) with its walls clearly intact (B, arrowheads).

In patients with hydronephrosis, use of the HASTE T2-weighted sequence enables acquisition of the collecting system, including the calyces, pelvis, and ureters. MRI with T1- and T2-weighted sequences can be used for urinary tract disorders in pregnant patients without any radiation exposure risk to the fetus.<sup>10</sup> Endoanal MRI is an invaluable method for assessing the integrity of the anal sphincter components in patients with incontinence.

## CLINICAL APPLICATIONS

### Bladder Imaging

MDCT and MRI have enabled more sophisticated, noninvasive bladder imaging primarily because of their unparalleled resolution and multiplanar display (Figs. 8-13 to 8-15). Both methods

**Figure 8-13** Coronal virtually rendered images of bilateral, simple ureterocele obtained with multidetector computed tomography show bilateral, mild intramural dilation at the opening into the urinary bladder filled with contrast medium (A). Radiolucent layers of adjacent mucosa and contrast-filled surrounding bladder resemble a cobra head (B).

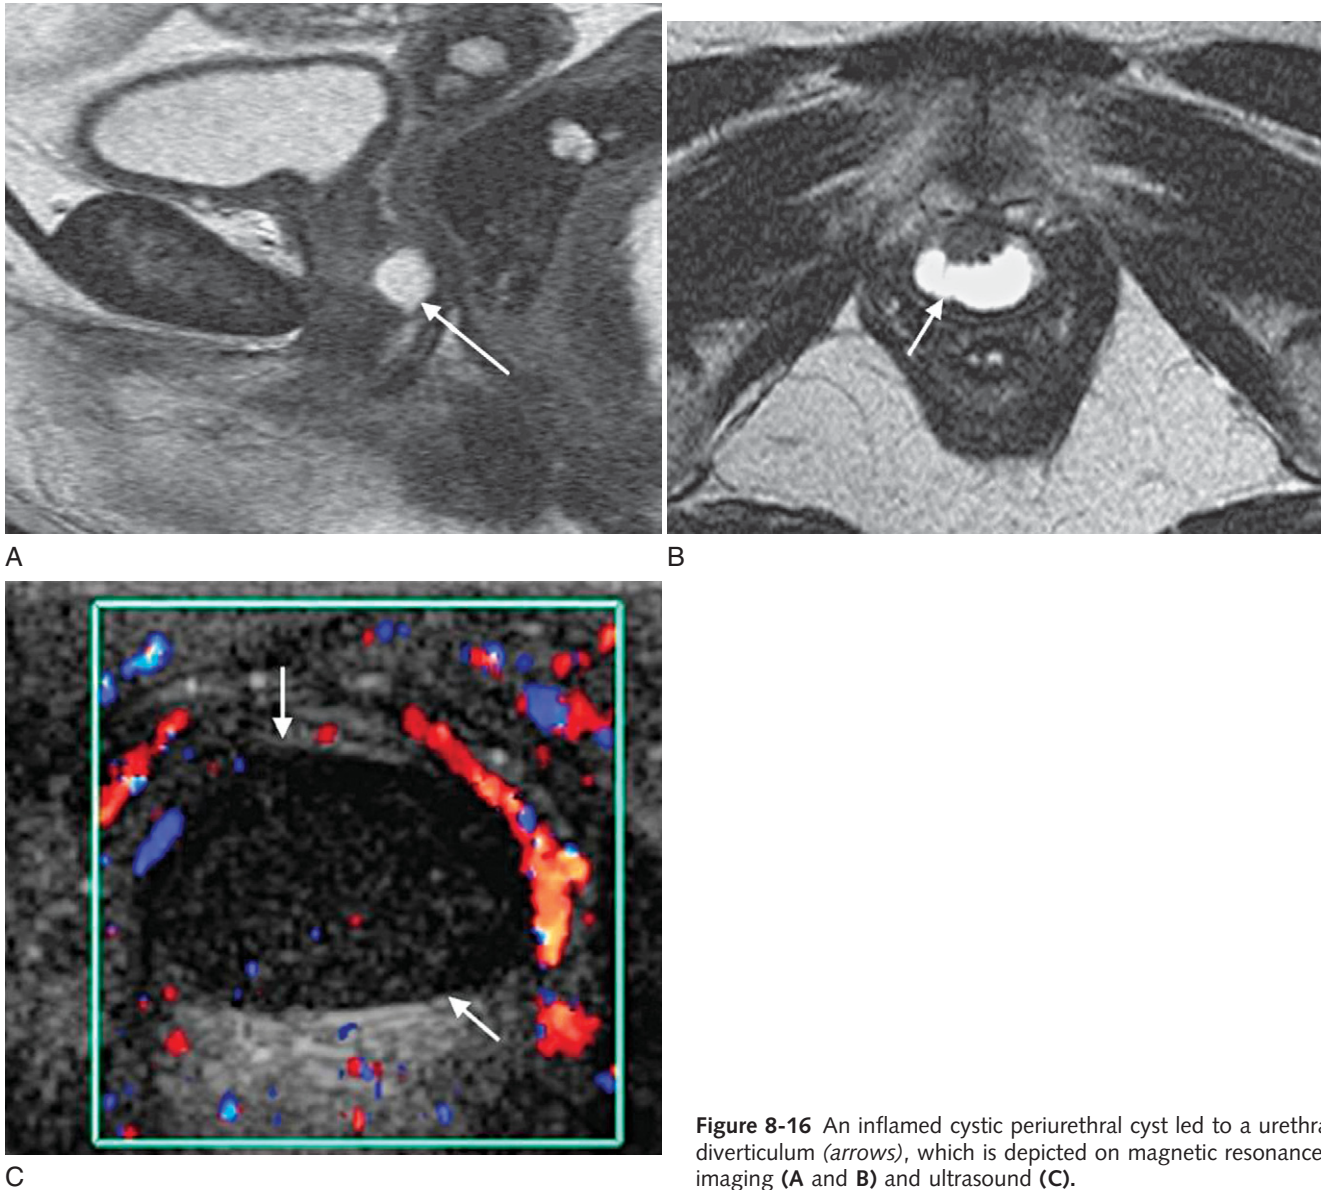

**Figure 8-14** A coronal virtually rendered image obtained with multidetector computed tomography shows a double collecting system on the right.

**Figure 8-15** A sagittal magnetic resonance image shows cervical carcinoma in the lower third of the vagina invading the bladder (arrows).

can easily detect bladder filling defects, demonstrate bladder-related fistulas, and determine the extent of extravascular tumor invasion. Based on the isotropic MR or CT 3D data sets, a virtual cystogram, similar to more clinically accepted virtual colonoscopy techniques, can be performed. Using 2D and 3D methods, CT and MRI have shown very high correlation with conventional cystoscopy in the detection of bladder lesions that are 0.5 cm or larger. Although CT and MRI are limited in detecting small and intramuscular lesions of the muscle layer of the bladder, contrast-enhanced techniques may help improve this approach. However, in cases of invasive neoplasms, MRI has been shown to be superior to transvesical ultrasound, clinical staging, and CT.<sup>11,12</sup>

**Figure 8-16** An inflamed cystic periurethral cyst led to a urethral diverticulum (*arrows*), which is depicted on magnetic resonance imaging (**A** and **B**) and ultrasound (**C**).

Although intraluminal ultrasound has been reported as an imaging technique for staging of bladder neoplasms, this application is limited to a handful of medical centers in the country and has not gained widespread acceptance.<sup>4</sup>

MRI can be used for dynamic imaging studies of the pelvic floor, enabling assessment of pelvic floor musculature and organs during relaxation phases and Valsalva maneuvers. MRI produces superb soft tissue detail without radiation or contrast exposure to help triage patients with a range of difficult-to-manage problems such as pelvic floor disorders and urinary and rectal incontinence. In the daily practice of uro radiology, ultrasonography has remained a rather useful modality in the determination of the postvoid residual urine volume and for characterizing the size and location of bladder diverticula, neoplasms, and radiolucent calculi.<sup>4</sup>

#### **Urethral Imaging: Urethral Diverticula**

Traditionally, VCUG has been the imaging study of choice for urethral diverticula. However, some investigators have shown

that high-resolution, fast spin-echo MRI has a higher sensitivity for detecting such diverticula and a higher negative predictive rate than double-balloon urethrography. Other experts in the field believe that a combination of VCUG and MRI leads to a more accurate diagnosis and localization of the lesion (Fig. 8-16).<sup>13</sup>

#### **Vaginal Imaging: Benign Cystic Lesions**

Benign cystic lesions of the vagina are a relatively common finding in female urologic practice and represent a spectrum of abnormalities ranging from an asymptomatic small finding to a cyst large enough to cause incontinence or urinary obstruction. They can originate in the vagina or the urethra and the surrounding tissues. Some of the more common examples of vaginal lesions are müllerian cysts, epidermal inclusion cysts, Gartner's duct cysts, Bartholin's gland cysts, and endometriotic-type cysts (Figs. 8-17 and 8-18).<sup>14</sup>

In addition to a careful physical examination, an imaging study is warranted to characterize lesions. Overall, the most

A

B

**Figure 8-17** A Gartner's duct is depicted on ultrasound (**A**, arrows) and magnetic resonance (MR) imaging (**B**, arrow). Notice the usual anterolateral paravaginal location, with the cyst typically bright on T1-weighted and dark on T2-weighted MR sequences.

useful imaging modalities are sonography and MRI, although CT and VCUG may be useful on occasion.<sup>15</sup> For instance, when evaluating a Skene duct cyst, it must be differentiated from a urethral diverticulum to assist in proper surgical planning, potentially preventing complications such as urethrovaginal fistulas. Pelvic MRI is useful for this purpose, because it enables the clinician to determine whether there is a communication between the lesion and the urethra, leading to the correct diagnosis.<sup>15</sup> Ultrasound, CT, or MRI can be used to detect a Bartholin duct cyst.

### Uterine Imaging

Transvaginal and transabdominal sonography are the most widely used imaging modalities for the detection and characterization of a wide variety of uterine anomalies and pathologies. Common indications include evaluation of congenital uterine anomalies; assessment of uterine leiomyomas in women with related symptoms such as pelvic pain, pressure, or heavy bleeding; and assessment of the endometrium. Hysterosonography, which involves instilling saline during continuous endovaginal sonographic uterine imaging, is particularly useful for detecting endometrial polyps, tumors, and leiomyomas.<sup>16,17</sup> However, over

the past few years, MRI has emerged as the definitive imaging modality for evaluation of uterine disorders. MRI enables evaluation of the uterine zonal anatomy with clear T2-weighted signal differences between endometrium (i.e., bright), junctional zone (i.e., dark), and myometrium (i.e., intermediate). If the appropriate views are acquired, a variety of congenital fusion anomalies, such as septate uterus and bicornuate uterus with obstructed horns, can be demonstrated.<sup>18</sup> Associated anomalies of the kidneys are also easily demonstrated. MRI is considered to be the best noninvasive method of assessment for women with symptoms related to uterine leiomyomas and adenomyosis (Fig. 8-19 and Fig. 8-20). MRI is the best modality to determine the vascular supply of pelvic vascular malformations and has been shown to be highly accurate in local staging of endometrial and cervical cancer.

MR angiography is performed with MRI to assess the arterial supply and venous drainage to the uterus. It is especially useful in delineating the collateral supply through the gonadal arterial branches.

### Endometriosis Imaging

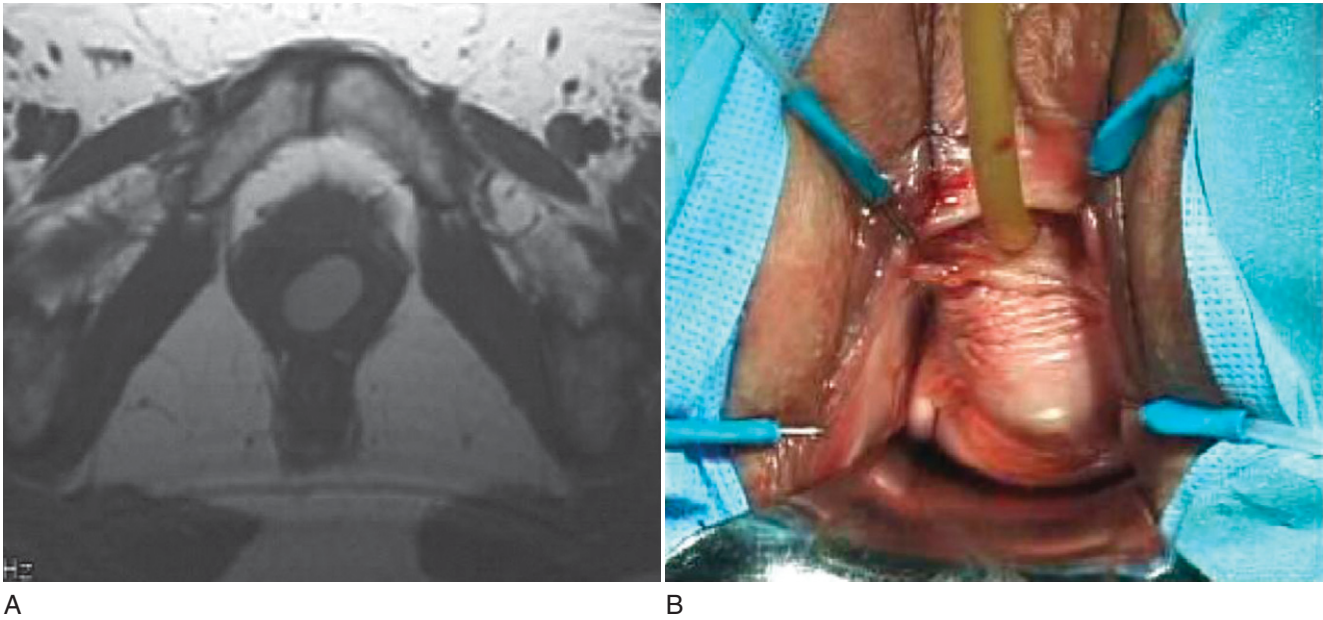

Laparoscopy has traditionally been the gold standard for diagnosis of endometriosis, which most commonly manifests as small implants with or without related adhesions on the parametrial surfaces, uterosacral ligament, ovaries, serosal surface of the uterus, and the cul-de-sac. Because laparoscopy is an invasive technique and visual inspection of the pelvis has limitations, especially in the diagnosis of retroperitoneal implants, major efforts are being made in the field of female urogynecology to improve the diagnostic utility of current noninvasive imaging modalities. Transvaginal ultrasonography and contrast-enhanced MRI have been used for noninvasive diagnosis and clinical follow-up of patients with endometriosis (Fig. 8-21; see Fig. 8-1). They allow imaging of the retroperitoneal space for determining the presence and characterization of deep pelvic endometriosis and bowel involvement.<sup>19,20</sup>

Although patients with endometriosis more commonly present to their gynecologists, these ectopic endometrial implants can create urinary symptoms due to direct bladder involvement or deep pelvic involvement causing ureteral obstruction. These patients therefore often present to urologists for clinical and radiographic evaluation. Bladder endometriosis, which is not easily palpable on vaginal examination, may mimic interstitial cystitis and interfere with bladder function.<sup>21,22</sup> In experienced hands, transvaginal ultrasonography performed on a slightly filled bladder can detect solid nodules (>0.5 cm) within the posterior bladder wall that cause urinary symptoms in these patients with dysmenorrhea. The presence of low to moderate vascularity demonstrated by color Doppler signal within these nodules and focal pain precipitated by mild pressure applied with the vaginal probe in the involved area helps confirm the diagnosis when suspected.<sup>19,20</sup> Nodules in the cul-de-sac may be biopsied transvaginally or percutaneously for confirmation. A high-resolution, contrast-enhanced MR scan of the pelvis at a field strength of 1.5 or 3 Tesla may help diagnose large, focal implants or confluent, small implants on the peritoneal surfaces by the findings of a concomitant thickened peritoneum and enhancement.

### Adnexal Imaging

A comprehensive examination of the female pelvis mandates evaluation of the adnexa for determining the ovarian volume,

**Figure 8-18** An inclusion cyst is shown first on a magnetic resonance image (A) and then in the operating room (B).

**Figure 8-19** Leiomyomas are appreciated on a sagittal magnetic resonance image.

assessing blood flow, and detecting and characterizing masses, especially in any evaluation of pelvic pain and other genitourinary symptoms. Functional ovarian disorders such as polycystic ovary syndrome also may be detected with limited sensitivity. In premenopausal women, ovarian ultrasonography has been the primary imaging modality for benign and pathologic adnexal

**Figure 8-20** Focal adenomyoma (arrowheads) and leiomyoma (arrow) are present on the same sagittal T2 Haste magnetic resonance image.

entities. However, MRI has become an invaluable addition in this field because of its superb soft tissue characterization, contrast resolution, and multiplanar capabilities. MRI enables the imager to determine with certainty whether a given mass is ovarian or extraovarian, which is an important distinction in evaluating the malignant potential of a tumor. It also plays an essential role in characterizing benign adnexal diseases such as mature teratomas, endometriomas, and ovarian fibromas because of their specific MR features (Fig. 8-22). For instance, MRI can delineate the internal architecture of cystic masses, such as thick internal septations and enhancing mural nodularity, especially after administration of Gd-DTPA-based contrast.<sup>8</sup>

### Pelvic Inflammatory Disease Imaging

Most ovarian infections in the Western world result from pelvic inflammatory disease of bacterial origin. They classically manifest

**Figure 8-21** Endometriosis is appreciated on ultrasound (**A** and **B**, arrow), which classically manifests as a cystic mass with diffuse, low-level echoes. Notice the septations, fluid-fluid levels, unilocularity or multilocularity, and an echogenic retracting clot.

**Figure 8-22** Endometrioma is appreciated on magnetic resonance imaging with T1-weighted (**A**) and T2-weighted (**B**) sequences. Notice characteristic high T1 and low T2 appearances, caused by high protein and iron content from recurrent bleeding and grading within the lesion.

with abdominal pain, fever, and an elevated white blood cell count. Some patients may present with vaginal discharge and urinary complaints. Involvement of the ovaries in this process usually results from salpingitis. In cases of delayed diagnosis and inadequate treatment, disease can progress to cause a tubo-ovarian abscess (TOA) (Fig. 8-23). In up to 20% of cases of infection that result in TOAs, the patients are afebrile and have normal white blood cell counts.<sup>23</sup>

The gold standard for the diagnosis of pelvic inflammatory disease is laparoscopy and tubal culture; the sensitivity and specificity of transvaginal ultrasound has not been reported in the literature.<sup>23</sup> Sonography is relied on heavily in the initial evaluation of a patient, because it can show pelvic and endometrial fluid in addition to other characteristic findings. Pyosalpinx and hydrosalpinx appear as cystic structures, with internal echoes resulting

in adnexal distortion.<sup>24</sup> A TOA usually appears as a well-defined, thick-walled, tubular structure, containing fluid-debris levels within the abscess. Most clinicians advocate a follow-up CT scan of the abdomen and pelvis to fully characterize any other intra-abdominal collections to prepare for a subsequent drainage procedure, especially when the abscesses do not respond to an antimicrobial treatment.<sup>25</sup>

When the clinical and ultrasonographic findings are questionable, MRI can play an important role (see Fig. 8-23). Pyosalpinx typically appears as a fluid-filled, tortuous, and dilated structure, and the signal intensity of the fluid depends on its viscosity and protein concentration. It is usually appreciated as a hypointense area on T2-weighted sequences in the peripheral area of a hyperintense, pus-filled cavity. The adjacent inflamed structures usually have low signal intensity

**Figure 8-23** A tubo-ovarian abscess is appreciated on sagittal (A) and axial (B) magnetic resonance images in a patient who presented with fever and chills after a uterine artery embolization procedure.

on T1-weighted sequences and intermediate to high signal intensity on T2-weighted MR images. Wall enhancement and thickening usually have greater signal intensity than those observed with hydrosalpinx. The TOA is usually a thick-walled, fluid-filled mass in an adnexal location with significant wall

enhancement and adjacent soft tissue inflammation characterized by similarly intense enhancement.<sup>8</sup> The most specific sign of an abscess is the presence of internal gas bubbles, best appreciated on T2-weighted sequences due to differences in magnetic susceptibility.<sup>26</sup>

# PELVIC FLOOR ULTRASOUND

*Hans Peter Dietz*

The increasing availability of ultrasound and magnetic resonance imaging (MRI) equipment has triggered a renewed interest in diagnostic imaging in female urology and urogynecology, after radiologic methods, developed since the 1920s,<sup>1-6</sup> had largely fallen into disuse. Because of cost and access problems, MRI has had limited clinical use in the evaluation of pelvic floor disorders, and until recently, slow acquisition speeds have precluded dynamic imaging. In contrast, ultrasound is almost universally available and provides real-time observation of diagnostic maneuvers. Beginning in the 1980s, transabdominal,<sup>7,8</sup> perineal,<sup>9,10</sup> transrectal,<sup>11</sup> and transvaginal ultrasound<sup>12</sup> have been investigated for use in women with urinary incontinence and pelvic organ prolapse. Because of its noninvasive nature, ready availability, and the absence of distortion, perineal or translabial ultrasound has become the most widely used method.

The development of three-dimensional (3D) ultrasound<sup>13,14</sup> has opened up new diagnostic possibilities. The first attempts at producing 3D-capable systems were made in the 1970s, when processing a single volume of data required 24 hours of computer time on a system that filled a small room.<sup>15</sup> Such data processing is now possible on a laptop computer and is achieved in real time. Transvaginal, transrectal, and translabial 3D ultrasound techniques have been reported, and significant development in this field is likely to occur in the next few years.

## TWO-DIMENSIONAL PELVIC FLOOR ULTRASOUND

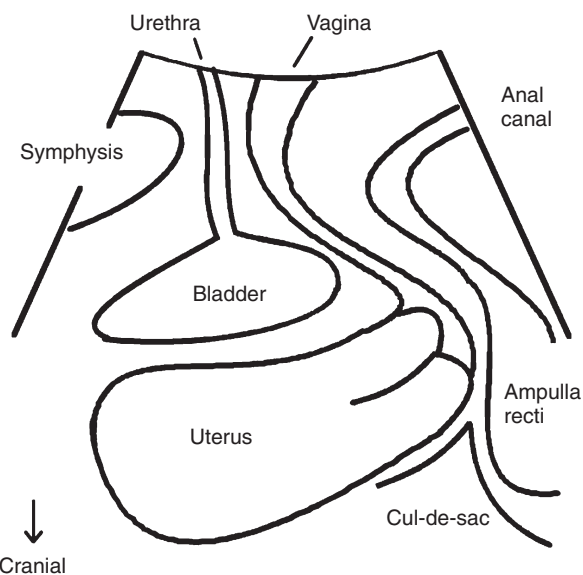

### Basic Methodology

Because translabial ultrasound is the most commonly used modality for pelvic floor evaluation, it is the focus of this chapter. A modification of the translabial or transperineal technique is introital imaging, which typically uses high-frequency endocavitary transducers placed in the introitus. This results in higher resolution of urethra and paraurethral tissues or of the anal sphincter complex, but it does not allow simultaneous imaging of all three compartments and may complicate quantification of findings because the symphysis pubis may not be included in the field of vision. Distortion of tissues is also more likely. However, most of the following discussion also applies to this technique.

A midsagittal view is obtained by placing a transducer (usually a curved array with frequencies between 3.5 and 9 MHz) on the perineum (Fig. 9-1) after covering the transducer with a glove or thin plastic wrap for hygienic reasons. Powdered gloves can markedly impair imaging quality because of reverberations and should be avoided. Imaging can be performed with the patient in the dorsal lithotomy position, with the hips flexed and slightly abducted, or in the standing position. Bladder filling should be specified; for some applications, prior voiding is preferable, and a full bladder can prevent complete development of a prolapse. The presence of a full rectum may also impair diagnostic accu-

racy and sometimes necessitates a repeat assessment after bowel emptying. Parting of the labia can improve image quality, which is optimal in pregnancy and poorest in menopausal women with marked atrophy, most likely due to various levels of tissue hydration. The transducer usually can be placed quite firmly against the symphysis pubis without causing significant discomfort, unless there is marked atrophy. The resulting image includes the symphysis pubis (specifically, the interpubic disk) anteriorly, the urethra and bladder neck, the vagina, cervix, rectum, and anal canal (see Fig. 9-1) with the internal and external anal sphincter. Posterior to the anorectal junction, a hyperechogenic area indicates the central portion of the levator plate, the puborectalis-pubococcygeus (or pubovisceral) muscle. The cul-de-sac may also be seen as filled with a small amount of fluid, echogenic fat, or peristalsing small bowel. Parasagittal or transverse views may yield additional information, such as enabling assessment of the puborectalis muscle and its insertion on the on the pelvic sidewall and imaging of transobturator implants.

There has been disagreement regarding image orientation in the midsagittal plane. Some clinicians prefer orientation as in the standing patient facing right,<sup>16</sup> which requires image inversion on the ultrasound system, a facility that is not universally available. Others (including me) prefer an orientation as on conventional transvaginal ultrasound (i.e., cranioventral aspects to the left, dorsocaudal to the right). The latter orientation seems more convenient when using 3D or 4D systems because it automatically results in rendered volumes that are oriented as on conventional MRI of the pelvic floor (discussed later). Because

**Figure 9-1** Drawing of the field of vision for translabial or perineal ultrasound in the midsagittal plane. Image adapted from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

**Figure 9-2** Lateral urethrocytogram with a bead chain outlining the urethra. The images are rotated by 180 degrees to allow comparison with standard translabial ultrasound views. The image on the *left* was obtained with the patient at rest; the image on the *right* was obtained during a Valsalva maneuver. Reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

any image reproduced in one of these orientations can be converted to the other by rotation through 180 degrees, formal standardization may be unnecessary. Orientations that require mirroring for conversion should be avoided.

Translabial ultrasound of the lower urinary tract, even if limited to B-mode imaging in the midsagittal plane, yields information equivalent or superior to the lateral urethrocytogram (Fig. 9-2, shown rotated by 180 degrees for comparison) or fluoroscopic imaging. Comparative studies have mostly shown good correlation between radiologic and ultrasound data.<sup>11,17-22</sup> The one remaining advantage of x-ray fluoroscopy may be the ease with which the voiding phase can be observed, although some investigators have used specially constructed equipment to document voiding with ultrasound.<sup>23</sup>

### Bladder Neck Position and Mobility

Bladder neck position and mobility can be assessed with a high degree of reliability. Points of reference are the central axis of the symphysis pubis<sup>24</sup> or its inferoposterior margin.<sup>17</sup> The former may be more accurate because measurements are independent of transducer position or movement; however, because of calcification of the interpubic disk, the central axis is often difficult to obtain in older women, reducing reliability. Imaging can be undertaken with the patient supine or erect and with a full or empty bladder. The full bladder is less mobile<sup>25</sup> and may prevent complete development of pelvic organ prolapse. In the standing position, the bladder is situated lower at rest but descends about as far as in the supine patient during a Valsalva maneuver.<sup>26</sup> Either way, it is essential to not exert undue pressure on the perineum to allow full development of pelvic organ descent, although this may be difficult in women with severe prolapse, such as vaginal eversion or procidentia.

Measurements of bladder neck position are generally performed at rest and during maximal Valsalva maneuver. The dif-

ference yields a numeric value for bladder neck descent. During a Valsalva maneuver, the proximal urethra may rotate in a posteroinferior direction. The extent of rotation can be measured by comparing the angle of inclination between the proximal urethra and any other fixed axis (Fig. 9-3). Some investigators measure the retrovesical (or posterior urethrovesical) angle between proximal urethra and trigone (see Fig. 9-3).<sup>27</sup> Others determine the angle  $\gamma$  between the central axis of the symphysis pubis and a line from the inferior symphyseal margin to the bladder neck.<sup>28,29</sup> Of all the ultrasound parameters of hypermobility, bladder neck descent may have the strongest association with urodynamic stress incontinence.<sup>30</sup> The reproducibility of this dynamic measurement has been assessed,<sup>31</sup> with a percent variation or coefficient of variation of 0.16 between multiple effective Valsalva maneuvers, 0.21 for interobserver variability, and 0.219 for a test-retest series at an average interval of 46 days. Intraclass correlations were between 0.75 and 0.98, indicating excellent agreement.<sup>31</sup>

There is no definition of *normal* for bladder neck descent, although cutoffs of 20 and 25 mm have been proposed to define hypermobility. Average measurements in stress-incontinent women are consistently around 30 mm (HP Dietz, unpublished data). Figure 9-4 shows a relatively immobile bladder neck before a first delivery and a marked increase in bladder neck mobility after childbirth. Figure 9-5 demonstrates typical ultrasound findings in a stress-incontinent patient with a first-degree cystourethrocele, 25.5 mm of bladder neck descent, and funneling. Bladder filling, patient position, and catheterization influence measurements,<sup>25,26,32,33</sup> and it sometimes is difficult to obtain an effective Valsalva maneuver, especially in nulliparous women. Perhaps not surprisingly, publications have presented widely different reference measurements in nulliparous women. Although two series documented mean or median bladder neck descent of only 5.1 mm<sup>34</sup> and 5.3 mm<sup>35</sup> in continent, nulliparous women, another study of 39 continent, nulliparous volunteers measured

**Figure 9-3** The ultrasound image (A) and line drawing (B) illustrate some of the parameters measured to quantify bladder and urethral mobility: the location of the bladder neck relative to the symphysis pubis (coordinates x-r, y-r, x-s, y-s), urethral rotation and retrovesical angle (RVA). This figure is reproduced from *Br J Obstet Gynecol* 2005; 112:334-339, with permission.

**Figure 9-4** Immobile bladder neck (bladder neck distance [BND] = 6 mm) before childbirth (*left pair of images*) and a marked increase in bladder neck mobility (BND = 38.1 mm) after vaginal delivery (*right pair of images*). The figure is reproduced from *Obstet Gynecol* 2003; 102:223-228, with permission.

an average bladder neck descent of 15 mm.<sup>36</sup> The author has obtained bladder neck descent measurements of 1.2 to 40.2 mm (mean, 17.3 mm) in a group of 106 stress-continent, nulligravid women between the ages of 18 and 23 years.<sup>37</sup> It is likely that methodologic differences, such as patient position, bladder filling, and quality of the Valsalva maneuver (i.e., controlling for confounders such as concomitant levator activation), account for the measurement discrepancies, with all known confounders tending to reduce descent. Attempts at standardizing Valsalva maneuvers<sup>38,39</sup> have not found widespread application because this requires intra-abdominal pressure measurement (i.e., use of a rectal balloon catheter). Other methods, such as the use of a spirometer, are likely to lead to suboptimal Valsalva maneuvers; the pressures used in the one study describing the use of such a

device<sup>38</sup> were clearly insufficient to achieve maximal or even near-maximal descent.<sup>39</sup>

The cause of increased bladder neck descent is likely to be multifactorial. The wide range of values obtained in young, nulliparous women suggests a congenital component, and a twin study has confirmed a high degree of heritability for anterior vaginal wall mobility.<sup>44</sup> Vaginal childbirth<sup>45-47</sup> is probably the most significant environmental factor (see Fig. 9-4), with a long second stage of labor and vaginal operative delivery associated with increased postpartum descent of the bladder neck.<sup>47</sup> This association between increased bladder descent and vaginal parity is also evident in older women with symptoms of pelvic floor dysfunction.<sup>48</sup> While the pelvic floor is undoubtedly affected by labor and delivery, it has been speculated that progress in labor

**Figure 9-5** Typical findings in a patient with stress incontinence and mild anterior vaginal wall descent (i.e., cystourethrocele grade 1): posteroinferior rotation of the urethra, opening of the retrovesical angle, and funneling of the proximal urethra (arrow). Figure reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

may not be independent of pelvic floor biomechanics.<sup>49</sup> Anterior vaginal wall mobility during a Valsalva maneuver was found to be a potential predictor of progress in labor in two independent studies.<sup>50,51</sup>

### Funneling

In patients with stress incontinence and in asymptomatic women,<sup>40</sup> funneling of the internal urethral meatus may be observed during a Valsalva maneuver (see Fig. 9-5) and sometimes even at rest. Funneling is often associated with leakage. Other indirect signs of urine leakage on B-mode real-time imaging are weak gray-scale echoes (i.e., streaming) and the appearance of two linear echoes defining the lumen of a fluid-filled urethra. However, funneling may also be observed in patients with urge incontinence, and it cannot be used to prove urodynamic stress incontinence. Its anatomic basis is unclear, but marked funneling is associated with poor urethral closure pressures.<sup>41,42</sup>

Classifications developed for the evaluation of radiologic imaging<sup>43</sup> can be modified for ultrasound; however, this approach is not generally accepted. The most common finding in cases of bladder neck hypermobility is a so-called rotational descent of the internal meatus (i.e., proximal urethra and trigone rotate around the symphysis pubis in a posteroinferior direction). In these cases, the retrovesical angle opens to up to 160 to 180 degrees from a normal value of 90 to 120 degrees, and the change in the retrovesical angle usually is associated with funneling. Often, there seems to be increased mobility of the entire urethra. A cystocele with intact retrovesical angle (90 to 120 degrees) is frequently seen in continent patients with prolapse (Fig. 9-6), and distal and central urethral fixation to the pubic rami usually seems to be relatively normal, resulting in urethral kinking. It has been surmised that this configuration distinguishes a central from a lateral defect of the endopelvic fascia,<sup>16</sup> although proof for

this hypothesis is lacking. Marked urethral kinking in these patients may protect against stress incontinence but can lead to voiding dysfunction and urinary retention. Occult stress incontinence may be unmasked once a successful prolapse repair prevents urethral kinking.

### Color Doppler

Color Doppler ultrasound has been used to demonstrate urine leakage through the urethra during a Valsalva maneuver or coughing.<sup>58</sup> Agreement between color Doppler and fluoroscopy results was high in a controlled group with indwelling catheters and identical bladder volumes.<sup>59</sup> Color Doppler ultrasound velocity (Fig. 9-7) and energy mapping (Color Doppler or power Doppler) (Fig. 9-8) were able to document leakage. Color Doppler ultrasound velocity was slightly more likely to show a positive result, probably because of its better motion discrimination. This results in less flash artifact and better orientation, particularly on coughing, although imaging quality depends on the systems used and selected color Doppler settings. As a result, routine sonographic documentation of stress incontinence during urodynamic testing has become feasible. Color Doppler imaging may also facilitate documentation of leak point pressures.<sup>60</sup> Whether this is desired depends on the clinician's preferences, because it may be argued that urine leakage and leak point pressures can be determined more easily with other methods.

### Bladder Wall Thickness

There has been considerable interest in the quantification of bladder wall thickness by transvaginal or translabial ultrasound.<sup>61,62</sup> Measurements are obtained after bladder emptying, and they are acquired perpendicular to the mucosa (Fig. 9-9). In the original description, three sites were assessed— anterior wall, trigone, and dome of the bladder—and the mean of all three was

**Figure 9-6** A cystocele with an intact retrovesical angle. Notice the absence of funneling. The bladder neck and proximal urethra are virtually inverted compared with their position at rest. Reproduced from *Textbook of Female Urology and Urogynecology*, Abingdon UK, 2006.

**Figure 9-7** Color Doppler velocity (CDV) demonstrates urine leakage (arrowhead) through the urethra during a Valsalva maneuver. Reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

**Figure 9-8** Color Doppler energy mapping (CDE) of stress urinary incontinence. The Doppler signal outlines most of the proximal urethra (arrowhead). Reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

calculated. A bladder wall thickness of more than 5 mm seems to be associated with detrusor instability,<sup>61,63</sup> although this has been disputed.<sup>64</sup> Increased bladder wall thickness is likely caused by hypertrophy of the detrusor muscle,<sup>64</sup> which is most evident at the dome; this may be the cause of symptoms or the effect of an underlying abnormality. Although bladder wall thickness on its own seems only moderately predictive of detrusor instability and is not in itself a useful diagnostic test, the method may be of value when combined with symptoms of the overactive bladder.<sup>65</sup> It remains to be seen whether determination of this parameter can contribute to the workup of a patient with pelvic floor and

bladder dysfunction, such as serving as a predictor of postoperative voiding function or de novo or worsened detrusor overactivity.

#### Levator Activity

Perineal ultrasound has been used for the quantification of pelvic floor muscle function in women with stress incontinence and in continent controls<sup>66</sup> before and after childbirth.<sup>67,68</sup> A cranioventral shift of pelvic organs imaged in a sagittal midline orientation is taken as evidence of a levator contraction. The resulting dis-

**Figure 9-9** Measurement of bladder wall thickness at the dome in four women with non-neuropathic bladder dysfunction. In all cases, the residual urine volume is well below 50 mL.

**Figure 9-10** Quantification of levator contraction. Cranioventral displacement of the bladder neck is measured relative to the inferoposterior symphyseal margin. The measurements indicate 4.5 (range, 31.9 minus 27.4) mm of cranial displacement and 16.2 (range, 17.9 minus 1.7) mm of ventral displacement of the bladder neck. Figure reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

placement of the internal urethral meatus is measured relative to the inferoposterior symphyseal margin (Fig. 9-10). In this way, pelvic floor activity is assessed at the bladder neck, where its effect as part of the continence mechanism is most likely to be relevant.<sup>69</sup> Another means of quantifying levator activity is to measure reduction of the levator hiatus in the midsagittal

plane or to determine the changing angle of the hiatal plane relative to the symphyseal axis. The method can also be used for pelvic floor muscle exercise teaching by providing visual biofeedback.<sup>70</sup> The technique has helped validate the concept of *the knack*, a reflex levator contraction immediately before increases in intra-abdominal pressure, such as those resulting

**Figure 9-11** Line drawing demonstrating the ultrasound quantification of uterovaginal prolapse. The inferior margin of the symphysis pubis serves as a line of reference against which the maximal descent of the bladder, uterus, cul-de-sac, and rectal ampulla on Valsalva maneuver can be measured. Figure reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

from coughing.<sup>71</sup> Good correlations have been found between cranioventral shift of the bladder neck and palpation or perineometry.<sup>72</sup>

### Prolapse Quantification

Translabial ultrasound can demonstrate uterovaginal prolapse.<sup>73,74</sup> The inferior margin of the symphysis pubis serves as a convenient (if arbitrary) line of reference against which the maximal descent of the bladder, uterus, cul-de-sac, and rectal ampulla during a Valsalva maneuver can be measured (Fig. 9-11). On Valsalva the transducer is withdrawn to allow full development of the prolapse, while retaining contact with the insonated tissues. Angling of the transducer should be avoided in order to prevent changes in the relative position of transducer and symphyseal axes. Figure 9-12 shows a three-compartment prolapse, with the uterus leading. Findings have been compared with clinical staging and the results of a standardized assessment according to criteria developed by the International Continence Society,<sup>75</sup> with good correlations shown for the anterior and central compartments.<sup>76</sup> Although there may be poorer correlation between posterior compartment clinical assessment and ultrasound, not the least due to variable rectal filling, it is possible to distinguish between true rectocele (i.e., defect of the rectovaginal septum) (Fig. 9-13A) and perineal hypermobility without fascial defects (see Fig. 9-13B). True rectoceles may be present in young, nulliparous women but are more common in parous women. In some instances, they arise in childbirth.<sup>77</sup> From imaging experience, fascial defects seem to almost always be found in the same area (i.e., very close to the anorectal junction), and they most commonly are transverse. Many are asymptomatic. Routine posterior repair often results in reduction or distortion of such defects without effecting closure.

The ability to differentiate different forms of posterior compartment descent should allow better surgical management in the future, especially because enterocele (Fig. 9-14) can easily be

**Figure 9-12** Three-compartment prolapse on translabial ultrasound. The line of reference is placed through the inferior margin of the symphysis pubis. Measurements indicate descent of the bladder to 6.8 mm below the symphysis pubis, of the uterus to 11.3 mm, and of the rectal ampulla to 3.9 mm below. Arrows indicate the leading edges of those organs. The clinical examination showed a second-degree uterine prolapse and first-degree anterior and posterior compartment descent.

distinguished from rectocele. It appears that colorectal surgeons are starting to use the technique to complement or replace defecography,<sup>78</sup> and perineal ultrasound can also be used for exoanal imaging of the anal sphincter.<sup>79,80</sup>

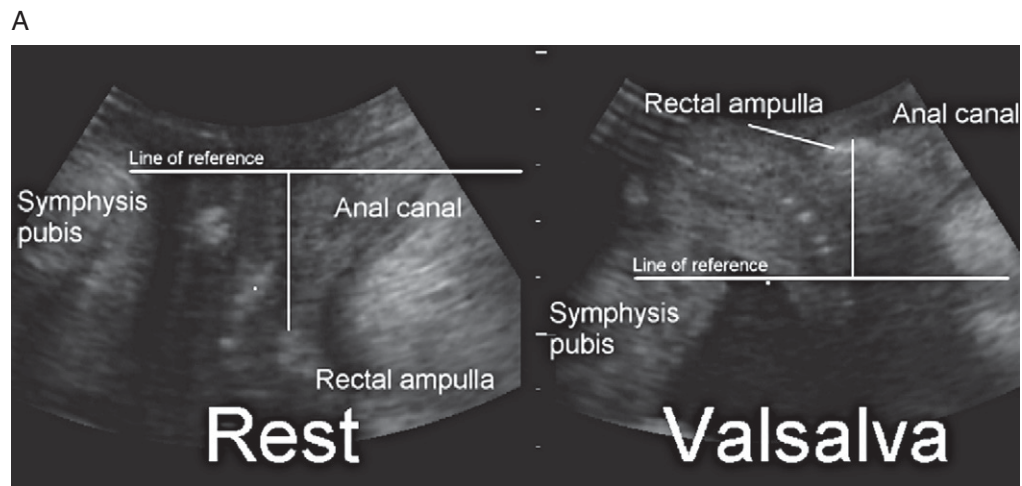

Disadvantages of the method include incomplete imaging of bladder neck, cervix, and vault with large rectoceles and possible underestimation of severe prolapse due to transducer pressure. Occasionally, apparent anterior vaginal wall prolapse turns out to be caused by a urethral diverticulum<sup>81,82</sup> (Fig. 9-15) or a paravaginal cyst.

The main use of this technique may prove to be in outcome assessment after prolapse and incontinence surgery for clinical and research applications. Elevation and distortion of the bladder neck arising from a colposuspension is easily documented.<sup>83,84</sup> Fascial and synthetic slings are visible posterior to the trigone or the urethra (Figs. 9-16 and 9-17). Bulking agents such as Macroplastique (Fig. 9-18) show up anterior, lateral, and posterior to the proximal urethra. It has been demonstrated that overelevation of the bladder neck on colposuspension is unnecessary for cure of urodynamic stress incontinence, and elevation may also have a bearing on postoperative symptoms of voiding dysfunction and de novo detrusor instability.<sup>83,84</sup>

### Implants

Ultrasound has contributed significantly to the investigation of new surgical procedures, such as wide-weave suburethral Prolene slings, showing that they act by urethral kinking or *dynamic compression* against the posterior surface of the symphysis pubis.<sup>85</sup> Available synthetic slings are easily visualized posterior to the urethra<sup>86-93</sup> (see Fig. 9-16). Wide-weave monofilament mesh such as tension-free vaginal tape (e.g., Gynecare TVT), SPARC sling, and Monarc Subfascial Hammock or transobturator (TOT) sling are more echogenic than more tightly woven multifilament implants, such as the IVS (i.e., polypropylene mesh) (see Fig.

**Figure 9-13** **A**, The top pair of images shows a first-degree rectocele. The anal canal is seen to the right of both images, with a small rectocele (deep 2 cm) clearly visible during a Valsalva maneuver (*right*). **B**, The lower pair of images demonstrates descent of the rectal ampulla without herniation of rectal contents into the vagina, a condition that may mimic rectocele and that has been called *perineal hypermobility* or *pseudorectocele*. Figure reproduced from Textbook of Female Urology and Urogynecology, Abingdon UK, 2006.

**B**

**Figure 9-14** Rectocele after Burch colposuspension with the patient at rest (*left*) and during a Valsalva maneuver (*right*). Usually, enteroceles (filled by peristalsing small bowel, epiploic fat, or omentum) appear more homogeneous and nearly isoechoic, whereas the rectocele is filled by a stool bolus and/or air, resulting in hyperechogenicity with distal shadowing. Figure reproduced from Ultrasound Obstet Gynecol 2005; 26:73-77, with permission.

**Figure 9-15** Urethral diverticulum (*arrow*), herniating downward and clinically simulating a cystourethrocele during a Valsalva maneuver. The neck of the diverticulum is close to the bladder neck. Reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

**Figure 9-16** Synthetic implants such as the tension-free vaginal tape or SPARC are easily visualized as highly echogenic structures posterior to the urethra. The images illustrate tape position relative to the symphysis pubis and urethra with the patient at rest (*left*) and during a Valsalva maneuver (*right*). Reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

9-17), but virtually all can be identified and followed in their course from the pubic rami laterally to the urethra centrally. The difference between transobturator tapes (e.g., Monarc, TOT) and tapes placed through the space of Retzius (e.g., TVT, SPARC, IVS) is evident when following the tapes in the parasagittal or axial planes. In the parasagittal plane, transobturator tapes often

can be seen to perforate the obturator fascia and muscle close to the insertion of the pubovisceral muscle; sometimes, they traverse the most inferomedial component of the levator before exiting the pelvis.<sup>93</sup> Wide-weave mesh implants used in procedures, such as the Perigee, Apogee or Prolift implants, are very echogenic and easily identified,<sup>94</sup> and their transobturator or

**Figure 9-17** A comparison of tension-free vaginal tape (TVT), SPARC mesh, and IVS mesh (left to right) on midsagittal imaging. The TVT often appears slightly curled, signifying a greater degree of tension compared with the SPARC material, which often is under less tension because of a central suture that avoids pretensioning of the tape on removal of plastic sheaths during surgery. Reproduced from *Ultrasound Obstet Gynecol* 2005; 26:175-179, with permission.

**Figure 9-18** Macroplastique (silicone macroparticles), an injectable used in USI surgery, is very echogenic and can be located ventral, dorsal and lateral to the proximal and mid-urethra. Figure reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

pararectal extensions can be followed for some distance, although 3D or 4D imaging allows much more comprehensive evaluation.

Ultrasound has demonstrated the wide margin of safety and efficacy of suburethral tapes in regard to placement (which helps explain their extraordinary success) and allayed concerns regarding tape shrinkage and tightening due to scar formation.<sup>90,91</sup> The assessment of bladder neck mobility before implantation of a suburethral sling may predict success or failure,<sup>95</sup> an observation that makes perfect sense considering that dynamic compression relies on relative movement of implant and native tissues.

### Paravaginal Defect Imaging

Transabdominal ultrasound has been used to demonstrate lateral defects of the endopelvic fascia, also called *paravaginal defects*. However, this method has not been fully validated, and a prospective study showed poor correlation with clinically observed defects.<sup>96</sup> Several factors may limit the predictive value of transabdominal ultrasound in the identification of paravaginal defects:

**Figure 9-19** A Gartner duct cyst is shown close to the bladder neck (arrow). Reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

the poor definition of an optimal scanning plane, the influence of uterine prolapse or a full rectum, and the inability to observe the effect of a Valsalva maneuver (which would dislodge the transducer) by transabdominal imaging. It is likely that levator trauma (see below) is frequently misinterpreted as a “paravaginal defect.” Fascial trauma is highly likely in patients with a full avulsion, but it is conceivable that fascial defects may occur in women with intact muscle. Much work remains to be done in this field.

### Other Findings

A range of other abnormalities, incidental or expected, may sometimes be detected on translabial ultrasound, although a full pelvic ultrasound assessment does require a transvaginal approach. Urethral diverticula (see Fig. 9-15),<sup>78,97</sup> labial cysts, Gartner’s duct cysts (Fig. 9-19), or bladder tumors (Fig. 9-20) may be identified, and intravesical stents and bladder diverticula also can be visualized.<sup>16</sup> Postoperative hematomas may be visible after vaginal surgery or TVT placement and sometimes explain clinical symptoms such as voiding dysfunction or persistent pain (Fig. 9-21).

Most recently, it has become clear that rectal intussusception and rectal prolapse can be diagnosed on pelvic floor ultrasound in the midsagittal plane. The pathognomonic feature of intussusception is splaying of the anal canal and inversion of the anterior rectal wall into the anal canal (see Figure 9-21). The intussusciens is propelled by small bowel or sigmoid colon, resulting in inversion of the rectal wall: an enterocele that does not develop into the vagina, but down the anal canal. Mucosal prolapse, on the other hand, is much more discrete as it does not involve the full thickness of the rectal wall, and seems limited to the area immediately proximal to the anal canal. The usefulness of translabial ultrasound in patients with symptoms of obstructed defecation, in particular as compared to defecation proctography, is not yet clear however. Several comparative studies are in progress in urogynaecological and colorectal units at the time of writing.

### THREE-DIMENSIONAL PELVIC FLOOR IMAGING

#### Technical Overview

Two main engineering solutions have been developed to allow integration of two-dimensional (2D) sectional images into 3D

**Figure 9-20** A transitional cell carcinoma (arrow) of the bladder is seen on parasagittal translabial ultrasound. Reproduced from *Ultrasound Obstet Gynecol* 2004; 23:80-92, with permission.

volume data: motorized acquisition and external electromagnetic position sensors. A simplified technique is the freehand acquisition of volumes without any reference to transducer position. In essence, this means that a cine loop of images is collated to form a volume data set; because the system has no information on transducer position relative to the insonated tissues, measurements on volume data are impossible. Nevertheless, qualitative information may be obtained, and such systems have been used for clinical research in urogynecology.<sup>98</sup>

Quantitative evaluation of volumes requires information on transducer position at the time of acquisition. If probe movement is achieved with the help of a motor, its characteristics will determine imaging data coordinates. Motorized acquisition may take the shape of automatic withdrawal of an endocavitary probe, motorized rotation of such a probe, or motor action within the transducer itself. The first such motorized probe was developed in 1974, and by 1987, transducers for clinical use were developed that allowed motorized acquisition of imaging data.<sup>99</sup> The first commercially available platform, the Kretz Voluson system, was developed around such a “fan scan” probe. Endocavitary probes make a freehand acquisition technique impractical, which is why the company did not develop this alternative approach further<sup>99</sup> and instead concentrated on a technology reminiscent of (otherwise obsolete) mechanical sector transducers. The results have been the abdominal and endovaginal probes used in systems such as the GE Kretz Voluson 530, 730, 730 expert, E8 and Volusoni System. The widespread acceptance of 3D ultrasound in obstetrics and gynecology was helped considerably by this development because these transducers do not require any movement relative to the investigated tissue during acquisition. Most of the major suppliers of ultrasound equipment have developed their own transducers along such lines, although it is widely recognized that this technology will probably be replaced by matrix array transducers within the next 5 to 10 years. Such transducers are already available for echocardiography.<sup>100</sup>

With current mechanical 3D transducers, automatic image acquisition is achieved by rapid oscillation of a group of elements within the transducer. This allows the registration of multiple sectional planes that can be integrated into a volume as the location of a given voxel (i.e., a pixel that has a defined location in space) is determined by transducer and insonation characteristics. Fortuitously, transducer characteristics on available systems for transabdominal use have been highly suitable for pelvic floor imaging. A single volume obtained at rest with an acquisition angle of 70 degrees or higher includes the entire levator hiatus

**Figure 9-21** Retroperitoneal hematoma and subcutaneous vaginal hematoma after mesh sacrocolpopexy and posterior repair. Reproduced from *ASUM Bulletin* 2007; 10:17-23, with permission.

**Figure 9-22** The usual acquisition or evaluation screen on Voluson-type systems shows the three orthogonal planes: sagittal (*top left*), coronal (*top right*), and axial (*bottom left*). It also shows a rendered volume (*bottom right*), which is a semitransparent representation of all gray-scale data in the region of interest (*arrows*).

with the symphysis pubis, urethra, paravaginal tissues, the vagina, anorectum, and pubovisceral (i.e., puborectalis or pubococcygeus part of the levator ani) muscle from the pelvic side wall in the area of the arcus tendineus of the levator ani (ATLA) to the posterior aspect of the anorectal junction (Fig. 9-22). Depending on the anteroposterior dimensions of the pubovisceral muscle, it may also include the anal canal and the external anal sphincter. This also holds true for volumes acquired on levator contraction. A Valsalva maneuver may result in lateral or posterior parts of the puborectalis being pushed outside the field of vision, especially in women with significant prolapse (discussed later). The abdominal 8-4-MHz volume transducer for Voluson systems allows acquisition angles of up to 85 degrees, ensuring that the levator hiatus can be imaged in its entirety, even in women with significant enlargement (i.e., ballooning) of the hiatus during a Valsalva maneuver.

### Display Modes

Figure 9-22 demonstrates the two basic display modes used on 3D ultrasound systems. The multiplanar or orthogonal display mode shows cross-sectional planes through the volume in question. For pelvic floor imaging, this most conveniently means the midsagittal, the coronal, and the axial or transverse plane.

One of the main advantages of volume ultrasound for pelvic floor imaging is that the method gives access to the axial plane. Until recently, pelvic floor ultrasound was limited to the midsagittal plane.<sup>9,101,102</sup> Parasagittal and coronal plane imaging have not been reported, perhaps because there are no obvious points of reference, unlike the convenient reference point of the sym-

physis pubis on midsagittal views. The axial plane was accessible only on MRI; Figure 9-23 provides an axial view of the levator hiatus on MRI and 3D ultrasound.<sup>103</sup> Pelvic floor MRI is an established investigational method, at least for research applications, with a multitude of papers published over the past 10 years.<sup>104-113</sup>

Imaging planes on 3D ultrasound can be varied in a completely arbitrary fashion to enhance the visibility of a given anatomical structure at the time of acquisition or offline at a later time. The levator ani, for example, usually requires an axial plane that is slightly tilted in a cranioventral to dorsocaudal direction. The three orthogonal images are complemented by a rendered image, which is a semitransparent representation of all voxels in an arbitrarily definable box, termed the Region of Interest (ROI). Figure 9-22 (bottom right image) shows a standard rendered volume of the levator hiatus, with the rendering direction set caudally to cranially, which seems to be most convenient for pelvic floor imaging. The possibilities for postprocessing are restricted only by the software used for this purpose; programs such as GE Kretz 4D View (GE Medical Systems Kretztechnik, Zipf, Austria) allow extensive manipulation of image characteristics and output of stills, cine loops, and rotational volumes in bitmap and AVI formats.

### FOUR-DIMENSIONAL IMAGING

The use of 4D imaging implies the real-time acquisition of volume ultrasound data, which can then be represented in orthogonal planes or rendered volumes. It has become possible

**Figure 9-23** The axial plane on magnetic resonance imaging (MRI) and ultrasound (rendered volume) in a young nulliparous volunteer. (MRI courtesy of J Kruger, Auckland.) Reproduced from *Obstet Gynecol* 2005; 106:707-712, with permission.

to save cine loops of volumes, which is important in pelvic floor imaging because it allows enhanced documentation of functional anatomy. Even on 2D, single-plane imaging, a static assessment at rest gives little information compared with the evaluation of maneuvers such as a levator contraction and Valsalva. Observation enables better assessment of levator function and improved delineation of levator or fascial trauma. Avulsion of the pubovisceral muscle from the arcus tendineus of the levator ani is often more evident on levator contraction, and most significant pelvic organ prolapse is not visible with the patient at rest in the supine position. Fascial defects such as those defining a true rectocele often only become visible during a Valsalva maneuver.

The ability to perform a real-time 3D (or 4D) assessment of pelvic floor structures makes the technology clearly superior to MRI. Prolapse assessment by MRI requires ultrafast acquisition,<sup>107,109</sup> which is of limited availability and does not allow optimal resolutions. Alternatively, some systems allow imaging of the sitting or erect patient,<sup>108</sup> but accessibility will remain limited for the foreseeable future. The sheer physical characteristics of MRI systems make it much harder for the operator to ensure efficient maneuvers because more than 50% of women do not perform a proper pelvic floor contraction when asked<sup>114</sup> and a Valsalva maneuver is often confounded by concomitant levator activation.<sup>115</sup> Without real-time imaging, it is impossible to control for these confounders. Ultrasound therefore has major potential advantages when it comes to describing prolapse, especially when it is associated with fascial or muscular defects, and for defining functional anatomy. Offline analysis packages such as the GE Kretz 4D View or Philips QL AB software allow distance, area, and volume measurements in any user-defined plane (e.g., oblique, orthogonal), which is superior to what is possible with Digital Imaging and Communications in Medicine (DICOM) viewer software on a standard set of single-plane MRI images. DICOM is a standard for distributing and viewing any kind of medical image, regardless of the origin.

### Speckle Reduction Techniques

Technical developments such as volume-contrast imaging (VCI) and speckle-reduction imaging (SRI) employ rendering algo-

rithms as a means of improving resolutions in the coronal plane. As a result, speckle artifact is markedly reduced.<sup>116</sup> Measuring in the axial or C plane has been limited to raw data without significant postprocessing. Consequently, resolutions were much poorer than in the sagittal plane, reducing the accuracy of measurements and our ability to identify structural changes. By using VCI on slices 1 to 3 mm thick, resolutions of about 1 mm can be reached on axial or oblique axial slices that allow distance and area measurements on the ultrasound system and offline on a computer. Figure 9-24 shows normal C-plane imaging and VCI in the axial plane in a patient with major bilateral levator trauma after rotational forceps delivery. Another technique using rendering algorithms to enhance single plane resolutions, Speckle Reduction Imaging or “SRI,” results in improved tissue discrimination, which should help to improve detection of morphologic abnormalities. Figure 9-22 provides an example of image quality using SRI for orthogonal planes and rendered volumes.

### Tomographic Ultrasound Imaging

During or after acquisition of volumes, it is possible to process imaging information into slices of predetermined number and spacing, reminiscent of computed tomography (CT) or nuclear MRI. This technique has been called *multislice imaging* or *tomographic ultrasound imaging* (TUI) by manufacturers. Unlike CT or MRI, the location, number, depth, and tilt of slices can be adjusted at will after volume acquisition. The combination of true 4D (volume cine loop) capability and TUI or multislice imaging allows simultaneous observation of the effect of maneuvers at many different levels.

The pelvic floor easily lends itself to such techniques, and I suggest using the plane of minimal dimensions as plane of reference: an oblique axial plane that is defined in the midsagittal plane by the shortest line between the posterior symphyseal margin and the levator ani immediately posterior to the anorectal angle (Fig. 9-25). For the sake of convenience, I use 8 × 2.5-mm steps recorded from 5 mm below this plane to 12.5 mm above, which should encompass the entire puborectalis muscle.

Figure 9-26 shows the standard TUI format most appropriate to pelvic floor imaging, with the coronal plane for reference

**Figure 9-24** Axial plane translabial imaging with the patient at rest, illustrating a severe case of delivery-related pelvic floor trauma. A bilateral avulsion and complete loss of tenting bilaterally is shown on conventional axial-plane, 3D ultrasound (*left*). The same plane in the same volume data set (*right*) is shown using volume-contrast imaging (VCI). This patient has severe stress incontinence and prolapse 3 years after a rotational forceps delivery.

**Figure 9-25** Determination of the plane of minimal hiatal dimensions. The minimal distance between the posterior symphyseal margin and the levator ani immediately posterior to the anorectal angle (*left*, midsagittal plane) identifies the correct axial plane (*right*), which in this case was obtained by volume-contrast C-plane imaging.

in the top left corner and eight axial-plane slices at a distance of 2.5 mm each, in a nulliparous patient with normal pelvic floor function and anatomy. The presence and extent of injuries is evident at a glance from one printout or film, without requiring any further manipulation of data, as is familiar from radiologic cross-sectional techniques. It is likely that such techniques will help with the standardization of assessment methods and allow more accurate classification and quantification of morphologic abnormalities.<sup>117</sup>

### PRACTICAL CONSIDERATIONS

Pelvic floor ultrasound is highly operator dependent, as is true for all real-time ultrasound procedures. The 3D systems have the potential to reduce this operator dependence because volume acquisition is easily taught and should be within the capabilities of every sonographer or sonologist after a day's training. Although

the method does require postprocessing (and the skills involved in this are more significant), static volume data typically of 1 to 6 MB can be de-identified and transmitted electronically so that evaluation may be obtained by e-mail, and this opens up new possibilities for local and international cooperation. Unfortunately, the de facto software standard of 3D image files provided by licensing of original technology has been lost, with many companies developing their own standards, which are incompatible with the others. A DICOM standard for 3D imaging data would be the solution, but standardization does not appear to be imminent. Consequently, increasing numbers of clinicians and researchers are frustrated by the inability to exchange volume data. Users need to exert significant pressure on manufacturers, who may not be inclined to cooperate with competitors on this issue.

Most publications on 3D ultrasound in obstetrics and gynecology deal with obstetric applications.<sup>15</sup> The visualization of fetal structures such as extremities, skeleton, and face has to a large

**Figure 9-26** Normal pelvic floor. Tomographic ultrasound imaging provides cross-sectional imaging at user-definable depths and intervals and at arbitrarily definable angles or tilts within the acquired volume. A cine loop of volumes allows observation of the effect of maneuvers in multiple cross sections at any time.

extent driven the research, development, and marketing of these systems. Although well-selected 3D data may enhance the understanding of certain conditions or abnormalities for patients and caregivers,<sup>15</sup> some critics contend that 3D ultrasound has been a technology searching for an application.

Pelvic floor imaging is a minor niche within the field of ultrasound diagnostics, but it may provide one of the first true indications for 3D and 4D volume ultrasound imaging. Pelvic floor 3D ultrasound has been used for the evaluation of the urethra and its structures, for imaging of the more inferior aspects of the levator ani complex (i.e., pubococcygeus and puborectalis), for the visualization of paravaginal supports, and for prolapse and implant imaging.

### Three-Dimensional Imaging of the Urethra

Technically, 3D pelvic floor ultrasound imaging became feasible in 1989 with the advent of the Kretz Voluson 530 system. However, there are no records of the early use of such systems; the first publication on 3D ultrasound in urogynecology was in 1994,<sup>118</sup> when Khullar et al demonstrated that this technique could be employed to assess the urethra.<sup>118</sup> They used transvaginal probes with motorized withdrawal to allow the use of calipers in all three planes. Subsequently, it was shown that urethral volumetric data correlated with urethral pressure profilometry<sup>118</sup> and that urethral volume decreased with parity. This technique has been used to assess delivery-related changes,<sup>119</sup> and 3D ultrasound with intracavitary transducers may also aid in identifying paraurethral support structures such as the pubourethral ligaments. Probes designed for prostatic imaging have also been

employed for the assessment of the urethra and paraurethral structures by the transrectal route.<sup>120</sup>

### Three-Dimensional Imaging of the Levator Ani Complex

The inferior aspects of the levator ani were identified on early studies using transvaginal techniques<sup>14</sup> and translabial freehand volume acquisition,<sup>98</sup> as well as on translabial ultrasound using a Voluson system,<sup>15</sup> but the focus of these reports was on the urethra and paraurethral tissues. With translabial acquisition, the whole levator hiatus and surrounding muscle (i.e., pubococcygeus and puborectalis) can be visualized, provided acquisition angles are at or above 70 degrees. Similar to MRI, it is impossible to distinguish the different components of the pubovisceral or puborectalis-pubococcygeus complex. In a series of 52 young, nulligravid women, no significant asymmetry of the levator was observed, supporting the hypothesis that morphologic abnormalities of the levator are likely to be evidence of delivery-related trauma.<sup>121</sup> Contrary to MRI data,<sup>112</sup> there was no significant side difference in thickness or area.

A number of biometric parameters of the puborectalis-pubococcygeus complex itself and of the levator hiatus have been defined.<sup>121</sup> Results agreed with MRI data obtained in small numbers of nulliparous women for the dimensions of the levator hiatus<sup>112</sup> and levator thickness.<sup>110</sup> Hiatal depth, width, and area measurements seem highly reproducible (intraclass correlation coefficients of 0.70 to 0.82) and correlate strongly with pelvic organ descent at rest and during a Valsalva maneuver.<sup>121</sup> This study was replicated in a Chinese population, with very similar results for repeatability measures and intriguing differences in

**Figure 9-27** Hiatal appearance in a patient during a Valsalva maneuver. At 36 weeks, the hiatus measured 25 cm<sup>2</sup>, and this had increased to 32 cm<sup>2</sup> 4 months after a normal vaginal delivery.

the shape of the hiatus.<sup>122</sup> Other investigators have confirmed good repeatability of this technique<sup>123-125</sup>, and a comparison with measures obtained on magnetic resonance imaging showed high levels of agreement.<sup>126</sup>

Although it is not surprising that the hiatal area during a Valsalva maneuver correlates with descent (because downward displacement of organs may displace the levator laterally), it is much more interesting that hiatal area at rest seems associated with pelvic organ descent during a Valsalva maneuver. These data constitute the first real evidence for the hypothesis that the state of the levator ani is important for pelvic organ support,<sup>127</sup> even in the absence of levator trauma. Relative enlargement of the hiatus during Valsalva maneuvers, or rather distention or elongation of its muscular component, may be a measure of compliance or elasticity and seems to correlate with resting tone as determined by palpation.<sup>128</sup> The population distribution for hiatal area enlargement during Valsalva maneuvers in nulligravid white women seems to be remarkably wide, with measurements from 6 to 36 cm<sup>2</sup> in one study.<sup>121</sup> The 95th percentile of the distribution seems to lie at about 25 cm<sup>2</sup>, and based on this and receiver operator characteristics,<sup>129</sup> the author considers hiatal enlargement in excess of this cutoff to be ballooning of the hiatus, indicating abnormal biomechanical properties. Figure 9-27 shows a case of de novo ballooning of the hiatus after vaginal childbirth. It is not clear whether such changes are due to myopathy, neuropathy or microtrauma to connective tissue structures. Pelvic floor compliance or distensibility deserves further study because it may be important for the progress of labor and in the diagnosis and treatment of pelvic organ prolapse. In fact, it is likely that surgical reduction of the levator hiatus, now feasible as a minimally invasive technique, will become an entirely new concept in pelvic reconstructive surgery.

The most common form of levator trauma, a unilateral avulsion of the pubococcygeus muscle off the pelvic side wall, is related to childbirth (Figs. 9-28 to 9-30; see Fig. 9-24) and is generally palpable as an asymmetric loss of substance in the inferomedial portion of the muscle at the site of its insertion on the pelvic side wall. It is usually occult but may occasionally be observed directly in women after major vaginal tears (see Fig. 9-28). Bilateral defects (see Figs. 9-24 and 9-30) are more difficult to palpate because of the lack of asymmetry and are much less common, probably in the order of 1% to 4% of the vaginally parous population. In one study,<sup>129</sup> the investigators found that more than one third of women delivering vaginally suffered avulsion injuries, an incidence that is unexpectedly high compared with observations in older, symptomatic women.<sup>130</sup>

The clinical significance of such defects is being studied. Our data<sup>130,131</sup> and evidence from MR studies<sup>132,133</sup> suggest that levator avulsion is common (affecting about 15% to 20% of vaginally parous women) and that it is associated with maternal age at first delivery, which is a concern in view of the continuing trend toward delayed childbearing in Western societies. It seems that the likelihood of major levator trauma at vaginal delivery triples during the reproductive years, from 15% at about 18 years of age to 45% at 40 years. Forceps seem to double the risk.<sup>131</sup> Taken together with the increasing likelihood of cesarean section, it seems that the likelihood of a successful vaginal delivery without levator trauma decreases from more than 80% at age 20 to less than 30% at age 40 (our unpublished data).

Levator avulsion is associated with anterior and central compartment prolapses,<sup>117,129,130</sup> and it likely represents the missing link between childbirth and prolapse, but the relationship with bladder dysfunction is not as obvious.<sup>130</sup> The larger a defect

**Figure 9-28** A comparison of intrapartum appearances (*left*), 4D pelvic floor ultrasound findings (*middle*) and magnetic resonance (*right*) imaging in the axial plane after a normal vaginal delivery that resulted in a right-sided levator avulsion \*. (MRI courtesy of Dr. Lennox Hoyte, Boston, MA.)

**Figure 9-29** Small, left-sided, unilateral levator avulsion. Normal antepartum findings are shown on the *left*, and the postpartum state is demonstrated on the *right*.

(width and depth), the more likely are symptoms and signs of prolapse.<sup>117</sup> However, cross-sectional studies of levator anatomy in asymptomatic and symptomatic older women are needed to determine whether such abnormalities are associated with clinical symptoms or conditions in the general population. Another interesting question is whether major morphologic abnormalities of the levator ani affect surgical outcomes. A study using MRI

demonstrated that recurrence after anterior colporrhaphy was much more likely in women with levator trauma.<sup>135</sup> From our experience, it appears that major levator trauma (i.e., avulsion of the puborectalis or pubococcygeus from the pelvic side wall) is associated with early presentation and recurrent prolapse after surgical repair. If this is the case, we should create in vitro models for such trauma and start thinking about surgical intervention.

**Figure 9-30** Major bilateral levator avulsion. Normal antepartum findings are shown on the *left*, and the postpartum state is demonstrated on the *right*.

The presence of levator avulsion may indicate the need for something other than conventional surgical management.

### Three-Dimensional Imaging of Paravaginal Supports

It has been assumed that anterior vaginal wall prolapse and stress urinary incontinence are at least partly caused by disruption of paravaginal and paraurethral support structures (i.e., endopelvic fascia and pubourethral ligaments) at the time of vaginal delivery. In a pilot study using the now-obsolete technology of freehand acquisition of 3D volumes, alterations in paravaginal supports were observed in 5 of 21 women seen before and after delivery, and the interobserver variability of the qualitative assessment of paravaginal supports was shown to be good.<sup>98</sup> In light of current knowledge, the loss of tenting documented in this study was probably at least partly caused by levator avulsion. Paravaginal tissues also can be assessed by transrectal or transvaginal 3D ultrasound using probes designed for pelvic or prostatic imaging.<sup>14</sup> One study using transrectal, high-frequency, 3D ultrasound suggested that defects of the subvesical or paravaginal fascia might be similar in appearance to striae gravidarum, making direct surgical repair impractical.<sup>136</sup>

### Three-Dimensional Imaging of Prolapse

The downward displacement of pelvic organs during a Valsalva maneuver in itself does not require MRI or ultrasound 3D imaging technology. Descent of the urethra, bladder, cervix, cul-de-sac, and rectum is easily documented in the midsagittal plane.<sup>76</sup> However, rendered volumes may allow a complete 3D visualization of a cystocele or rectocele (Figs. 9-31 to 9-33) and help with operative planning. When processed into rotational volumes,

hyperechoic structures such as a rectocele become particularly evident (see Fig. 9-33). The ease with which preoperative and postoperative data can be compared with the help of stored imaging volumes can be especially useful in audit activities.

### Three-Dimensional Imaging of Synthetic Implant Materials

The imaging of synthetic implants may prove to be a major factor in the uptake of this new investigational technique into clinical practice. Suburethral slings such as the TVT, SPARC, IVS, Monarc, and TOT have become very popular during the past 10 years<sup>137-139</sup> and have become the primary anti-incontinence procedure in many developed countries. These slings are not without their problems, even if biocompatibility is markedly better than for previously used synthetic slings, and they differ in some important aspects. Imaging may be indicated in research to determine the location and function of such slings and possibly for assessing in vivo biomechanical characteristics. Clinically, complications such as sling failure, voiding dysfunction, erosion, and postoperative symptoms of the irritable bladder may benefit from imaging assessment. Often, patients do not remember the exact nature of an incontinence or prolapse procedure, and implants may be identified in women who are not aware of their presence or type.

Most modern synthetic implant materials are highly echogenic; TVT Sparc, TVT-O, Monarc and TOT are usually more visible than the IVS sling. Implants can be located with 3D ultrasound, usually over most of their intrapelvic course.<sup>140</sup> (Fig 9-34). Variations in placement, such as asymmetry, varying width, the effect of tape division, and tape twisting, can be visualized. The difference between transobturator tapes and the TVT-type

**Figure 9-31** A large cystocele (arrow) is seen in the three standard planes (sagittal, *top left*; coronal, *top right*; axial, *bottom left*) and in a rendered image (axial, caudocranial rendering), showing a view through the cystocele onto the bladder roof. Reproduced from *Textbook of Female Urology and Urogynecology*, Chapter 26; Informa Healthcare, Abingdon UK, 2006.

**Figure 9-32** Second-degree true rectocele imaged in the three orthogonal planes and a rendered volume (*bottom right*). Stars indicate the rectocele, showing it to be symmetrical, arising from the anorectal junction, and filling most of the hiatus.

**Figure 9-33** A rectocele is shown in a rendered volume of the levator hiatus during a Valsalva maneuver. Reproduced from *Textbook of Female Urology and Urogynecology*, Chapter 26, Informa Healthcare, Abingdon UK, 2006.

**Figure 9-34** The tension-free vaginal tape (TVT) sling is imaged on an oblique rendered volume of the levator hiatus. The mesh structure of the tape is clearly visible. There is also a very unusual local abnormality of the levator on the patient's right side (i.e., left side of the image, *arrow*). Reproduced from *Obstet Gynecol* 2004; 23:615-625, with permission.

**Figure 9-35** Monarc sling (left) compared with tension-free vaginal tape (TVT) sling in rendered volumes of the levator hiatus. Notice the difference in placement. The Monarc sling is inserted through the obturator foramen, and the TVT sling is inserted through the space of Retzius. As a result, the TVT sling arms are situated much more medially. Reproduced from *Obstet Gynecol* 2004; 23:615-625, with permission.

implants, which is difficult to distinguish on 2D imaging, is readily apparent in the axial plane (Fig. 9-35). It is therefore likely that 3D imaging will turn out to be very helpful in the assessment of patients with suburethral slings.

The same holds true for mesh implants used in prolapse surgery. There is a worldwide trend toward mesh implantation, especially for recurrent prolapse, and complications such as failure and mesh erosion are not uncommon.<sup>141,142</sup> Polypropylene meshes such as the Perigee, Prolift, and Apogee are highly echogenic, and their visibility is limited only by persistent prolapse and transducer distance. Translabial 3D ultrasound has demonstrated that the implanted mesh often does not remain as flat as it was on implantation (Fig. 9-36).<sup>143</sup> Surgical technique seems to

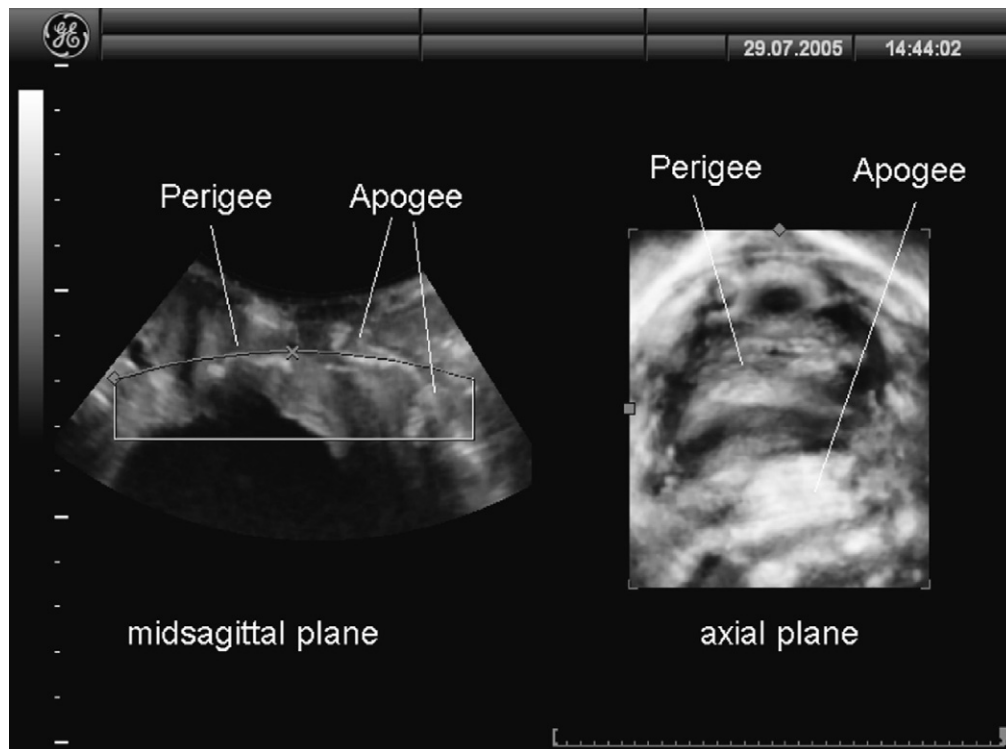

play some role, because fixation of mesh to underlying tissues results in a flatter, more even appearance (Fig. 9-37). The position, extent, and mobility of anterior vaginal wall mesh can be determined and may sometimes uncover complications such as dislodgment of anchoring arms.<sup>94</sup>

Translabial 4D ultrasound can be useful in determining functional outcome and the location of implants, and it can help in optimizing implant design and surgical technique. Although it is not much more than an afterthought in this age of minimally invasive slings, most of the injectables used in anti-incontinence surgery are highly echogenic and can be visualized as a hyperechoic donut shape surrounding the urethra (Fig. 9-38).

**Figure 9-36** A Perigee transobturator mesh implant is imaged in the midsagittal plane (*left*) and as an oblique axial rendered volume (*right*). Reproduced from ASUM Bulletin 2007; 10:17-23, with permission.

**Figure 9-37** Perigee and Apogee mesh implants are seen in a patient with massive levator ballooning, and despite this, prolapse repair was successful. Both implants appear flat and smooth, and both are functional, blocking a large part of the hiatus during a Valsalva maneuver.

## CONCLUSIONS

Ultrasound imaging, particularly translabial or transperineal ultrasound, is becoming the new diagnostic standard in urogynecology. Several factors have contributed to its acceptance, but the most important is the availability of suitable equipment. Developments such as the assessment of levator activity and prolapse and the use of color Doppler to document urine leakage enhance the clinical usefulness of the method. Increasing standardization of parameters should make it easier for clinicians and researchers to compare data.

The convenience with which pretreatment and post-treatment imaging data is obtained can simplify outcome studies after prolapse and incontinence surgery. Ultrasound imaging may be able to significantly enhance our understanding of the different mechanisms by which conservative and surgical methods achieve—or fail to achieve—continence. It may even be possible to identify distinct fascial defects, such as defects of the rectovaginal septum in true rectoceles, which should generate new surgical possibilities.

Regardless of which methodology is used to determine descent of pelvic organs, it is evident that there is a wide variation in

**Figure 9-38** Macroplastique as demonstrated in a rendered axial volume, axial plane, surrounding the urethra in a donut shape. Figure reproduced from *Obstet Gynecol* 2004; 23:615-625, with permission.

pelvic organ mobility, even in young, nulliparous women. This variation is likely to be at least partly genetic in origin. Ultrasound imaging allows quantification of the phenotype of pelvic organ prolapse, which will facilitate molecular and population genetic approaches to evaluate the cause of pelvic floor and bladder dysfunction.

Childbirth causes significant alterations of pelvic organ support and levator structure and function, and there is some relationship between the prior state of pelvic organ supports and labor outcome. Pelvic floor ultrasound can help us in identify women

at high risk of emergency operative delivery,<sup>144</sup> and in the future we will be able to predict significant pelvic floor trauma. It remains to be seen, however, whether such information can have a positive effect on clinical outcomes in what is no doubt a highly politicized environment.

The use of 3D volume ultrasound adds several dimensions to pelvic floor imaging, particularly in its most recent incarnations using automatic volume acquisition, 4D cine volume ultrasound, SRI techniques, and TUI. Spatial resolutions now equal or exceed those obtained on static MRI, and temporal resolutions are far superior, although most clinicians working in this field are largely unaware of recent developments because of a traditional lack of access to imaging techniques. The technology opens up new possibilities for observing functional anatomy and examining muscular and fascial structures of the pelvic floor. Data acquisition can be simplified and research capabilities enhanced, and surgical audits in this field are likely to undergo a significant change. Modern imaging will allow us to optimize current surgical techniques and to develop new ones.

There is no evidence to prove that modern imaging techniques can improve outcomes in pelvic floor medicine for patients. However, this limitation is true for many diagnostic modalities in clinical medicine. Because of methodologic problems, the situation is unlikely to improve soon. In the meantime, it must be recognized that any diagnostic method is only as good as the operator behind the machine, and diagnostic ultrasound is well known for its operator-dependent nature. Training is essential to ensure that imaging techniques are used appropriately and effectively.

# ELECTROPHYSIOLOGIC EVALUATION OF THE PELVIC FLOOR

*Simon Podnar and Clare J. Fowler*

Clinical neurophysiologic tests have been proposed for research applications in patients with sacral dysfunction, but the emphasis in this chapter is on describing investigations with established diagnostic value. The roles of electrodiagnostic tests in various clinical conditions are described first, and brief descriptions of these investigative procedures are given at the end of the chapter.

### CLINICAL APPLICATION OF SACRAL ELECTRODIAGNOSTIC TESTS

Electrodiagnostic tests are an extension of the clinical neurologic examination, and they are helpful in evaluating patients in whom a neurologic lesion is suspected. An international consensus statement proposes that sacral electrodiagnostic studies are most useful in patients with focal peripheral sacral lesions (i.e., conus medullaris, cauda equina, sacral plexus, and pudendal nerve lesions), in patients with multiple system atrophy, and in women with urinary retention.<sup>1</sup> They can document the severity of a clinically diagnosed lesion and provide data on the integrity of various neurologic structures. However, these tests have limitations. They require trained personnel to be properly performed, they are not useful for screening, and they are uncomfortable for the patient. The results do not correlate well with clinical bladder, anorectal, or sexual dysfunction.

Neurogenic sacral organ dysfunction can be caused by a variety of neurologic disorders, but the value of sacral electrodiagnostic studies in such patients may be minor. In patients with brain and spinal cord disease, who may have pronounced pelvic organ complaints, imaging studies—magnetic resonance imaging (MRI) in particular—are more useful for establishing the underlying neurologic diagnosis. In this context, neurophysiologic testing outside the pelvic region may provide information about relevant abnormal spinal conduction, and somatosensory evoked potentials (SEPs) elicited by stimulation of the tibial nerve are more useful in these circumstances than pudendal SEPs.<sup>2,3</sup> Similarly, in patients with sacral dysfunction due to a generalized peripheral neuropathy such as diabetes, nerve conduction studies in the lower limbs are a more sensitive adjunct to clinical examination than are sacral electrodiagnostic studies.<sup>4</sup>

### ASSESSMENT OF PATIENTS BEFORE ELECTRODIAGNOSTIC TESTING

Clinical and laboratory evaluation of a woman with pelvic organ dysfunction is necessary before electrodiagnostic investigations can be considered. This order is followed so that there can be

proper formulation of the questions for those in the clinical neurophysiology laboratory carrying out the tests. Examples of such questions are listed in Box 10-1.

Necessary preliminary investigations may include urodynamics, anorectal manometry, cine defecography, or colonic transit studies. Imaging studies such as ultrasound, computed tomography (CT), and MRI of the anorectum and the lower urinary and genital tracts may aid the diagnosis because they can exclude structural abnormalities (e.g., anal sphincter tears, abnormal position of the bladder neck, vaginal wall prolapse) that can cause or contribute to sacral organ dysfunction.

### ELECTRODIAGNOSTIC TESTING IN WOMEN WITH SACRAL COMPLAINTS

#### Incontinence after Childbirth

Research studies have used needle electromyography to examine the extent of nerve damage contributing to urinary stress incontinence after childbirth. The first studies using single-fiber electromyography (SFEMG) to look at fiber density showed partial reinnervation changes in the external anal sphincter (EAS)<sup>5</sup> and pubococcygeus muscles in women with stress incontinence and genital prolapse.<sup>6</sup> Needle electromyographic examination of the pubococcygeus muscle revealed a significant increase in motor unit potential (MUP) duration (i.e., an indication of reinnervation) after vaginal delivery, which was most marked in women with urinary incontinence 8 weeks after delivery, a prolonged second stage, and heavier babies.<sup>7</sup> However, an electromyographic study, using less biased methods of automated MUPs and interference pattern analysis, questioned the widely held notion that significant damage to the innervation of the EAS occurs even during uncomplicated deliveries. Although vaginal delivery was related to minor electromyographic abnormalities, there was no indication that this correlated with loss of sphincter function.<sup>8</sup> A

#### Box 10-1 Questions to Consider before Requesting Electrodiagnostic Testing

Is there a neurogenic component to this patient's complaint?

How severe is the neurologic damage?

Are there signs of acute denervation or chronic reinnervation?

Is there abnormal sphincter electromyographic activity suggesting a cause for obstructed voiding or urinary retention?

histomorphologic study supported these data by failing to demonstrate significant neuropathic changes in pelvic floor muscles.<sup>9</sup> In the urethral sphincter, in contrast, electromyography and muscle biopsy showed more neuropathic changes in women with stress incontinence than in controls.<sup>10</sup> Even uncomplicated delivery may cause some distal pudendal nerve damage. Significant neurogenic damage proximal to the EAS muscle innervation probably occurs only rarely,<sup>11</sup> and it is mainly caused by compression of the sacral plexus by fetal head.<sup>12</sup> The prevalence and relevance of minor proximal injuries is unknown.

Kinesiologic electromyography performed using hook electrodes so that a prolonged recording could be made without causing discomfort showed some loss of coordination between the two sides of the pubococcygeus muscle in women with stress incontinence, implying an abnormal primary role of the central nervous system or a neurologic response to muscle or tendon damage.<sup>13</sup> In addition to age-related neurogenic changes, the interference pattern changes consistent with motor unit loss, and failure of central activation has been found in the levator ani and EAS muscles of women with stress incontinence.<sup>14</sup>

Sufficient research data exist for us to know that the changes of denervation in pelvic floor in stress incontinence do occur, but they are quite subtle. Sphincter electromyography does not have an important role in the routine investigation in stress incontinence.

Although extensively used in the past,<sup>15,16</sup> the pudendal nerve terminal motor latency test is probably of no clinical use in women with urinary stress incontinence.<sup>11</sup> Nerve latencies evaluate only the fastest nerve fibers and are therefore not sensitive to axonal loss, which is the major type of damage causing muscle denervation.

### Detrusor Overactivity

Detrusor overactivity may result from neurologic disease or occur in an otherwise healthy individual, in which case the condition is called *idiopathic detrusor overactivity*. Clinical neurologic examination is the most useful means of differentiating these two entities. In addition to the clinical examination, imaging studies and electrodiagnostic tests of central nervous system conduction (i.e., motor evoked potentials [MEPs] and SEPs) may reveal underlying spinal cord disease, such as multiple sclerosis. In this respect, tibial SEPs are the most useful investigation.<sup>2,3</sup>

Extensive neurophysiologic investigations (e.g., electromyography of the EAS, bulbocavernosus reflex after dorsal clitoral nerve stimulation, tibial and pudendal SEPs, MEPs on cortical magnetic stimulation, recording from the EAS and abductor hallucis brevis muscles) in women with idiopathic detrusor overactivity failed to reveal any abnormality.<sup>17</sup> No significant differences were reported in comparing this group with a group of 13 age-matched, healthy control women, thereby excluding even an occult neurologic abnormality. This result supports the view that idiopathic detrusor overactivity is caused by intrinsic bladder defects (i.e., neurogenic or myogenic). The role of electrodiagnostic investigations in detrusor overactivity is limited to establishing or excluding an underlying neurologic disease.

### Urinary Retention

Isolated urinary retention in young women was formerly considered to be psychogenic or the first symptom of multiple sclerosis. However, needle electromyography of the urethral sphincter

**Figure 10-1** Profuse pathologic spontaneous activity (i.e., complex repetitive discharges) in the urethral sphincter muscle of a 26-year-old, otherwise healthy woman with an 8-year history of difficult emptying of the bladder. Her sister has similar problems and electromyographic abnormalities of the urethral sphincter muscle. Activity was provoked by movement of the concentric needle electrode or by voluntary muscle contraction.

muscle has demonstrated that many such patients have profuse, complex, repetitive discharges and decelerating burst activity (Fig. 10-1).<sup>18</sup> The cause of this activity is unknown, but an association with polycystic ovaries was described in a syndrome by Fowler and colleagues.<sup>19</sup> The explanation probably lies with some unidentified hormonal susceptibility of the female striated urethral sphincter muscle that causes a loss of stability of the muscle membrane and permits direct muscle fiber to muscle fiber (ephaptic) transmission to develop, which manifests as complex, repetitive discharges. The current hypothesis is that the sustained contraction of the urethral sphincter has an inhibitory effect on the detrusor, resulting in urinary retention.

When recording from the striated urethral sphincter in this condition, only complex repetitive discharges (which sound like helicopters) may be heard, and the distinction between these and reinnervated motor units can be problematic, but if decelerating bursts (which sound like underwater recordings of whales) are also present, it is easier to be certain that the characteristic electromyographic activity has been recorded. Although electromyography may indicate the presence of an abnormality, it is inevitably only a very limited sample of the muscle activity in the immediate vicinity, and it is difficult to know whether the abnormality is sufficient to account for the clinical finding of complete or partial urinary retention. The investigations that have proved to be useful adjuncts are measurement of the urethral pressure profile and volume of the urethral sphincter muscle estimated with ultrasound.<sup>20</sup> Young women with urinary retention due to the urethral sphincter abnormality often have urethral pressure profiles in excess of 100 cm H<sub>2</sub>O.

The typical clinical presentation of Fowler's syndrome is of a young woman with spontaneous onset of urinary retention or retention after some sort of operative intervention. The mean age of a series of women with this problem was 27 years, and a spontaneous onset appears to be more common in women younger than 30 years.<sup>21</sup> The woman may present with a bladder capacity in excess of 1 L, and although this may cause painful distention, she lacks any of the expected sensations of urinary urgency. There may or may not be a history of infrequent voiding before the onset of urinary retention. These women are taught to do clean, intermittent self-catheterization and commonly experience difficulties with the technique, particularly pain and difficulty in

removing the catheter. A retrospective study of 248 women presenting with urinary retention over a 5-year period showed that this was by far the most common cause for urinary retention in young women.<sup>22</sup>

Patients with Fowler's syndrome seem to respond particularly well to sacral neuromodulation.<sup>23</sup> Although the mechanism of its action is still the subject of research using functional brain imaging methods,<sup>24</sup> stimulation does not appear to lower the urethral pressure profile or cause a cessation of the abnormal electromyographic activity.<sup>25</sup>

The same type of abnormal spontaneous electromyographic activity may also occur in women with obstructed voiding. The electromyographic abnormality may persist during attempts at micturition,<sup>26</sup> leading to interrupted flow, high detrusor pressure, low flow, and incomplete bladder emptying. It is thought that in this condition, the overactive urethral sphincter, although it produces obstruction, does not have the same inhibitory effect on the detrusor muscle as it does in women who become unable to void and develop urinary retention. Because needle electromyography of the urethral sphincter detects changes related to denervation and reinnervation, as well as this peculiar abnormal, spontaneous activity, it has been proposed that needle electromyography of the urethral sphincter muscle should always be undertaken in women with unexplained urinary retention.<sup>1,18</sup>

### Anal Incontinence

Needle electromyography of the EAS was thought to be useful in patients with anal incontinence.<sup>27</sup> However, there is no consensus regarding the utility of electrophysiologic testing in neurologically normal patients with isolated anal incontinence. In a series evaluated by Podnar and coworkers,<sup>28</sup> patients with isolated anal incontinence rarely had neuropathic electromyographic changes in sacral segments. In a subgroup of patients in whom no cause of anal incontinence could be established (i.e., idiopathic anal incontinence), the only electrophysiologic abnormality found was a diminished number (absence) of continuously firing, low-threshold motor units during relaxation.<sup>28</sup> In patients with fecal incontinence and an increased fiber density on SFEMG, lower anal squeeze pressures and diminished rectal sensation have been demonstrated. If marked changes of denervation and reinnervation are found in the EAS in the appropriate clinical setting, a more generalized disorder, such as multiple system atrophy or a cauda equina or conus medullaris lesion, should be considered. If performed, it is probably better that needle electromyography follows an anal ultrasound examination that excludes structural lesions of the sphincter mechanism.<sup>29</sup>

### Chronic Constipation

Constipation occurs for a variety of reasons. Its prevalence depends on the diagnostic criteria applied. Radiographic methods can demonstrate prolonged colonic transit (using radiopaque markers) and abnormal pelvic floor movement during defecation (using cine defecography), which are the main mechanisms.<sup>30</sup> Electromyography can be used to demonstrate continuous puborectalis muscle contraction characteristic of a subtype of obstructed defecation (i.e., nonrelaxing puborectalis syndrome),<sup>31</sup> but this would be considered only if other investigations suggested that particular pathophysiology.

Chronic constipation with repetitive straining was thought to be the main cause of advancing pudendal neuropathy and

increased fiber density identified on SFEMG in patients with urinary and anal incontinence.<sup>32</sup> Semiquantitative or quantitative MUP changes on conventional electromyography of the EAS muscles of severely constipated subjects have been reported by some investigators. In a study using advanced MUP and interference pattern analysis, no abnormalities were demonstrated in the EAS muscles of patients with mild chronic constipation. This finding is important for the interpretation of electromyographic findings in patients with other conditions, a significant proportion of whom also suffer from chronic constipation.<sup>33</sup>

### Sexual Dysfunction

Neurophysiologic techniques have been applied extensively in the research of male erectile dysfunction, but much less research has gone into female sexual dysfunction. Pudendal SEP recordings have been employed in women with sexual dysfunction due to spinal cord lesions, multiple sclerosis, and diabetes,<sup>34</sup> but in a placebo-controlled trial of the effect of sildenafil citrate in women with sexual dysfunction and multiple sclerosis, the pudendal SEP was not found to be contributory.<sup>35</sup> Pudendal SEPs usually have been found to be of no greater value than clinical examination in detecting relevant spinal cord disease.<sup>3</sup>

## ELECTRODIAGNOSTIC TESTING IN WOMEN WITH ESTABLISHED NEUROLOGIC DISEASE

### Cauda Equina and Conus Medullaris Lesions

Lesions of the cauda equina or conus medullaris may cause severe bladder, bowel, and sexual dysfunction. The sacral roots that innervate pelvic organs may be compressed within the spinal canal by intervertebral disk herniation, spinal fractures, hematomas, and tumors or may be a result of lumbar disk surgery.

After detailed clinical examination of the lumbosacral segments (with particular emphasis on perianal sensation), neurophysiologic testing can assess the severity of the lesion and clarify the diagnosis. In our series, approximately 10% of patients with cauda equina lesions reported normal perianal sensation. Bilateral needle electromyography of the EAS muscle (Fig. 10-2) and sometimes of the bulbocavernosus muscle and electrophysiologic evaluation of the bulbocavernosus reflex (Fig. 10-3) are the electrodiagnostic tests that should be considered. Most of these lesions cause partial denervation. Three weeks to several months after injury, spontaneous denervation activity and later reinnervation MUP changes can be demonstrated by needle electromyography (Fig. 10-4). The bulbocavernosus reflex complements electromyography and increases sensitivity of electrodiagnostic studies in patients with cauda equina or conus medullaris lesions.

### Sacral Plexus and Pudendal Nerve Lesions

After uncomplicated deliveries, electromyographic changes in the EAS are minor,<sup>8</sup> but they may be more pronounced in the urethral sphincter muscle.<sup>10</sup> It is commonly assumed that these lesions may be contributory to some degree in the pathogenesis of urinary stress incontinence and pelvic organ prolapse in women.<sup>11</sup> However, electrodiagnostic testing in these women is recommended only when a proximal peripheral sacral neurogenic lesion is a possibility.<sup>1</sup>

Other lesions of the sacral plexus and pudendal nerves are less common than are cauda equina or conus medullaris lesions. They can be caused by pelvic fractures, hip surgery, complicated deliveries,<sup>12</sup> malignant infiltration, local radiotherapy, and use of orthopedic traction tables. They are usually unilateral. There are no validated techniques for differentiating cauda equina lesions from more distal lesions.

### Parkinsonism and Multiple System Atrophy

Multiple system atrophy is a progressive neurodegenerative disease of unknown origin that is often mistaken for Parkinson's disease in its early stages. It is characterized at onset by an akinetic, rigid parkinsonian syndrome; cerebellar ataxia; or auto-

**Figure 10-2** Motor unit potential (MUP) analysis of the external anal sphincter (EAS) muscles of a 53-year-old woman 8 years after a traumatic fracture of the L4 vertebra. She continues to have back pain radiating to the right leg, right leg weakness with paresthesia, and moderate bladder, bowel, and sexual dysfunction. MUPs were within normal limits in the left EAS muscle and definitely abnormal in the right EAS muscle. Quantitative sphincter electromyography findings were compatible with a lesion of the right half of the cauda equina.

nomous failure, usually accompanied by severe incontinence. In the advanced stages of the disease (formerly called Shy-Drager syndrome), all these features may be present. The severe and early incontinence probably results from neuronal atrophy in the brainstem, which causes detrusor overactivity, and in the sacral spinal cord, where degeneration of the parasympathetic intermedialateral cell columns causes incomplete emptying and degeneration of the somatic anterior horn cells forming Onuf's nucleus causes incontinence.

Using needle electromyography of the sphincter muscles prolonged duration of MUPs has been described as the main electrodiagnostic marker for degeneration of Onuf's nucleus.<sup>36-38</sup> Changes consistent with chronic reinnervation can also be demonstrated as an increase in fiber density on SFEMG. Sphincter electromyography may not be sensitive in the early phase of the disease, and it is not specific after 5 years of parkinsonism. The changes of chronic reinnervation may also be found in another parkinsonian syndrome, progressive supranuclear palsy,<sup>39</sup> a disease in which neuronal loss in Onuf's nucleus has been demonstrated histologically.<sup>40</sup>

Unilateral needle electromyography, including observation of denervation activity and quantitative MUP analysis, is indicated in patients with suspected multisystem atrophy, particularly in its early stages if the diagnosis is unclear.<sup>38,41</sup> If the test result is normal, but suspicion of the diagnosis persists, it may be of value to repeat the test later. Kinesiologic electromyography performed during urodynamics can also help to document detrusor-sphincter dyssynergia in patients with Parkinson's disease or multiple system atrophy.<sup>42</sup>

### Primary Muscle Diseases

There are no reports of a myopathy manifesting or remaining confined to the pelvic floor or sphincter muscles. Even in patients with a generalized myopathy, normal and abnormal muscle biopsy and needle electromyographic findings and abnormal histology with normal electromyographic findings have been reported.

**Figure 10-3** Bulbocavernosus reflex (BCR) on electrical stimulation in a 42-year-old woman with a sudden onset of urinary frequency, urgency, and incontinence 4 years earlier. On clinical examination, she reported normal sensation of touch and abnormal sensation of temperature and pinprick (i.e., dissociated sensory loss) in sacral segments on the right. Notice a very prolonged latency of the BCR on the right (56 ms) and a normal latency response on the left (34 ms). On concentric needle electromyography, definite motor unit potential abnormalities were found in the right and normal results in the left external anal sphincter muscle. She had an episode of right-sided retrobulbar neuritis 6 years before the onset of transient urinary dysfunction. Brain magnetic resonance imaging revealed several lesions in the white substance of the brain consistent with demyelination. Based on these data, the diagnosis of multiple sclerosis was made.

**Figure 10-4** Spontaneous denervation electromyographic (EMG) activity is seen during relaxation (*top*), and a single, extremely polyphasic motor unit potential (MUP) is recruited on maximal voluntary contraction (*bottom*). The former is a sign of muscle fiber denervation, and the latter is a sign of collateral reinnervation. Both signals were recorded by a concentric EMG needle in the left subcutaneous external anal sphincter muscle of a 50-year-old woman 3 months after surgery for a large, centrally herniated intervertebral disk (between L5 and S1).

### Exclusion of a Neurologic Lesion

Occasionally, it may be necessary to exclude a neurologic basis for bladder dysfunction. A normal EAS muscle electromyographic pattern indicates integrity of the sacral lower motor neuron, a normal bulbocavernosus reflex indicates preservation of the sacral reflex arc (including conus medullaris with parasympathetic sacral center), a normal sympathetic skin response indicates preservation of the sympathetic lumbosacral center, and a normal pudendal SEP correlates with preserved spinal somatosensory pathways.<sup>43</sup>

## ELECTRODIAGNOSTIC TESTS

### Electromyography

Electromyography relies on the extracellular recording of spontaneous and reflexively or voluntarily provoked bioelectrical activity generated by muscle fibers. Bioelectrical activity consisting of action potentials is generated by depolarization of muscle fibers. Motor neurons that innervate striated pelvic floor and sphincter muscle lie in the anterior horn of the sacral spinal cord (i.e., conus medullaris). Within the muscle, the motor axon

tapers and then branches to innervate muscle fibers constituting an individual motor unit. In health, muscle fibers that belong to the same motor unit do not lie adjacent to one another (i.e., checkerboard pattern of muscle innervation).

### Concentric Needle Electromyography

The needle electrode most commonly used in electromyography is the single-use, disposable, concentric needle electrode. It can provide information on insertion activity, spontaneous activity, MUPs, and interference patterns.<sup>41</sup>

In healthy skeletal muscle, initial placement of the needle elicits a short burst of insertion activity due to mechanical stimulation of excitable membranes. Absence of insertion activity with an appropriately placed needle electrode (if all technical causes have been excluded) may mean complete denervation of the muscle being examined. In contrast to most other skeletal muscles, the sphincter muscles exhibit continuous firing of low-threshold motor units. This activity can be quantified most easily and reproducibly by template-operated MUP sampling techniques (e.g., multi-MUP analysis), which provides information on excitability and loss of motor units.<sup>28</sup> An abnormal, spontaneously active type of activity may be recorded from the urethral sphincter muscle in some young women with retention or obstructed voiding, so-called decelerating bursts and complex repetitive discharges (see Fig. 10-1).<sup>18,21</sup>

Between 10 and 20 days after an acute denervating injury, the abnormal, spontaneous activity appears: fibrillation potentials and positive sharp waves (Fig. 10-4). This type of activity originates from denervated, single muscle fibers. In partially denervated sphincter muscle, this activity is mingled with continuously firing MUPs, and examination of the bulbocavernosus muscle, which in contrast to sphincter muscles lacks on-going MUP firing during relaxation, is particularly useful.<sup>41</sup>

Examination of MUPs recorded by a needle electrode has proved to be the most valuable process in the neurophysiologic assessment of the pelvic floor. A MUP is generated by summation of action potentials of all muscle fibers constituting individual motor unit, and MUP morphology is determined by the bioelectrical characteristics of muscle fibers constituting the motor unit and by their spatial distribution. In partially denervated muscle, collateral reinnervation tends to take place, and surviving motor nerves sprout and grow out to reinnervate muscle fibers that have lost their nerve supply. This results in a change in the arrangement of muscle fibers within the motor unit and in a consequent change in MUP shape (see Figs. 10-2 and 10-4), which can be quantitatively described by several MUP parameters (Fig. 10-5). For diagnosis of neuropathic changes in the EAS muscle, an optimal set of MUP parameters (i.e., area, duration, and number of turns) was identified.<sup>44</sup> In addition to duration, MUP amplitude and number of phases traditionally were used.

MUPs are identified by their repetitive appearance in a prolonged recording of electromyographic activity (i.e., manual-MUP analysis), using a trigger and delay line (i.e., single-MUP analysis) or using the template-based multi-MUP analysis. The multi-MUP analysis is an automated computer operated analysis, and is fast (5 to 10 minutes per muscle), easy to apply, and minimizes examiner's bias.<sup>45</sup> A representative sample of 20 MUPs (i.e., standard number in limb muscles) must be analyzed for the test to be valid (see Fig. 10-2).

The EAS muscle is regarded as the best indicator muscle for proximal neuropathic sacral lesion, and bilateral examination of only the subcutaneous EAS muscle usually suffices.<sup>46</sup> Normative

**Figure 10-5** Motor unit potential (MUP) parameters. Amplitude is the voltage difference ( $\mu\text{V}$ ) between the most positive and most negative point of the MUP trace. The MUP duration is the time (ms) between the first deflection and the point when MUP waveform finally returns to the baseline. The number of MUP phases (*circles*) is defined by the number of MUP areas alternately below and above the baseline and can be counted as the number of baseline crossings plus one. Turns (*asterisks*) are defined as changes in direction of the MUP trace that are larger than the specified amplitude ( $50 \mu\text{V}$ ). MUP area measures the integrated surface of the MUP waveform (*shaded area*).

data for the EAS muscle have been published and show no significant changes with age, gender, number of uncomplicated vaginal deliveries,<sup>8</sup> and mild, chronic constipation.<sup>33</sup> Similar in-depth analysis of normative data from standardized technique for other pelvic floor and perineal muscles is not available.

At increased levels of voluntary and reflex activation, a more dense interference pattern can be seen. This can be quantitatively assessed, but its sensitivity for detecting neuropathic EAS muscles is only about one half of that for MUP analysis techniques.<sup>45</sup> Qualitative assessment of the interference pattern has been recommended for sphincter and pelvic floor muscles to assess motor unit loss.<sup>41</sup>

### Kinesiologic Electromyography

The aim of kinesiologic electromyography is to assess patterns of individual muscle activity during physiologic maneuvers (e.g., electromyographic activity patterns of pelvic floor muscle during bladder filling and voiding). Various types of surface or intramuscular (needle or hook wire) electrodes can be used for recording kinesiologic electromyography, but there are often technical problems to overcome, such as electrical artifacts and contamination with electromyographic signals from other muscles. Large pelvic floor muscles are not adequately represented by the signal measured with intramuscular electrodes.

Little is known about the normal activity patterns of different pelvic floor and sphincter muscles. It is assumed that they all act in a coordinated fashion, which is frequently lost in abnormal conditions.<sup>26</sup> On voiding, disappearance of all electromyographic activity in the urethral sphincter precedes detrusor contraction. In central nervous system disorders, however, detrusor contractions may be associated with an increase of sphincter electromyographic activity (i.e., detrusor-sphincter dyssynergia),<sup>47</sup> which can be most easily demonstrated by kinesiologic electromyography performed during cystometry.

### Conduction Studies

Conduction studies examine the capacity of a nerve (or a nervous pathway) to transmit a test volley of depolarization along its length. If the tested nerve contains motor fibers, its responsiveness can be recorded from the muscle as a compound muscle action potential (CMAP).<sup>48</sup> The time taken from stimulation to muscle response (i.e., latency) and the amplitude of the muscle response can be measured. The latency reflects the conduction speed of only the fastest motor fibers and is therefore a poor guide to the overall function of the nerve. The amplitude of the CMAP reflects the number of intact motor units and gives a somewhat better guide to the severity of a neuropathic lesion. However, in anatomically complex muscles of the pelvis, recording of a well-formed CMAP is difficult.<sup>49</sup>

### Pudendal Nerve Terminal Motor Latency

Terminal motor latency of the pudendal nerve can be measured by recording with a concentric needle electrode from the bulbocavernosus, EAS, or urethral sphincter muscles in response to bipolar stimulation placed on the perianal or perineal surface. The latencies of MEPs obtained by this means are between 4.7 and 5.1 ms.<sup>50</sup>

The more widely employed technique of obtaining the pudendal terminal motor latency relies on a bipolar stimulating electrode fixed to the tip of the gloved index finger, with the recording electrode pair placed 8 cm proximally on the base of the finger (i.e., St. Mark's stimulator).<sup>51</sup> The finger is inserted into the rectum or vagina, and stimulation is performed close to the ischial spine. Using this stimulator, the terminal motor latency for the EAS CMAP is typically about 2 ms.<sup>51</sup> If a catheter-mounted electrode is used, responses from the urethral sphincter can also be obtained. The difference in latencies obtained by the perineal and transrectal methods has not yet been explained. Unfortunately, amplitudes of the pudendal CMAP have not proved contributory because of their large variability.<sup>1</sup>

### Electrical and Magnetic Stimulation of Sacral Roots

With development of special electrical and magnetic stimulators, transcutaneous stimulation of deeply situated nervous tissue became possible. When applied over the spine, the roots at the exit from the vertebral canal mainly are stimulated.<sup>49</sup> Recording of MEPs with magnetic stimulation has been less successful, at least with standard coils, than with electrical stimulation, and there is often a large stimulus artifact. Positioning of the ground electrode between the recording electrodes and the stimulating coil should decrease the artifact.<sup>49,52</sup>

### Sacral Reflexes

Sacral reflexes refer to electrophysiologically recordable responses of perineal or pelvic floor muscles to electrical stimulation in the urinary-genital-anal region. Two reflexes, the anal and the bulbocavernosus reflex, are commonly clinically elicited in the lower sacral segments. Both have the afferent and efferent limb of their reflex arc in the pudendal nerve, and both are centrally integrated at the S2 to S4 cord levels.<sup>49,53</sup> In women, the bulbocavernosus reflex is clinically elicited by squeezing or tapping of the clitoris and observing movement of the perineum or anal sphincter. It is, however, much less reliable than in men,<sup>53,54</sup> and in our opinion, is not useful. The anal reflex is elicited by a pinprick of the perianal skin, producing an anal wink.

Electrophysiologic correlates of these reflexes have been described using electrical, mechanical, and magnetic stimulation. Whereas the latter two modalities have been applied only to the clitoris, electrical stimulation can be applied to other sites, such as the dorsal clitoral nerve and perianal area. Responses are usually detected by needle electrode inserted into the EAS or bulbocavernosus muscle. The bulbocavernosus detection site is preferred because traces do not contain continuously firing, low-threshold MUPs.

The bladder neck or proximal urethra can be stimulated using a catheter-mounted ring electrode, and reflex responses can be obtained from perineal muscles. With visceral denervation, such as after radical hysterectomy, these reflexes may be lost while the sacral reflex mediated by pudendal nerve is preserved. Loss of vesicourethral reflex with preservation of vesicoanal reflex has been described for patients with urethral afferent injury after recurrent urethral operations.

Reports of sacral reflexes obtained after electrical stimulation of the clitoral nerve give consistent mean latencies of between 31 and 39 ms (see Fig. 10-3). Sacral reflex responses obtained on perianal, bladder neck, or proximal urethra stimulation have latencies between 50 and 65 ms.<sup>49</sup> This more prolonged response is thought to be caused by the afferent limb of the reflex being conveyed by thinner myelinated pelvic nerves with slower conduction velocities than the thicker myelinated pudendal afferents. The longer-latency anal reflex, the contraction of the EAS on stimulation of the perianal region, may also have thinner myelinated fibers in its afferent limb because it is produced by a nociceptive stimulus.<sup>49</sup>

### Sympathetic Skin Response

The sympathetic skin response is a reflex served by myelinated sensory fibers (i.e., afferent limb), a complex central integrative mechanism, and sympathetic postganglionic nonmyelinated C fibers (i.e., efferent limb).<sup>55</sup> The responses can be recorded from the perineum with some difficulty. The stimulus used in clinical practice typically is an electrical pulse delivered to a peripheral nerve in the limbs, but the genital organs also can be stimulated. Only an absent sympathetic skin response can be considered abnormal. The response is reportedly useful in the assessment of patients with neuropathies involving unmyelinated nerve fibers<sup>56</sup> and patients with spinal cord injury. In the latter group, it may serve as an indicator of the preserved sympathetic lumbosacral center, which is particularly important for bladder neck competence.<sup>57</sup>

### Cerebral Somatosensory Evoked Potentials

The pudendal evoked response is easily recorded after electrical stimulation of the dorsal clitoral nerves. The first positive peak at  $41 \pm 2.3$  ms (called P1 or P40) is usually clearly defined in healthy subjects. This SEP is of the highest amplitude (0.5 to 12  $\mu$ V) at a site central over the sensory cortex and is highly reproducible. Later negative (at about 55 ms) and then additional positive waves are quite variable in amplitude and expression and have little known clinical relevance.<sup>49</sup>

Cerebral SEPs can be obtained on stimulation of the bladder urothelium. These cerebral SEPs have low amplitudes ( $\leq 1$   $\mu$ V), have variable configurations, and may be difficult to identify in some control subjects. The typical latency of the most prominent negative potential (N1) is about 100 ms. The responses are of more relevance to neurogenic bladder dysfunction than the pudendal SEP, because the A $\delta$  sensory afferents from bladder and proximal urethra accompany the autonomic fibers in the pelvic nerves. Another stimulation site is the anal canal; after stimulation, cerebral SEPs with a slightly longer latency than those obtained after stimulation of the clitoris have been reported. However, because it is not possible to record this response from all control subjects, these tests have not proved clinically useful. The rectum and sigmoid colon have also been stimulated, and cerebral SEPs of two types have been recorded. One was similar in shape and latency to the pudendal SEP, and the other was similar to the SEP recorded on stimulation of bladder and posterior urethra.

## CONCLUSIONS

Several electrodiagnostic tests have been proposed for evaluation of the sacral nervous system in women with bladder, bowel, and sexual dysfunction. Although all of the tests discussed here are of research interest, concentric needle electromyography is of greatest value in the diagnostic evaluation of selected groups of patients with pelvic floor dysfunction: those with traumatic lesions and those with atypical parkinsonism. Bulbocavernosus reflex and pudendal SEP studies are useful in the evaluation of selected patients with suspected peripheral or central neurogenic sacral lesions. Probably the only patients in whom sacral dysfunction in itself should be considered an indication for electromyography of the urethral sphincter are young women with unexplained urinary retention.

# URODYNAMICS

*H. Henry Lai, Christopher P. Smith, and Timothy B. Boone*

The term *urodynamics* was first coined by Davis<sup>1</sup> in 1953 to define the study of the storage and emptying phases of the lower urinary tract. Patients with voiding and storage symptoms cannot be reliably diagnosed by history and physical examination alone.<sup>2,3</sup> Urodynamic studies offer objective measurements of bladder and urethral functions and dysfunctions while reproducing the patient's presenting symptoms.

## REPRODUCTION OF SYMPTOMS FOR URODYNAMIC EVALUATION

The urodynamic armamentarium is extensive, including bedside eyeball urodynamics, noninvasive uroflowmetry, and multi-channel fluoroscopic studies (Table 11-1). A "reflex hammer" approach to urodynamic testing is condemned. Before any urodynamic evaluation, the clinician must formulate specific questions about the case, and a working diagnosis must be in place. The most accurate and least invasive study tailored to answer specific questions and to confirm the diagnosis is performed. It is crucial that urodynamic tests reproduce the patient's presenting symptoms. A study that does not duplicate the patient's symptoms is not diagnostic.<sup>4</sup> For instance, if a patient states that she loses urine only in an upright position, little is gained by a supine cystometrogram.<sup>5</sup> Failure to record an abnormality on urodynamic assessment does not rule out its clinical existence.<sup>4</sup> Conversely, not all abnormalities detected on urodynamic tests are clinically significant.<sup>4</sup> If urodynamic testing reveals information that is totally unexpected, the history and working diagnosis should be re-evaluated.

Urodynamic testing should be done in a quiet, private, and orderly suite with as little distraction and as few observers as possible so that patients can relax to replicate their usual voiding habits. Patients must be told what to expect, how the tests are done, and what information the clinician is seeking. For example, in evaluating incontinence, patients need to understand that the goal of the study is to demonstrate leakage characteristic of their experience, so that they do not voluntarily and mistakenly contract the external sphincter to avoid the embarrassment of incontinence and falsely elevate the abdominal leak point pressure (ALPP). In evaluating outlet obstruction, patients are encouraged to void as close to their normal pattern as possible so that they does not strain excessively nor involuntarily tighten the pelvic floor out of anxiety. Accurate interpretation of urodynamic studies is an art. It relies on patient cooperation and open communication between the patient and the clinician during the procedure, allowing urodynamic events to be correlated with the patient's symptoms in real time.

## INDICATIONS, CONTRAINDICATIONS, AND PATIENT PREPARATION

Urodynamic assessment is indicated if the diagnosis is uncertain, empirical treatment has failed, or an invasive procedure or surgery is contemplated. Urodynamic testing is deferred during an active urinary tract infection or after recent instrumentation. When possible, patients with a chronically indwelling catheter should be started on intermittent catheterization before the study because bladder sensation, capacity, and compliance may be altered by a chronic Foley catheter. Routine antibiotic prophylaxis is unnecessary unless the patient is at high risk for urinary infection, endocarditis, or prosthetic infection.<sup>6</sup> Patients with a history of or at risk for autonomic dysreflexia (i.e., T6 or above spinal cord injury) should be pretreated with oral nifedipine or  $\alpha$ -blockers and have their blood pressures monitored during urodynamic studies.<sup>7,8</sup> If sweating, headache, flushing, severe hypertension, and reflex bradycardia do not respond to bladder drainage, oral nifedipine or intravenous hydralazine, or both, should be administered immediately. Pharmacologic agents may alter bladder and sphincter functions. Whether these medications should be stopped before the study depends on the goal of the study. If the goal is to evaluate the response to medications (e.g., response of bladder compliance to anticholinergics), the medications should be taken. If the goal is to uncover the cause of urge symptoms, the medications should be stopped before the study.

### Urodynamic Evaluation for Stress Urinary Incontinence

The indications for urodynamic evaluation of stress urinary incontinence (SUI) are controversial and deserve special consideration. Many investigators argued that patients with classic SUI symptoms and obvious urethral hypermobility without associated irritative symptoms (e.g., urge, urge incontinence, nocturia), voiding dysfunction (e.g., weak stream, high postvoid residual volume), pelvic organ prolapse, neurologic disease, or history of incontinence surgery or radical pelvic surgery require no invasive urodynamic testing if they choose nonoperative treatments. Urodynamic tests are indicated when empirical therapy is ineffective and surgery is planned; patients complain of a confusing mix of urge and stress incontinence symptoms or significant emptying symptoms; or patients have equivocal urethral hypermobility, large prolapse, neurologic disease, or a history of failed incontinence surgery or pelvic surgery.

Classically, preoperative urodynamic assessments help to define the exact cause of incontinence and therefore guide the SUI surgical approach; evaluate detrusor function (e.g., capacity, instability, poor contractility) and identify patients at risk for voiding dysfunction (i.e., instability, retention) after SUI surgery; predict the impact of prolapse and its correction on storage and voiding functions; and identify urodynamic factors (e.g., high detrusor leak point pressure) that place the upper tract at risk postoperatively.<sup>9</sup> In the modern era of minimally invasive pubovaginal and mid-urethral slings, the roles of preoperative urodynamics become more controversial. Although few would argue that additional information could be gleaned from preoperative testing (albeit with a finite risk of urinary infection), it remains unclear whether urodynamics can improve SUI surgical success or alter the surgical approach.<sup>10,11</sup> Pubovaginal and mid-urethral slings appear to have reasonable success for any type and severity of SUI.<sup>12-15</sup> Patients without preoperative urodynamic evaluation before mid-urethral synthetic slings appear to do as well as those who underwent preoperative urodynamics routinely.<sup>16</sup> Nevertheless, urodynamics may identify subpopulation of patients at risk for postoperative failure or voiding complications (e.g., urge, retention).<sup>17-19</sup>

## EVALUATION OF STORAGE FUNCTION

### Eyeball Urodynamics

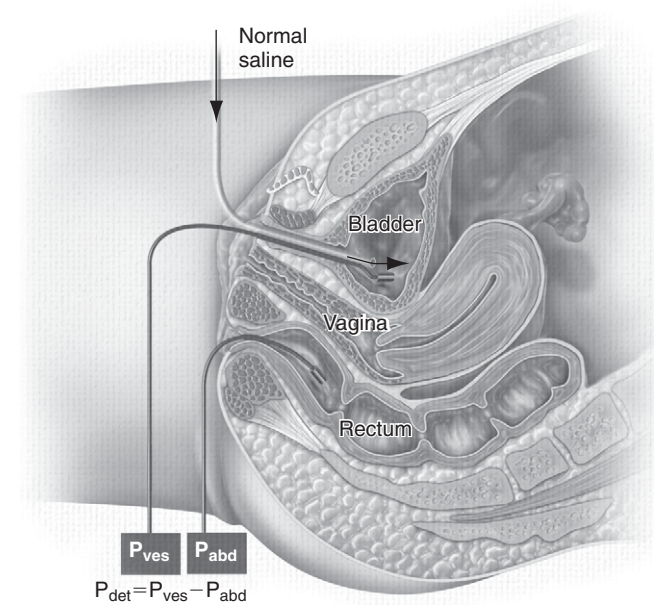

The so-called bedside eyeball urodynamics is the simplest of all tests. It enables detection of bladder sensation, overactivity, and capacity without sophisticated instruments. It requires only a catheter, filling syringe, normal saline, and careful observation. After voiding, a red rubber catheter is inserted, and the postvoid residual (PVR) volume is measured. A 60-mL syringe (with its barrel removed) is then used to fill the bladder under gravity. Intravesical pressure is estimated by the height of the saline column above the pubic symphysis. Changes in intravesical pressure are detected as slowing of the rate of fall or a rise in the fluid meniscus. Rising intravesical pressure may result from involuntary detrusor contraction (i.e., associated with a sudden urge to void and possibly leakage around the catheter), abdominal straining (i.e., the abdomen can be palpated or inspected to confirm a Valsalva response), or poor bladder compliance. The bladder is filled until the patient is comfortably full. The catheter is removed, and the patient is asked to cough and perform a Valsalva maneuver with increasing abdominal force. Stress incontinence, ure-

thral hypermobility, and pelvic organ prolapse are assessed in the lithotomy and upright positions. Pure SUI and stress-induced detrusor instability may be distinguished by the characteristics of the incontinence; the former is associated with a few drops of leakage, and the latter is associated with urge and continuous, uncontrollable voiding after the stress maneuver.

### Cystometrography

A cystometrogram measures the intravesical pressure ( $P_{ves}$ ) during bladder filling. The bladder is filled physiologically (i.e., diuresis) or through a catheter using room-temperature saline, water, or contrast (for video urodynamic studies [VUDS]). Fluid infusion is preferred over gas ( $CO_2$ ) infusion because the fluid is less irritative to the bladder than  $CO_2$ , fluid is noncompressible and can detect smaller detrusor contractions than  $CO_2$ , fluid leakage (i.e., incontinence) can be easily demonstrated, and leak point pressures, pressure-flow studies (PFSS), and anatomic studies can be performed using fluid but not a gaseous medium. Pressure is transmitted through an intravenous line to an external strain gauge transducer, or it is measured directly on a catheter-mounted, solid-state microtip transducer or fiberoptic transducer.<sup>20</sup>

In the single-channel cystometrogram, only  $P_{ves}$  is monitored, whereas in the multichannel cystometrogram, the  $P_{ves}$  and intra-abdominal pressure ( $P_{abd}$ ) are measured. A rectal balloon catheter is advanced well past the anal sphincter to measure  $P_{abd}$  to avoid interference with rectal contractions.<sup>21</sup> In patients with no anus (e.g., after abdominoperineal resection),  $P_{abd}$  can be monitored inside a colostomy, ileostomy, or vagina. Detrusor pressure ( $P_{det}$ ) is calculated by subtracting intra-abdominal pressure from intravesical pressure ( $P_{det} = P_{ves} - P_{abd}$ ) (Fig. 11-1).  $P_{det}$  is a computer-generated number and is subject to error if negative abdominal pressures are recorded. Having both  $P_{ves}$  and  $P_{abd}$  monitored simultaneously allows the examiner to differentiate bladder

**Figure 11-1** Intravesical pressure ( $P_{ves}$ ) and intra-abdominal pressure ( $P_{abd}$ ) are measured independently during multichannel cystometrography. Detrusor pressure ( $P_{det}$ ) is calculated by subtracting  $P_{abd}$  from  $P_{ves}$ .

contractions from abdominal straining. This is particularly useful in the evaluation of SUI to differentiate stress-induced detrusor overactivity from genuine SUI during cystometrography; in the evaluation of obstruction to distinguish bladder hypocontraction or straining from high-pressure detrusor contraction during PFSs; and to monitor bladder behavior during leak point pressure determinations and VUDS.

The rate of bladder filling (slow: <10 mL/min; medium: 10 to 100 mL/min; fast: >100 mL/min; physiologic:  $\leq$ body weight [kg]/4 [mL/min]; nonphysiologic) and the size of urethral catheter must be specified. Most patients are filled at medium rate initially. Filling is slowed if poor compliance, neurogenic bladder, decreased capacity, or excessive detrusor overactivity is encountered. Filling is increased during provocative maneuvers. Because large catheters may cause obstruction, smaller catheters (<10 Fr) are used.<sup>22</sup> A two-catheter technique, in which the larger, infusing catheter (8 to 12 Fr) is removed before voiding (i.e., voids along the smaller, pressure-monitoring catheter [3 to 4 Fr], has been described.<sup>23</sup>

To avoid artifacts, all lines are flushed to remove any air, and all transducers are zeroed at the superior edge of the pubic symphysis.<sup>25</sup> The patient is then asked to perform a Valsalva maneuver to ensure equal pressure transmission to the  $P_{ves}$  and  $P_{abd}$  catheters. Changes in  $P_{abd}$  must be accompanied by corresponding changes in  $P_{ves}$ ; otherwise, the calculated  $\Delta P_{det}$  represents artifacts rather than true detrusor contractions. Potential source of errors include pressure measurement artifacts (e.g., air bubbles and kinks in tubing, incorrect placement or migration of catheters, rectal contractions, incorrect zeroing), infusion artifacts (e.g., too rapid infusion in neurogenic and overactive bladders), unanticipated “pop-off” mechanisms (e.g., incompetent urethra that leaks, large bladder diverticulum or vesicoureteral reflux that falsely improves bladder compliance), and patient-related issues (e.g., lack of cooperation, ineffective communication, anxiety, psychological inhibition).<sup>21,24</sup>

Parameters that are measured by cystometrography include the following:

1. **Sensation.** Volumes at first sensation of bladder filling, first desire to void, strong desire to void, urgency, and pain are recorded.<sup>25</sup> These values are subjective, and the absolute volumes at which these symptoms occur are clinically less relevant. The more important issues are whether bladder sensation is increased, decreased, or absent and whether a particular sensation (e.g., urgency) is correlated or not with urodynamic findings (e.g., inhibited bladder contraction) during cystometrography.
2. **Capacity.** Functional bladder capacity measured on the voiding diary dictates the volume that the bladder should be filled during cystometrography. Maximal cystometric capacity measured on cystometrography tends to be larger than the functional bladder capacity. Urodynamic findings and symptoms experienced at filling volume beyond the functional bladder capacity should be interpreted with caution. Before surgical correction for SUI, it is prudent to ensure that bladder capacity and compliance are adequate.
3. **Compliance.** Bladder compliance ( $\Delta V/\Delta P_{det}$ ) describes the relationship between changes in bladder volume ( $\Delta V$ ) and changes in detrusor pressure ( $\Delta P_{det}$ ).<sup>25</sup> It is a measure of bladder vesicoelasticity and reflects the sum of two factors: the passive mechanoelastic property of the bladder wall

**Figure 11-2** Detrusor compliance ( $\Delta V/\Delta P_{det}$ ) remains high during the flat filling phase (phase II) of the cystometrogram in a normal subject. (Adapted from Steers WD, Barrett DM, Wein AJ: Voiding dysfunction: Diagnosis, classification and management. In Gillenwater JY, Grayhack JT, Howards SS, Duckett JW (eds): Adult and Pediatric Urology, 3rd ed. St. Louis, Mosby-Year Book, 1996.)

(correlated with collagen content) and the active neuromuscular force called *tonus* under neural modulation. The normal bladder has high compliance and is able to expand to capacity (large  $\Delta V$ ) with minimal changes in intravesical pressure ( $\Delta P_{det} < 15$  to  $20$  cm H<sub>2</sub>O) (Fig. 11-2, flat slope). Decreased compliance is defined as  $\Delta V/\Delta P_{det}$  less than 20 mL/cm H<sub>2</sub>O, measured from the moment of bladder filling to the point of cystometric capacity or immediately before the start of detrusor contraction that causes significant leakage.<sup>25</sup> Poor compliance may be caused by infection (e.g., cystitis, tuberculosis, schistosomiasis), inflammation (e.g., calculus, interstitial cystitis, carcinoma, radiation), obstruction, chronic indwelling catheter, neurologic disease (e.g., spinal cord injury, Shy-Drager disease), or surgical denervation (e.g., after hysterectomy, abdominoperineal resection), or it may be an artifact of too-rapid bladder filling. The rate of filling should be slowed if poor compliance is encountered. Compliance may be falsely overestimated if a pop-off mechanism prevents adequate bladder filling (e.g., intrinsic sphincter deficiency or vesicoureteral reflux). Low bladder compliance is a harbinger of upper tract disease in neurogenic patients. Patients with poor compliance who are slated for potentially obstructive outlet surgery (e.g., sling, artificial sphincter) need their compliance corrected before or concurrent with the outlet surgery to protect the upper tracts.

4. **Detrusor overactivity.** Involuntary bladder contraction due to neurogenic disorders is called *neurogenic detrusor overactivity* (formerly designated detrusor hyperreflexia), and that not attributed to neurogenic causes is called *idiopathic detrusor overactivity* (formerly designated detrusor instability).<sup>25</sup> Historically a  $\Delta P_{det}$  of more than 15 cm H<sub>2</sub>O was necessary to diagnose detrusor overactivity, but any involuntary pressure increase that is associated with urgency now qualifies as overactivity.<sup>21</sup> In patients in whom detrusor overactivity is suspected but not detected on the cystometrogram, provocative maneuvers such as rapid filling (>100 mL/min), filling with cold saline, coughing, heel bouncing, squatting, and hand washing may unmask the

**Figure 11-3** Detrusor leak point pressure (DLPP) measurement in the absence of straining or detrusor contraction. The shaded area represents the “danger zone,” with the DLPP and filling pressure higher than 40 cm H<sub>2</sub>O.

abnormalities. Up to 40% of patients with urge incontinence fail to demonstrate detrusor overactivity on conventional cystometrography.<sup>26</sup> The absence of documented detrusor overactivity on cystometrography does not rule out its existence. Conversely, patients with detrusor overactivity may not have any symptoms, and its documentation on cystometrography may have no clinical significance.<sup>27</sup> Even though patients with irritative symptoms and stress-induced detrusor overactivity often improve after bladder neck suspension surgery,<sup>28</sup> presumably as a result of eliminating the entrance of urine into the proximal urethra,<sup>29</sup> patients with mixed incontinence as a group appear to fare worse than those with pure SUI after tension-free tape surgery (69% versus 97% cure).<sup>16</sup> There is no consensus about whether the finding of detrusor overactivity in addition to SUI on preoperative cystometrography alters the outcome after surgery.<sup>30</sup>

### Detrusor Leak Point Pressure

A concept first introduced by McGuire and associates<sup>31</sup> in 1981 in the evaluation of myelodysplasia patients, detrusor leak point pressure (DLPP) is defined as the lowest detrusor pressure ( $P_{det}$ ) at which leakage occurs in the absence of detrusor contraction or increased abdominal pressure (Fig. 11-3).<sup>25</sup> The bladder is filled until overflow incontinence occurs, and the instantaneous  $P_{det}$  at which leakage occurs (i.e., DLPP) reflects the resistance of the urethra against the expulsive force of bladder storage pressure. When outlet resistance is high, high bladder pressure is needed to overcome this resistance and cause leakage. Bladder pressure higher than 40 cm H<sub>2</sub>O impedes ureteral peristalsis, causes hydronephrosis, and damages the upper tracts. In the classic study of McGuire and colleagues,<sup>31</sup> 81% and 68% of myelodysplasia patients with DLPP greater than 40 cm H<sub>2</sub>O developed hydronephrosis and vesicoureteral reflux, respectively. In long-term follow-up, 100% of patients with DLPP greater than 40 cm H<sub>2</sub>O exhibited upper tract deterioration or reflux, or both.<sup>32</sup> A DLPP higher than 40 cm H<sub>2</sub>O is a prognostic marker for upper tract damage.

**Figure 11-4** Abdominal leak point pressure (ALPP) measurement in the presence of straining but without detrusor contraction.

Patients with low bladder compliance and a low DLPP may be floridly incontinent, but their upper tracts are safe because the low-resistance urethra functions as a pop-off mechanism to relieve the high detrusor pressure. Patients with low bladder compliance and a DLPP higher than 40 cm H<sub>2</sub>O risk upper tract damage unless the outlet resistance is reduced or compliance is improved with medication or surgery. Correction of outlet resistance in patients with detrusor–external sphincter dyssynergia (DESD) by sphincter dilation results in an immediate decrease in DLPP and a gradual but significant improvement of bladder compliance over time.<sup>33</sup> Failure to reduce DLPP to below 40 cm H<sub>2</sub>O after sphincterotomomy predicts surgical failure, persistent DESD, and upper tract deterioration.<sup>34</sup> The use of intermittent catheterization, anticholinergics, and vesicostomy are effective in protecting the upper tracts of neonates with myelodysplasia.<sup>35</sup> Plotting the danger zone on a filling cystometrogram is an effective method to establish a storage baseline for patients with neurogenic dysfunction and subsequently track effective management by reducing the danger zone.

### Abdominal Leak Point Pressure

The idea of ALPP emerged from McGuire’s group a decade after the description of DLPP.<sup>36</sup> Originally designed to categorize women with SUI into two groups—urethral hypermobility and intrinsic sphincter deficiency (ISD)—ALPP measurement and Q-tip examination became indispensable tools in the diagnosis of SUI. The International Continence Society defined ALPP as the intravesical pressure ( $P_{ves}$ ) at which urine leakage occurs due to increased abdominal pressure in the absence of a detrusor contraction.<sup>25</sup> The bladder is half-filled to an arbitrary volume of 200 to 250 mL. The patient is then asked to perform a Valsalva maneuver or cough until leakage occurs. If no leakage is observed, the bladder is filled in 50-mL increments. The smallest recorded  $P_{ves}$  associated with urodynamic demonstration of SUI is the ALPP (Fig. 11-4). ALPP (leakage) usually occurs on the upward slope of the curve and not at the peak pressure generated unless the peak pressure represents the exact ALPP (i.e., exact moment of incontinence).

### Abdominal Leak Point Pressure versus Detrusor Leak Point Pressure

Unlike DLPP, which is a static reflection of urethral resistance to bladder intrinsic storage pressure, ALPP measures the dynamic urethral resistance to brief increases in abdominal pressure. Abdominal pressure (ALPP) and detrusor pressure (DLPP) are different expulsive forces with respect to the urethra. Whereas detrusor pressure tends to open the bladder neck, abdominal pressure tends to close the internal sphincter shut. Normally, the internal sphincter does not leak or open, regardless of how much abdominal pressure is exerted. For instance, during blunt trauma to a full bladder, the bladder will rupture before the bladder neck is forced open. If SUI occurs as a result of an increase in abdominal pressure, the proximal urethra and bladder neck are rotated and descended away from its resting intra-abdominal position during a Valsalva maneuver (i.e., urethral hypermobility), or there is an intrinsic malfunction of the internal urethral sphincter (i.e., ISD).<sup>37</sup> All women with urethral hypermobility and SUI are considered to have some degree of ISD, because the normal internal sphincter should remain closed no matter how much stress and rotational descent it experiences.<sup>23</sup> ISD is a spectrum of urethral dysfunction.

### Abdominal Leak Point Pressure, Urethral Hypermobility, and Internal Urethral Sphincter

SUI patients with urethral hypermobility leak at considerably higher abdominal pressures than those with pure ISD. Leakage at an ALPP less than 60 cm H<sub>2</sub>O is characteristic of ISD. Eighty-one percent of patients with an ALPP less than 60 cm H<sub>2</sub>O reported a history of severe incontinence, and 76% of patients with an ALPP less than 60 cm H<sub>2</sub>O demonstrated type III SUI on fluoroscopic studies (i.e., no urethral hypermobility). Leakage at an ALPP greater than 90 cm H<sub>2</sub>O is indicative of urethral hypermobility. These patients reported lesser degrees of incontinence and exhibited type I or type II SUI on VUDS (i.e., minimal to gross hypermobility).<sup>36</sup> Patients with an ALPP between 60 and 90 cm H<sub>2</sub>O have type II or type III SUI. Patients with an ALPP less than 60 cm H<sub>2</sub>O classically failed to respond to suspension operations designed for the hypermobile urethra. They should be treated with pubovaginal slings, periurethral bulking agents (if there is no associated hypermobility), or artificial sphincters. Subdividing patients into hypermobility or ISD groups based on ALPP measurement and Q-tip test results on physical examination may become less important because pubovaginal slings and mid-urethral slings have been shown to be effective for anatomic incontinence.<sup>12-15</sup>

### Abdominal Leak Point Pressure and Pelvic Organ Prolapse

ALPP measurements are more difficult to interpret in the presence of pelvic organ prolapse. Anterior vaginal wall prolapse may falsely elevate the ALPP because the prolapse functions as a sink to dissipate and absorb the effect of abdominal pressure on the proximal urethra.<sup>38</sup> The urethra may be kinked or compressed by the prolapsed organ, causing partial obstruction and elevating the ALPP. This is why patients with high-grade cystoceles rarely complain of clinical SUI. When the prolapse is reduced, up to 60% of patients with grade 1 to 2 cystocele and 91% of patients with grade 3 to 4 cystocele who do not complain of incontinence demonstrate SUI on urodynamic evaluations.<sup>39</sup> If the cystocele is repaired without addressing the urethra, occult stress incontinence may be unmasked postoperatively. It is unclear what per-

centage of patients with no symptoms of SUI will be symptomatic after a prolapse repair. It is also unclear whether performing ALPP with a pessary helps to predict that population. Whether prophylactic sling should be placed at the time of concomitant prolapse surgery and what roles preoperative ALPP plays in that decision remain controversial. Nevertheless, all patients undergoing ALPP measurements should have a pelvic examination in supine and upright positions to determine whether prolapse exists. If significant prolapse is found, upright ALPP measurements should be repeated with the prolapse reduced.<sup>40</sup>

### Abdominal Leak Point Pressure Measurement

The technique for ALPP determination has not been standardized. ALPP decreases significantly as the bladder volume increases.<sup>41</sup> There is no consensus about whether ALPP should be measured at an absolute volume (e.g., 150 mL),<sup>36</sup> one-half the functional bladder capacity,<sup>42</sup> or near capacity.<sup>43</sup> Most experts agree that testing should be done at a "moderate filling volume" that is sufficient to provide a urine bolus for abdominal pressure to act on but not full enough to induce a detrusor contraction, which opens the bladder neck and gives a false impression of ISD.<sup>38</sup> Cough leak point pressure is significantly higher and more variable than Valsalva leak point pressure,<sup>44</sup> possibly due to reflex contraction of the pelvic floor during cough.<sup>45</sup> The size and necessity of bladder catheters have not been standardized. Larger catheters correlate with higher ALPP values, presumably due to partial obstruction.<sup>45</sup> Patients with a history of SUI who do not leak with a urethral catheter in place should have ALPP measurements repeated with the catheter removed.<sup>46</sup> Some investigators recommended measuring ALPP using a rectal catheter alone to measure  $P_{abd}$ .<sup>46,47</sup> Others argued that  $P_{det}$  should be monitored to ensure that the detrusor is stable during a Valsalva maneuver.

It is unclear whether the *absolute pressure value*<sup>48</sup> or the *subtracted pressure value from baseline pressure*<sup>49</sup> should be used. It is recommended that the location of pressure sensors, type of catheters, position of patient, status of prolapse (reduced or not), methods in which the bladder is filled (e.g., diuresis, catheter fill), types of ALPP (e.g., cough, Valsalva maneuver), and volume at which measurements are made should be specified. ALPP measurement is inaccurate if the patient cannot generate adequate abdominal pressure.

### Resting Urethral Pressure Profilometry

Urethral pressure profilometry (UPP) is a topographic curve that plots the urethral closure pressure (UCP) along the length of the urethra. Intravesical pressure ( $P_{ves}$ ) and intraluminal urethral pressure ( $P_{ure}$ ) are measured simultaneously while a mechanical puller withdraws the pressure transducer from the urethra at a set rate (1 to 2 mm/sec). The difference between these two pressures is defined as UCP ( $UCP = P_{ure} - P_{ves}$ ), and it is plotted on the  $y$ -axis. The urethral length is plotted on the  $x$ -axis. UPP attempts to quantify the contributions of urinary sphincters and periurethral structures to urethral closure at rest (i.e., resting UPP), during periods of straining (i.e., stress UPP), and during voiding (i.e., micturitional UPP).

Resting UPP measures the static urethral pressure along its length in a resting patient with a full bladder (i.e., no Valsalva maneuver and no voiding). It is measured using the technique of Brown and Wickham.<sup>50</sup> A urethral catheter with radially drilled side holes is slowly withdrawn from the urethra while being

**Figure 11-5** Schematic diagram of the resting urethral pressure profile (UPP) shows the calculated urethral closure pressure (UCP), which is equal to the urethral pressure minus the intravesical pressure ( $P_{ure} - P_{ves}$ ) along the length of the urethra.

infused. The intraluminal urethral pressure that is recorded corresponds to the pressure needed to lift the urethral wall off the catheter side holes, and it is presumed that this reflects the radial stress at the urethral surface.<sup>51</sup> The intravesical pressure is simultaneously measured with the end holes of the same catheter. The maximal urethral closure pressure (MUCP), the highest point along the UCP curve, corresponds anatomically to the area of mid-urethra where the striated and smooth muscle sphincters overlap (Fig. 11-5).

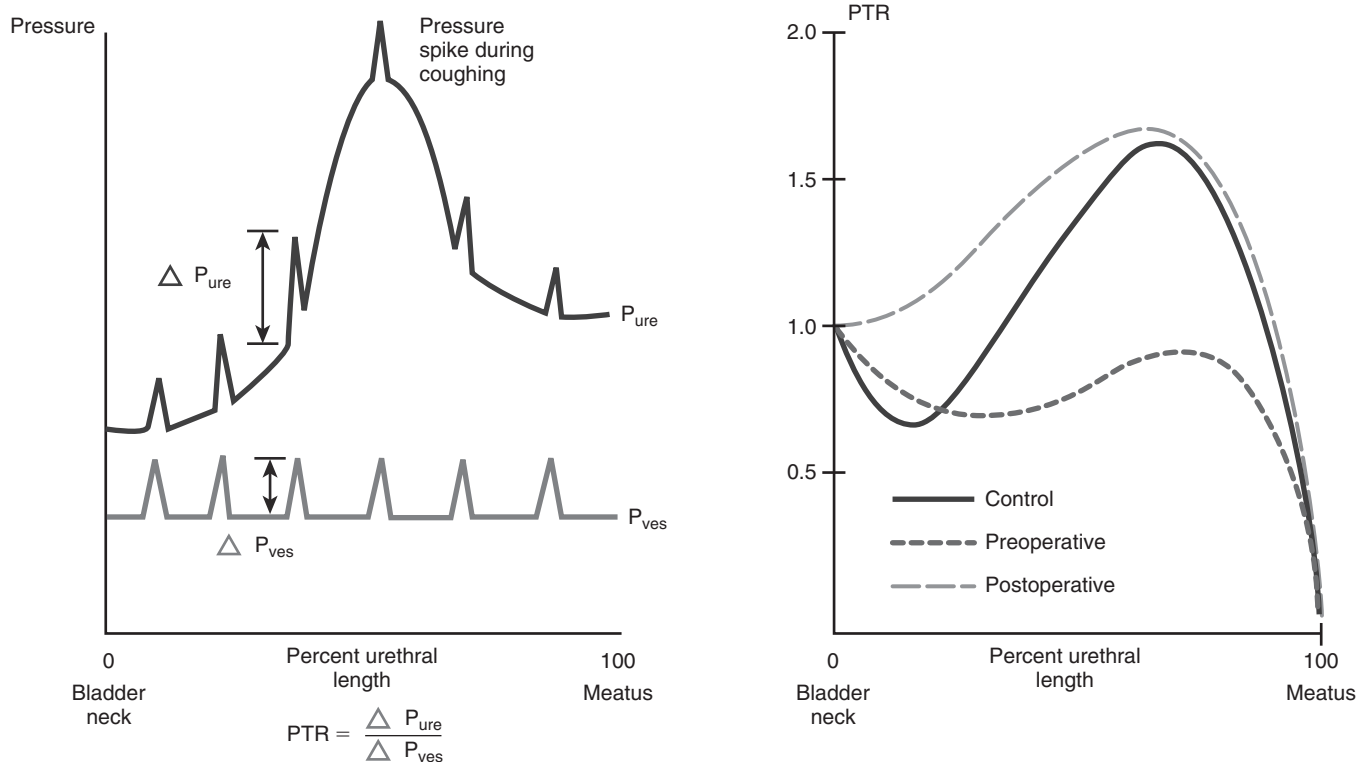

Resting UPP has no role in the evaluation of the patient with SUI.<sup>52,53</sup> MUCP lacks the sensitivity and specificity to diagnose and classify incontinence.<sup>54</sup> MUCP cannot be used to distinguish continent from incontinent patients. A low MUCP (<20 cm H<sub>2</sub>O) does not predict stress incontinence; many continent women have a low MUCP, and the MUCP cannot characterize the severity of incontinence.<sup>55</sup> An MUCP less than 20 cm H<sub>2</sub>O, however, does predict failure of classic retropubic suspension surgery.<sup>56-59</sup> This “low-pressure urethra” was considered to be associated with ISD. No change in UPP has been recorded in patients achieving continence after successful collagen injections<sup>60</sup> or urethropexy.<sup>61</sup> Studies have repeatedly demonstrated that there is no relationship between ALPP and MUCP.<sup>54</sup> This is not surprising because many believe that continence is maintained at the bladder neck, not at the mid-urethral high-pressure zone where MUCP is recorded. (The success of mid-urethral sling surgery challenges this view). Incontinence or continence is not determined by urethral pressure at rest (i.e., MUCP) but by urethral resistance to abdominal pressure during straining (i.e., ALPP). Resting UPP is a rudimentary measurement of urethral closure at rest, and it cannot capture the complex interactions among the detrusor, the sphincters, and the pelvic floor during the dynamic moment of straining. The reproducibility of resting

UPP is poor because techniques of its measurement have not been standardized.<sup>55</sup>

### Stress Urethral Pressure Profilometry

Stress UPP measures the dynamic urethral resistance along its length as the patient strains. It reflects the patient’s ability to maintain continence in the face of abdominal pressure. Pressure spikes are generated intravesically ( $\Delta P_{ves}$ ) and intraurethally ( $\Delta P_{ure}$ ) during a Valsalva maneuver or coughing. The pressure-transmission ratio (PTR) is calculated as the ratio ( $\Delta P_{ure}/\Delta P_{ves}$ ) along the urethral length during the pressure spikes (Fig. 11-6). A PTR greater than 100% implies positive-pressure transmission (i.e., the urethral pressure spikes exceed the bladder pressure spikes), whereas a PTR less than 100% suggests that more pressure is transmitted to the bladder than to the urethra.

Normally, the proximal urethra remains intra-abdominal during straining, with equal pressure transmission to the bladder and the urethra ( $\Delta P_{ure} \geq \Delta P_{ves}$ , or PTR  $\geq$  100%). In patients with SUI and urethral hypermobility, posterior rotation and descent of the proximal urethra during straining results in unequal pressure transmission<sup>62</sup> and therefore a PTR less than 100% ( $\Delta P_{ure} < \Delta P_{ves}$ ). Although it is true that patients with anatomic SUI tend to have lower PTR values (usually < 90%) than continent subjects,<sup>63,64</sup> there are significant overlaps between the PTR values of continent and incontinent patients,<sup>65,66</sup> rendering the test insensitive in diagnosing anatomic SUI.<sup>67</sup> The reason for the large overlap may be explained by the observation that not all patients with urethral hypermobility and low PTR are incontinent; a certain degree of ISD must exist for leakage to occur. Unlike MUCP, PTR increases after successful bladder suspension<sup>68-71</sup> and mid-urethral sling procedures.<sup>72</sup>

**Figure 11-6** The pressure-transmission ratio (PTR) is plotted along the urethral length as the ratio between urethral pressure spikes ( $\Delta P_{ure}$ ) and bladder pressure spikes ( $\Delta P_{ves}$ ):  $PTR = \Delta P_{ure} / \Delta P_{ves}$ . *Controls* are defined as normal, healthy volunteers with no symptoms of urinary incontinence. *Preoperative* indicates patients with stress incontinence. *Postoperative* indicates the same patients after bladder neck suspension. (Adapted from Constantinou CE: Urethrometry: Consideration of static dynamic and stability characteristics of the female urethra. *Neuroradiol Urolyn* 7:521, 1998.)

## EVALUATION OF VOIDING FUNCTION

### Uroflowmetry

#### Uroflowmetry Measurement

First described by von Garrelts in the 1950s,<sup>73</sup> uroflowmetry is the measurement of the rate of urine flow ( $Q$ ) over time. Urine flow rate can be measured by weight transducers, rotating disks, or electronic capacitance dipsticks.<sup>74</sup> The seated position is recommended for female patients. Patients should be well hydrated and have a reasonably full bladder before the study. An overly distended bladder may decompensate and result in reduced urine flow. However, a small voided volume (<150 mL) may affect flow rate interpretation. Voiding should be done in privacy, with as little distraction and as few observers as possible so that the patient can relax to replicate her usual urine flow. An anxious and tense patient may be psychologically inhibited and involuntarily contract her pelvic floor. Her flow rate may be altered, or she may not be able to empty at all. The patients should always be asked if the void is typical with respect to its volume, force, and pattern.<sup>74</sup> If in doubt, several measurements may be obtained to exclude variations. Studies have shown that between 20% and 40% of patients have a difference of  $Q_{max} \pm 2$  mL/sec between successive voids.<sup>75,76</sup> Maximal flow rate ( $Q_{max}$ ) is the most commonly reported parameter (Fig. 11-7). It is important to visually confirm the  $Q_{max}$  value on the flow curve because machine-read values are on average 1.5 mL/sec higher than manually read (true) values due

to wag artifacts.<sup>77</sup> It is also crucial to interpret the quantitative measurements in the context of the shape of the flow curve (i.e., normal versus intermittent versus obstructive patterns).

#### Normal Uroflowmetry in Females

Normal uroflow patterns in female patients have been described in the literature.<sup>78,79</sup> Unlike men, in whom  $Q_{max}$  decreases with age, the  $Q_{max}$  is not influenced by age in women.<sup>80</sup> As in men,  $Q_{max}$  in women is influenced by bladder volume. The Liverpool nomogram plots the  $Q_{max}$  and  $Q_{ave}$  values against bladder volumes based on measurements from 249 normal female volunteers.<sup>81</sup> The 10th percentile curve was picked arbitrarily as the lower limit of normality. Other uroflow nomograms (e.g., Siroky, Bristol) do not apply to females because they were based on male patients.<sup>82</sup> A small voided volume (<150 mL) may affect flow rate interpretation. In women with frequency or urgency syndromes, the flow rate curves may be nondiagnostic because of small voided volumes. In general, normal women have a higher  $Q_{max}$  value for a given voided volume than age-matched men, usually on the order of 5 mL/sec,<sup>83,84</sup> because of lower outlet resistance.

#### Clinical Applications of Uroflowmetry

Uroflow reflects the final summation of detrusor contraction, abdominal straining, urethral resistance, and sphincteric or pelvic floor relaxation. A  $Q_{max}$  greater than 15 mL/sec with a voided volume greater than 100 mL and minimal PVR essentially rules out obstruction in female patients.<sup>86</sup> However, it is not possible

**Figure 11-7** Uroflowmetry. The voided volume is the total volume of urine expelled through the urethra. The maximal flow rate ( $Q_{\max}$ ) is the maximal measured rate of flow, and the time to maximal flow ( $T_{\max}$ ) is the time elapsed from onset of flow to maximal flow. The flow time is the time during which flow occurs, and the average flow rate ( $Q_{\text{ave}}$ ) is determined by dividing the voided volume by the flow time. In patients with intermittent flow patterns, the flow time is measured by disregarding the time intervals between flow episodes.  $Q_{\text{ave}}$  cannot be accurately calculated if the flow is intermittent or dribbling.

to tell from a low  $Q_{\max}$  whether there is bladder outlet obstruction or impaired detrusor contractility.<sup>87</sup> PFSs, micturitional UPP, and video-urodynamic or sphincteric electromyography are needed to differentiate obstruction from detrusor underactivity. Flow rate does not tell whether or why a female patient is incontinent. Patients with SUI and low outlet resistance may present with a superflow pattern. Patients with SUI who are slated for surgery should be screened with uroflowmetry and PVR. Those with an abnormally low  $Q_{\max}$  and high PVR deserve further urodynamic evaluations to rule out detrusor underactivity or outlet obstruction before SUI surgery. This is particularly important for patients who had prior posterior pelvic exenteration, radical hysterectomy, abdominoperineal resection, or pelvic reconstructive surgery. These procedures are associated with a high incidence of voiding dysfunction due to vascular, neural, and anatomic disruption to the lower urinary tract.<sup>88</sup> In summary, uroflow is a fast, cheap, and noninvasive urodynamic screening test for voiding dysfunction.

### Pressure-Flow Studies

A PFS is usually performed after cystometry. The patient is instructed to void while bladder pressure and flow rate are simultaneously measured throughout the micturition cycle. The flow pattern should be representative of that observed during uroflowmetry. The flow rate measured by PFS (with a catheter) may be slightly lower than the free flow rate measured during uroflowmetry (without a catheter).<sup>89</sup> The patient should be specifically asked if the void is typical with respect to its volume, force, and pattern.<sup>74</sup> PFS allows bladder outlet obstruction to be differentiated from detrusor underactivity when a low  $Q_{\max}$  is detected. High-pressure low flow is diagnostic of functional or

**Figure 11-8** Normal electromyographic pattern. The electromyographic signals become more intense and frequent as the bladder fills because of recruitment of the pelvic floor and urinary sphincter during filling (i.e., guarding reflex). The signal is quieted before actual detrusor contraction and flow. (Adapted from Blaivas JG: Pathophysiology of lower urinary tract dysfunction. Clin Obstet Gynaecol 12:295, 1985.)

anatomic outlet obstruction. However, low-pressure low flow does not rule out obstruction in female patients (Fig. 11-8). PFS alone cannot identify the site or mechanism of obstruction; VUDS or sphincteric electromyography is needed instead.

### Female Outlet Obstruction

Female outlet obstruction is most commonly encountered after anti-incontinence surgery, particularly if an associated anterior wall defect (e.g., cystocele) was not repaired at the time of anti-incontinence surgery. Large prolapse can also cause outlet obstruction by kinking the urethra, distorting the bladder neck anatomy, or direct compression. There is no consensus regarding a critical value of pressure and flow that is diagnostic for obstruction in females. Commonly used pressure-flow plots (i.e., Abrams-Griffith, Schafer, urethral resistance factor, and International Continence Society provisional nomograms) are not applicable to female patients because they were developed for use in men with bladder outlet obstruction.<sup>90-93</sup> Nomograms for obstruction in females have been published but are not widely used.<sup>94</sup> Massey and Abrams<sup>95</sup> proposed a definition of obstruction if two of the following conditions exist:  $Q_{\max}$  less than 12 mL/sec;  $P_{\text{det}}$  greater than 50 cm H<sub>2</sub>O; resistive index greater than 0.2, which is defined as  $P_{\text{det}}/(Q_{\max})^2$ ; or a high PVR volume. Axelrod<sup>96</sup> defined primary bladder neck obstruction as  $P_{\text{det}}$  greater than 20 cm H<sub>2</sub>O and  $Q_{\max}$  less than 12 mL/sec. In light of the low specificity and lack of standardization of PFS results, Nitti<sup>97</sup> proposed the use of VUDS to diagnose obstruction, which was defined as radiographic evidence of obstruction between the bladder neck and the external sphincter in the presence of sustained bladder contraction.

The voiding dynamics of women are different from those of men. In men, a significant  $P_{\text{det}}$  is recorded during voiding because the detrusor has to exert a force strong enough to move the urine bolus through a relatively high-resistance conduit (i.e., prostatic urethra). In normal women, however, there is very little increase in  $P_{\text{det}}$  during voiding, even when bladder contractility is normal, because the flow of urine encounters minimal resistance against the female urethra. Inability to record a strong detrusor contrac-

**Table 11-2 Stress Urinary Incontinence Types Based on Video Urodynamics Appearance**

Type of SUI	SUI Seen on VUDS?	Bladder Neck at Rest		Bladder Neck During Valsalva		Cystocele Present?
		Status	Position	Status	Position	
0	No	Closed	At/above PS	Open	Descends < 2 cm	No
I	Yes	Closed	At/above PS	Open	Descends < 2 cm	No
IIA	Yes	Closed	At/above PS	Open	Rotational descent	No or small
IIB	Yes	Closed	Below PS	Open	Rotational descent	Large

From Blaivas JG, Olsson CA: Stress incontinence: Classification and surgical approach. *J Urol* 139:727, 1988.

tion in females is common during PFS and should not be a cause for alarm if the patient's history, physical examination, and voiding diary are otherwise normal.<sup>98</sup> Even in the setting of bladder outlet obstruction, many patients fail to generate a high  $P_{det}$  on PFS, probably because women void by pelvic floor relaxation rather than high-pressure detrusor contraction. Habitual Valsalva-induced voiding across a relaxed pelvic floor is a common pattern seen in women. For instance, in patients who underwent bladder suspension complicated by obstruction and irritative voiding who improved after successful urethrolisis, only one third to one half have obstructive PFS patterns before urethrolisis.<sup>99-101</sup> Although a high-pressure, low-flow PFS result is diagnostic of obstruction, a low-pressure, low-flow PFS result does not necessarily rule out obstruction (depending on the definition of obstruction). This observation calls into question the need to perform urodynamic evaluation of patients who are presumably obstructed after anti-incontinence surgery and who are slated for urethrolisis. Patients unable to generate adequate  $P_{det}$  on preoperative a PFS may be at higher risk for prolonged postoperative retention after cadaveric pubovaginal slings.<sup>102</sup> Patients most likely to report de novo urgency, presumably due to partial obstruction, after tension-free tape procedures are those in whom Valsalva-induced voiding or low  $P_{det}$  was present on preoperative PFSs.<sup>18</sup> Patients with preoperative dysfunctional voiding on the PFS ( $P_{det} > 20$  cm H<sub>2</sub>O and  $Q_{max} < 12$  mL/sec) are less likely to be cured (based on pad tests) and more likely to have a diminished quality of life after tension-free tape surgery.<sup>103</sup> The role of the preoperative PFS in the evaluation of SUI is evolving.

### Micturitional Urethral Pressure Profilometry

Described originally by Yalla and associates,<sup>104</sup> micturitional urethral pressure profilometry (MUPP) is used to diagnose and localize the site of urethral obstruction. During steady midstream voiding,  $P_{ves}$  and  $P_{det}$  are the same (i.e., isobaric). If an obstruction exists in the urethra, the intraurethral pressure distal to the obstruction is lower, and the pressures in the urethra proximal to the obstruction and in the bladder are higher. When a significant pressure drop is encountered on catheter withdrawal, it corresponds to the site of the obstruction. In a patient with a normal urethra, the bladder and almost the entire length of urethra are isobaric, except the terminal 1 cm of the distal urethra.<sup>105</sup> This normal pressure drop occurs distal to the point of MUCP and proximal to the external meatus. In an obstructed urethra, the site of obstruction can be identified by an additional drop in urethral pressure that occurs proximal to the normal

pressure drop point. Even though the concept is elegant, MUPP lacks anatomic resolution to define the exact location and mechanism of obstruction (VUDS is far superior). The exact location of the pressure being transduced is difficult to ascertain without fluoroscopy. MUPP is difficult to perform correctly because it is prone to micturitional artifacts.<sup>106</sup>

### VIDEO URODYNAMICS

First described in the late 1960s,<sup>107</sup> the use of VUDS adds real-time, high-resolution anatomic details to a cystometrogram and PFS. Regarded as the gold standard of urodynamic evaluation, VUDS allow structural-functional correlations to be investigated because transducer pressures, patients' symptoms, and live fluoroscopic images are studied simultaneously. Historically, SUI was classified as type 0, I, II, or III based on the fluoroscopic appearance of the bladder neck on VUDS (Table 11-2).<sup>108</sup> ALPP measurements and Q-tip tests are commonly used to classify patients with urethral hypermobility or ISD, or both. VUDS are not indicated in many situations.<sup>109</sup> For instance, VUDS are rarely needed to diagnose detrusor overactivity. If obstruction is suspected, PFS can be obtained. VUDS are not indicated in SUI patients with obvious hypermobility and no overactive bladder symptoms. If ISD is suspected, ALPP can be performed. Because of the expense and radiographic exposure, VUDS are reserved for patients with complex pathophysiology, as in the following circumstances:

1. *Neurogenic bladder.* VUDS can detect vesicoureteral reflux and the pressure and volume at which it occurs. With cystometrography alone (without fluoroscopy), the reflux pop-off mechanism can artificially overestimate the bladder compliance and capacity and falsely decrease the DLPP, making the compliance, capacity, and DLPP appear better than they really are. Other "bladder hostile factors," such as bladder diverticulum, trabeculation, and detrusor-external sphincter dyssynergia (DESD) or detrusor-internal sphincter dyssynergia (DISD), can also be easily identified on VUDS.
2. *Failed prior anti-incontinence surgery.* VUDS allow simultaneous determination of the presence and degree of vesical neck hypermobility, the degree and presence of ISD, the degree and type of cystocele, the presence and location of obstruction, and ALPP simultaneously. Although these characteristics can be identified with a simple cystogram, the presence of an open bladder neck on radiography has little significance without knowing whether the detrusor is

contracting. In the presence of a detrusor contraction, an open bladder neck is a normal response, whereas an open bladder neck in the absence of a detrusor contraction in a woman with SUI may be a sign of ISD. Only by simultaneously recording the detrusor behavior by VUDS can such a distinction be made.<sup>23</sup> Fluoroscopy may also improve the accuracy of ALPP measurement because it is easier to observe leakage of contrast agent than it is to observe leakage from an upright patient directly using a flashlight.

3. *Obstructive voiding.* It is easier to define the exact anatomic location and mechanism of obstruction (e.g., stricture, DESD, DISD, pseudo-dyssynergia, urethral kinking) by VUDS. Filling is done in a standing position, and voiding is done seated.
4. *Significant pelvic organ prolapse.* VUDS demonstrates the real-time anatomic effects of prolapse on bladder and urethral function. Dynamic magnetic resonance imaging may also offer additional insights on the effect of posterior or apical vaginal wall defects on voiding.
5. *Urinary diversion and augmentation.* VUDS can be used to investigate the cause of incontinence and hydronephrosis after continent urinary diversion, orthotopic bladder substitution, or bladder augmentation. Incontinence may be caused by an incompetent outlet in the native sphincter or the reconstructed continence mechanism, high-pressure intestinal or bladder contraction, or poor neobladder or augmented bladder compliance (often caused by ischemia). These possibilities can be distinguished on VUDS. The sphincteric mechanism in orthotopic bladder may be evaluated in the same manner as ISD in the native bladder. Vesicoureteral reflux causing hydronephrosis can be easily detected. DLPP measurement (at catheterization volume) should be measured regularly after bladder augmentation in neurogenic patients to ensure that the goal of low-pressure filling is accomplished.<sup>110,111</sup>

## SPHINCTER ELECTROMYOGRAPHY

### Electromyographic Measurement

Electromyography measures the electrical activities of the striated urinary sphincter through an electrode. It provides kinesiological information about the urethral sphincter and the pelvic floor muscles. Needle electrodes or surface electrodes can be used. The needle electrode is inserted directly into the striated urinary sphincter and records activities directly from that muscle group. Needle insertion causes discomfort, and it is easily dislodged during posture change, but it provides high-quality signals directly from the muscle of interest. Surface electrodes are placed on the skin or mucosa overlying the muscle of interest, and they pick up the potentials produced by various muscles in the vicinity. Commonly, the surface electrode is applied around the anus and records activities from the striated anal sphincter. Usually, anal sphincter activity and urinary sphincter activity are congruent. In patients with neurologic disease, this relationship cannot be assumed, and when possible, needle electrodes should be used instead. Before bladder filling, the examiner should ensure that sphincteric activity is recorded appropriately by eliciting a burst of electromyographic activity by asking the patient to contract her sphincter voluntarily, asking the patient to

perform a Valsalva maneuver or cough, or stimulating the bulbocavernosus reflex.

### Clinical Applications of Electromyography

Electromyography is indicated in the evaluation of spinal cord injury; neurologic disease, such as multiple sclerosis or Parkinson's disease; voiding dysfunction after radical pelvic surgery or back surgery; and in young women with idiopathic urinary retention. Clinically, the most important information is whether bladder contraction and sphincter relaxation are coordinated during volitional voiding. During normal voiding, electromyographic activity is quieted (i.e., relaxation of striated sphincter and pelvic floor) before initiation of detrusor contraction (see Fig. 11-8). Increased electromyographic activity and sphincter closure at the time of volitional voiding is detrimental to the bladder (e.g., poor compliance, diverticulum formation, trabeculation) and the upper tract (e.g., renal insufficiency, hydronephrosis, vesicoureteral reflux, recurrent sepsis, stone formation) due to high voiding pressure.

In DESD, there is true discoordination between the detrusor and the external sphincter due to suprasacral spinal cord injury. The sphincter involuntarily closes shut when the bladder contracts. DESD should not be confused with the pseudo-dyssynergia commonly seen after a stroke. In pseudo-dyssynergia, there is a voluntary increase in sphincter activity with the sudden onset of a bladder contraction and sense of urgency. Pseudo-dyssynergia is a volitional response to urgency to prevent urge incontinence rather than a true discoordination between the bladder and the sphincter. DESD can be differentiated from pseudo-dyssynergia by asking the patient if she is voluntarily contracting the sphincter or pelvic floor in response to urgency during periods of increased electromyographic activities. Hinman's syndrome is a subconscious contraction of the sphincter with a bladder contraction. Unlike true DESD, no spinal cord injury or neurologic disease exists in Hinman's syndrome. For this reason, Hinman's syndrome is also called *non-neurogenic neurogenic bladder*, and it is thought to be a learned voiding dysfunction.<sup>112</sup> DESD can be treated with sphincterotomy,<sup>34</sup> external sphincter dilation,<sup>34</sup> urinary diversion, or a combination of clean intermittent catheterization and anticholinergic drugs.<sup>35</sup> Hinman's syndrome can be treated by behavioral modification combined with medications. Sphincteric bradykinesia in patients with Parkinson's disease can be diagnosed with electromyography in conjunction with fluoroscopic imaging.

## AMBULATORY URODYNAMICS

Conventional cystometrography may fail to reproduce the patient's symptoms and may provoke symptoms or findings not usually experienced by the patient. Ambulatory urodynamic tests offer the theoretical advantage of being able to monitor the patient's storage and voiding function in a more physiologic manner. The bladder is filled naturally (i.e., diuresis), and the patient has the freedom to move freely and to perform daily activities that normally trigger the presenting symptoms (e.g., incontinence, urgency). Nonphysiologic bladder filling through a catheter is avoided. The psychological inhibition and intimidation associated with voiding in front of strangers in an unfamiliar laboratory is minimized.

Different methods of recording have been described.<sup>113,114</sup> Cystometry is monitored through intravesical and rectal catheters, and the signal is transmitted to a portable, battery-powered recorder. Flow measurements can be made using home uroflowmetry. Incontinence is measured using regular pads or electronic moisture-sensitive pads. The premise of ambulatory urodynamics is that it may offer additional insights when conventional urodynamics is unable to reproduce the patient's presenting symptoms.

Because the investigator is not present during the telemetry, significant problems may arise in the proper interpretation of the tracing. For events (e.g., urgency, incontinence, voiding) to be properly recorded, the patient must take an active role and conscientiously press an event marker or write in a diary every time the event happens. This reliance on patient compliance may be a source of significant error. Detrusor after-contractions, aberrant rectal pressures, movement artifacts, and catheter movements are common.<sup>115</sup> It may be difficult to distinguish these artifacts from physiologic events. It remains difficult to resolve the different findings with conventional and ambulatory cystometry and explain what these differences mean clinically.

A higher incidence of unstable detrusor contractions was recorded during ambulatory urodynamics compared with conventional cystometry in symptomatic and asymptomatic patients. Van Waalwijk van Doorn and associates<sup>116</sup> found unstable detrusor contractions in 69% of asymptomatic women using ambulatory urodynamics, whereas conventional cystometry detected detrusor instability in only 18% of asymptomatic

women. Robertson's group<sup>115</sup> similarly found significantly more detrusor instability on ambulatory studies compared with cystometry (38% versus 17%) in asymptomatic men and women. Ambulatory urodynamics can also detect detrusor instability in patients for whom a cystometrogram is nondiagnostic. The significance of this increased detection of detrusor instability is unclear, given the high incidence found in asymptomatic patients. It is unclear whether ambulatory cystometry is more sensitive or it has a higher false-positive rate of diagnosing detrusor overactivity than conventional cystometry. Whether this increased phasic detrusor activity is a physiologic finding or caused by movement artifacts of the catheter or interpretation ambiguity is debated. Although the terminology, methodology, analysis, and reporting of ambulatory urodynamics have been standardized by the International Continence Society,<sup>116</sup> widespread adoption of the technique has been limited by its technical complexity, time consumption, potential artifacts, difficult result interpretation, and uncertain clinical applicability.

In patients with chronic retention and neurogenic bladder, bladder compliance measured by ambulatory urodynamics is much higher than that measured by conventional cystometry.<sup>117,118</sup> Patients with hydronephrosis and high filling pressures on conventional cystometry were found to have normal filling pressures and better bladder compliance on ambulatory urodynamics. It is possible that the low compliance seen on conventional cystometry in some patients may be an artifact related to too-rapid bladder filling.

# MEASUREMENT OF URINARY SYMPTOMS, HEALTH-RELATED QUALITY OF LIFE, AND OUTCOMES OF TREATMENT FOR URINARY INCONTINENCE

*Larry T. Sirls*

The evaluation of lower urinary tract symptoms (LUTS) in women involves several objective and subjective parameters. The difficulty in evaluating treatment outcomes for urinary incontinence is that the objective measures of improvement and cure do not necessarily correlate with the subjective outcomes patients report. This becomes complicated when we consider that the outcomes after surgery for stress urinary incontinence (SUI) include assessment of the surgery (e.g., success, persistent or recurrent SUI); the resolution, persistence, or development of urgency and urge incontinence (UUI); and evaluation of voiding dysfunction. This is an almost overwhelming task, and it remains controversial. Most agree that measuring treatment outcomes requires the collection of objective data to help evaluate the success of treatment and the incidence of complications, as well as subjective patient reports of their outcomes and the influence of post-treatment changes on their health-related quality of life (HRQOL).

To improve the initial evaluation and post-treatment assessment of urinary incontinence, noninvasive outcome measures, including pad tests,<sup>1</sup> voiding diaries,<sup>2</sup> and questionnaires, have been developed.<sup>3,4</sup> A critical addition to the measurement of subjective outcome is the symptom questionnaire.<sup>5,6</sup> Although limitations remain in what can be accomplished through the use of a symptom questionnaire, they are clearly more objective than retrospective reviews and can be validated in a systematic fashion. Retrospective chart reviews and the opinions of the surgeons or their surrogates have several limitations, including patient reluctance to complain to surgeons about minor symptoms,<sup>7,8</sup> different definitions of success by patients and physicians,<sup>9</sup> and potential loss to follow-up of symptomatic patients who seek medical attention elsewhere.<sup>7</sup>

Although various outcome measures have been proposed, no single tool has met with widespread acceptance. There are no standard definitions of cure or failure, and there are no standardized widely accepted clinical tools to assess outcomes after anti-incontinence surgery. Although attempts to standardize the evaluation of treatment outcomes in urinary incontinence have been made, these recommendations are often not followed. There are no specific recommendations on how to assess patient HRQOL or gather this information.<sup>10</sup>

In this chapter, we discuss the development and composition of many questionnaires used to evaluate LUTS and the impact of those symptoms on patients' HRQOL. We discuss the difficulty in evaluating patients after treatment for urinary incontinence

and the apparent dissociation of objective measures of SUI such as cure and complicating symptoms such as UUI. We then address the role of combined objective and subjective data to evaluate treatment outcomes.

### HEALTH-RELATED QUALITY OF LIFE

The most common outcome measures for urinary incontinence assess the quantity and frequency of urine loss through voiding diaries, pad tests, or urodynamic testing such as leak point pressure and pressure-flow studies. These observations may confirm the degree of leakage, but they do not reflect the impact of the symptoms on the patients' quality of life. Norton<sup>11</sup> first reported that there was no direct relationship of objective measures of urinary incontinence with the degree of improvement experienced by the patient. Several others have found only weak relationships of the perceived impact of incontinence with measures of frequency and quantity of urine loss.<sup>12-15</sup> Consequently, quality-of-life instruments have become an important outcome measure for surgical interventions.<sup>16</sup> It is mainly in the past decade that researchers have developed and used several different self-administered questionnaires for urinary incontinence that measure of bother, symptom impact, and HRQOL.

HRQOL is a multidimensional paradigm defined as the impact of health status, including disease and treatment on physical, psychologic, and social functioning. HRQOL can be assessed with generic or condition-specific measures. Generic measures are developed for use with patients regardless of their medical condition and can be used for patients with different disease processes to compare the HRQOL impacts of various diseases. In contrast, condition-specific measures assess aspects of disease and treatment that are unique to the specific disease. Compared with generic measures, condition-specific instruments tend to be more sensitive to clinically relevant changes and treatment effects.

### DEVELOPMENT AND VALIDATION OF QUESTIONNAIRES

Questionnaires to evaluate LUTS may provide information about the nature of the patient's problem, the frequency of symptoms, the extent of symptoms, and the impact of symptoms on HRQOL.

The ideal questionnaire would help the clinician establish the cause of the problem (i.e., differentiate SUI from UII) and limit the need for invasive and expensive testing. Questionnaires may include a wide range of items depending on the purpose and target subjects of the study population.

### Measurement of Symptoms on Questionnaires

Applying scientific methods to evaluate symptoms that are generated by a great variety of underlying conditions can be complicated. How can the physician be sure that the score from a symptom questionnaire accurately reflects the symptoms the subject reports? Psychometrics is the science of measurement of responses to phenomena that are not easily quantifiable, and the principles of psychometrics govern the development of symptom questionnaires. Symptom scores are only as good as the instrument measuring the symptoms, and psychometric testing provides assurance that symptoms questionnaires measure symptoms.<sup>17</sup>

### Validity

Validity refers to the degree that an instrument measures what it is intended to measure. *Content validity* is usually evaluated early in development of the questionnaire and assesses how representative the contents are. This is often done with literature review and through consultation with experts and patients. The questions chosen should cover all of the important aspects of the condition, and all items should be relevant to the condition. *Criterion validity* determines how accurately the new instrument predicts findings of the gold standard, and it can be determined by using several methods. Correlation coefficients are frequently used, the choice of which depends on the nature of the data under analysis. *Sensitivity* is the proportion of people identified by the questionnaire as having the condition who do suffer from the condition. *Specificity* refers to the ability of the questionnaire to correctly identify subjects who do not have the condition. Related measurements include predictive values, accuracy, and receiver operation characteristic (ROC) curves. These measures are only accurate if the gold standard is highly accurate.

Although urodynamic evaluation is generally accepted as the best available diagnostic test for LUTS, many other standards—history, voiding diary, demonstration of incontinence on examination, and pad testing—have been used for criterion validation of LUTS questionnaires. No one method accurately assesses the scope of LUTS, the severity of the problem, and the cause of LUTS well enough to be the undisputed gold standard.<sup>18-21</sup> Nevertheless, results from questionnaires should be compared with several of these objective measures, particularly urodynamic findings, as part of the validation process.

When no gold standard is available for comparison, *construct validity* is used to assess questionnaires. One approach to establishing construct validity is to examine hypothetical associations of the measure with other domains, such as pain, anxiety, and life satisfaction. For example, anxiety may correlate moderately with quality of life. The Spearman or Pearson correlation coefficients typically are used. *Convergent validity* (similar to sensitivity) may be determined by demonstrating good correlation with a measure known to be related to the subject of the questionnaire,

and it should have high correlation coefficients. *Discriminant validity* (similar to specificity) may be confirmed by showing poor correlation to characteristics unrelated to the subject of the questionnaire.

### Reliability

Questionnaires that measure the same characteristics should produce similar responses from a subject. The same questionnaire also should produce similar results for a subject over short intervals of time. Reliability is the quantifiable assessment of these sources of error in a questionnaire. Reliability implies the instrument is dependable.<sup>17</sup> *Internal reliability* estimates how the individual items of a questionnaire relate to each other and to the total score. Questionnaires may be divided into two similar tools, each of which may give results similar to each other and to the parent questionnaire. Selected items may be used to construct a short form that is consistent with the original long form of the questionnaire. Cronbach's  $\alpha$  (0-1) indicates the level of internal consistency; values greater than 0.7 are considered acceptable, greater than 0.8 are good, and greater than 0.9 are excellent. Although high internal consistency is desirable, removing redundant items from questionnaires improves clinical speed but diminishes internal consistency. Longer or multiple questionnaires are probably needed for research purposes, but in most clinical situations, we are looking for brevity. *Test-retest reliability* is evaluated by repeat administration of the questionnaire to subjects over time. Enough time should have elapsed for the subjects to forget their responses to the items, but no change in their symptoms should be evident. A Pearson and Spearman correlation coefficient value of greater than 0.8 indicates high reliability.

*Responsiveness* is evaluated to confirm that a questionnaire reflects a clinically important change in the patient's condition. The questionnaire is used before and after treatment of known efficacy, and the patient's perception of change is correlated with the quality of life scores. The Student *t* test is often used to report responsiveness.

The psychometric evaluation of a questionnaire must be evaluated in the context of the study subjects used. Questionnaires may perform very differently after translation to another language or when used in different countries with different races or socioeconomic groups.<sup>22</sup> The accuracy of questionnaire data depends on choosing the appropriate tool for the population under study.

The method of data collection can dramatically influence the cure rates reported after anti-incontinence surgery.<sup>6,23</sup> Physicians' biases with the use of retrospective chart review have been repeatedly documented. To eliminate this bias, prospective studies that contain HRQOL assessments have nearly replaced the retrospective chart review. Rodriguez and colleagues<sup>24</sup> addressed the question of whether medical personnel (physicians in particular) could reliably fill out HRQOL questionnaires with information obtained from medical interviews? Seventy-nine patients completed the Urogenital Distress Inventory (UDI-6) and a quality-of-life survey. An interviewing physician then completed these same instruments based on the interview of the patient. Overall, the physicians underestimated the patient's degree of bother by 25% to 37%. Self-administered questionnaires minimize bias and are preferred over medical personnel-administered instruments because of labor, time, and cost.

## TYPES OF QUESTIONNAIRES

### Questionnaires for Lower Urinary Tract Symptoms

Self-administered symptom questionnaires are designed to accomplish at least one of three objectives: discriminate between SUI and UUI, quantify the amount of symptoms, or assess the impact of symptoms on daily activity and HRQOL. Brief descriptive information and references for each questionnaire are presented in Table 12-1.

### Questionnaires for Differentiating Stress Urinary Incontinence from Urgency Urinary Incontinence

The Detrusor Instability Score (DIS) quantifies the extent of detrusor instability symptoms to discriminate stress from urge as the cause for incontinence. The tool is translated from Finnish but has been validated for use in English. DIS scores have been compared with urodynamic findings, demonstrating a low DIS score (0-5) had reasonable predictive value for the absence of detrusor instability. Although sensitivity and specificity are

LUTS, lower urinary tract symptoms; OAB, overactive bladder; SUI, stress urinary incontinence; UI, urinary incontinence; UUI, urge urinary incontinence.

marginal, the DIS has a positive predictive value of 0.82 for determining which patients would not demonstrate detrusor instability on urodynamic evaluation.<sup>25,26</sup>

The Gaudenz Incontinence Questionnaire has been used widely in Europe as a diagnostic tool to discriminate between SUI and UUI. Initial studies demonstrated high validity. A validation study evaluated the ability of the two subscales to predict urodynamic findings in 1938 women with incontinence. The strict urodynamic criteria used demonstrated detrusor instability in only 2% of women, with 5% having mixed incontinence, making interpretation of this questionnaires performance difficult.<sup>27</sup> A shorter, English-language variation of the Gaudenz Incontinence Questionnaire used in Japan was compared with physical examination, pad test, and urodynamic data before and after intervention. Post-treatment scores for both parameters were significantly reduced.<sup>28</sup>

### Questionnaires that Quantify the Amount of Urinary Symptoms

The Stress Incontinence Questionnaire (SIQ) was created to evaluate whether specific activities women routinely perform that result in SUI have diagnostic value. Subjects use a 4-point scale to respond about urinary leakage when performing 18 specific maneuvers. Statistical analysis identified four subscales or factors designated active maneuvers, passive maneuvers, planned maneuvers, and unplanned maneuvers. Psychometric testing using clinical and urodynamic data demonstrated good reliability. The correlation of the four factors with different clinical characteristics suggests that the factors identify different aspects of incontinence.<sup>29</sup>

The Severity Index attempts to determine the extent that women are bothered by incontinence.<sup>30</sup> There are two questions;

one asks about the frequency of urinary incontinence, and the second assesses the amount of leakage per urinary incontinence event. The numeric values 1 to 4 for the frequency and 1 to 3 for the amount are multiplied to give the score ranging from 1 to 12. The scores are then divided into four levels of severity. The severity level correlated reasonably well with leakage by 48-hour pad tests, but there was overlap between the severity groups. An updated version includes a *very severe* category, which identified a subgroup of older women when used in an epidemiologic study. The investigators recommend adding a *no leakage* response if the questions are being used to monitor outcome.<sup>31</sup>

### Questionnaires that Assess the Amount of Symptoms and the Impact of Symptoms

The Severity Index and the Symptom Impact Index for stress incontinence are paired indices specific for SUI that divide *severity* and *impact* into separate scores. The three items of the Symptom Impact Index assess the degree to which women avoid activities because of stress incontinence. After a comprehensive development process, the instrument was found to have good reliability, but convergent validity was demonstrated only through a significant correlation with body mass index. The instrument was not significantly related to the more relevant characteristic of whether a woman had undergone previous surgery for stress incontinence. Conversely, discriminant validity was shown by the lack of correlation between index scores, demographic variables, and unrelated medical history.<sup>32</sup>

The Bristol Female Lower Urinary Tract Symptoms Questionnaire (BFLUTS) was developed from the International Continence Society male questionnaire, retaining the same format and many of the items. Thirty-three questions evaluate four domains: incontinence severity, associated symptoms, quality of life, and sexual function. Many of the questions have an additional component assessing the level of associated bother.<sup>33</sup> Initial psychometric testing compared BFLUTS scores with voiding diaries and pad tests in 85 incontinent women and control subjects. The frequency of reported symptoms and the degree of bother were significantly higher for all symptoms in the clinical cohort. Criterion validity was confirmed by comparing items assessing urinary frequency and incontinent episodes to the voiding diaries. All voiding diary parameters except daytime frequency correlated well with BFLUTS scores. Subjective assessment of the degree of incontinence correlated with pad test results. Internal consistency and test-retest reliability were confirmed. The BFLUTS questionnaire is a comprehensive tool for evaluating urinary incontinence in women. Its large size may limit general use by clinicians.

The International Consultation on Incontinence Questionnaire (ICIQ) is a four-item questionnaire composed of three scored items and an unscored self-diagnostic item that assesses the prevalence, frequency, and perceived cause of urinary incontinence and its impact on everyday life. It was developed for a wide range of patients for clinical practice and research settings. The ICIQ is easily completed, with low levels of missing data (mean, 1.6%), and it is able to discriminate among different groups of individuals, indicating good construct validity. Convergent validity was acceptable, and reliability was good, with “moderate” to “very good” stability in test-retest analysis and a Cronbach’s  $\alpha$  value of 0.95. Statistically significant reductions in symptoms from baseline after surgical and conservative

treatment were observed, demonstrating that the ICIQ is responsive.<sup>34</sup>

The ICIQ, a 24-hour pad test, Stamey grade, and 3-day frequency volume diary used to assess severity were further evaluated in 95 women with primary or recurrent SUI. In the primary SUI group, there was a strong correlation between the ICIQ and the 24-hour pad test results. The ICIQ and 24-hour pad test results also correlated with the mean frequency of urinary loss on the diary but not with the Stamey grade. Although good correlation between the 24-hour pad test and ICIQ in women with primary SUI was demonstrated, no subjective or objective tests correlated for women with recurrent SUI.<sup>35</sup> Intraobserver and interobserver reliabilities of the ICIQ have been established by observing that the results obtained from administering the ICIQ at the office or at home were not different from those obtained by the physician during an interview, a potentially unique advantage of this tool.

The ICIQ has been shown to be an effective tool for the assessment of the frequency, severity, and impact on quality of life of urinary incontinence in a wide range of patients. Because it is brief and simple, is responsive to treatment, and includes a measure of quality-of-life impact, the ICIQ may prove to be extremely useful as an outcome measure in patients in clinical and research settings.<sup>36</sup>

Four of 10 items on the Urinary Incontinence Severity Score assess the amount of leakage, and the other six items refer to the impact of urinary incontinence on a woman’s daily life.<sup>37</sup> Although this measure was found to have adequate psychometric properties, the instrument yields only a total score that combines the four symptom items and six symptom impact items. This instrument therefore does not provide a pure indication of symptom impact or quality of life.

### Questionnaires that Assess the Impact of Urinary Symptoms

The Incontinence Impact Questionnaire (IIQ) and the Urogenital Distress Inventory (UDI) are paired symptom questionnaires that measure the HRQOL effect and the level of distress in women with stress incontinence.<sup>3</sup> Variations of these two products include short forms and urge-specific forms. The 30-question IIQ has four domains: physical activity, travel, social or relationships, and emotional health. The UDI is more of a measure of “bothersomeness” and contains three domains of irritative, obstructive or discomfort, and stress symptoms. Validation was established with convergent and discriminant correlation with several clinical parameters, including final diagnosis, pad test results, and voiding diaries. However, a subsequent study found it to have poor construct validity as indicated by weak correlations with a clinical measure.<sup>38</sup> The instrument recently was re-examined using factor analysis, and a new subscale assessing embarrassment was identified. This revised version (IIQ-R) was found to have good psychometric properties.<sup>38</sup> A version of the IIQ with two additional items has been shown to perform well in assessing men with urinary incontinence.<sup>39</sup>

In 1995, the original psychometric test data was re-analyzed to produce the short forms of both the IIQ and the UDI. The seven-item IIQ (IIQ-7) retains the four subscales. The UDI-6 was constructed by taking two items from each of the three original subscales. Regression analysis confirmed adequate validity and consistency. Correlation between the long and short forms of both indices (total scores and subscale scores) was high.<sup>40</sup>

The original IIQ and UDI were validated primarily among patients with stress incontinence and subsequently have been adapted to be more specific for the urge component of incontinence. The Urge IIQ (U-IIQ) domains are travel, activities, feelings, physical activity, relationships, and sexual function. The Urge-UDI (U-UDI) has 9 items, some of which have an associated bother question. Eighty-three women with racial and socioeconomic diversity were used for initial psychometric testing. All women had pure or predominantly urge UUI. A large percentage of women did not answer some questions on physical and sexual activity. Only minimal correlation was seen between these questionnaires and the general quality-of-life index Short Form-36 Item Health Survey (SF-36). All subscales demonstrated high internal consistency. Test-retest correlation was adequate for the U-IIQ subscales and low for the U-UDI.<sup>22,40</sup>

The Incontinence Quality of Life Measure (I-QOL) is a 22-item questionnaire designed to assess the quality of life of men and women with urinary incontinence. There are three subscales of avoidance and limiting behaviors, psychosocial impact, and social embarrassment. A number of items address worry about certain things that may happen, such as worry about not getting to the toilet or worry about being embarrassed. Reliability and validity have been demonstrated, but the reported psychometric results have focused primarily on the total score rather than the subscales.<sup>41,42</sup> Construct and discriminant validity were demonstrated further in later studies.<sup>43,44</sup> Although the I-QOL was designed for use in men and women, it has been used primarily in women. The instrument has been translated into more than 20 languages. The I-QOL has been used as an outcome measure in clinical trials of treatment for SUI, and it has been used as a fundamental tool to validate patient global impression questionnaires.<sup>45</sup>

The Urge Impact Scale (URIS-24) is a 24-item quality-of-life measure specifically for older persons (65 years or older) with UUI. The original 32-item questionnaire was developed from comprehensive interviews with 21 older men and women with UUI. Questions were formulated by using language recorded during the interviews.<sup>46</sup> Analysis revealed three factors or subscales: psychological burden, perception of personal control, and self-concept. URIS-24 scores demonstrated moderate correlation with mean incontinent episodes per day. Reliability was acceptable. Although there was some test-retest variability for individual items, the composite score was reproducible. As is common with HRQOL questionnaires, criterion validity is lacking. This seems to be a well-constructed tool with a defined target population of older adults.<sup>47</sup>

The York Incontinence Perception Scale (YIPS) is a one-dimensional index of eight items that measures the psychosocial impact of incontinence in women. Psychometric techniques were used to select the items. Voiding diaries, response to treatment, and comparison with the IIQ were used for validation. Responsiveness was tested in a randomized trial of behavioral therapy for incontinence. YIPS scores substantially increased in the treatment group relative to the control group.<sup>48</sup> The YIPS is a brief incontinence impact questionnaire with good psychometric characteristics.

The King's Health Questionnaire (KHQ) is a 21-item quality-of-life index specific for women and for urinary incontinence.<sup>49</sup> The KHQ was developed to assess HRQOL in women with general symptoms of incontinence, but it has since been shown to be valid and reliable for use in men and women with overactive bladder symptoms.<sup>50</sup> Eight domains were identified: general

health, incontinence impact, role limitations, physical limitations, social limitations, personal limitations, emotional problems, and sleep or energy disturbances and severity measures. The reliability and validity were assessed in 285 women before urodynamic evaluation. Internal consistency and test-retest reliability were excellent. Common domains between the KHQ and the SF-36 correlated highly. Scores were analyzed relative to urodynamic diagnosis. Although women with genuine SUI tended to report more severe leakage, those suffering from detrusor instability reported poorer general health and greater impact of incontinence on their lives. The KHQ is reliable and valid in women with incontinence and in men and women with overactive bladder.

The CONTILIFE is an HRQOL questionnaire that has been validated in five languages among women with SUI.<sup>51</sup> Psychometric properties were good with some exceptions, including internal consistency of the effort activities, responsiveness of sexuality, and well-being dimensions.

The Overactive Bladder Questionnaire (OAB-q) consists of an eight-item symptom bother scale and 25 items assessing HRQOL in four domains: coping, concern, sleep, and social interaction. This instrument is unique in that it was directly based on perceptions of continent and incontinent patients with overactive bladder.<sup>52</sup> In community and clinical samples, it has been shown to have strong psychometric properties, including responsiveness to change in the continent overactive bladder symptoms of urgency and frequency and nocturia.<sup>52</sup> The OAB-q has been shown to discriminate between patients with different levels of nocturia and among patients with stress, urge, or mixed incontinence in a community sample.<sup>53</sup>

The Incontinence Stress Questionnaire for Patients (ISQ-P) was developed to evaluate patients' psychologic distress associated with urinary incontinence in long-term care.<sup>54</sup> The final 20-item version of the questionnaire was derived from a broad item pool of 109 items based on interviews with patients and factor analyses. The published validation study reports good internal consistency and construct validity, although test-retest reliability was assessed over a longer period (11 weeks) than is preferred. The instrument was validated among a sample of 96 elderly women with cognitive impairment and therefore may not be applicable to a more general sample of patients with urinary incontinence.

The 24-item Quality-of-life Questionnaire for Urinary Urge Incontinence questionnaire is grouped into five dimensions: activities, emotional repercussions, self-image, sleep, and well-being.<sup>57</sup> Although the instrument appears to have sound psychometric properties, subsequent instruments have been developed and validated specifically for patients with urge incontinence.

The Urinary Incontinence Handicap Inventory (UIHI) was based on the perceptions of 10 individuals in the target population (i.e., elderly women with urinary incontinence) on emotions, activities, social interaction, and physical functioning.<sup>56</sup> The instrument demonstrated good internal consistency reliability, test-retest reliability, and construct validity.

The Leicester Impact Scale is a 21-item, condition-specific quality-of-life measure for men and women with LUTS, with or without incontinence. The questionnaire was interviewer administered to a community sample of men and women older than 40 years. The distribution of scores was skewed with low levels of impact, which may reflect a community sample rather than a treatment sample, but it was responsive to conservative treatment. Limitations include the length, the fact that it is interviewer

administered (e.g., costly, time intensive, bias,) and the poor interrater reliability for some items, specifically the “depressed” and “angry” items.<sup>57</sup>

### THE ROLE OF INCONTINENCE QUESTIONNAIRES

The perfect LUTS symptom questionnaire would be short, easily administered and scored, discriminate between SUI and UUI, measure severity, and measure the effect of the symptoms on HRQOL. It would minimize the need for invasive and expensive testing. All clinicians treating incontinence would regularly use this tool, helping create a standardized means for evaluating LUTS and measuring the outcomes of treatment. Unfortunately, this questionnaire does not exist, and using more than one questionnaire may be necessary. Because stress and urge incontinence probably represent different disease processes, scales that discriminate between them or score them separately may more accurately reflect a patient’s condition than a more general scale.

To reduce bias and inadvertent outside influence when using HRQOL questionnaires, several guidelines should be followed. The questionnaire should be self-administered by the patient, and the patient should be given a specific timeframe for their answers. Usually, patients are asked to think about their symptoms over the past 4 weeks. Longer timeframes may predispose patients to report how they act or feel, decreasing responsiveness.<sup>58</sup> The psychologic effect of surgical intervention must be considered because it has been shown there may be a false sense of well-being immediately after surgery (from anxiety and stress relief), regardless of the effect of the surgery.<sup>59</sup> Surgeons reporting on this subject would agree that the outcomes of incontinence therapy should not be evaluated too soon after surgery. Patients must complete the questionnaire in the same setting, which may be most practical in the office while waiting for the physician. Patients must not have assistance, unless by trained personnel, to eliminate inadvertent bias through personal interpretation or explanation of the questions.

When selecting which HRQOL instrument to use in a specific situation, several factors should be considered. The functional domains assessed by items and subscales among different tools vary, and one instrument may be preferable over another. For example, because the IIQ has a travel subscale, it can be used to evaluate the impact of treatment on patients’ ability to travel.

It is critical to match the questionnaire with the intended study sample. There are inherent differences between urinary symptoms in terms of causes and HROQL impacts. For example, SUI has less HROQL impact than urge or mixed urinary incontinence, and mixed urinary incontinence has a greater impact than urge alone.<sup>60</sup> Because different urinary symptoms affect patients in different ways, it is necessary to choose a questionnaire that has been developed and validated for use among the study population. Instruments validated among samples with SUI include the CONTILIFE and the Symptom Impact Index for Stress Incontinence in Women, whereas the URIS and U-IIQ were designed specifically for patients with urge urinary incontinence. The ISQ-P would be useful to study a population of cognitively impaired older women in long a term care facility.

Of the urinary incontinence-specific HRQOL instruments, the KHQ has been validated in a large and diverse population, and many translations are available. Other sound urinary incontinence-specific instruments for women include the IIQ, UDI, I-

QOL, and ICIQ. When a brief questionnaire is desired, the IIQ-7 and UDI-6 or the ICIQ would be appropriate. The OAB-q is an HRQOL instrument that was specifically developed and validated for use in continent and incontinent patients with overactive bladder, and it may be appropriate for diverse populations of patients with symptoms of urgency, frequency, or nocturia, but not incontinence.

The ICIQ has been shown to be an effective tool for the assessment of the frequency, severity, and impact on quality of life of urinary incontinence in a wide range of patients. Because it is brief and simple, is responsive to treatment, and includes a measure of quality-of-life impact, the ICIQ may prove to be extremely useful as an outcome measure.

Many have reported that urinary incontinence HRQOL questionnaires do not always correlate with *preoperative* objective measures of urinary incontinence. There is poor correlation between the severity of scores in the IIQ and UDI and the 1-hour pad test in a community population.<sup>15</sup> The poor predictive value of the IIQ and the UDI for patients with the urodynamic diagnosis of stress or urge incontinence has been reported,<sup>61</sup> but these tools have been shown to be responsive to treatment of SUI after reconstructive pelvic surgery.<sup>62</sup> Others have shown poor correlation between the severity of incontinence determined by Valsalva leak point pressure and scores on the UDI-6, but specific items from the UDI-6 were able to provide predictive information regarding urodynamic findings in women.<sup>63</sup> For example, 85% of patients with detrusor overactivity reported a moderate or great response to urge-related leakage (item 2) of the UDI-6. Preoperative use of the UDI-6 could therefore have avoided 52 of 128 urodynamic studies, and only six patients with detrusor overactivity would have been missed. This type of information may help eliminate the discomfort and potential complications of invasive urodynamic testing and reduce the associated costs.

The *postoperative* evaluation of incontinence treatment is complicated. Our objective tools that evaluate incontinence are extremely insensitive and miss the incontinence in many of patients, or our symptom questionnaires reveal some unknown characteristics that do not relate to objective urinary incontinence. We know that women may report satisfaction with surgery even if they have not achieved continence. Satisfaction rates decrease with pad use, with the increasing frequency of stress symptoms, and with urge incontinence.<sup>64</sup> Can this be measured accurately, and does it predict or correlate with patients’ subjective outcomes?

A comprehensive discussion of the role of urodynamic testing is beyond the scope of this chapter, but several observations can be offered. In a prospective, randomized study comparing the use of tension-free vaginal tape with colposuspension, the objective cure rate (defined as negative pad test and negative cystometric results) was 66% in the tension-free vaginal tape group and 57% in the colposuspension group.<sup>65</sup> When patients completed validated questionnaires, only 59% and 53%, respectively, reported cure of their SUI. Only 36% and 28%, respectively, reported no urine leakage under any circumstance. However, 84% in the tension-free vaginal tape group and 82% in the colposuspension group reported being satisfied or very satisfied with their surgery and were willing to recommend it to a friend. Fulford and colleagues<sup>66</sup> identified six patients with demonstrable stress incontinence on postoperative video urodynamics who had no subjective complaints of stress incontinence. In the same study, despite 83 of 85 patients reporting symptomatic resolution of

stress incontinence, only 66 were satisfied with the surgical result, mainly because of persistent urge symptoms. These data are similar to those of Litwiller and coworkers,<sup>67</sup> who reported just over one half of patients subjectively satisfied in the presence of persistent urgency or urge incontinence, compared with a 100% satisfaction rate for those without an urge component.

Although postoperative stress incontinence may not correlate with patient satisfaction, detrusor overactivity and urgency symptoms are important factors in poor subjective outcomes after surgery. Rodriguez and coworkers<sup>68</sup> evaluated postoperative patients who had preoperative detrusor overactivity on urodynamic study. Although these patients reported similar improvement in SUI symptoms, their postoperative symptoms of frequency, urgency, urge incontinence, and use of pads for protection were significantly more severe than those without preoperative detrusor overactivity. In this study, perception of overall quality of life was not different for patients with or without detrusor overactivity on urodynamic studies, regardless of their worse outcome. This finding may reflect realistic patient expectations that UI symptoms may not improve after surgery (perhaps because of good preoperative counseling) or the fact that overall improvement (85% versus 88%) and decrease in daily pad use (69% versus 71%) was similar between groups.

Many investigators have evaluated patients' expectations for surgery<sup>9,69-74</sup> and have shown that the patients' goals can range from improvement of a specific symptom to restoration of a general lifestyle. Patients' expectations for surgery to improve quality of life are critical, and preoperative counseling is essential to clarify and negotiate reasonable surgical outcomes. Failure to meet these expectations is an important reason why patients report dissatisfaction after surgery. Lifestyle factors may include the goal of return to missed activities ("I want to be able to play with my grandchildren" or "I want to go back to an exercise routine"), whereas other patients may desire resolution of a particular problem ("I want the bulge gone" or "I don't want to leak when I cough").

Although we cannot predict individual goals, achievement of specific goals appears to be a primary reason for undergoing surgery. Elkadry and associates<sup>74</sup> observed that women's expectations of goal achievement are so strong that even extensive preoperative counseling did not eliminate unrealistic hopes such as relief of urinary frequency and urgency from the personal goals list. Further study is needed to establish whether the inclusion of patient goals into preoperative evaluation improves patient outcomes.

### COMBINED MEASURES OF TREATMENT OUTCOMES

Most clinicians would agree that the ultimate definition of success is the patient's subjective outcome. However, objective data obtained through testing are critical to assess a procedure's efficacy and its complications, allow accurate comparison of different procedures, and ultimately allow the clinician to provide realistic outcomes expectations and counseling to patients. Although the perfect questionnaire could help us sort out these symptoms without invasive testing, it does not exist. We are left with a dilemma about how to evaluate and report patient outcomes after incontinence therapy. The Urodynamics Society recommended that the post-treatment evaluation of incontinence should include at least the patient's opinion of treatment outcome, a micturition questionnaire, a voiding diary, a pad test,

### Box 12-1 Groutz-Blaivas Anti-Incontinence Surgery Response Score

The Groutz-Blaivas anti-incontinence surgery response score combines the patient's objective clinical data with their subjective report of outcome. The three measures of incontinence—the patient questionnaire, 24-hour pad test, and 24-hour voiding diary—are scored from 0 to 2, and the cumulative score determines the outcome category of cure, good, fair, poor, or failure.

#### Postoperative 24-Hour Voiding Diary

- 0 = No urinary incontinence (urge or stress) episodes.
- 1 = 1 or 2 incontinence episodes
- 2 =  $\geq 3$  incontinence episodes

#### Postoperative 24-Hour Pad Test

- 0 = Total weight gain of the pads:  $\leq 8$  g
- 1 = Total weight gain of the pads: 9 to 20 g
- 2 = Total weight gain of the pads:  $>20$  g

#### Patient Questionnaire

- 0 = The patient considers herself cured.
- 1 = The patient considers herself improved.
- 2 = The patient considers the operation to have failed.

#### Cumulative Score

Outcome	Total score
Cure	0
Good response	1-2
Fair response	3-4
Poor response	5
Failure	6

From Groutz A, Blaivas JG, Rosenthal JE: A simplified urinary incontinence score for the evaluation of treatment outcomes. *Neurourol Urodyn* 19:127-135, 2000.

a physical examination, uroflowmetry, and postvoid residual volume.<sup>10</sup>

An innovative system to combine subjective and objective evaluation of incontinence, the SEAPI QMM, was published by Raz and Erickson in 1992.<sup>4</sup> This system is conceptually similar to the TNM system, with each letter of SEAPI QMM representing an aspect of incontinence (stress-related leakage, bladder emptying ability, anatomy, protection, inhibition of bladder activity, quality of life, mobility, and mental status) and each factor assigned a number grade.<sup>4</sup>

The quality-of-life measure consists of a 15-item questionnaire that looks at several domains, including social interactions, personal strain, global health and quality of life, satisfaction and financial impact. This quality-of-life measure was further assessed for reliability and secondarily evaluated the gender differences in the impact of incontinence before and after treatment. The self-directed SEAPI QMM quality-of-life index was evaluated in 315 patients (102 men and 213 women) with incontinence and 35 without incontinence.<sup>75</sup> A voiding diary reported the frequency of incontinence episodes and the number of pads or type of protection used daily for incontinence. Mean scores before and after treatment with medical or surgical management were significantly different for both genders. Women reported that urinary incontinence had the greatest impact in the social domain,

and men reported the greatest impact was on sexual relations. This instrument demonstrated a high degree of reliability relating to stability and internal consistency across a wide age range in men and women. The length of this instrument may limit its general acceptance by clinicians.

Groutz and Blaivas<sup>76</sup> developed and presented a compilation of noninvasive outcome measures to better assess and report the combination of the patients' objective clinical data with their subjective reports of outcome. They use three measures of incontinence: patient questionnaire, 24-hour pad test (which the patient completes before the postoperative visit), and 24-hour voiding diary. Ninety-four patients who underwent pubovaginal sling procedures had their outcomes evaluated twice, first by each of these three measures separately and by assigned outcome categories of cure, improvement, and failure and, second, by combining the three outcome tools into a new response score. The new response score summed these three incontinence measures from 0 to 2, with the total score added from the three categories (therefore combining the objective and subjective outcome data) to determine the new outcome categories of cure, good, fair, poor, and failure (Box 12-1). The strict criterion for cure in the new response score category was no incontinence episode, a negative pad test result, and subjective cure. Using the new response score, 44.7% of patients were classified as cured, whereas the old system had classified 64% as cured by pad test and questionnaire results and 69% according to voiding diary information. Seven patients who were reclassified as having a poor response reported subjective improvement by means of the questionnaire. The 44.7% cure from this combined score correlates well with previous reports of subjective outcome after pubovaginal sling of 46% by Haaband colleagues<sup>77</sup> and of 47% after modified Pereyra procedures by Sirls and associates.<sup>7</sup> The incorporation

of these noninvasive objective data with patient questionnaires to generate a global outcome score seems to be an effective tool in evaluating treatment outcomes for SUI. More sophisticated urodynamic testing and the addition of a validated HRQOL tool would strengthen the outcome data but may discourage patient follow-up.

## CONCLUSIONS

Evaluating treatment outcome for urinary incontinence is complicated by studies that have different surgical technique, patient selection, length of follow-up, study methodology, and investigator definition of cure. Standardizing outcomes measures would be a great stride in achieving comparable data for treatment evaluation. Until the evaluation of urinary incontinence is standardized, it is most reasonable to suggest that investigators present complete data sets, including any urodynamic data (e.g., Valsalva leak point pressure, pressure-flow data), postvoid residual volume, pad test weights, voiding diary data, and HRQOL questionnaire data for review. This would allow more accurate interpretation and evaluation of the effect and complications of different treatments. Choosing a single questionnaire may not be sufficient for most purposes, and combining two or more questionnaires may prove comprehensive and practical for most clinical environments. Longer symptom questionnaires may be necessary to provide the data set for clinical research to help understand urinary incontinence and the impact of treatment on symptoms. The incorporation of noninvasive objective data with patient questionnaires, such as that presented in the response score of Groutz and Blaivas,<sup>76</sup> seems to be the most effective means of evaluating treatment outcomes for SUI.

# CATEGORIZATION OF VOIDING DYSFUNCTION

Alan J. Wein and M. Louis Moy

The lower urinary tract functions as a group of interrelated structures in the adult to bring about efficient and low-pressure bladder filling, low-pressure urine storage with perfect continence, and periodic, complete, voluntary urine expulsion at low pressure. Because in the adult the lower urinary tract is normally under voluntary neural control, it is different from other visceral organs, whose regulation is solely by involuntary mechanisms.

For the purposes of description and teaching, the micturition cycle is best divided into two relatively discrete phases: bladder filling with urine storage and bladder emptying or voiding. The micturition cycle normally displays these two modes of operation in a simple on-off fashion. The cycle involves switching from inhibition of the voiding reflex and activation of storage reflexes to inhibition of the storage reflexes and activation of the voiding reflex—and back again.

This chapter begins with a functional, physiologic, and pharmacologic overview of normal and abnormal lower urinary tract function. A simple way of looking at the pathophysiology of all types of voiding dysfunction is presented, followed by a discussion of various systems of classification and categorization.

### NORMAL LOWER URINARY TRACT FUNCTION

#### Two-Phase Concept of Function: Filling or Storage and Emptying or Voiding

Whatever disagreements exist regarding the anatomic, morphologic, physiologic, pharmacologic, and mechanical details involved in the storage and expulsion of urine by the lower urinary tract, most experts agree on certain points.<sup>1</sup> The first is that the micturition cycle involves two relatively discrete processes: bladder filling with urine storage and bladder emptying. The second is that, whatever the details involved, these processes can be summarized from a conceptual point of view as follows.

Bladder filling and urine storage require the following:

1. Accommodation of increasing volumes of urine at a low intravesical pressure and with appropriate sensation
2. A bladder outlet that is closed at rest and remains so during increases in intra-abdominal pressure
3. Absence of involuntary bladder contractions

Bladder emptying requires the following:

1. Coordinated contraction of the bladder smooth musculature of adequate magnitude and duration
2. Concomitant lowering of resistance at the level of the smooth and striated sphincter
3. Absence of anatomic (as opposed to functional) obstruction

The smooth sphincter refers to the smooth musculature of the bladder neck and proximal urethra. This is a physiologic but not an anatomic sphincter and one that is not under voluntary control. The striated sphincter refers to the striated musculature, which is a part of the outer wall of the proximal urethra in males and females (this portion is often referred to as the *intrinsic* or *intramural striated sphincter*), and the bulky skeletal muscle group that surrounds the urethra at the level of the membranous portion in the male and the middle segment in the female (often referred to as the *extrinsic* or *extramural striated sphincter*). The extramural portion is the classically described *external urethral sphincter* and is under voluntary control.<sup>2</sup>

Any type of voiding dysfunction must result from an abnormality of one or more of the factors just listed. This two-phase concept of micturition, with the three components of each, related to the bladder or to the outlet provides a logical framework for a functional categorization of all types of voiding dysfunction and disorders of filling and storage or to voiding (Boxes 13-1 and 13-2). Some types of voiding dysfunction represent combinations of filling with storage and voiding abnormalities. Within this scheme, however, these become readily understandable, and their detection and treatment can be logically described. Various aspects of physiology and pathophysiology are always related more to one phase of micturition than another. All aspects of urodynamic and video-urodynamic evaluation can be conceptualized in this functional manner according to what they evaluate in terms of bladder or outlet activity during filling with storage or voiding (Table 13-1). All known treatments for voiding dysfunction can be classified in the broad categories of whether they facilitate filling with storage or voiding and whether they do so by an action primarily on the bladder or on one or more of the components of the bladder outlet (see Box 13-2 and Table 13-1).

#### Mechanisms Underlying the Two Phases of Function

This section summarizes pertinent points regarding the physiology of the various mechanisms underlying normal bladder filling with storage and voiding, abnormalities of which constitute the

The information is consistent with that detailed by de Groat and associates,<sup>3,4</sup> Zderic and colleagues,<sup>2</sup> and Steers,<sup>5</sup> and references are provided only when particularly applicable.

**Bladder Response during Filling**

The normal adult bladder response to filling at a physiologic rate is an almost imperceptible change in intravesical pressure. During at least the initial stages of bladder filling, after unfolding of the bladder wall from its collapsed state, this very high compliance ( $\Delta$  volume/ $\Delta$  pressure) of the bladder primarily results from its elastic and viscoelastic properties. *Elasticity* allows the constituents of the bladder wall to stretch to a certain degree without any

increase in tension. *Viscoelasticity* allows stretch to induce a rise in tension, followed by a decay (i.e., stress relaxation) when the filling (i.e., stretch stimulus) slows or stops. Brading and colleagues<sup>6</sup> think there is continuous contractile activity in the smooth muscle cells to adjust their length during filling but without (normally) synchronous activity that would increase intravesical pressure, would impede filling, and could cause urinary leakage. Clinically and urodynamically, the bladder seems relaxed. The urothelium also expands but must preserve its barrier function while doing so. There may be an active component to the storage properties of the bladder. The mucosa and lamina propria are normally the most compliant layers of the bladder. Coplen and associates<sup>7</sup> have hypothesized that the smooth muscle layer may have a chronic effect on compliance in the midportion of the cystometric filling curve through a complex interaction between muscle and extracellular matrix. This layer may acutely affect compliance in response to neurologic input as well.

In the usual clinical setting, filling cystometry seems to show a slight increase in intravesical pressure, but Klevmark<sup>8,9</sup> elegantly showed that this pressure rise is a function of the fact that cystometric filling is carried out at a greater than physiologic rate and, at physiologic filling rates, there is essentially no rise in bladder pressure until bladder capacity is reached.

The viscoelastic properties of the stroma (i.e., bladder wall less smooth muscle and epithelium) and the urodynamically relaxed detrusor muscle account for the passive mechanical properties and normal bladder compliance seen during filling. The main components of the stroma are collagen and elastin. When the collagen component increases, compliance decreases. This can occur with various types of injury, chronic inflammation, bladder outlet obstruction, and neurologic decentralization. After decreased compliance has occurred because of a replacement by collagen of other components of the stroma, it is generally unresponsive to pharmacologic manipulation, hydraulic distention, or nerve section. Most often, under those circumstances, augmentation cystoplasty is required to achieve satisfactory reservoir function.

Does the nervous system affect the normal bladder response to filling? At a certain level of bladder filling, spinal sympathetic reflexes facilitatory to bladder filling and storage are evoked in animals, a concept developed over the years by de Groat and associates,<sup>3</sup> who have also cited indirect evidence to support such a role in humans. This inhibitory effect is likely mediated primarily by sympathetic modulation of cholinergic ganglionic transmission. Through this reflex mechanism, two other possibilities exist for promoting filling and storage. One is neurally mediated stimulation of the predominantly  $\alpha$ -adrenergic receptors in the area of the smooth sphincter, the net result of which would be to cause an increase in resistance in that area. The second is neurally mediated stimulation of the predominantly  $\beta$ -adrenergic receptors (inhibitory) in the bladder body smooth musculature, which would cause a decrease in bladder wall tension. McGuire and colleagues<sup>10</sup> also cited evidence for direct inhibition of detrusor motor neurons in the sacral spinal cord during bladder filling that results from increased afferent pudendal nerve activity generated by receptors in the striated sphincter. Good evidence exists to support a tonic inhibitory effect of other neurotransmitters on the micturition reflex at various levels of the neural axis. Bladder filling and consequent wall distention may also release autocrine-like factors (e.g., nitric oxide, prostaglandins, peptides) that influence contractility.

**Table 13-1 Urodynamics Simplified**

Phase Assessed*	Bladder Assessment	Outlet Assessment
Filling and storage phase	Total $P_{ves}$ and $P_{det}$ during a filling cystometrogram Detrusor leak point pressure	Urethral pressure profilometry Valsalva leak point pressure Fluoroscopy
Emptying phase	Total $P_{ves}$ and $P_{det}$ during a voiding cystometrogram  Flowmetry <sup>†</sup> Residual urine <sup>†</sup>	Micturitional urethral pressure profilometry  Fluoroscopy Electromyography of periurethral striated musculature Flowmetry <sup>†</sup> Residual urine <sup>†</sup>

$P_{det}$ , detrusor pressure;  $P_{ves}$ , bladder pressure.

\*This functional conceptualization of urodynamics categorizes each study according to whether it examines bladder or outlet activity during the filling and storage phase or emptying phase of micturition.

<sup>†</sup>In this scheme, uroflow and residual urine integrate the activity of the bladder and the outlet during the emptying phase.

### Outlet Response during Filling

There is a gradual increase in urethral pressure during bladder filling, contributed to by at least the striated sphincteric element and perhaps by the smooth sphincteric element as well. The rise in urethral pressure seen during the filling and storage phase of micturition can be correlated with an increase in efferent pudendal nerve impulse frequency and in electromyographic activity of the periurethral striated musculature. This constitutes the efferent limb of a spinal somatic reflex, the so-called guarding reflex, which results in a gradual increase in striated sphincter activity.

Although it seems logical and compatible with neuropharmacologic, neurophysiologic, and neuromorphologic data to assume that the muscular component of the smooth sphincter also contributes to the change in urethral response during bladder filling, it is extremely difficult to prove this experimentally or clinically. The direct and circumstantial evidence in favor of such a hypothesis has been summarized by Wein and Barrett,<sup>1</sup> Elbadawi,<sup>11</sup> and Brading.<sup>12</sup> The passive properties of the urethral wall deserve mention because they undoubtedly play a large role in the maintenance of continence.<sup>6,13</sup> Urethral wall tension develops within the outer layers of the urethra; however, urethral pressure is a product of the active characteristics of smooth and striated muscle and of the passive characteristics of the elastic, collagenous, and vascular components of the urethral wall, because this tension must be exerted on a soft or plastic inner layer capable of being compressed to a closed configuration—the “filler material” representing the submucosal portion of the urethra. The softer and more plastic this area is, the less pressure required by the tension-producing area to produce continence. Whatever the compressive forces, the lumen of the urethra must be capable of being obliterated by a watertight seal. This mucosal seal mechanism explains why a thin-walled rubber tube requires less pressure to close an open end when the inner layer is coated with a fine layer of grease than when it is not, and the latter case is much like scarred or atrophic urethral mucosa.

### Voiding with a Normal Bladder Contraction

Although many factors are involved in the initiation of micturition, intravesical pressure producing the sensation of distention is primarily responsible for the initiation of voluntarily induced

emptying of the lower urinary tract in adults. Although the origin of the parasympathetic neural outflow to the bladder, the pelvic nerve, is in the sacral spinal cord, the organizational center for the micturition reflex in an intact neural axis is in the brainstem, and the complete neural circuit for normal micturition includes the ascending and descending spinal cord pathways to and from this area and the facilitatory and inhibitory influences from other parts of the brain.

The final step in voluntarily induced micturition involves inhibition of the somatic neural efferent activity to the striated sphincter and an inhibition of all aspects of any spinal sympathetic reflex evoked during filling. Efferent parasympathetic pelvic nerve activity is ultimately responsible for a highly coordinated contraction of the bulk of the bladder smooth musculature. A decrease in outlet resistance occurs, with adaptive shaping or funneling of the relaxed bladder outlet. Besides the inhibition of any continence-promoting reflexes that have occurred during bladder filling, the change in outlet resistance may also involve active relaxation of the smooth sphincter area through a nonadrenergic, noncholinergic mechanism, probably mediated by nitric oxide. The adaptive changes that occur in the outlet in part result from the anatomic interrelationships of the smooth muscle of the bladder base and proximal urethra (i.e., longitudinal smooth muscle continuity). Other reflexes that are elicited by bladder contraction and by the passage of urine through the urethra may reinforce and facilitate complete bladder emptying. Superimposed on these autonomic and somatic reflexes are complex, modifying supraspinal inputs from other central neuronal networks. These facilitatory and inhibitory impulses, which originate from several areas of the nervous system, allow for the full conscious control of micturition in the adult.

### Urinary Continence during Abdominal Pressure Increases

During voluntarily initiated micturition, the bladder pressure becomes higher than the outlet pressure, and certain adaptive changes occur in the shape of the bladder outlet, with consequent passage of urine into and through the proximal urethra. Why do such changes not occur with increases in intravesical pressure that are similar in magnitude but that are produced only by changes in intra-abdominal pressure, such as straining or coughing? A coordinated bladder contraction does not occur in response

to such stimuli, emphasizing the fact that increases in total intravesical pressure are by no means equivalent to emptying ability. Normally, for urine to flow into the proximal urethra, there be an increase in intravesical pressure; the increase must be a product of a coordinated bladder contraction, occurring through a neurally mediated reflex mechanism; and it must be associated with characteristic conformational and tension changes in the bladder neck and proximal urethral area.

Assuming that the bladder outlet is competent at rest, a major factor in the prevention of urinary leakage during increases in intra-abdominal pressure is the fact that there is at least equal pressure transmission to the proximal urethra during such activity. This phenomenon was first described by Enhorning<sup>14</sup> and has been confirmed in virtually every urodynamic laboratory since then. Failure of this mechanism, generally associated with hypermobility of the bladder neck and proximal urethra (another way of describing pathologic descent with abdominal straining), is an almost invariable correlate of genuine stress urinary incontinence in the female. No such hypermobility occurs in the male. The increase in urethral closure pressure that is seen with increments in intra-abdominal pressure normally exceeds the intra-abdominal pressure increase, indicating that active muscular function due to a reflex increase in striated sphincter activity or other factors that increase urethral resistance, in addition to simple transmission of pressure, is also involved in preventing such leakage. Tanagho<sup>15</sup> was the first to provide direct evidence of this.

#### OVERVIEW OF THE MICTURITION CYCLE

Bladder accommodation during filling is a primarily passive phenomenon that depends on the elastic and viscoelastic properties of the bladder wall and the lack of parasympathetic excitatory input. An increase in outlet resistance occurs by means of the striated sphincter somatic guarding reflex. In some species, a sympathetic reflex also contributes to storage by increasing outlet resistance by increasing tension on the smooth sphincter, inhibiting bladder contractility through an inhibitory effect on parasympathetic ganglia, and causing a decrease in tension of bladder smooth muscle. Continence is maintained during increases in intra-abdominal pressure by the intrinsic competence of the bladder outlet and the pressure transmission ratio to this area with respect to the intravesical contents. A further increase in striated sphincter activity, on a reflex basis, is also contributory.

Voiding can be voluntary or involuntary and involves inhibition of the spinal somatic and sympathetic reflexes and activation of the vesical parasympathetic pathways, the organizational center for which is in the brainstem. Initially, there is a relaxation of the outlet musculature, mediated by the cessation of the somatic and sympathetic spinal reflexes and probably by a relaxing factor, possibly nitric oxide, released by parasympathetic stimulation or by some effect of bladder smooth muscle contraction itself. A highly coordinated, parasympathetically induced contraction of the bulk of the bladder smooth musculature occurs, with shaping or funneling of the relaxed outlet, caused in part by a smooth muscle continuity between the bladder base and the proximal urethra. With amplification and facilitation of the bladder contraction from other peripheral reflexes and from spinal cord supraspinal sources and the absence of anatomic obstruction between the bladder and the urethral meatus, complete emptying occurs.

#### OVERVIEW OF PATHOPHYSIOLOGY: ABNORMALITIES OF FILLING OR STORAGE AND EMPTYING OR VOIDING

The failure of the lower urinary tract to fill with or store urine adequately is caused by pathologic conditions of the bladder or the outlet, or both.<sup>1,16</sup> Overactivity of the bladder during filling can be expressed as phasic involuntary contractions, as low compliance, or as a combination. Involuntary contractions are most commonly associated with suprasacral neurologic disease or occur after suprasacral neurologic injury; however, they also may be associated with aging, inflammation, or irritation of the bladder wall, bladder outlet obstruction, or stress urinary incontinence, or they may be idiopathic. Decreased compliance during filling may result from neurologic injury or disease, usually at a sacral or infrasacral level, but it may also result from any process that destroys the viscoelastic or elastic properties of the bladder wall. Storage failure may also occur in the absence of hyperactivity resulting from hypersensitivity or pain during filling. Inflammation and irritation can be responsible, as can neurologic, psychological, or idiopathic causes. The classic clinical example is interstitial cystitis.

Decreased outlet resistance may result from any process that damages the innervation, structural elements, or support of the smooth or striated sphincter. This may occur with neurologic disease or injury, surgical or other mechanical trauma, or aging. Classically, sphincteric incontinence in the female patient has been categorized as genuine stress incontinence and as what was originally described as type III stress incontinence, which is now referred to as intrinsic sphincter dysfunction. Genuine stress incontinence in the female is associated with hypermobility of the vesicourethral junction, with poor pelvic support, and with an outlet that is competent at rest but loses its competence only during increases in intra-abdominal pressure. Intrinsic sphincter dysfunction describes a nonfunctional or very poorly functional bladder neck and proximal urethra at rest. The division between these two situations is not absolute, and virtually every case of sphincteric incontinence involves various proportions of genuine stress incontinence and intrinsic sphincter dysfunction. The implication of classic intrinsic sphincter dysfunction is that a surgical procedure designed to correct only urethral hypermobility will have a relatively high failure rate compared with one designed to improve urethral coaptation and compression; however, this approach has become less dogmatic with newer surgical therapies for urinary incontinence.

Stress urinary incontinence is a symptom that arises from damage to muscles, nerves, and connective tissue within the pelvic floor.<sup>17</sup> Urethral support is important; the urethra normally is supported by the action of the levator ani muscles through their connection to the endopelvic fascia of the anterior vaginal wall. Damage to the connection between this fascia and this muscle, damage to the nerve supply, or direct muscle damage can influence continence. Bladder neck function is likewise important, and loss of normal bladder neck closure can result in incontinence despite normal urethral support. In older reports, the urethra was sometimes ignored as a factor contributing to continence in women, and the site of continence was thought to be exclusively the bladder neck. However, in approximately 50% of continent women, urine enters the urethra during increases in abdominal pressure. The continence point in these women is at the middle of the urethra, where urine is stopped before it can escape from the urethral meatus.

With urethral hypermobility, there is weakness of the pelvic floor. During increases in intra-abdominal pressure, there is descent of the bladder neck and proximal urethra. If the outlet opens concomitantly, stress urinary incontinence ensues. In the classic form of urethral hypermobility, there is rotational descent of the bladder neck and urethra. However, the urethra may also descend without rotation (i.e., it shortens and widens), or the posterior wall of the urethra may be pulled open while the anterior wall remains fixed. However, urethral hypermobility is often present in women who are not incontinent, and the mere presence of urethral hypermobility is not sufficient to make a diagnosis of a sphincter abnormality unless urinary incontinence is also demonstrated. The *hammock hypothesis* of John DeLancey<sup>18</sup> proposes that for stress incontinence to occur with hypermobility, there must be a lack of stability of the suburethral supportive layer. This theory proposes that the effect of abdominal pressure increases on the normal bladder outlet, if the suburethral supportive layer is firm, is to compress the urethra rapidly and effectively. If the supportive suburethral layer is lax or movable, compression is not as effective. Intrinsic sphincter dysfunction denotes an intrinsic malfunction of the urethral a misnomer, because many believe that the drop in urethral pressure represents simply the urethral component of a normal voiding reflex in an individual whose bladder does not measurably contract because of myogenic or neurogenic reasons.

In theory, categories of outlet-related incontinence in the male are similar to those in the female. In reality, there is little information regarding the topic of urethral instability in the male. Sphincteric incontinence in the male is not associated with hypermobility of the bladder neck and proximal urethra but is rather more similar to what is called intrinsic sphincter dysfunction in the female.

The treatment of filling and storage abnormalities is directed toward inhibiting bladder contractility, decreasing sensory input, or mechanically increasing bladder capacity and toward increasing outlet resistance, continuously or only during increases in intra-abdominal pressure.

Absolute or relative failure to empty the bladder results from decreased bladder contractility (i.e., decrease in magnitude or duration) or increased outlet resistance, or both. Absolute or relative failure of bladder contractility may result from temporary or permanent alteration in one of the neuromuscular mechanisms necessary for initiating and maintaining a normal detrusor contraction. Inhibition of the voiding reflex in a neurologically normal individual may also occur; it may be inhibited by a reflex mechanism resulting from painful stimuli, especially from the pelvic and perineal areas, or it may be psychogenic. Non-neurogenic causes include impairment of bladder smooth muscle function, which may result from overdistention, various drugs, severe infection, or fibrosis.

Pathologically, decrease outlet resistance is the result of change to the sphincter mechanism itself. In its most overt form, it is characterized by a bladder neck that is open at rest and at a low Valsalva leak point pressure and urethral closure pressure, and it is usually the result of prior surgery, trauma with scarring, or a neurologic lesion.

*Urethral instability* refers to the rare phenomenon of episodic decreases in outlet pressure unrelated to increases in bladder or abdominal pressure. The term *urethral instability* is probably more common in men than in women. Although it is most often caused by anatomic obstruction, it may result from a failure of relaxation or active contraction of the striated or smooth sphincter during

bladder contraction. Striated sphincter dyssynergia is a common cause of functional or nonanatomic (as opposed to fixed anatomic) obstruction in patients with neurologic disease or injury.

The treatment of emptying failure consists of attempts to increase intravesical pressure or facilitate the micturition reflex or to decrease outlet resistance, or both. If other means fail or are impractical, intermittent catheterization is an effective way to circumvent emptying failure.

## CATEGORIZATION OF VOIDING DYSFUNCTIONS

Based on the data obtained from the neurourologic evaluation, a given voiding dysfunction can be categorized by an ever-increasing number of descriptive systems. The purpose of any classification system should be to facilitate understanding and management and to avoid confusion among those who are concerned with the problem for which the system was designed. A good classification should serve as intellectual shorthand and should convey in a few key words or phrases the essence of a clinical situation. An ideal system for all types of voiding dysfunction would include or imply several factors: the conclusions reached from urodynamic testing, expected clinical symptoms, and approximate site and type of a neurologic lesion or a lack of one. If the various categories accurately portray pathophysiology, the treatment options should be evident. Most systems of classification for voiding dysfunction were formulated primarily to describe dysfunction caused by neurologic disease or injury. The ideal system should be applicable to all types of voiding dysfunction. No one system is perfect. Most major systems or types of systems in use are reviewed, along with their advantages, disadvantages, and applicability. Understanding the rationale and shortcomings of each system significantly improves the urologist's knowledge of voiding function and dysfunction.

### Bors-Comarr Classification

Bors and Comarr<sup>19</sup> made a remarkable contribution by logically deducing a classification system from clinical observation of their patients with traumatic spinal cord injury (Box 13-3). This system applies only to patients with neurologic dysfunction and considers three factors: anatomic localization of the lesion, neurologic completeness or incompleteness of the lesion, and whether lower urinary tract function is *balanced* or *unbalanced*. The latter terms are based solely on the percentage of residual urine relative to bladder capacity. *Unbalanced* signifies the presence of more than 20% residual urine in a patient with an upper motor neuron (UMN) lesion or 10% in a patient with a lower motor neuron (LMN) lesion. This relative residual urine volume was ideally meant to imply coordination (i.e., synergy) or dyssynergia between the smooth and the striated sphincters of the outlet and the bladder during bladder contraction or during attempted micturition by abdominal straining or the Credé maneuver. Determination of the completeness of the lesion is made on the basis of a thorough neurologic examination.

The system erroneously assumes that the sacral spinal cord is the primary reflex center for micturition. *LMN* implies collectively the preganglionic and postganglionic parasympathetic autonomic fibers that innervate the bladder and outlet and originate as preganglionic fibers in the sacral spinal cord. The term is used in an analogy to efferent somatic nerve fibers, such as those of the pudendal nerve, which originate in the same sacral cord

segment but terminate directly on pelvic floor striated musculature without the interposition of ganglia. *UMN* is used in a similar analogy to the somatic nervous system to describe the descending autonomic pathways above the sacral spinal cord, the origin of the motor efferent supply to the bladder.

In this system, *UMN bladder* refers to the pattern of micturition that results from an injury to the suprasacral spinal cord after the period of spinal shock has passed, assuming that the sacral spinal cord and the sacral nerve roots are intact and that the pelvic and pudendal nerve reflexes are intact. *LMN bladder* refers to the pattern resulting if the sacral spinal cord or sacral roots are damaged and the reflex pattern through the autonomic and somatic nerves that emanate from these segments is absent. This system implies that if skeletal muscle spasticity exists below the level of the lesion, the lesion is above the sacral spinal cord and is by definition a *UMN* lesion. This type of lesion is characterized by involuntary bladder contraction during filling. If flaccidity of the skeletal musculature below the level of a lesion exists, an *LMN* lesion is assumed to be present, implying detrusor areflexia. Exceptions occur and are classified in a *mixed lesion* group characterized by involuntary bladder contraction with a flaccid paralysis below the level of the lesion or by detrusor areflexia with spasticity or normal skeletal muscle tone neurologically below the lesion level.

The use of this system is illustrated as follows. A *UMN lesion, complete, imbalanced*, implies a neurologically complete lesion above the level of the sacral spinal cord that results in skeletal muscle spasticity below the level of the injury. Involuntary bladder contraction occurs during filling, but a residual urine volume of more than 20% of the bladder capacity is left after bladder contraction, implying obstruction in the area of the bladder outlet during the involuntary detrusor contraction. This

Peripheral autonomic neuropathy  
Muscular lesion

From Hald T, Bradley WE: The Urinary Bladder: Neurology and Dynamics. Baltimore, Williams & Wilkins, 1982.

obstruction usually is caused by striated sphincter dyssynergia, typically occurring in patients who are paraplegic and quadriplegic with lesions between the cervical and the sacral spinal cord. Smooth sphincter dyssynergia also may be seen in patients with lesions above the level of T6, usually in association with autonomic hyperreflexia. An *LMN lesion, complete, imbalanced*, implies a neurologically complete lesion at the level of the sacral spinal cord or of the sacral roots, resulting in skeletal muscle flaccidity below that level. Detrusor areflexia results, and whatever measures the patient may use to increase intravesical pressure during attempted voiding are not sufficient to decrease residual urine to less than 10% of bladder capacity.

This classification system is best applied to spinal cord injury patients with complete neurologic lesions after spinal shock has passed. It is difficult to apply to patients with multicentric neurologic disease and cannot be used for patients with non-neurologic disease. The system fails to reconcile the clinical and urodynamic variability exhibited by patients who, by neurologic examination alone, seem to have similar lesions. The period of spinal shock that immediately follows severe cord injury usually is associated with bladder areflexia, whatever the status of the sacral somatic reflexes. Temporary or permanent changes in bladder or outlet activity during filling and storage or voiding may be caused by several factors, such as chronic overdistention, infection, and reinnervation or reorganization of neural pathways after injury or disease; such changes make it impossible to always accurately predict lower urinary tract activity solely on the basis of the level of the neurologic lesion. Although the terms *balanced* and *imbalanced* are helpful because they describe the presence or absence of a certain relative percentage of residual urine, they do not necessarily imply the true functional significance of a lesion, which depends on the potential for damage to the lower or upper urinary tracts and on the social and vocational disability that results.

**Hald-Bradley Classification**

Hald and Bradley<sup>20</sup> described what they called a simple neurotopographic classification (Box 13-4). A supraspinal lesion is characterized by synergy between detrusor contraction and the smooth and striated sphincters, but defective inhibition of the voiding reflex exists. Involuntary bladder contraction typically occurs, and sensation is usually preserved. However, depending on the site of the lesion, detrusor areflexia and defective sensation may occur. A suprasacral spinal lesion is roughly equivalent to what is described as a *UMN* lesion in the Bors-Comarr classification. An infrasacral lesion is roughly equivalent to an *LMN* lesion. Peripheral autonomic neuropathy is most frequently encountered in the diabetic patient and is characterized by deficient bladder sensation, gradually increasing residual urine volumes,

and ultimate decompensation, with loss of detrusor contractility. A muscular lesion can involve the detrusor itself, the smooth sphincter, or any portion or all of the striated sphincter. The resultant dysfunction depends on which structure is affected. Detrusor dysfunction is the most common, and it usually results from decompensation after long-standing bladder outlet obstruction.

### Bradley Classification

Bradley's "loop system" of classification is a primarily neurologic system based on his conceptualization of central nervous system control of the lower urinary tract that identifies four neurologic loops.<sup>20</sup> Dysfunctions are classified according to the loop affected.

*Loop 1* consists of neuronal connections between the cerebral cortex and the pontine-mesencephalic micturition center, which coordinate voluntary control of the detrusor reflex. Loop 1 lesions are seen in conditions such as brain tumor, cerebrovascular accident or disease, and cerebral atrophy with dementia. The final result is characteristically involuntary bladder contraction.

*Loop 2* includes the intraspinal pathway of detrusor muscle afferents to the brainstem micturition center and the motor impulses from this center to the sacral spinal cord. Loop 2 is thought to coordinate and provide a detrusor reflex of adequate temporal duration to allow complete voiding. Partial interruption by spinal cord injury results in a detrusor reflex of low threshold and in poor emptying with residual urine. Spinal cord transection of loop 2 acutely produces detrusor areflexia and urinary retention (i.e., spinal shock). After this has passed, involuntary bladder contraction results.

*Loop 3* consists of the peripheral detrusor afferent axons and their pathways in the spinal cord; these terminate by synapsing on pudendal motor neurons that ultimately innervate periurethral striated muscle. Loop 3 was thought to provide a neurologic substrate for coordinated reciprocal action of the bladder and striated sphincter. Loop 3 dysfunction could be responsible for detrusor-striated sphincter dyssynergia or involuntary sphincter relaxation.

*Loop 4* consists of two components. Loop 4A is the suprasacral afferent and efferent innervation of the pudendal motor neurons to the periurethral striated musculature. Loop 4B consists of afferent fibers from the periurethral striated musculature that synapse on pudendal motor neurons in Onuf's nucleus—the segmental innervation of the periurethral striated muscle. In contrast to the stimulation of detrusor afferent fibers, which produce inhibitory postsynaptic potentials in pudendal motor neurons through loop 3, pudendal nerve afferents produce excitatory postsynaptic potentials in the motor neurons through loop 4B. They enable contraction of the periurethral striated muscle during bladder filling and urine storage. The related sensory impulses arise from muscle spindles and tendon organs in the pelvic floor musculature. Loop 4 provides volitional control of the striated sphincter. Abnormalities of the suprasacral portion result in abnormal responses of the pudendal motor neurons to bladder filling and emptying, manifested as detrusor-striated sphincter dyssynergia or loss of the ability to voluntarily contract the striated sphincter.

The Bradley system is sophisticated and reflects the ingenuity and neurophysiologic expertise of its originator, himself a neurologist. For neurologists, this method may be an excellent way

### Box 13-5 Lapidus Classification

to conceptualize the neurophysiology involved, assuming that there is agreement on the existence and significance of all four loops. Most urologists find this system difficult to use for many types of neurogenic voiding dysfunction and not at all applicable to non-neurogenic voiding dysfunction. Urodynamically, it may be extremely difficult to test the intactness of each loop system, and multicentric and partial lesions are difficult to describe.

### Lapidus Classification

Lapidus<sup>21</sup> contributed significantly to the classification and care of the patient with neuropathic voiding dysfunction by slightly modifying and popularizing a system originally proposed by McLellan in 1939 (Box 13-5).<sup>22</sup>

Lapidus' classification differs from that of McLellan in only one respect: the division of the group of "atonic neurogenic bladder" into sensory neurogenic and motor neurogenic bladder. This remains one of the most familiar systems to urologists and nonurologists because it describes in recognizable shorthand the clinical and cystometric conditions of many types of neurogenic voiding dysfunction.

A sensory neurogenic bladder results from disease that selectively interrupts the sensory fibers between the bladder and the spinal cord or the afferent tracts to the brain. Diabetes mellitus, tabes dorsalis, and pernicious anemia are most commonly responsible. The first clinical changes are described as those of impaired sensation of bladder distention. Unless voiding is initiated on a timed basis, various degrees of bladder overdistention can result, producing hypotonicity. If bladder decompensation occurs, significant amounts of residual urine are found, and at this point, the cystometric curve usually demonstrates a large-capacity bladder with a flat, high-compliance, low-pressure filling curve.

A motor paralytic bladder results from disease processes that destroy the parasympathetic motor innervation of the bladder. Extensive pelvic surgery or trauma may produce this. Herpes zoster has been listed as a cause, but evidence suggests that the voiding dysfunction seen with herpes infection is more related to a problem with afferent pathways. The early symptoms of a motor paralytic bladder vary from painful urinary retention to only a relative inability to initiate and maintain normal micturition. Early cystometric filling is normal but without a voluntary bladder contraction at capacity. Chronic overdistention and decompensation may occur, resulting in a large-capacity bladder with a flat, low-pressure filling curve; a large residual urine volume may result.

An uninhibited neurogenic bladder was described originally as resulting from injury to or disease of the "corticoregulatory tract." The sacral spinal cord was presumed to be the micturition reflex center, and this corticoregulatory tract was believed to

normally exert an inhibitory influence on the sacral micturition reflex center. A destructive lesion in this tract would then result in overfacilitation of the micturition reflex. Cerebrovascular accident, brain or spinal cord tumor, Parkinson's disease, and demyelinating disease were listed as the most common causes in this category. The voiding dysfunction is most often characterized symptomatically by frequency, urgency, and urge incontinence, and it is urodynamically characterized by normal sensation with involuntary contraction at low filling volumes. The residual urine volume typically is low unless anatomic outlet obstruction or true smooth or striated sphincter dyssynergia occurs. The patient usually can initiate a bladder contraction voluntarily but is often unable to do so during cystometry because sufficient urine storage cannot occur before involuntary contraction is stimulated.

Reflex neurogenic bladder describes the post-spinal shock condition that exists after complete interruption of the sensory and motor pathways between the sacral spinal cord and the brain stem. Most commonly, this occurs in traumatic spinal cord injury and transverse myelitis, but it may occur with extensive demyelinating disease or any process that produces significant spinal cord destruction. Typically, there is no bladder sensation, and there is an inability to initiate voluntary micturition. Incontinence without sensation generally results because of low-volume involuntary contraction. Striated sphincter dyssynergia is the rule. This type of lesion is essentially equivalent to a complete UMN lesion in the Bors-Comarr system.

An autonomous neurogenic bladder results from complete motor and sensory separation of the bladder from the sacral spinal cord. This may be caused by any disease that destroys the sacral cord or causes extensive damage to the sacral roots or pelvic nerves. There is an inability to voluntarily initiate micturition, no bladder reflex activity, and no specific bladder sensation. This type of bladder is equivalent to a complete LMN lesion in the Bors-Comarr system and is the type of dysfunction seen in patients with spinal shock. The characteristic cystometric pattern is initially similar to the late stages of the motor or sensory paralytic bladder, with a marked shift to the right of the cystometric filling curve and a large bladder capacity at low intravesical pressure. However, decreased compliance may develop from chronic inflammatory changes or the effects of denervation and centralization with secondary neuromorphologic and neuropharmacologic reorganizational changes. Emptying capacity may vary widely, depending on the ability of the patient to increase intravesical pressure and on the resistance offered during this increase by the smooth and striated sphincters.

These classic categories in their usual settings are generally easily understood and remembered, which is why this system provides an excellent framework for teaching some fundamentals of neurogenic voiding dysfunction to students and nonurologists. Unfortunately, many patients do not exactly fit into a Lapedes category. Gradations of sensory, motor, and mixed lesions occur, and the patterns produced after different types of peripheral denervation or defunctionalization may vary widely from those that are classically described. The system is applicable only to neuropathic dysfunction.

### Urodynamic Classification

As urodynamic techniques have become more accepted and sophisticated, systems of classification have evolved based solely on objective urodynamic data (Box 13-6). Among the first to

popularize this concept were Krane and Siroky.<sup>23</sup> When exact urodynamic classification is possible, this system provides a precise description of the voiding dysfunction that occurs. If a normal or hyperreflexic detrusor exists with coordinated smooth and striated sphincter function and without anatomic obstruction, normal bladder emptying should occur.

Detrusor hyperreflexia is most commonly associated with neurologic lesions above the sacral spinal cord. Striated sphincter dyssynergia is most commonly seen after complete suprasacral spinal cord injury following the period of spinal shock. Smooth sphincter dyssynergia is seen most classically in autonomic dysreflexia, when it is characteristically associated with detrusor hyperreflexia and striated sphincter dyssynergia.

Detrusor areflexia may result from bladder muscle decompensation or other conditions that produce inhibition at the level of the brainstem micturition center, the sacral spinal cord, bladder ganglia, or bladder smooth muscle. Patients with a voiding dysfunction caused by detrusor areflexia usually attempt bladder emptying by abdominal straining, and their continence status and the efficiency of their emptying efforts are determined by the status of their smooth and striated sphincter mechanisms.

This classification system is easiest to use when detrusor hyperreflexia or normoreflexia exists. A typical T10-level paraplegic patient after spinal shock exhibits detrusor hyperreflexia, smooth sphincter synergy, and striated sphincter dyssynergia. When a voluntary or a hyperreflexic contraction cannot be elicited, the system is more difficult to use, because it is not appropriate to speak of true sphincter dyssynergia in the absence of an opposing bladder contraction. There are many variations and extensions of such a system. These systems work well when total urodynamic agreement exists among classifiers. Unfortunately, many voiding dysfunctions do not fit neatly into a urodynamic classification system that is agreed on by all experts. As sophisticated urodynamic technology and understanding improve, this type of classification system may supplant some others in general use.

### International Continence Society Classification

The classification system proposed by the International Continence Society (ICS) is in essence an extension of a urodynamic classification system. The storage and voiding phases of micturition are described separately, and within each, various designations are applied to describe bladder and urethral function.<sup>24</sup>

Normal detrusor function during filling and storage implies no significant increases in detrusor pressure with filling. *Detrusor overactivity* is the urodynamic observation of involuntary detrusor contractions during the filling phase that may be spontaneous or provoked. If caused by a neurologic disease, the term *neurogenic detrusor overactivity* (which replaces detrusor hyperreflexia) is used; if there is no defined cause, the term *idiopathic detrusor overactivity* (which replaces detrusor instability) is applied. Bladder sensation can be categorized only in qualitative terms as indicated. Bladder capacity and compliance ( $\Delta$  volume/ $\Delta$  pressure) are cystometric measurements. Normal urethral function during filling and storage indicates a positive urethral closure pressure (i.e., urethral pressure minus bladder pressure) even with increases in intra-abdominal pressure. Incompetent urethral function during filling or storage implies urine leakage in the absence of a detrusor contraction. This may be caused by genuine stress incontinence, intrinsic sphincter dysfunction, or an involuntary decrease in urethral pressure in the absence of a detrusor contraction.

During the voiding phase of micturition, normal detrusor activity implies voiding by a voluntarily initiated sustained contraction that also can be suppressed voluntarily. Detrusor underactivity defines a contraction of inadequate magnitude or duration to empty the bladder within a normal time span. An acontractile detrusor is one that cannot be demonstrated to contract during urodynamic testing. Normal urethral function during voiding indicates a urethra that opens and is continually relaxed to allow bladder emptying at normal pressures. An obstructed urethra is one that contracts against a detrusor contraction or fails to open (nonrelaxation) with attempted micturition. Contraction may result from smooth or striated sphincter dyssynergia. *Detrusor-sphincter dyssynergia*, the occurrence of an involuntary contraction of the urethral or periurethral striated muscle with a detrusor contraction, is a term that should be applied only when neurologic disease is present. A similar syndrome but without neurologic disease is called *dysfunctional voiding*. *Nonrelaxing urethral sphincter* occurs in individuals with a neurologic lesion who have reduced urine flow because of a nonrelaxing, obstructing urethra. *Bladder outlet obstruction* is defined as an increased detrusor pressure and low urine flow rate due to obstruction during voiding. This is a generic term that has been poorly defined in women and children.

Voiding dysfunction in a classic T10-level paraplegic patient after spinal shock has passed is classified as follows:

1. Storage phase: neurogenic detrusor overactivity, absent sensation, low capacity, normal compliance, and normal urethral closure function
2. Voiding phase: overactive obstructive urethral function and normal (?) detrusor activity (i.e., hyperreflexic)

The voiding dysfunction of a stroke patient with urgency incontinence would most likely be classified during storage as neurogenic detrusor overactivity, normal sensation, low capacity, normal compliance, and normal urethral closure function. During voiding, the dysfunction would be classified as normal detrusor activity and normal urethral function, assuming that no anatomic obstruction existed.

### Functional System of Classification

Classification of voiding dysfunction can be formulated on a simple functional basis, describing the dysfunction in terms of

whether the deficit produced is primarily one of the filling and storage phase or the voiding phase of micturition (see Box 13-1).<sup>1,16</sup> The system was proposed initially by Quesada and associates.<sup>25</sup> This type of system is an excellent alternative when a particular dysfunction does not readily lend itself to a generally agreed on classification elsewhere. This simple scheme assumes only that, whatever their differences, all experts would agree on the two-phase concept of micturition (i.e., filling with storage and voiding) and on simple overall mechanisms underlying the normality of each phase (discussed earlier).

Storage failure results because of bladder or outlet abnormalities or a combination. The bladder abnormalities include involuntary bladder contractions, low compliance, and hypersensitivity. The outlet abnormalities can include an intermittent or continuous decrease in outlet resistance.

Emptying failure can occur because of bladder or outlet abnormalities or a combination. The bladder abnormalities include inadequate or unsustainable bladder contractility, and the outlet problems include anatomic obstruction and sphincter dyssynergia.

Failure in either category usually is not absolute, but more often relative. This functional system can easily be expanded to include etiologic or specific urodynamic connotations (see Box 13-2). However, the simplified system is workable and avoids argument about complex situations in which the exact cause or urodynamic mechanism for a voiding dysfunction cannot be agreed on.

Proper use of the functional system for a given voiding dysfunction requires a reasonably accurate notion of what the urodynamic data show. However, an exact diagnosis is not required for treatment. Some patients do not have only a discrete storage or emptying failure, and the existence of combination deficits must be recognized to properly use this system of classification. For instance, the classic T10-level paraplegic patient after spinal shock typically exhibits a relative failure to store urine because of involuntary bladder contractions and a relative failure to empty the bladder because of striated sphincter dyssynergia. With such a combination deficit, to use this classification system as a guide to treatment, the physician must assume that one of the deficits is primary and that significant improvement will result from its treatment alone or that the voiding dysfunction can be converted primarily to a disorder of storage or emptying by means of non-surgical or surgical therapy. The resultant deficit can then be treated or circumvented.

Using the same example, the combined deficit in a T10-level paraplegic patient can be converted primarily to a storage failure by procedures directed at the dyssynergic striated sphincter; the resultant incontinence (caused by involuntary contraction) can be circumvented (in a male) with an external collecting device. Alternatively, the deficit can be converted primarily to an emptying failure by pharmacologic or surgical measures designed to abolish or reduce the involuntary contraction, and the resultant emptying failure can then be circumvented with clean intermittent catheterization. Other examples of combination deficits include impaired bladder contractility with sphincter dysfunction, bladder outlet obstruction with detrusor overactivity, bladder outlet obstruction with sphincter malfunction, and detrusor overactivity with impaired contractility.

One of the advantages of this functional classification is that it allows the clinician the liberty of using the system to suit his or her preferences without an alteration in the basic concept of keeping it simple but accurate and informative. For instance, the

physician can substitute the terms *overactive bladder* and *outlet insufficiency* for *because of the bladder* and *because of the outlet* under “Failure to Store” in Box 13-1. A urologist can further categorize the bladder reasons for overactivity (see Box 13-2) in terms of neurogenic, myogenic, or anatomic causes and further subcategorize *neurogenic* in terms of decreased inhibitory control, increased afferent activity, increased sensitivity to efferent activity, and so on. The system is flexible.

### THE OVERACTIVE BLADDER: DEFINITIONS

There is some confusion about and misuse of the terms *overactive detrusor* and *overactive bladder*. The term *overactive detrusor function*, commonly shortened to *overactive detrusor*, is a term that was originated and defined by the ICS to describe a urodynamic finding of involuntary detrusor contractions during filling. The term *overactive bladder* is frequently substituted for *overactive detrusor*, even though this is not a part of the ICS lexicon. *Overactive bladder* can be defined in terms of urodynamic findings or symptoms. The urodynamic definition of *overactive bladder* approximates that of the ICS term *overactive detrusor* or *overactive detrusor function*.

Using a strict urodynamic definition has limitations.<sup>26,27</sup> On a worldwide basis, it is impossible, impractical, and unnecessary for all patients with symptoms compatible with overactive detrusor function (e.g., urgency, frequency, incontinence due to involuntary bladder contraction) to be initially evaluated and treated by the type of specialist capable of performing and interpreting

urodynamic studies. However, with the current urodynamic-based definition, these specialists are the only ones capable of making this exact diagnosis. Critics of a solely urodynamic-based definition also point out that the demonstration of involuntary contraction during urodynamic studies varies with the type of study done. Most individuals who have symptoms of overactive detrusor function but who fail to demonstrate intraventricular contraction on conventional urodynamic studies will do so on repeated or more complex urodynamic studies.<sup>28</sup> A substantial portion of individuals who, by symptoms and bother index, do not have characteristics of overactive detrusor function do exhibit involuntary bladder contractions on urodynamic studies (38% to 69% of normal asymptomatic patients).<sup>29,30</sup> Many believe that overactive bladder also should be defined by symptoms.<sup>31,32</sup>

We have suggested that the overactive bladder is a medical condition referring to the symptoms of frequency and urgency, with or without urge or reflex incontinence, when appearing in the absence of local pathologic or metabolic factors that would account for these symptoms. Incontinence is not a necessary condition for diagnosis, because roughly two thirds of the people with overactive bladder do not have incontinence. Nevertheless, there is a profound impairment in their quality of life because of urge and frequency symptoms. These local or metabolic factors may include urinary tract infection, malignant or premalignant conditions of the bladder, calculi, interstitial cystitis, diabetes, polydipsia, diuretics, and pregnancy. The urodynamic definition of overactive bladder would then describe the demonstration of involuntary bladder contraction causing symptoms or signs of frequency and urgency.

# VOIDING DYSFUNCTION AND NEUROLOGIC DISORDERS

Gary E. Lemack

Perhaps more than any other situation facing physicians who care for patients with bladder dysfunction, care of the neurologic patient requires a thorough initial investigation, frequently with upper and lower urinary tract evaluations in addition to periodic assessments to minimize the urologic morbidity often associated with these conditions. Development and refinement of urodynamic techniques to assess bladder function in patients with neurogenic voiding dysfunction have enhanced our understanding of their condition and improved our ability to identify when these patients require more intense monitoring and intervention. As new treatment strategies for these conditions have surfaced and as patients at risk for morbidity associated with neurogenic voiding dysfunction are recognized more promptly, the likelihood of finding advanced urologic dysfunction at the time of initial presentation is gradually decreasing. This chapter focuses on evaluation of patients with neurogenic voiding dysfunction and discusses specific aspects of some of the more common subgroups.

### EVALUATION OF THE NEUROLOGIC PATIENT

#### Neurologic History

Establishing the onset of bladder and systemic symptoms in patients with progressive neurologic conditions (which often predate the diagnosis) and documenting recent changes in symptom severity are essential, because this information usually influences treatment recommendations. Disease duration has been correlated with the development of urinary symptoms, particularly in patients with multiple sclerosis or Parkinson's disease.<sup>1</sup> Even those with presumably fixed neurologic conditions (e.g., spinal cord injury, myelomeningocele) may have insidious but progressive symptomatic deterioration (e.g., from development of a syrinx or tethered cord), and therefore any recent changes in sensory or motor function should be directly assessed.

Patients with movement disorders should be carefully questioned about the onset of their neurologic symptoms compared with their urinary symptoms, because those with more progressive syndromes, such as multiple systems atrophy, often develop autonomic disturbances such as bladder and erectile dysfunction early during the course of their illness. Every attempt should be made to identify these patients because their overall response to surgical urologic interventions is poor.<sup>2</sup> The Hoehn and Yahr stage should be documented in patients with Parkinson's disease. This staging information can be useful in predicting the severity of bladder dysfunction and prospects for further deterioration.<sup>3</sup>

Patients with multiple sclerosis should be queried about the timing of the onset of symptoms and about recent exacerbations,

because such exacerbations frequently are initiated by urologic events.<sup>4</sup> Patients should be specifically questioned about the development of lower extremity motor dysfunction, because there is a strong correlation between pyramidal symptoms, such as weakness and spasticity, and bladder dysfunction in patients with multiple sclerosis.<sup>5</sup> Symptoms of urge incontinence, urgency, and nocturia are strongly correlated with severe pyramidal dysfunction as measured by Kurtzke scores.<sup>6</sup> Inquiring about the classification of their condition (e.g., relapsing remitting, primary progressive, secondary progressive) and the timing and findings of their most recent magnetic resonance imaging (MRI) studies may be important in planning therapy, particularly when considering surgical options, which may require considerable dexterity.

In patients with recent acute events, such as cerebrovascular accidents (CVAs), information about the stroke location and the recovery since the event is useful because stroke location impacts the prognosis.<sup>7</sup> Specific questions regarding the presence of voiding disturbance and urinary leakage episodes before the stroke are required, because the persistence of new-onset urinary incontinence after stroke can indicate a poor overall prognosis and is a strong indicator of eventual functional dependence in patients after stroke.<sup>8</sup>

Patients with history of back surgery and intervertebral disk protrusion should be questioned about the vertebral level of the surgery or affected disk and about the presence of ongoing sensory deficit because patients with multiple operations or advanced disk prolapse may be at higher risk for voiding disturbances.<sup>9</sup> Patients should also be evaluated for a diagnosis of cervical myelopathy, because these patients frequently have symptomatic bladder dysfunction that may be independent of the severity of other symptoms associated with this condition, such as spasticity.<sup>10</sup>

Current treatments should be documented, with particular attention to medications. Medications with properties that can affect the bladder outlet (typically those with  $\alpha$ -agonist or  $\alpha$ -antagonist properties) or detrusor contractility (typically those with anticholinergic properties) should be recorded, along with the use of narcotics and skeletal muscle relaxants. Diuretic use should also be documented. Altering the timing of diuretic intake may affect the severity of nocturia. Patients on diuretics and those with a history of congestive heart failure probably are not suitable candidates for treatment with vasopressin for nocturia and nocturnal enuresis.

#### Physical Examination

##### General Observations

Although most patients with neurologic impairment are followed elsewhere for the primary condition, certain aspects of the physi-

cal examination are essential to document when evaluating them urologically, particularly if surgical intervention is being considered. Patients should be assessed for ambulatory disturbances at the initial visit. The degree of physical dependence of the patient, particularly as it relates to the ability to void independently, may affect the frequency of leakage episodes. Self-catheterization of the urethra may be impossible in patients who are not ambulatory, particularly those with severe lower extremity spasticity or contractures.

Hand function in patients with cervical spinal cord injury, particularly the ability to grasp firmly between the thumb and index or middle finger, must be carefully judged in patients who may require intermittent catheterization after treatment. With the advent of single-system catheterization techniques, it is not mandatory that patients have bilateral hand function, although a careful assessment of the patient's ability to work with such products is essential, particularly before considering surgery that will require clean intermittent catheterization postoperatively.

An evaluation of the skin, particularly in the gluteal region, should be carried out, because localized skin and subcutaneous infections and even more severe skin breakdown can occur in patients with restricted mobility. These issues need to be addressed before major reconstructive procedures are considered. Some patients may have intrathecal pumps in place, and their location and that of the tubing should be assessed before surgical endeavors.

### Neurologic Examination

A brief neurologic examination is essential when first evaluating patients with presumed neurovesical dysfunction. Mental status should be assessed because significant cognitive dysfunction and memory disturbances have been independently associated with abnormal voiding function. An appreciation of past and current intellectual capacity may provide insight into the progression of lower urinary tract disorders and thereby guide the degree of complexity of treatment strategies. Motor strength and sensory level should be determined because distribution of motor and sensory disturbances can often predict lower urinary tract dysfunction, particularly in patients with multiple sclerosis.<sup>5</sup>

Cutaneous and motor reflexes require a thorough evaluation at the time of the initial encounter. The bulbocavernosus reflex, which is elicited by gently squeezing the glans penis in men or gentle compression of the clitoris against the pubis in women and simultaneously feeling for an anal sphincter contraction (by placing a finger in the rectum), assesses the integrity of the S2-S4 reflex arc. The anal reflex, which assesses integrity of S2 to S5, can be checked by applying a pinprick to the mucocutaneous junction of the anus and evaluating for anal sphincter contraction. The cremasteric reflex may be somewhat less reliable, but it assesses sensory dermatomes supplied by L1 to L2.

Muscle motor reflexes should be routinely evaluated. The most common of these are the biceps reflex (assesses C5 to C6), patellar reflex (L2 to L4), and Achilles (ankle) reflex (L5 to S2). Evidence of an upper motor neurologic injury includes spasticity of the involved skeletal muscle, heightened response to reflex testing, and an upgoing toe on gentle stroking of the plantar surface of the foot (i.e., positive Babinski's sign).

### Other Testing

A thorough investigation for upper tract abnormalities (imaging) and lower urinary tract dysfunction (video urodynamic testing)

is mandatory when first evaluating patients with neurogenic voiding dysfunction and at periodic intervals thereafter. The frequency of testing is not readily agreed on, although many experts recommend annual upper tract evaluation (nuclear renal scan or renal ultrasound) and at least biannual urodynamic testing in high-risk patients (e.g., traumatic spinal cord injury).<sup>11</sup> Others have advocated less frequent evaluations in stable patients.<sup>12</sup> Regardless of the frequency of evaluations, the most important aspect of testing is to identify patients at risk for upper tract deterioration and to monitor them closely. Although a description of the technique of urodynamic testing is beyond the scope of this chapter, it is clear that in no other situation in urology is the importance of properly performed urodynamic testing as important as it is when evaluating the patient with neurogenic voiding dysfunction.

## BLADDER DYSFUNCTION IN SPECIFIC NEUROLOGIC CONDITIONS

### Traumatic Spinal Cord Injury

#### Suprasacral Injuries

The classification scheme most commonly used for patients with spinal cord injury is that developed by the American Spinal Injury Association (ASIA). Using this scheme, the level and completeness of the injury are assessed by careful examination of the affected dermatomes and muscle groups (Table 14-1). Normally, at least 3 months must pass from the time of injury to assess the patient's neurologic status, because the spinal shock phase can last this long or longer. During this time, spinal reflex activity below the level of the lesion is rendered inactive, resulting in transient skeletal muscle paralysis. Smooth muscle activity (i.e., detrusor) is similarly depressed, whereas in most situations, the bladder neck and external sphincter remain closed, and as a result, most patients are in retention or dribbling small amounts of urine. Immediate management therefore focuses on bladder drainage (i.e., indwelling or clean intermittent catheterization) until reflex bladder activity returns.

After suprasacral injuries, several pathologic bladder reflexes occur. In most situations, neurogenic detrusor overactivity

**Table 14-1 American Spinal Injury Association Classification of Spinal Cord Injury**

Class	Description
A	<i>Complete:</i> No motor or sensory function is preserved in the sacral segments from S4 to S5.
B	<i>Incomplete:</i> Sensory but not motor function is preserved below the neurologic level and includes the sacral segments from S4 to S5.
C	<i>Incomplete:</i> Motor function is preserved below the neurological level, and more than one half of key muscles below the neurologic level have a muscle grade less than 3.
D	<i>Incomplete:</i> Motor function is preserved below the neurologic level, and at least one half of key muscles below the neurologic level have a muscle grade of 3 or more.
E	<i>Normal:</i> Motor and sensory function are normal.

Figure 14-1 Detrusor external sphincter dyssynergia in patient with T5 level spinal cord injury.

replaces the flaccid detrusor of the spinal shock phase, resulting in a small-capacity, overactive bladder, which cannot be inhibited by the patient. With an interruption of the spinobulbospinal reflex, there is loss of coordination between the normal detrusor contraction and simultaneous inhibition of the pudendal-mediated external sphincter contraction. Detrusor–external sphincter dyssynergia (DESD) emerges, resulting in a staccato-type voiding pattern, impaired bladder emptying, and sustained increases in intravesical pressure (Fig. 14-1). These sustained elevations in pressure are thought to be responsible for upper tract damage in patients with spinal cord lesions.<sup>13</sup> In patients with lesions above spinal cord level T6–T8, smooth muscle dyssynergia of the bladder neck generally occurs in conjunction with DESD because of a loss of the normal inhibition provided by supraspinal sympathetic activity at the level of the bladder neck.

Afferent fibers are altered after traumatic spinal cord injury. Whereas in the normal micturition reflex, A $\delta$  afferent fibers are active in bladder sensation, unmyelinated C fibers appear to become active in inflammatory conditions of the bladder and after spinal cord injury. Although the emergence of C fibers may not be essential to the micturition reflex after a spinal cord injury, their presence does contribute to the emergence of overactivity and dyssynergia,<sup>14</sup> and treatment with agonists of the vanilloid receptor (found mainly on unmyelinated C fibers), such as cap-

saicin and resiniferatoxin, can desensitize (after initially exciting, in the case of capsaicin) the receptor and attenuate the clinical effects of spinal cord injury on bladder function.<sup>15</sup>

Any discussion of bladder dysfunction in spinal cord injury would not be complete without reference to autonomic dysreflexia, the syndrome of unopposed sympathetic outflow normally initiated by a visceral disturbance in patients with spinal cord injury. Typically, it is seen in patients with spinal cord injury above the level of T6 to T8, and it may result in profound hypertension, headache, flushing, and sweating. Bradycardia is the most likely arrhythmia to be seen, although tachyarrhythmias have also been described. The most common stimulus for this syndrome is distention of the bladder or rectum, or both, during cystoscopy or urodynamic assessment. All patients at risk should be hemodynamically monitored during bladder studies, and some authorities have advocated the administration of oral nifedipine approximately 30 minutes before urologic procedures.<sup>16</sup> Alternatively, sublingual nifedipine can halt an acute episode if removing the offending stimulus does result in immediate improvement.<sup>17</sup>

### Sacral Injuries

Injuries affecting the sacral spinal cord (usually below the vertebral level of T12 to L1) cause a loss of parasympathetic innerva-

**Figure 14-2** Phasic neurogenic detrusor overactivity in patient with multiple sclerosis. Notice the pseudo-dyssynergic electromyographic pattern in the patient attempting to prevent leakage.

tion of the detrusor smooth muscle and resultant areflexia and urinary retention. In most cases, the bladder neck appears to be competent, and the external sphincter maintains fixed tone, although volitional control is lacking. There exists some variability because certain patients have leaks due to sphincteric deficiency, and reduced urethral closure pressures have been documented in patients with lower spinal cord lesions.<sup>18</sup>

### Multiple Sclerosis

Although only 2% to 10% of patients with multiple sclerosis present with lower urinary tract symptoms (LUTS) as their initial complaint, up to 97% eventually develop symptoms during the course of their disease. The most common subjective complaints include urinary frequency, urgency, and urge-related incontinence. Urinary hesitancy, recurrent urinary tract infections, and voiding dysfunction (e.g., straining, incomplete emptying) may also typify the symptoms of up to 40% of patients.

Although it is difficult to predict who will develop LUTS, it is rare to develop the symptoms in the absence of pyramidal dysfunction involving the lower extremities. In a study of 186 patients

with multiple sclerosis, Betts and colleagues<sup>5</sup> found only two patients had LUTS in the absence of pyramidal dysfunction affecting the legs. There is a strong correlation between the presence of LUTS and Kurtzke scores for pyramidal dysfunction and total disability scores.<sup>6</sup>

The most common urodynamic finding in patients with multiple sclerosis is neurogenic detrusor overactivity. In general, 60% to 90% of patients undergoing urodynamics will be found to have neurogenic detrusor overactivity (Fig. 14-2). Symptoms of urgency and frequency commonly are associated with the finding of detrusor overactivity, accompanied by urge incontinence if high-grade, unstable contractions or insufficient outlet resistance (typically, pelvic floor voluntary contractions are impaired) are present. Detrusor-sphincter dyssynergia, which may lead to poor emptying and elevated intravesical pressures, is seen in approximately 25% to 40% of patients. Both bladder neck (smooth muscle) and external sphincter dyssynergia seem to contribute to the voiding dysfunction in many of these patients. Recurrent bladder infections, prolonged voiding, extreme hesitancy, and incontinence typify the symptoms of multiple sclerosis patients with DESD, although symptoms are not always a reliable

indicator of the type of bladder dysfunction responsible in these patients. Detrusor hyporeflexia, which is the lack of a sufficient contraction during voiding to facilitate bladder emptying, occurs in approximately 20% of patients with multiple sclerosis.

Renal insufficiency due to bladder dysfunction is fairly uncommon among multiple sclerosis patients. However, certain multiple sclerosis populations, including those with untreated DESD, those with elevated intravesical filling pressures, and those with indwelling catheters, may be at risk for renal deterioration over time.<sup>19</sup> Nonetheless, in a series of 120 patients undergoing initial urologic evaluation, we found abnormal ultrasonographic results of any clinical significance to be extremely uncommon, regardless of the urodynamic diagnosis, age, sex, and duration of multiple sclerosis.<sup>20</sup> This apparent improvement may be a result of earlier recognition of patients at risk for urologic dysfunction and prompt treatment.

### **Movement Disorders: Parkinson's Disease and Multiple Systems Atrophy**

It has been estimated that 70% of patients with movement disorders develop LUTS. Although it is believed that patients with Parkinson's disease tend to develop symptoms later in the course of the disease, it has been shown that patients with mild to moderate Hoehn and Yahr symptom scores still are more symptomatic than age-matched counterparts.<sup>3</sup> In contrast, patients with multiple systems atrophy typically do show signs of autonomic dysfunction early in the course of their disease, and men may report erectile dysfunction before other neurologic disturbances are noticed.

Overall, most patients with Parkinson's disease, when studied urodynamically, are found to have detrusor overactivity. Cell loss in the substantia nigra, which is thought to inhibit detrusor activity at baseline, is believed to be responsible for the emergence of detrusor overactivity in patients with Parkinson's disease. Reflecting the diffuse neuronal cell loss seen in multiple systems atrophy, patients with this condition can have a variety of conditions affecting the bladder and sphincter. In particular, neuronal cell loss in Onuf's nucleus leads to sphincteric denervation and insufficiency, whereas neuronal cell loss in the intermediolateral cell columns may lead to detrusor hyporeflexia. Although the risk of postprostatectomy incontinence in men with Parkinson's disease is high (approximately 20%), the risks may be prohibitively high (80%) in patients with multiple systems atrophy due to specific sphincteric disturbances.<sup>21</sup> It is thought that a relative bradykinesia, which is a failure to relax the external sphincter, is present in some patients with Parkinson's disease, manifesting as an obstructive picture that is unrelated to prostate encroachment. These patients, although perhaps presenting with elevated residual volumes and voiding disturbances, are unlikely to be helped by surgical therapy to relieve outlet obstruction.

Several trials have investigated the impact of Parkinson's disease therapies on LUTS. The dopamine receptor agonist apomorphine has no reliable effect on detrusor overactivity, although it has been shown to improve urodynamic indices of bladder outlet obstruction.<sup>22</sup> The effects of levodopa on bladder function appear to be somewhat mixed. One hour after administering levodopa in patients with more advanced disease, urodynamics revealed diminished bladder capacity and a reduced threshold volume for overactivity, thereby worsening urgency, although an improvement in voiding efficiency occurred because

of enhanced detrusor contractility.<sup>23</sup> Patients undergoing subthalamic nucleus stimulation were found to have improved bladder capacity and threshold volume for detrusor overactivity during active treatment.<sup>24</sup>

### **Cerebrovascular Accident**

The development or progression of LUTS after a CVA may be found in up to 70% of patients. Because most patients affected by CVA are elderly and may have preexisting disturbances of micturition or incontinence, it is often difficult to decipher what is acute and what chronic in the weeks to months after a stroke. This is particularly troublesome when patients have difficulty communicating after a CVA because of aphasia, and preexisting symptoms are unknown. Because many strokes can affect the suprapontine centers, which provide input (largely inhibitory) to the pontine micturition center, such as the thalamus, basal ganglia, cerebellum, and cerebral cortex, the development of new urinary symptoms after a stroke is common.

From a clinical standpoint, the development of urinary retention shortly after a CVA is quite common. Generally, unless preexisting detrusor dysfunction or coexisting outlet obstruction is present, retention is later replaced by frequency, urgency, and often, urge incontinence. Urodynamically, neurogenic detrusor overactivity is the most common finding, with the external sphincter being synergic in most cases, although patients with internal capsule or cerebral cortex CVA may be more vulnerable to incontinence due to uninhibited sphincteric relaxation.<sup>7</sup> True detrusor-sphincter dyssynergia is quite uncommon after CVA. Detrusor areflexia may also be seen in a significant number of patients after CVA, regardless of CVA location, and overall, it is not clear that stroke location can accurately predict the nature of bladder dysfunction.<sup>25</sup>

Data have emerged regarding the pathogenesis of detrusor dysfunction after CVA, opening the door for new treatments. In animal models, occlusion of the middle cerebral artery has been associated with increases in nitric oxide production at the level of the bladder and spinal cord (by neuronal nitric oxide synthase), and intracerebral injections of nitric oxide inhibitors have rapidly increased bladder capacity that had been diminished after middle cerebral artery occlusion.<sup>26,27</sup> Treatment with an ATP-dependent potassium channel opener has improved bladder capacity after cerebral infarction in rats, whereas others have found that specific alterations in the glutamatergic and dopaminergic pathways may be responsible for detrusor overactivity after a CVA.<sup>28,29</sup> These findings and others have provided hope that alternative treatment strategies may be available to help reduce the impact of CVA on bladder function when used in the acute setting.

### **Cervical Spondylosis**

Cervical spondylosis is most commonly associated with intermittent but severe neck pain, and it can lead to gait disturbance and progressive LUTS. A form of degenerative disk disease, cervical spondylosis can result in a significant myelopathy, causing loss of manual dexterity, arm and hand weakness, sensory abnormalities (C3 to C5 levels), lower extremity spasticity, loss of proprioception, and ultimately, gait imbalance (C5 to C8). Shooting electric shock sensations may occur in the extremities (i.e., Lhermitte's sign) on neck flexion and extension in some patients with cervical spondylosis. The development of radiculopathy

symptoms (typically neck or arm pain with paresthesias) may also occur.

Urinary symptoms seem to be present in most patients with cervical spondylosis; however, as with CVA, the presence of pre-existing non-neurogenic LUTS must also be considered. Frequency, urgency, and nocturia are most commonly reported (60%), and neurogenic detrusor overactivity is the most common urodynamic finding (40% to 73%).<sup>30</sup> Outlet obstruction resulting from DESD occurs in 0% to 36% of patient series.<sup>10</sup> It is believed that patients with more advanced forms of cervical spondylosis tend to have more debilitating urologic symptoms and are more likely to experience DESD.<sup>31</sup>

## CONCLUSIONS

Patients with neurogenic voiding dysfunction are challenging to treat because of the progressive nature of the disease process. Common treatment approaches often do not render the same quality results seen in other patients. The treating urologist must use all tools available to pinpoint the nature of the bladder dysfunction, including complex video urodynamic testing. The physician must have a good understanding of the underlying neurologic disorder to be able to offer appropriate and reasonable solutions to what are often very complex voiding disorders.

# VOIDING DYSFUNCTION AFTER PELVIC SURGERY

*Hari Siva Gurunadha Rao Tunuguntla,  
and Angelo E. Gousse*

Pelvic surgery can result in urinary retention or other voiding dysfunction by causing inadvertent damage to the pelvic plexus. It occurs most often after abdominoperineal resection and radical hysterectomy, although it may be seen after transvaginal or abdominal surgery for urinary incontinence (e.g., colposuspension, use of tension-free vaginal tape [TVT]) and pelvic organ prolapse, hysterectomy for benign disease, and laparoscopic hysterectomy.

### SURGICAL ANATOMY OF THE PELVIC NERVOUS SYSTEM

The bladder receives innervation from the pelvic plexus (i.e., input from the S2 to S4 spinal cord segments by way of the presacral nerve), which is situated on the lateral aspect of the rectum. The portion of the pelvic plexus that specifically supplies the bladder is also called the vesical plexus.

The primary supply to the detrusor is by parasympathetic nerves that are uniformly and diffusely distributed throughout the detrusor. In contrast, the sympathetic nerve supply to the detrusor is rather sparse.<sup>1</sup> In women, numerous parasympathetic nerves, identical to those innervating the detrusor, supply the bladder neck and urethral muscle. The female bladder muscle and urethra receive a poor supply of sympathetic innervation.<sup>2</sup> The sympathetic preganglionic nuclei are located in the L1 and L2 spinal segments and possibly in the T12 segment. Afferent sensory fibers from the bladder exit along the sympathetic or parasympathetic pathways.

The superior hypogastric plexus is a fenestrated network of fibers anterior to the lower abdominal aorta. The hypogastric nerves exit bilaterally at the inferior poles of the superior hypogastric plexus that lie at the level of the sacral promontory. The network of nerve structures is located between the endopelvic fascia and the peritoneum. The hypogastric nerves unite the superior hypogastric plexus and the inferior hypogastric plexus or pelvic plexus bilaterally. The inferior hypogastric plexus has connections with the sacral roots from S3 and some contributions from S4 and S2.<sup>3</sup> The superior hypogastric plexus and hypogastric nerves are mainly sympathetic, the pelvic splanchnic nerves are mainly parasympathetic, and the inferior hypogastric plexus contains both types of fibers.

Bladder afferent fibers convey mechanoreceptive input essential for voiding. These visceral afferent fibers also transmit sensations of bladder fullness, urgency, and pain.

Ablative pelvic surgery may result in injury to the pelvic plexus and pudendal nerve, leading to abnormal function of parasympathetic, sympathetic, and somatic function.

The resultant urodynamic abnormalities include any combination of reduced compliance, hypocontractile detrusor, bladder neck incompetence identified on fluoroscopic screening, reduced urethral closure pressure, and electromyographic changes in the perineal musculature.<sup>4-6</sup>

### PATHOPHYSIOLOGY OF VOIDING DYSFUNCTION

Voiding dysfunction after pelvic surgery may be caused by anatomic or functional disturbances of the lower urinary tract. The causes may be divided into two broad categories: failure to store (i.e., altered bladder or bladder outlet function) and failure to empty (i.e., altered bladder or bladder outlet function).

Failure to store may be caused by detrusor overactivity, which may result from denervation supersensitivity after pelvic dissection or from surgery-related bladder outlet obstruction (e.g., after tight suburethral slingplasty). Bladder outlet obstruction may be the most common factor in the development of postoperative voiding dysfunction.<sup>7</sup> Bladder outlet obstruction is intimately involved with the onset of postoperative voiding dysfunction. Harrison and associates<sup>8</sup> and Speakman and colleagues<sup>9</sup> proposed that parasympathetic denervation supersensitivity develops as a result of bladder outlet obstruction, and others<sup>10</sup> have postulated that denervation hypersensitivity may develop from the surgical dissection alone in the absence of bladder outlet obstruction. Other studies suggested that bladder outlet obstruction might result in changes in cholinergic and purinergic signaling. Likewise, inadequate tension during sling placement, although uncommon, may result in failure of the bladder to store.

Postvoid residual (PVR) volume (achieved by a Valsalva maneuver or effective detrusor contraction) is an indicator of voiding efficiency. Preoperatively, increased PVR volumes due to loss of contractility or obstruction, or both, can be a demonstration of efficiency loss, and consequently, it is a risk factor for postoperative voiding dysfunction.

Bladder outlet obstruction after sling surgery is related to increased tension resulting in urethral compression.<sup>7</sup> It may result from different causes after different procedures for incontinence. Retropubic and transvaginal needle suspensions stabilize lateral juxtaurethral tissues; obstruction is often related to hyper-elevation of the bladder neck and kinking of the proximal urethra. Pubovaginal slings provide suburethral support to augment urethral coaptation during periods of increased intra-abdominal pressure. Midurethral slings using TVT (Gynecare, Ethicon,

Somerville, NJ) or SPARC mesh material (American Medical Systems, Minnetonka, MN) are the new class of anti-incontinence procedures and are placed without tension at the mid-urethral level to simulate the supportive function of the pubourethral ligaments. Obstruction after these procedures has been attributed to compression from excessive tension or sling misplacement or migration.<sup>7</sup>

Voiding with a weak detrusor contraction (identified by cystometrogram) or during a Valsalva maneuver has been associated with a higher risk of urinary retention and surgical failure.<sup>11-13</sup> Miller and colleagues<sup>11</sup> observed that of 21 women who voided without contraction on the preoperative test, 4 (19%) presented with postoperative urinary retention, compared with none of 48 other women with normal contraction. In the same study, no patient with a contraction pressure greater than 12 cm H<sub>2</sub>O presented with retention. Among the parameters tested for voiding dysfunction, only PVR volume was a significant factor. However, the investigators emphasized that the small sample limited the conclusions of the study.<sup>11</sup>

### EVALUATION OF VOIDING DYSFUNCTION

The presence and extent of preoperative storage and voiding symptoms are useful for comparison with de novo or persistent symptoms after incontinence surgery. Important factors include preoperative emptying status and PVR volume. These assessments are important for those with elevated PVR volumes after slingplasty. If preoperative voiding parameters and emptying are normal, incomplete emptying or retention after surgery increases the suspicion of obstruction.

Studies have found that patients with poor detrusor contractility and those who void with abdominal straining may require a longer period of postoperative catheterization (e.g., after retro-pubic suspensions and pubovaginal sling) and take longer to resume normal voiding.<sup>14,15</sup> However, McLennan and coworkers<sup>16</sup> found no association between returning to normal voiding and length of postoperative catheterization in those undergoing autologous fascia lata sling surgery. Urethral erosion (Fig. 15-1) and bladder perforation (Fig. 15-2) during placement of a synthetic sling should be excluded by a thorough cystourethroscopy (if necessary, by a retroflexed flexible cystoscope) during the evaluation of a patient with urgency, urge incontinence, UTI, and or hematuria after slingplasty.

### History and Physical Examination

Postoperative evaluation demands a thorough history that includes assessment of storage symptoms such as frequency, dysuria, urgency, and urge incontinence and voiding symptoms such as hesitancy, incomplete emptying, straining, positional voiding, and complete urinary retention. The physical examination evaluates symptoms or signs of hyperelevated bladder neck, frank stress urinary incontinence (SUI), worsening or new-onset pelvic organ prolapse, and erosion of the mesh in the vaginal canal. UTI should be ruled out with urinalysis and culture. The PVR volume should be documented, although an elevated PVR volume cannot accurately separate bladder outlet obstruction from impaired detrusor contractility.

The findings on physical examination may vary from normal to a frankly hypersuspended urethra. Midurethral slings (e.g., SPARC suburethral sling, TVT) typically do not result in over-

**Figure 15-1** Urethral erosion by a tension-free vaginal tape suburethral sling.

**Figure 15-2** Bladder perforation by a tension-free vaginal tape suburethral sling.

correction of the urethrovesical angle.<sup>17</sup> Bladder neck slings, however, can pull or scar the urethra against the pubic bone and result in a negative urethrovesical angle. The surgeon may also encounter an iatrogenic obstruction without hypersuspension or elevation of the bladder neck or urethra. Any additional outlet resistance may be enough to cause retention or de novo obstruction in patients with a hypocontractile detrusor.

Cystocele may create a fulcrum or point of obstruction and should be excluded in the evaluation of voiding dysfunction after sling surgery. Urethral or vaginal erosion of the sling, SUI, and persistent urethral hypermobility also should be considered.

### Video Urodynamic Study

Although commonly performed by most clinicians, the evidence-based value of urodynamic study in the evaluation of voiding dysfunction after incontinence surgery remains controversial. Most studies have shown a poor correlation between findings on urodynamics and outcomes after urethrolysis.<sup>17</sup>

Urodynamic studies may provide information on detrusor overactivity or impaired compliance in patients in urinary retention or increased PVR capacity.<sup>18</sup> They may also confirm the diagnosis of obstruction as demonstrated by high pressure or low flow. McGuire and colleagues,<sup>19</sup> Nitti and coworkers,<sup>20</sup> and Cross and associates<sup>21</sup> have shown that presence of an adequate detrusor contraction has no association with successful voiding after transvaginal urethrolysis and sling takedown. Urodynamic study may provide a specific diagnosis of voiding dysfunction (e.g., impaired pelvic floor relaxation during voiding) and therefore can be helpful in directing therapy. It may also ascertain the cause of concomitant incontinence, guiding concurrent surgery during urethrolysis.

Absolute urodynamic criteria for obstruction in women have not been defined despite several proposed cutoff values. Chasagne and associates<sup>22</sup> noticed that at a cutoff value of 15 mL/sec or less, flow with a combined detrusor pressure of at least 20 cm H<sub>2</sub>O was able to define bladder outlet obstruction in women with a sensitivity of 74% and specificity of 91%. Blaivas and Groutz<sup>23</sup> used a “free uroflow” parameter in 600 women to provide useful information for those unable to void during the study. They classified obstruction on the basis of a detrusor pressure of more than 20 cm H<sub>2</sub>O despite no flow or an inability to void with a catheter in place. Nitti and coworkers<sup>24</sup> used a combination of multichannel urodynamic study and videofluoroscopy to aid in the diagnosis of bladder outlet obstruction as a sustained detrusor contraction with reduced flow and radiographic evidence of obstruction between the bladder neck and urethra. However, if a patient does not demonstrate a contraction during the voiding phase with concomitant uroflow, it is not as useful. Notwithstanding these limitations, a urodynamic study confirming obstruction can make the surgeon feel more confident in his or her decision to perform urethrolysis. Urodynamic study provides information regarding bladder capacity, SUI, compliance, detrusor overactivity, or learned voiding dysfunction.

### Cystoscopy

All patients with persistent storage symptoms after pelvic surgery should undergo cystoscopy to rule out urethral erosion (see Fig. 15-1) and bladder perforation (see Fig. 15-2) from sutures, the suture passer, or sling material. Cystoscopy may also show a hypersuspended mid-urethra or bladder neck (indicating excessive sling tension), scarring, deviation of the urethra, misplacement or migration, or even a fistula. Vaginoscopy also can be performed to exclude vaginal erosion of a sling.

### Postoperative Recovery

Some delay in initiating volitional voiding may occur up to 4 weeks after any anti-incontinence surgery. Management depends on the nature of symptoms. Those with high PVR volumes or complete retention should be initially treated with intermittent or continuous catheterization for up to 3 or 4 weeks. The clinician can use his or her judgment to intervene sooner. Significant incomplete emptying or total retention persisting beyond this period rarely resolves without intervention. Evaluation and treatment can therefore be considered at this point. Experience with midurethral polypropylene slings suggests that incomplete emptying or urinary retention can be addressed as early as 1 week postoperatively.<sup>25</sup> However, the outcomes after earlier intervention have not been established. In patients with voiding symp-

toms alone, a temporal relationship of severe symptoms after surgery, and normal preoperative voiding and emptying, urethrolysis may be undertaken without urodynamic assessment. This principle also applies to obstruction after any incontinence procedure when a temporal or causal relationship between surgery and voiding dysfunction exists.

Evaluation in those with de novo or worsening storage symptoms and normal emptying is based on the severity of both compared with that from preoperative symptoms. Such patients should initially undergo conservative treatment with fluid restriction and antimuscarinic agents. If symptoms persist, urodynamic study and cystoscopy should be performed. If symptoms fail to resolve over an arbitrary 3 months' waiting period and obstruction is the cause of the storage symptoms, urethrolysis should be considered. Although 3 months is the minimal period before surgical intervention in most urethrolysis series,<sup>26</sup> we feel that treatment should be individualized for each patient with storage symptoms after pelvic organ prolapse or sling surgery.

## PELVIC SURGERY

### Radical Hysterectomy

Short-term and long-term bladder dysfunction remains a common side effect after radical hysterectomy, with bladder atony (requiring indwelling catheter drainage for more than 2 weeks) reported in as many as 42% of patients.<sup>27</sup> Mundy and colleagues<sup>28</sup> reported voiding dysfunction in 52% to 85% of patients after radical total hysterectomy.

Mundy and colleagues<sup>28</sup> reported urinary retention in only 0.5% of patients after radical hysterectomy, whereas straining was required by 85%. Buchsbaum and associates<sup>29</sup> reported urinary retention in 10% to 60% of patients after radical hysterectomy. Compared with surgery, adjuvant pelvic irradiation is more often associated with contracted and overactive bladders. Retention is usually treated with clean intermittent self-catheterization. Bandy and associates<sup>30</sup> have shown that prolonged indwelling catheterization (>30 days) after radical hysterectomy is associated with worse long-term PVR and total bladder capacity. Fortunately, this voiding dysfunction becomes permanent in less than 5% of patients.<sup>30</sup>

In a prospective study of 18 patients who underwent modified radical hysterectomy (involving restricted dissection of the anterior parts of the cardinal ligament and preservation of the posterior cardinal ligament), Chuang and coworkers<sup>31</sup> demonstrated only temporary (<6 months) vesicourethral dysfunction attributable to transient somatic and autonomic demyelination with or without denervation. These investigators studied the patients by pudendal motor nerve conduction and urodynamic studies, including urethral pressure profiling, cystometry, and uroflowmetry.

### Central Compartment Surgery and Voiding Dysfunction

#### *Hysterectomy for Benign Disease*

Urologic complications occur after 0.1% of the abdominal and 0.05% of the vaginal procedures.<sup>32</sup> Most controlled, prospective studies have found minimal effect of hysterectomy for benign disease on bladder function, and urinary retention therefore appears to be related to other factors.<sup>33</sup> Voiding dysfunction is

more common after total than after subtotal hysterectomy performed for benign causes (see Fig. 15-1).<sup>34</sup>

Loss of bladder-filling sensation is the suggested pathophysiologic mechanism of urinary retention after hysterectomy.<sup>35</sup> Everaert and colleagues<sup>35</sup> showed that urinary retention after hysterectomy for benign disease was associated with deafferentiation of the bladder wall in four patients and of the bladder neck in one. Decreased visceral sensation of the bladder or bladder neck is associated with neurogenic disease.<sup>36</sup> Functionally, these patients have absent filling sensation on cystometry, together with partial or complete sensory denervation of the bladder, resulting in increased bladder capacity and secondary urinary retention. Compared with subtotal hysterectomy, total hysterectomy has been associated with a more prominent decrease in voiding frequency and increased bladder capacity.<sup>34</sup> Mild symptoms of deafferentiation are more frequent after hysterectomy but are temporary.<sup>33</sup> Partial or complete deafferentiation, together with a concomitant factor (e.g., preexisting pelvic floor dysfunction, histrionic personality, medications) may result in urinary retention.

Although retention is rare after hysterectomy for benign disease, it is bothersome for the patient. Selected patients may be candidates for sacral nerve neuromodulation.<sup>35</sup> Everaert and associates<sup>35</sup> reported good response in 50% and partial long-term success in 33% of 15 patients.

### *Laparoscopic Hysterectomy and Voiding Function*

Most women undergoing hysterectomy are in the perimenopausal age group, and urinary symptoms are common in all women in this age group. Long and colleagues<sup>37</sup> have shown improvement in urinary symptoms after laparoscopic hysterectomy. These investigators showed a significant decrease in the number of women with one or more urinary symptoms, from 81 (53.6%) of 151 preoperatively to 58 (38.4%) of 151 postoperatively. Urinary frequency, SUI, and nocturia were the most common preoperative symptoms that improved after surgery. This improvement may result from the postoperative changes in the urodynamics and mobility of the bladder neck.<sup>38</sup> The investigators suggest that these effects may be attributed to the anchoring of the vaginal cuff to the cardinal-uterosacral ligament complex during hysterectomy. Similarly, Virtanen and coworkers<sup>39</sup> noticed a decrease in the incidence of urinary frequency and SUI after total hysterectomy.

## **Anterior Compartment Surgery and Voiding Dysfunction**

### *Anti-incontinence Surgery and Voiding Dysfunction*

Anti-incontinence procedures are designed to correct SUI by restoring support to the urethrovesical junction and, in cases of intrinsic sphincter dysfunction, by improving coaptation of the urethra. Persistent voiding dysfunction from postoperative urethral hypersuspension is a known but not well-characterized complication after female anti-incontinence surgery. It has been reported to occur in 2.5% to 24% of patients.<sup>40</sup> In a large series of 503 patients comparing the Burch colposuspension with Stamey endoscopic needle suspension, voiding dysfunction was found to be the most common complication (12.1%).<sup>41</sup>

In most patients, postoperative voiding dysfunction is caused by obstruction from the incontinence procedure itself.<sup>42</sup> Urodynamic obstruction has been reported in 2.5% to 24% of patients after incontinence operations.<sup>43,44</sup> Some of these patients have

“clinical obstruction.” Others may have obvious voiding symptoms or retention *de novo* after surgery. However, storage symptoms without incomplete emptying also may be a manifestation of obstruction. Carr and Webster<sup>45</sup> reported irritative symptoms as the most common presenting symptoms, occurring in 75% of women, most of whom emptied their bladder satisfactorily.

Bladder outlet obstruction occurs in 5% to 20% of patients after a Marshall-Marchetti-Krantz procedure,<sup>46</sup> in 4% to 7% after a Burch colposuspension,<sup>47,48</sup> in 5% to 7% after a needle suspension,<sup>49</sup> and in 4% to 10% after pubovaginal sling operations.<sup>50</sup> Although the vaginal TVT is placed without tension at the mid-urethra, studies have shown that it may still be associated with voiding dysfunction in 4.9% to 10% of patients.<sup>51,52</sup>

Postoperative voiding and storage symptoms are common in the immediate postoperative period, although most resolve within the first 4 weeks. Workup and intervention is warranted in patients with persistent symptoms. Contemporary sling series<sup>53-55</sup> revealed a less than 5% rate of postoperative retention or uroynamically proven obstruction requiring surgical intervention.

Incidence of voiding dysfunction after anti-incontinence surgery is likely greater than reported. Although this is not a common outcome, it is possible to underestimate its actual incidence because there exists a spectrum of bladder outlet obstruction from frank retention to obstructive (i.e., weak stream, intermittency, or straining to void) or irritative voiding symptoms (i.e., frequency, urgency, or urge incontinence) alone.<sup>17</sup> Some patients may develop *de novo* instability or detrusor overactivity after surgery. Patients with preoperative irritative voiding symptoms may be at risk for continued symptoms after surgery. Which patients need correction of potential bladder outlet obstruction or alternative therapy rests on the clinician's judgment.

Carr and Webster<sup>45</sup> found that among 51 patients presenting for urethrolysis, 75% had irritative complaints, 61% had obstructive symptoms, and 55% experienced *de novo* urge. Urinary retention as the sole symptom (with or without the need for intermittent self catheterization) was uncommon, occurring only in 24%. Urethral erosion (see Fig. 15-1) may occasionally manifest with obstructive or irritative voiding symptoms.<sup>56</sup>

Patients with long-term retention may choose to continue intermittent or continuous catheterization rather than risk recurrent incontinence from urethrolysis. Surgery has been reserved for patients with frank voiding symptoms, whereas patients with *de novo* or worsening storage symptoms are more often managed nonoperatively. Initial therapy includes fluid management, timed voiding, and antimuscarinic medications. Surgical procedures such as sacral neuromodulation and augmentation cystoplasty are reserved for the more refractory cases. Botulinum toxin type A intradetrusor injection may have a role in these cases in the future.

### *Surgical Intervention for Retention after Slingplasty*

Urethrolysis (Fig. 15-3) performed in patients with persistent voiding dysfunction has consistently been shown to ameliorate voiding complaints and urinary retention after sling surgery for SUI. Factors important for decision-making include the type of sling or anti-incontinence procedure used, the nature of voiding dysfunction (i.e., frank retention versus irritative voiding), and the patient's desired outcome. If a patient is content with the current status of retention compared with her severe preoperative incontinence and is not willing to take the risk of recurrent

**Figure 15-3** Transvaginal suprimeatal urethrolysis. **A**, Inverted U incision is made between 9 and 3 o'clock positions 1 cm from urethral meatus. **B**, plane is dissected above urethra to base of symphysis pubis. **C**, Lateral dissection identifies wings of fibrous tissue overlying obstructing suburethral sling. **D**, Residual obstructing tissue ventral to midurethra.

SUI after urethrolysis, she may decide to manage the problem with clean intermittent self-catheterization.

The 3-month waiting period for surgical intervention arose from data on autologous fascia slings that might have loosened with time, allowing the patient to void to completion. Many question whether the patient who “opens up” at 3 months is actually achieving balanced voiding with a low detrusor pressure (i.e., unobstructed). The trend has been to perform urethrolysis as soon as 4 weeks into the postoperative period. The available literature suggests short-term symptomatic success.<sup>7,17</sup>

Surgical technique depends on type of material or approach used for initial surgery, duration of symptoms after surgery, and any associated surgery (e.g., cystocele repair). Operative approaches include sling incision, transvaginal urethrolysis, retropubic urethrolysis, suprimeatal (see Fig. 15-3) transvaginal urethrolysis, and interposition grafts.<sup>17</sup> The overall success rate of urethrolysis is acceptable (Table 15-1).

In surgery for retention after slingplasty, a midline incision over the sling (see Fig. 15-1) should be attempted initially. If the sling cannot be identified or bladder neck mobility is not restored, formal transvaginal urethrolysis (see Fig. 15-3) should be per-

formed.<sup>7</sup> Suprimeatal dissection (see Fig. 15-3) may be helpful in lysing scarred fibrous attachments between the urethra and pubis. Retropubic urethrolysis is reserved for patients with voiding dysfunction after retropubic suspension and for initial transvaginal urethrolysis failures. Resuspension of the urethra may be considered if the patient has concomitant SUI. Patients with persistent obstruction or voiding dysfunction after initial urethrolysis should undergo a workup similar to that for primary voiding dysfunction after anti-incontinence surgery and may be considered for aggressive repeat urethrolysis if obstruction is diagnosed. This approach may prevent chronic bladder dysfunction.<sup>57</sup>

Leng and coworkers<sup>57</sup> observed an association between prolonged time to urethrolysis for obstructive voiding symptoms after slingplasty and greater likelihood of persistent bladder dysfunction after urethrolysis. Time to urethrolysis for the whole cohort ranged from 2 to 66 months, with a mean follow-up after urethrolysis of  $17.3 \pm 22.9$  months. If their observation can be corroborated by other studies, it would be prudent to lower the threshold of clinical suspicion to detect bladder outlet obstruction after slingplasty. Video urodynamics testing can help differ-

Adapted from Vasavada SP: Evaluation and management of postoperative bladder outlet obstruction in women. *Issues Incontinence* Fall:5-7, 2002.

entiate between outlet obstruction and de novo urge incontinence. Rather than curtailing evaluation before urethrolisis, routine urodynamic testing can help us obtain the data for the pathologic condition of female bladder outlet obstruction. We do not know the role of sacral neuromodulation in nonobstructive retention after sling surgery.

### *Colposuspension and Voiding Function*

Wang<sup>58</sup> attributed the postoperative voiding dysfunction (i.e., frequency, urgency, and obstructive voiding symptoms) to outflow obstruction. He reported higher postoperative voiding dysfunction after a Stamey bladder neck suspension procedure.

Bombieri and associates<sup>59</sup> demonstrated that bladder neck elevation and compression (anterior and lateral) during colposuspension were responsible for voiding symptoms using magnetic resonance imaging. Postoperative voiding was assessed clinically and by voiding cystometry. At 3 months, 21.4% of patients developed de novo symptoms of overactive bladder. Bump and colleagues<sup>60</sup> demonstrated higher pressure transmission ratios in women with postoperative detrusor overactivity compared with women without detrusor overactivity after colposuspension and controls with overactive bladder symptoms who did not undergo surgery.

### *Pelvic Organ Prolapse Surgery and Voiding Function*

Uterine prolapse may negatively affect pelvic floor function, resulting in voiding symptoms, defecation symptoms, and sexual dysfunction.<sup>61</sup> In a multicenter, randomized, controlled trial comparing abdominal and vaginal prolapse surgery in their effects on urogenital function, Roovers and coworkers<sup>62</sup> found higher (indicating more discomfort) Urogenital Distress Inventory scores (i.e., discomfort/pain domains and obstructive micturition domains) in the abdominal group than in the vaginal group. The investigators concluded that vaginal hysterectomy with anterior or posterior colporrhaphy, or both, was preferable to abdominal sacrocolpopexy with preservation of the uterus as surgical correction in patients with uterine prolapse stages II to IV. Urinary frequency, urgency, nocturia, and obstructive voiding symptoms requiring doctor's visits occurred in 7% of patients after vaginal repair and in 20% of patients after abdominal repair.

Rosenzweig and colleagues<sup>63</sup> reported improvement in urgency and urinary incontinence after simple anterior repair. However, in a study of the functional and anatomic outcome of anterior and posterior vaginal prolapse repair with Prolene mesh, Milani and associates<sup>64</sup> reported persistent urge incontinence (16% before and after surgery) and clinical SUI (25% before surgery and 22% after surgery) but improved urgency (50% before

surgery and 40% after surgery) and urodynamically confirmed SUI (54% before surgery and 44% after surgery), whereas urodynamic detrusor overactivity worsened after surgery (56% versus 22%). The investigators attributed these outcomes to a "reduced capacity of the bladder to expand because of the anelasticity of the Prolene mesh." Larger, prospective studies may settle the issue.

Theofrastous and coworkers<sup>65</sup> reported improvement in the length of postoperative bladder catheterization in postmenopausal women undergoing pelvic organ prolapse repair with preoperative estrogen replacement.

### *Cystocele Repair and Voiding Dysfunction*

Most patients with advanced pelvic organ prolapse and elevated RVR volumes demonstrate normalization of the PVR volumes after surgical correction of the pelvic organ prolapse.<sup>66</sup> Patients who had stress or urge urinary incontinence 8 weeks after grade 4 cystocele repair are evaluated with cystoscopy and video urodynamic evaluation when indicated.<sup>67</sup>

Voiding function (in terms of SUI) improves after cystocele repair. None of the patients in the series by Safir and colleagues<sup>67</sup> had de novo SUI. For 112 patients in this study, urinary incontinence resolved in 39 (87%) of 45, whereas 5 (7%) of the remaining 67 patients with no detrusor overactivity preoperatively had de novo urinary incontinence.

One study<sup>68</sup> enrolled 45 women (mean age, 65 years) who underwent grade 4 cystocele repair and had preoperative parameters of grade 4 cystocele in 43 (100.0%), SUI in 24 (55.8%), urge urinary incontinence in 26 (60.4%), and obstructive voiding symptoms in 26 (60.4%).<sup>68</sup> Patients were evaluated using the stress, emptying, anatomic, protection, and instability (SEAPI) test, with a follow-up of 15 months. Leboeuf and associates<sup>68</sup> demonstrated statistically significant improvement in all the SEAPI domains. Two patients (4.7%) had postoperative urinary retention, and de novo urge incontinence occurred in two patients (11.7%).

In a study by Frederick and Leach,<sup>69</sup> 8.5% of patients experienced de novo urge incontinence after acadaveric prolapse repair with sling procedure for combined SUI and cystocele. Three of 251 patients experienced prolonged urinary retention (>1 month); one required urethrolisis.

### *Enterocoele Repair and Voiding Dysfunction*

Enterocoele was consistently found to be associated with reduced maximum and average uroflow rate centiles.<sup>70</sup> Winters and colleagues<sup>71</sup> reported the outcomes for 20 women between 45 and 82 years old (mean age, 67.9 years) with complex pelvic floor prolapse (all patients had cystocele, enterocoele, and vaginal vault

prolapse) managed by abdominal sacral colpopexy and abdominal enterocele repair. Three patients developed SUI postoperatively, two despite having a Burch suspension and one after a pubovaginal sling. Two patients were successfully managed by collagen injection. No complications involving the mesh have been encountered.

### *Sacrospinous Ligament Fixation and Voiding Dysfunction*

Cespedes<sup>72</sup> reported outcomes of treating total vault prolapse using bilateral sacrospinous ligament fixation through an anterior vaginal approach in 28 patients. All patients had grade 3 or 4 vault prolapse, and all patients had associated enteroceles, cystoceles, and rectoceles. At a mean follow-up of 17 months (range, 5 to 35 months), SUI had been cured in all patients; however, two patients continued to have mild urge incontinence requiring less than 1 pad per day. One patient had elevated PVR volumes requiring intermittent catheterization for 2 months.

### *Orthotopic Neobladders and Voiding Function*

In a multicenter study of orthotopic neobladders, Carrion and coworkers<sup>73</sup> did not show any difference in outcomes after ileal neobladder versus colonic neobladder. Even a moderate degree of nocturnal incontinence is a significant problem for these patients. The incidences of diurnal incontinence, nocturnal incontinence, and intermittent catheterization were 7%, 31%, and 14% of patients undergoing ileal neobladder, respectively. The corresponding figures for those that underwent colonic neobladder are 12%, 30%, and 11%, respectively.

Fujisawa and colleagues<sup>74</sup> have shown that the location of the neobladder and avoidance of angulation (>90 degrees) of the

outlet are important for obtaining normal voiding after neobladder reconstruction in women. These investigators showed that intrareservoir pressure is less critical for normal voiding function. Although an increased intrareservoir pressure (contributed mostly by abdominal straining) was associated with increased frequency, it did not correlate with the peak urinary flow rate (Table 15-2).

## CONCLUSIONS

Female bladder outlet obstruction after pelvic surgery is a multifaceted topic because of the lack of defined criteria for the evaluation. The long-term outcome is often not as good as expected. Short-term and long-term bladder dysfunction remains a common side effect after radical hysterectomy, with bladder atony reported in as many as 42% of patients. Bladder outlet obstruction can occur after a Marshall-Marchetti-Krantz procedure, Burch colposuspension, and pubovaginal sling procedure. Although the vaginal TVT is placed without tension at the mid-urethra, studies have shown that it may still be associated with voiding dysfunction in 4.9% to 10% of patients. Urethral erosion may occasionally manifest with obstructive or irritative voiding symptoms. Most patients with advanced pelvic organ prolapse and elevated PVR volumes had normalization of PVR volumes after surgical correction of the pelvic organ prolapse. De novo urge incontinence occurs in 11% of patients after high-grade cystocele repair. Postoperative urinary retention after sacrospinous ligament fixation is less affected by the vault suspension than by the preoperative and postoperative management and

**Table 15-2 Incidence of Voiding Dysfunction after Pelvic Surgery**

Type of Surgery	Incidence of Voiding Dysfunction (%)	Study
Radical hysterectomy	42	Artman et al <sup>27</sup>

<sup>‡</sup>Incidence of de novo urge incontinence.

concurrent pelvic surgical procedures (e.g., cystocele repair). Postoperative stress incontinence may occur in 10% of patients when the bladder neck and urethra are not adequately supported.

Guidelines on postoperative outcome measures offer a more effective way to manage this problem. Quality-of-life scores,

including the 7-item Incontinence Impact Questionnaire (IIQ-7), 6-item Urogenital Distress Inventory (UDI-6), and American Urological Association (AUA) symptom scores may be used to gain more information on the quality-of-life changes that may be induced with management of bladder outlet obstruction in these patients.

# IDIOPATHIC URINARY RETENTION IN THE FEMALE

*Priya Padmanabhan and Nirit Rosenblum*

Urinary retention describes the inability to void voluntarily with a bladder volume exceeding the expected bladder capacity. More attention has been placed on male urinary retention caused by benign prostatic hypertrophy than urinary retention in women. Causes of incomplete bladder emptying in women are as variable and numerous as in men, but the presumed infrequency and difficulty in diagnosis accounts for less focus on them.<sup>1</sup> The largest body of medical literature on causes of female urinary retention, even in the past decade, assumes a psychogenic or hysterical basis to the problem.<sup>2</sup> The exact incidence of female urinary retention is unknown, but proper workup ensures that psychogenic retention is a diagnosis of exclusion and not an assumption. Excellent reviews of causes, workup, and management of urinary retention in females were published by Nitti and Raz<sup>1</sup> and Smith and coworkers.<sup>3</sup> Classically cited causes of urinary retention include neurologic, pharmacologic, anatomic, myopathic, functional, and psychogenic origins.

There are no quantitative definitions for bladder volumes associated with urinary retention. Instead, it is the effects of the urinary retention on the female patient that is of clinical concern. Diagnosis and management are not directed at addressing a specific volume or postvoid residual (PVR) volume; instead, the focus is on treating the effects of urinary retention. The symptomatic female patient may present with abdominal discomfort, irritative voiding symptoms, recurrent urinary tract infections, and incontinence and may eventually suffer from the sequelae of long-term retention, upper tract deterioration.

Instead of describing all of the causes of urinary retention in women, we focus on the area of idiopathic urinary retention, a group of causes that was previously gathered under the term *psychogenic retention*. The following sections provide an overview of common causes of urinary retention, discuss the history and basis of idiopathic retention, and describe the diagnostic tools and treatment options for the management of *pseudomyotonia*, a term coined by Fowler in 1986.

### ETIOLOGY AND PATHOPHYSIOLOGY OF URINARY RETENTION

Reviews have classified urinary retention as transient or established (i.e., requiring a more comprehensive workup). Transient causes include immobility (especially postoperative), constipation or fecal impaction, medications, urinary tract infections, delirium, endocrine abnormalities, and psychological problems. After the underlying cause is treated or the offending agent is removed, there is usually a return to normal voiding.<sup>1,3</sup> Common causes of established urinary retention are listed in Box 16-1.

### Neurogenic Causes

Disruption in neural pathways and non-neurogenic causes can cause bladder outlet obstruction and decreased bladder contractility, leading to urinary retention. Normal voiding requires the coordinated contraction by the detrusor of adequate magnitude and concomitant lowering of resistance at the smooth and striated sphincters, with an absence of obstruction.<sup>4</sup> The pontine micturition center controls voiding by stimulating parasympathetic fibers at S2 to S4, causing a detrusor contraction and inhibiting sympathetic fibers (T11 to L2) and somatic fibers of the pudendal nerve (S2 to S4). This causes relaxation of the bladder neck and proximal urethra and the external urethral sphincter, respectively.<sup>3</sup>

Detrusor–external sphincter dyssynergia (DESD) is a neurogenic cause of bladder outlet obstruction resulting from a suprasacral spinal cord lesion. DESD is associated with myelitis, spinal cord injury (i.e., upper motor neuron), and multiple sclerosis. Video urodynamics studies (VUDS) demonstrate detrusor hyperreflexia, high detrusor pressures, an increase in external sphincter activity, and small voided volumes. The ideal treatment for DESD is anticholinergics with clean intermittent catheterization (CIC).<sup>1,5</sup>

Multiple sclerosis is a focal demyelinating disease with a predilection for women between the ages of 20 and 50 years. Multiple sclerosis is associated with upper motor neuron and lower motor neuron lesions and therefore causes bladder outlet obstruction and decreased bladder contractility. Between 50% and 90% of patients with multiple sclerosis complain of voiding symptoms, usually urinary retention.<sup>6</sup> Detrusor hyperreflexia is the most common findings on VUDS, with areflexia identified in up to 40% and DESD in up to 66%.<sup>7</sup> The most important factors predisposing a multiple sclerosis patient to complications are high detrusor filling pressure (>40 cm H<sub>2</sub>O) and an indwelling Foley catheter.<sup>8</sup> Management includes anticholinergics with or without CIC and behavioral therapy.<sup>9</sup>

Cauda equina syndrome is caused by distal spinal cord injury, intervertebral disk protrusion, myelodysplasia, neoplasms, and vascular malformations, leading to decreased bladder contractility. It is associated with a complex of lower back pain, sciatica, saddle anesthesia, lower extremity weakness, sexual dysfunction, and bowel or bladder dysfunction. Urinary retention and straining are the most common urologic presentation. Diagnosis is made by computed tomography, magnetic resonance imaging (MRI), or myelography.<sup>1,3</sup> VUDS indicate an areflexic bladder, variable detrusor pressures, and sphincter denervation on electromyography.<sup>10</sup> The extent of sensory deficit in the perineal or saddle area is the most significant negative predictor of bladder function recovery.<sup>11</sup> Recovery of bladder function occurs

### Box 16-1 Causes of Urinary Retention in Females

- I. Neurogenic causes
  - A. Obstruction
    1. Detrusor-sphincter dyssynergia
      - a. Suprasacral spinal cord injury
      - b. Myelitis
      - c. Multiple sclerosis
    2. Parkinson's disease
  - B. Decreased bladder contractility
    1. Lower motor neuron lesion
      - a. Cauda equina injury (e.g., distal spinal cord, intervertebral disk protrusion, myelodysplasia, primary and metastatic neoplasms, vascular malformations)
      - b. Pelvic plexus injury
      - c. Peripheral neuropathy (e.g., diabetes mellitus, pernicious anemia, alcoholic neuropathy, tabes dorsalis, herpes zoster, Guillain-Barré syndrome, Shy-Drager syndrome)
    2. Multiple sclerosis
- II. Non-neurogenic causes
  - A. Obstruction
    1. Anatomic causes
      - a. Primary bladder neck obstruction
      - b. Inflammatory processes (e.g., bladder neck fibrosis, urethral stricture, meatal stenosis, urethral caruncle, Skene's gland cyst or abscess, urethral diverticulum)
      - c. Pelvic prolapse
      - d. Neoplasm (e.g., urethral carcinoma)
      - e. Gynecologic, extrinsic compression (e.g., retroverted uterus, vaginal carcinoma, cervical carcinoma, ovarian mass)
      - f. Iatrogenic obstruction (e.g., anti-incontinence procedures, multiple urethral dilations, urethral excision or reconstruction)
      - g. Miscellaneous causes (e.g., urethral valves, ectopic ureterocele, bladder calculi, atrophic vaginitis, reconstruction)
    2. Functional causes
      - a. Dysfunctional voiding
      - b. External sphincter spasticity
  - B. Decreased bladder contractility
    1. Hypotonia or atony
      - a. Chronic obstruction
      - b. Radiation cystitis
      - c. Tuberculosis
    2. Detrusor hyperactivity with impaired contractility
    3. Psychogenic retention
    4. Infrequent voider's syndrome
- III. Idiopathic causes (e.g., Fowler's syndrome)

over 3 to 4 years in 25% of patients with prompt surgical intervention.<sup>3</sup>

Pelvic plexus injury is most common during abdominoperineal resection, radical hysterectomy, proctocolectomy, and low anterior resection after injury or malignant extension to pelvic, hypogastric, and pudendal nerves. Findings of VUDS are similar

to those for cauda equina syndrome. Urinary retention usually resolves within months, with one third of patients having permanent voiding dysfunction. Urodynamically, permanent voiding dysfunction is characterized by fixed, residual, striated sphincter tone and an open, nonfunctional smooth sphincter. CIC is the management of choice until normal voiding returns.<sup>1,12</sup>

Multiple infectious, endocrine, and nutritional abnormalities cause peripheral neuropathy and decreased bladder contractility, leading to urinary retention. The classic example is diabetic cystopathy, but others include pernicious anemia, alcoholic neuropathy, tabes dorsalis, herpes zoster infection, Guillain-Barré syndrome, and Shy-Drager syndrome. Diabetic cystopathy often has insidious loss or impairment of bladder sensation, with progressive increase in bladder volumes and hypocontractility.<sup>13-16</sup> Management combines behavioral modification (e.g., timed voiding, Credé voiding) and CIC to facilitate emptying.<sup>1</sup>

### Non-neurogenic Causes

There are many non-neurogenic causes of bladder outlet obstruction and decreased bladder contractility that lead to urinary retention in the female patient (see Box 16-1). Most obstruction is classified as anatomic and functional. Anatomic obstruction includes primary bladder neck obstruction, inflammatory processes, prolapse, neoplasm, gynecologic, iatrogenic, and other causes. Functional obstruction is usually described in terms of dysfunctional voiding and external sphincter spasticity.

*Primary bladder neck obstruction* was introduced in 1933 by Marion<sup>17</sup> as a diagnosis of exclusion. Typically, these women present with irritative voiding symptoms and are given a trial of anticholinergics or antispasmodics; the course is eventual progression to periodic urinary retention or high PVR urine volumes. The exact cause is unknown, but the advent of video urodynamic testing has made diagnosis more accurate. The hallmark of primary bladder neck obstruction is incomplete opening or funneling of the bladder neck in the setting of sustained detrusor contraction of normal or high amplitude. There is resultant poor or nonexistent flow but a synergic external urethral sphincter. Management is medical and surgical. Terazosin has been used with improvement in flow rate and reduction of PVR volumes. Surgical options include transurethral incision of the bladder neck and Y-V-plasty of the bladder neck. Care is taken to avoid injury to the external sphincter, which can lead to stress urinary incontinence.<sup>1,3,18-20</sup>

Inflammatory processes, such as bladder neck fibrosis, urethral stricture, meatal stenosis, urethral caruncle, Skene's gland cyst or abscess, and urethral diverticulum, are associated with anatomic obstruction. Management usually involves treatment of the offending infection and surgical excision of obstructing lesions.

Patients with pelvic prolapse (e.g., uterine, cystocele, enterocele, rectocele) usually present with incomplete emptying, lower urinary tract symptoms, and recurrent urinary tract infections with or without stress urinary incontinence. They may describe positional changes or the need to reduce the prolapse to void. Bladder outlet obstruction is caused by kinking or compression of the urethra during voiding. VUDS are useful in making the diagnosis. After the initial diagnosis, a pessary or packing should be used to reduce the prolapse and confirm the diagnosis. This helps predict the outcome of prolapse repair. Treatment of symptomatic prolapse is usually surgical.<sup>1,21</sup> In cases of significant morbidity or age, a pessary alone may be used.

There are multiple neoplastic, obstetric, and gynecologic causes of bladder outlet obstruction in women. Urethral carcinoma is the only urologic malignancy more frequent in women (0.2%), although it remains rare. Patients present with bleeding and develop irritative and obstructive symptoms. Treatment ranges from local excision to anterior exenteration with complementary radiation therapy.<sup>22</sup> Gynecologic neoplasms and masses usually cause urinary retention by external compression or direct invasion. A retroverted, impacted uterus that occurs in the first trimester of pregnancy is associated with urinary retention. Gravid females are usually managed with manual dislodging of the uterus or a pessary until voiding resumes.<sup>1</sup>

The most common iatrogenic cause of urinary retention is surgical correction of stress urinary incontinence. The published incidence ranges from 2.5% to 24%, which may be underestimated. The irritative or obstructive voiding symptoms and recurrent urinary tract infections that result may be overlooked if the patient demonstrates normal emptying. The placement of sutures is the key factor determining a procedure's likelihood of causing obstruction. For example, sutures placed too medially cause urethral deviation or periurethral scarring; those placed too distally can cause kinking, leading to stress urinary incontinence; and tying sutures too tightly leads to hypersuspension, closing the bladder neck.<sup>1</sup> Newer mid-urethral slings can cause bladder outlet obstruction if the urethra is injured or the tape is placed under tension. The diagnosis is made by a patient's history before the procedure, physical examination, VUDS, endoscopy, and imaging. Urethrolisis is the treatment of choice. However, several studies have not correlated urodynamics and successful voiding after urethrolisis.<sup>23-25</sup>

Other iatrogenic causes of bladder outlet obstruction include a history of recurrent urethral dilation and postoperative urethral strictures. Urethral dilation leads to postdilatation bleeding or urine extravasation into periurethral tissue, causing scarring of the urethral wall and periurethral fibrosis.<sup>26</sup> This is diagnosed with VUDS and managed with transurethral resection or incision. Urethral strictures are rare in women, but they are seen endoscopically after urethral surgery and prior instrumentation. They are usually managed with periodic self-catheterization, permanent CIC, transurethral incision, or urethral reconstruction.<sup>1</sup>

Dysfunctional voiding and external sphincter spasticity are non-neurogenic functional causes of bladder outlet obstruction. Both conditions have been associated with inappropriate electromyographic activity during micturition with decreased urinary flow<sup>27</sup> and with high pressure increases in the urethral pressure profile. Dysfunctional voiding is referred to as *pseudodysynergia* (which mimics DESD), because it is a learned behavior that can be treated and cured. Treatment combines timed voiding, biofeedback, and anticholinergics.<sup>1</sup> External sphincter spasticity, characterized by "spasticity of the external sphincter and pelvic floor"<sup>28</sup> results from introital or vaginal infections, Skene's gland abscesses, adnexal disease, or cystitis. Pudendal nerve block improves voiding. VUDS reveal a bladder with intact sensation without the ability to contract due to cortical inhibition from the spastic pelvic floor.<sup>21</sup> After managing painful or inflammatory lesions, treatment involves pharmacologic agents, including muscle relaxants and  $\alpha$ -blockers.  $\alpha$ -Blockers relax the bladder neck and urethra and enhance pelvic ganglionic transmission, which improves detrusor contraction.  $\alpha$ -Blockers also treat the urinary retention that develops from transient spasticity.<sup>1,26,28</sup>

Non-neurogenic bladder hypocontractility is associated with radiation cystitis, chronic obstruction, and tuberculosis. Irradiation causes fibrosis of the lamina propria and muscular layers, leading to muscle cell death. The enlarged intercellular gaps in circular and longitudinal muscle fibers cause spasms and poorly coordinated detrusor contractions, with eventual hypocontractility or areflexia.<sup>29-31</sup> In chronic obstruction, the detrusor develops smooth muscle hypertrophy, a reduction in myofilaments, and damaged mitochondria within detrusor smooth muscle cells. This leads to a progressive decrease in detrusor contractility.<sup>32</sup> In all of these cases, complete VUDS are required for diagnosis and treatment of the urinary retention.

Decreased bladder contractility occurs in the detrusor hyperactivity with impaired contractility syndrome. This was discovered in a nursing home population; the women had opposite bladder reflex and contractile functions. Uninhibited contractions emptied less than one half of the bladder. Impaired neuromuscular transmission at the detrusor or myopathic processes (e.g., cellular degeneration) are proposed causes of the decreased contractility.<sup>33,34</sup> VUDS are essential for diagnosis, with the addition of fluoroscopically monitored synchronous cystosphincterometry to rule out other conditions. CIC is the mainstay of therapy.<sup>33</sup>

When urinary retention occurs with no organic disease but with centrally mediated, subconscious inhibition of detrusor contraction or sphincter relaxation, it is referred to as *psychogenic retention*. Psychological trauma (e.g., sexual) is one cause. Findings of VUDS are normal except for delayed sensation and a large-capacity bladder. It is usually temporary and responds well to supportive management. Treatment includes psychiatric support and CIC until normal voiding returns. With severe detrusor degeneration, some patients become dependent on CIC.<sup>35</sup>

## IDIOPATHIC URINARY RETENTION: FOWLER'S SYNDROME

### Pathogenesis

Historically, women with chronic, painless bladder distention were labeled as having a psychological problem. In 1986, Fowler and Kirby<sup>36</sup> identified a group of 19 young women with long-standing urinary retention who had distinctive electromyographic activity and impaired urethral relaxation. Electromyography with a concentric-needle electrode was used to study the striated muscle of the urethral sphincters in these patients. Concentric needle electromyography is useful in testing the integrity of the motor innervation arising from the S2 to S4 spinal levels and the activity associated with urethral sphincter striated muscle impairment. The impairment identified by Fowler and Kirby<sup>36</sup> was referred to as decelerating bursts and complex repetitive discharges (CRDs). CRDs are caused by direct spread of electrical activity from one muscle fiber to another, producing a low "jitter" sound on the audio output of the electromyographic machine. The decelerating bursts produce a sound similar to whales singing in the ocean, and laboratory research describes patients in retention with these findings as "whale noise, positive or negative."<sup>37-39</sup> The bursts of depolarizing activity in the semicircular urethral sphincter muscle impair normal relaxation of the muscle. This impedes normal bladder emptying, causing an insidious increase in residual volumes and bladder distention. The investigators noticed the similarity of this electromyographic activity and the bizarre, high-frequency discharges associated with reinnervation.<sup>36</sup> However, reinnervation was thought unlikely, because

abnormal burst discharges are infrequent in patients with cauda equina lesions or Shy-Drager syndrome.<sup>40,41</sup>

Fowler and colleagues<sup>42</sup> further associated these electromyographic abnormalities with endocrine dysfunction and polycystic ovarian disease (PCOD). Thirty-three of 57 women with urinary retention or voiding dysfunction had abnormal electromyographic activity. Sixty-four percent of this group had polycystic ovaries, seen on pelvic ultrasound. The other women in the group also demonstrated ovarian disturbances (e.g., single or bilateral oophorectomy, premature ovarian failure). High concentrations of circulating androgens and estrogens and low levels of progesterone are seen in women with PCOD. Progesterone stabilizes membranes. Progesterone deficiency in PCOD was hypothesized to reduce urethral sphincter muscle membrane stability, enabling the establishment of a circuitous excitatory pathway between muscle fibers.<sup>42</sup>

Concentric needle electromyographic measurements of the external urethral sphincter during micturition in women with voiding dysfunction and proximal urethral dilation (on VUDS) by Deindl and coworkers<sup>43</sup> confirmed the correlation between abnormal bursts of CRD and poor urinary stream. This provided support for the association between sphincter electromyographic overactivity and impaired relaxation.<sup>44</sup> A significant number of women with voiding dysfunction also have symptoms of fecal incontinence. Webb and colleagues<sup>45</sup> described the dysfunction of the urethral sphincter in idiopathic urinary retention as part of a more widespread disorder of the entire pelvic floor. All of the women studied had undergone urethral dilation in the past and were performing CIC. Similar abnormalities in the urethral and anal sphincters were seen, including polyphasic and abnormally long duration of potentials and CRD.<sup>45</sup> Anatomically, the striated sphincter muscle of the urethra and the anal sphincter receive their nerve supply through the pudendal nerve from the sacral plexus, explaining the correlation in electromyographic abnormalities.<sup>46</sup>

### Clinical Presentation

Using a survey questionnaire, Swinn and associates<sup>2</sup> described the typical profile of a woman with idiopathic urinary retention. Of 91 women who completed the survey, the mean age at retention onset was 27.7 years (range, 10 to 50 years), with a mean maximal bladder capacity of 1208 mL at the initial episode of retention. Thirty-five percent of these women developed retention spontaneously, 43% developed retention after a surgical procedure (usually gynecologic), and in 15%, childbirth was the preceding event. Eighty-six (94%) of the 91 women performed CIC, with 69% complaining of difficulty passing the catheter because of “something gripping” it. Fifty percent of the study group had PCOD. Voiding spontaneously returned in 38 patients. Sacral neuromodulation was the only therapy that restored function in the other 53 patients.<sup>2</sup>

### Diagnosis

There are no universally accepted criteria for diagnosing bladder outlet obstruction in women. Many investigators<sup>47-51</sup> have proposed urodynamic criteria for classification of bladder outlet obstruction, attempting to identify cutoffs for maximal flow rate, maximal detrusor pressure, and PVR volumes. Consistently, the absolute values were not as dramatic as seen in men, and diagnosis relied on imaging of the bladder outlet during micturi-

tion.<sup>47-51</sup> Based on the criteria used to evaluate bladder outlet obstruction, women with idiopathic retention are within the mildly obstructed range. VUDS in these patients typically show a prolonged filling phase and large bladder capacity, with reduced sensations of filling and limited detrusor pressure rise during the voiding phase. However, there are no definite urodynamic criteria to diagnose idiopathic retention in women. The basis for diagnosis remains a typical history and the abnormalities of the sphincter electromyographic activity as described earlier.<sup>52,53</sup>

Other ancillary indicators used in the diagnosis of idiopathic retention include urethral pressures and urethral sphincter volumes. Urethral pressure measurements have been used for almost a century to assess urethral closure function,<sup>54</sup> representing the urethra's ability to leak. Urethral pressures are criticized for not being a “real physical pressure” in a fluid, based on Griffiths' definition of urethral pressure as the fluid pressure needed to open a closed (collapsed) tube.<sup>55,56</sup> Measurement of urethral pressure (UPM) requires introduction of a Foley catheter, which introduces a nonzero cross-sectional area (zero cross-sectional area when urethra collapses) and changes the shape of the urethral lumen.<sup>57</sup> Historically, these measurements have not been standardized and fluctuate based on catheter type, cross section of the probe, patient position, and bladder filling pressures. The standard parameters do not discriminate between voiding dysfunctions, identify underlying pathophysiology, return to normal after surgery (as seen after incontinence procedures), or provide a reliable indicator of surgical success. UPM is useful in identifying strictures or diverticula and targeting interventions (e.g., low-pressure urethra).<sup>55</sup> In 2002, The Standardisation Sub-committee of the International Continence Society attempted to define UPM and recommend standards for measurement.<sup>57</sup>

The abnormal, myotonia-like electromyographic activity seen in women with idiopathic retention is theoretically expected to increase the bulk of urethral sphincter muscle by work-induced hypertrophy. Transvaginal or transrectal ultrasound (TRUS) has been used to image bladder outlet obstruction and identify pelvic pathology.<sup>58,59</sup> Later, MRI was used for the diagnosis of female urethral pathology.<sup>60</sup> Noble and associates<sup>61</sup> used TRUS to compare urethral sphincter volumes in women with obstructed voiding with age-matched controls. The volume of the urethral sphincter in obstructed women was more than 2 cm<sup>3</sup> greater ( $P < .001$ ) than in the control group. TRUS was unable to visualize the three layers of the urethral sphincter, which is elucidated better with MRI.<sup>61</sup> Wiseman and colleagues<sup>62</sup> evaluated urethral closure pressure and sphincter volume transvaginally in women with electromyographic abnormalities and idiopathic urinary retention. The maximum urethral closure pressure and ultrasound volume were significantly higher in the group with electromyographic abnormalities.<sup>62</sup> These studies support the concept of sphincter electromyographic overactivity producing sphincteric hypertrophy. These assessments may be improved with the use of MRI instead of ultrasound for volume measurement.<sup>53</sup>

### Treatment

All management strategies are directed at successful bladder emptying. Successful treatment abolishes the myotonia-like electromyographic activity and improves urethral relaxation. CIC, rather than indwelling or suprapubic cystostomy, is traditionally the option given to many women with idiopathic retention. Other medical and surgical options, such as oral agents, urethral

botulinum toxin, sacral neuromodulation, and biofeedback, have been used. The only treatment that has conclusively restored voiding is sacral neuromodulation.<sup>53</sup>

### Oral Agents

There are limited data on the use of oral agents, such as  $\alpha$ -blockers or  $\beta$ -agonists, in the treatment of functional bladder neck obstruction. In a study of 24 women with retention treated with  $\alpha$ -blockers and initial CIC, only 50% had a significantly sustained improvement in PVR and peak flow. The group that failed  $\alpha$ -blocker treatment returned to CIC or had a bladder neck incision.<sup>63</sup>

The effects of tamsulosin on urethral pressures in healthy women were studied at rest and after sacral magnetic stimulation. Tamsulosin did significantly reduce the mean and maximal urethral pressures acquired in all three segments (i.e., proximal, middle and distal) of the urethra. The amplitude of urethral contractions after sacral magnetic stimulation was unchanged after tamsulosin. These results may support tamsulosin's use in female retention from an overactive or nonrelaxing urethra.<sup>64</sup>

Bethanechol has been used as treatment for retention caused by detrusor acontractility, but it has not been used in women with sphincteric overactivity.<sup>65</sup> Its treatment value is therefore unknown.

### Botulinum A Toxin

There has been mixed success with the use of botulinum toxin in treating chronic urinary retention in women. Botulinum A toxin is an inhibitor of acetylcholine release at the presynaptic neuromuscular junction, which decreases regional muscle contractility and causes muscle atrophy at the site of injection.<sup>66,67</sup> Fowler and coworkers<sup>68</sup> evaluated six women with a characteristic pattern of electromyographic activity by injecting botulinum toxin into each of their striated urethral sphincters. Three of the six women experienced stress incontinence for 10 days, and three had no change. Although the botulinum toxin did not have a beneficial effect, the result of stress incontinence did ensure that sufficient botulinum was given to weaken the striated sphincter muscle. This supported the hypothesis that abnormal sphincteric activity results from an "ephaptic transmission of impulses between muscle fibers" and not repetitive firing of reinnervated motor units.<sup>68</sup>

Phelan and colleagues<sup>66</sup> were the first to report successful outcomes with botulinum A injections in women and in non-neurogenic voiding dysfunction. They studied 21 patients (13 women) with impaired bladder emptying who were dependent on catheterization. All except one were able to void spontaneously after an injection of 80 to 100 units of botulinum toxin.<sup>66</sup> This denervation by botulinum is reversible because new axons sprout in 3 to 6 months.<sup>69</sup> Patients had repeat injections at intervals consistent with this regrowth. In some cases, the injection had clinical efficacy beyond 6 months, suggesting neural plasticity or altered neuromuscular junction dynamics.<sup>69</sup> Kuo and associates<sup>70</sup> repeated this study in 20 patients with urinary retention or dysuria due to detrusor hypocontractility and nonrelaxing urethral sphincter who were refractory to conservative therapy. This study clearly showed that botulinum toxin is effective in decreasing urethral sphincter resistance and improving voiding efficiency in patients with various type of lower urinary tract dysfunction.<sup>70</sup> Botulinum A toxin injections do have therapeutic value in urethral spasticity, but larger, controlled trials are necessary to establish their role.<sup>71</sup>

Tanagho and Schmidt<sup>72</sup> are responsible for the first implantable sacral nerve stimulators (SNSs). The effects of SNSs depend on the electrical stimulation of somatic afferent axons in spinal roots, which modulate voiding and continence reflex pathways in the central nervous system. In urinary retention, SNSs are responsible for turning off excitatory outflow to the urethral outlet, which promotes bladder emptying.<sup>73</sup> Traditionally, a test percutaneous nerve evaluation is performed under local anesthesia by inserting a stimulating electrode through the S3 foramen. This lead is left in place for 4 to 7 days, during which a voiding diary is kept. If the patient has a more than 50% improvement in voiding function, the implant is considered effective, and a permanent implantable pulse generator (IPG) is placed.

Recognized complications of neuromodulation include lead migration, pain at the IPG box site or ipsilateral leg, infection, and lack of efficacy.<sup>53</sup> To improve the efficacy of chronic sacral neuromodulation, the placement of bilateral SNSs has been proposed. Scheepens and colleagues<sup>74</sup> compared unilateral with bilateral SNSs in a series of women with urinary retention and found no significant differences, except for two patients with complete obstruction, who voided only with bilateral stimulation.

### Sacral Neuromodulation

Sacral neuromodulation has been shown in many studies to restore voiding function in women with urinary retention. The results of peripheral nerve evaluation testing in 34 patients with Fowler's syndrome revealed an overall success rate of 68%. This compares favorably with a reported success rate of 30% to 50% for the period of trial stimulation of all lower urinary tract dysfunctions.<sup>75</sup> Shaker and Hassouna<sup>76</sup> treated 20 patients (19 women) with idiopathic, nonobstructing, chronic urinary retention dependent on CIC who had at least a 50% improvement on percutaneous nerve evaluation screening. These patients were followed for a mean of 15.2 months and had significant improvement in voiding function, pelvic pain, and sensation of emptiness after voiding. The study authors emphasize that the lack of change in cystometrography after SNS implantation indicates that the cause of the problem is not the bladder but the pelvic floor musculature.<sup>76</sup>

Investigators have reported good results after SNS when there are pelvic floor electromyographic activity abnormalities. Their explanation is that patients with chronic urinary retention fail to identify their pelvic floor muscles and are incapable of relaxing the pelvic floor to initiate the voiding reflex. The permanent contraction of the pelvic floor is thought responsible for detrusor inhibition. Neuromodulation provides increased awareness of the pelvic floor and allows relaxation of the hypertonic pelvic floor musculature. The mechanism involves sacral stimulation of presynaptic inhibition of afferents to the spastic muscle motor neurons at the level of the dorsal column.<sup>77-80</sup>

A prospective, randomized, multicenter trial enrolled 177 patients with urinary retention (74% were female), with a follow-up of 18 months. Sixty-eight of these women qualified for an IPG and were divided into treatment and control groups. At 6 months, 83% of the implant groups had successful results, compared with 9% of the controls. Temporary inactivation of the SNS resulted in a significant increase in the PVR volume. This supports the idea that the SNS does not cure the underlying mechanism of urinary retention, but instead controls aberrant dysfunctional reflexes causing voiding dysfunction.<sup>77,81</sup>

Dasgupta and colleagues<sup>82</sup> provided long-term results of SNSs in women with Fowler's syndrome. This retrospective study included 26 women who were followed for more than 6 years. Seventy-seven percent were voiding successfully more than 5 years postoperatively; 54% required revision surgery. The longevity of an IPG battery is 7 to 10 years. This study supported the effectiveness of SNSs for at least 5 years after implantation.<sup>82</sup>

### Behavioral Treatment and Biofeedback

Behavioral and biofeedback treatments are safe, noninvasive, and effective interventions that are useful in the management of idiopathic urinary retention. Behavioral changes enlighten patients about their fluid intake and voiding behavior. Biofeedback involves surface or internal (vaginal or rectal) electrodes that transduce muscle potentials into auditory or visual signals. This helps the patient learn to increase or decrease voluntary muscle activity.<sup>83</sup>

### CONCLUSIONS

There are many neurogenic and non-neurogenic causes of urinary retention in the female patient. Idiopathic urinary retention and Fowler's syndrome should be considered in any young female with insidious, painless retention and urethral sphincter overactivity identified on electromyography. The diagnosis combines a thorough history with abnormal electromyographic and urodynamic findings. Sacral neuromodulation offers the best option in restoring voiding function. Although the exact mechanism of action of sacral stimulation is not established, evidence supports action through the afferent pathways. Other accessory treatment options, such as botulinum and tamsulosin, have some therapeutic merits, but they require larger, long-term, case-controlled studies in women with urethral overactivity. Behavioral modification and biofeedback are safe and effective and should be considered as first-line treatment for voiding dysfunction.

# CLINICAL DIAGNOSIS OF OVERACTIVE BLADDER

*Samih Al-Hayek and Paul Abrams*

### TERMINOLOGY

Overactive bladder (OAB) is a newly described condition. It was probably first alluded to by Dudley in 1905 when he distinguished between active and passive incontinence due to sphincter weakness.<sup>1</sup> In 1917, Taylor and Watt reported the importance of urgency, as a symptom, during history taking, to distinguish incontinence with and without urgency.<sup>2</sup> Bates and colleagues introduced the term *unstable bladder* in 1970 when they used cinecysturethrography to investigate urge incontinence.<sup>3</sup>

The International Continence Society (ICS) established a committee for the standardization of terminology of lower urinary tract function to facilitate comparison of results and enable effective communication by investigators. Since 1976, a large number of standardization reports have been published, the latest in 2002.<sup>4-19</sup>

In 2002, the ICS subcommittee restated the principle of describing any lower urinary tract dysfunction from four aspects: as a symptom (taken by detailed history), a sign (physical examination and bedside tests), a condition, and a urodynamic observation in addition to the terminology related to therapies.<sup>1</sup>

The lower urinary tract is composed of the bladder and the urethra. When reference is made to the whole anatomic organ, “vesica urinaria,” the correct term is *bladder*. When the smooth muscle structure known as the “m. detrusor urinae” is being discussed, the correct term is *detrusor*.

OAB was defined by the ICS in 2002 as urgency, with or without urge incontinence, usually with frequency and nocturia, in the absence of local pathologic or endocrine factors.

The OAB term was introduced for use in a consensus conference in 1996, as an alternative to “unstable bladder.” It was believed that the term “overactive bladder” would facilitate communication between patients and health care staff.

OAB symptoms are part of the storage symptoms that are experienced during the storage phase of the bladder and include the following:

- *Urgency* is the complaint of a sudden compelling desire to pass urine that is difficult to defer.
- *Increased daytime frequency* is the complaint by the patient who considers that she voids too often by day. This term is equivalent to “pollakisuria,” a term used in many countries.
- *Nocturia* is the complaint that the patient has to wake at night one or more times to void. The term *nighttime frequency* differs from nocturia, because it includes voids that occur after the patient has gone to bed but before he or she has gone to sleep, as well as voids that occur in the early morning and prevent the patient from getting back to sleep as he or she wishes. These voids before and after sleep may

need to be considered in research studies (e.g., nocturnal polyuria). If this definition were used, then an adapted definition of daytime frequency would need to be used with it.

- *Urinary incontinence* (UI) is the complaint of any involuntary leakage of urine. In each specific circumstance, UI should be further described by specifying relevant factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, measures used to contain the leakage, and whether the patient seeks or desires help because of UI. Urinary leakage may need to be distinguished from sweating or vaginal discharge.
- *Urgency urinary incontinence* (UUI) is the complaint of involuntary leakage accompanied by or immediately preceded by urgency. UUI can manifest in various symptomatic forms; for example, as frequent small losses between micturitions or as a catastrophic leak with complete bladder emptying.

These symptom combinations of OAB are suggestive of *detrusor overactivity* (DO), a urodynamic diagnosis, which is characterized by involuntary detrusor contractions during bladder filling; it may be spontaneous or provoked. Figure 17-1 represents the relationships among OAB, UUI, and DO.

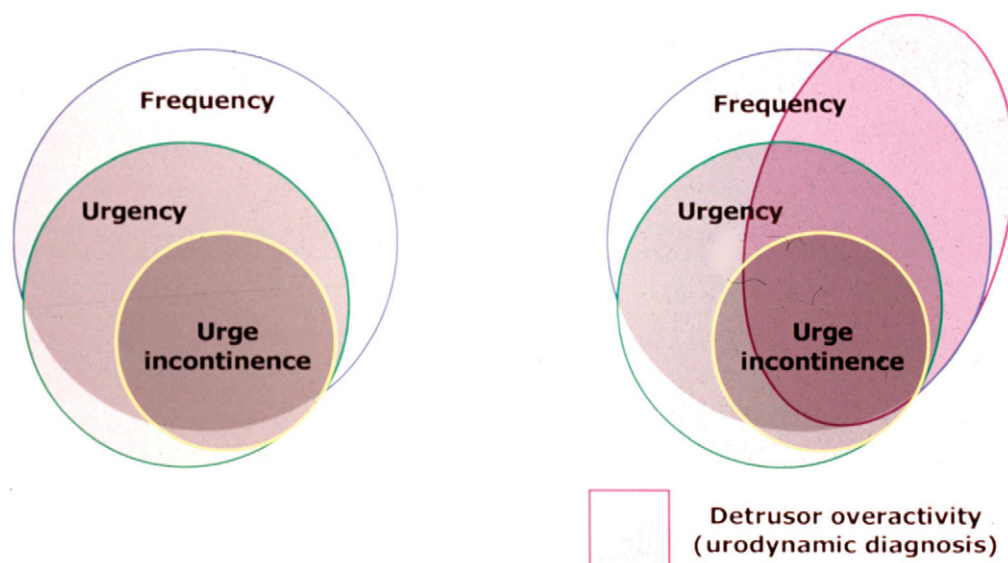

### EPIDEMIOLOGY

Until recently, most studies have looked at the prevalence of UI; as a result, prevalence data on OAB are lacking. The other difficulty in estimating the scale of the problem is the variation among studies in definitions used, methods of collecting data, and populations studied.

Almost all surveys on UI concluded that stress urinary incontinence (SUI) is the most common type of UI in women. In the large Epidemiology of Incontinence in the County of Nord-Trøndelag (EPINCONT) study, 50% of the incontinent women had SUI, 36% had mixed urinary incontinence (MUI), and 11% had UUI.<sup>20</sup> The recent literature review by Minassian and colleagues reported similar prevalence rates for the various types of UI.<sup>21</sup> The survey carried out by Diokno and associates<sup>22</sup> showed that symptoms of MUI were most frequently reported; however, this study differed from the others in that only elderly people were assessed.

The results of these studies were based on symptoms only; if urodynamics had been used to confirm the diagnosis, the results might have been different. In one study with 863 women, most of the subjects with symptoms of MUI were diagnosed to have pure SUI (42%) during urodynamic testing.<sup>23</sup> Weidner and

**Figure 17-1** The relationships among symptoms of overactive bladder (OAB), urgency urinary incontinence (UUI), and detrusor overactivity (DO).

Sanvik and their colleagues showed similar results.<sup>24,25</sup> This reinforces the fact that SUI is the major type of UI in women.

A large population-based survey that was conducted in France, Germany, Italy, Spain, Sweden, and the United Kingdom defined OAB as the presence of chronic frequency, urgency, and urge incontinence (either alone or in any combination). This definition is somewhat different from the new ICS definition, which uses urgency as the cornerstone of the diagnosis. The authors reported that the overall prevalence of OAB symptoms in subjects aged 40 years or older was 16.6%. Frequency (85%) was the most commonly reported symptom, followed by urgency (54%) and urge incontinence (36%). The prevalence of OAB symptoms increased with advancing age. Overall, 60% of respondents with symptoms had consulted a doctor, but only 27% were currently receiving treatment.<sup>26</sup>

The National Overactive Bladder Evaluation (NOBLE) Program that was undertaken in the United States used the new ICS definition from 2002 in a clinically validated interview and a follow-up nested study. A sample of 5204 adults aged 18 years or older was studied. The overall prevalence of OAB was similar between men (16.0%) and women (16.9%), but sex-specific prevalence differed substantially by severity of symptoms: 55% of the women with OAB symptoms had OAB associated with urge incontinence (“wet OAB”), and the rest had OAB without incontinence (“dry OAB”). In women, prevalence of urge incontinence increased with age, from 2.0% among those 18 to 24 years of age to 19% among those 65 to 74 years of age, with a marked increase after 44 years of age. However, the dry OAB tended to have gradual increase before 44 years of age and reached a plateau at that point. The prevalence of urge incontinence increased in relation to increased body mass index across all age groups. Dry OAB was more common in men than in women.

The NOBLE study does not support the commonly held notion that women are considerably more likely than men to have urgency-related symptoms. However, sex-specific anatomic differences may increase the probability that OAB is expressed as urge incontinence among women compared with men.<sup>27</sup> The

prevalence of OAB among women in this study was higher than what was reported by Milsom<sup>26</sup> but similar to the prevalence of UI reported by Simeonova<sup>28</sup> and by Samuelsson (20- to 59-year-olds).<sup>29</sup>

Not all studies distinguish wet from dry OAB. On average, urgency without UI appears to be as common as urgency with UI (Table 17-1).

## EVALUATION

### History

Because OAB is a symptomatic diagnosis, history plays an important part in assessing the patient. The purpose of the clinical history is to have an empiric diagnosis, to exclude other causes for the patient’s symptoms, and to assess the effects of the problem on the patient’s daily activities that would help in deciding the treatment strategy. Excluding secondary causes is important; these include diabetes, congestive heart failure, bladder cancer, urinary tract infection (UTI), medications, and pregnancy or recent birth.

Questions should include details of the following:

- Nature and duration of symptoms
- Which symptoms are most bothersome
- Current management, including pad usage
- Previous medical or surgical treatment for the condition
- History of radiation exposure
- Environmental issues
- Patient mobility
- Mental status
- Other disease status, especially neurologic conditions (stroke, trauma)
- Patient medication
- Sexual function
- Bowel function, bearing in mind that irritable bowel syndrome may be associated with OAB<sup>35</sup>

**Table 17-1 Prevalence of Urgency and Urgency Urinary Incontinence (UII) in Community-Dwelling Women\***

First Author and Ref. No.	Year	Age (yr)	Sample size	Definition of urgency or UII	Prevalence of urgency (%)	Prevalence of UII (%)	Ratio <sup>†</sup>
Swithinbank <sup>30</sup>	1999	19+	2,075	Any	61	46	1.3
Lapitan <sup>31</sup>	2001	18+	5,502	Any	35	11	3.2
Milsom <sup>26</sup>	2001	40+	16,776	Current	54	36	1.5
Van Der Vaart <sup>32</sup>	2002	20-45	1,393	Any	45	15	3.0
Chen <sup>33</sup>	2003	20+	1,253	Any	13	9	1.4

\*There are few data on the incidence of new cases of overactive bladder (OAB), the incidence of new cases of detrusor overactivity (DO), or the natural history of established cases of OAB or DO (or the combination of both).

<sup>†</sup>Overall median: 2.1.

From Hunksaar H, Burgio K, Diakno AC, et al: Epidemiology and natural history of urinary incontinence. In Abrams P, Cardozo L, Khoury S, Wein A (eds): Incontinence. Plymouth, UK, Health Publication Ltd., 2002, pp 515-551.

- Gynecologic and obstetric history, especially pelvic organ prolapse
- The effect of the condition on daily activity (social restriction, reduced physical activities)
- Patient's goals or expectations of treatment
- Patient's fitness for possible surgical procedures
- For a complicated history, other symptoms, such as the presence of pain or hematuria

## Quantification of Symptoms

### Questionnaires

Taking a detailed history from the patient depends to a great deal on the physician's skills. The questions, and the aspects tackled, are different for each clinician. Another issue is the embarrassment of the patient, which can lead her to avoid talking about some or all of her symptoms. In addition, clinicians tend to rate the patient's quality of life lower than the patients themselves do.<sup>36</sup> For all of these reasons, patient-completed questionnaires were developed. They provide details regarding the presence of symptoms, their frequency, their severity, and the bother caused to the patient. Questionnaires also assess quality of life in general and in relation to the symptoms. In theory, validated questionnaires can be used for making the diagnosis, as a tool in prevalence studies, and to measure the outcome of treatment.

Several questionnaires have been developed to assess UI. The modular International Consultation on Incontinence Questionnaire (ICIQ) has been validated and includes modules for lower urinary tract symptoms (LUTS) as well as OAB.<sup>37</sup> ICIQ-OAB is a short form based on the Bristol Female Lower Urinary Tract Symptoms Questionnaire (BFLUTS) and should be a helpful tool in assessing these patients (Box 17-1).<sup>38,39</sup> The full list of ICI questionnaires may be found by visiting the web site, [www.icicq.net](http://www.icicq.net).

### Fluid Input/Output Charts

Asking the patient to record each micturition for a period of days provides valuable information. For some women, it may be therapeutic, because it provides them with insight into their bladder behavior. Micturition events can be recorded in three main forms:

- *Micturition time chart*: records only the times of micturitions, day and night, for at least 24 hours.

### Box 17-1 Questions Included in the International Consultation on Incontinence Modular Questionnaire on Overactive Bladder

Do you have to rush to the toilet to urinate?  
Does urine leak before you can get to the toilet?  
How often do you pass urine during the day?  
During the night, on average, how many times do you have to get up to urinate?  
Do you have a sudden need to rush to the toilet to urinate?  
Does urine leak after you feel a sudden need to go to the toilet?

- *Frequency-volume chart (FVC)*: records the volumes voided as well as the time of each micturition, day and night, for at least 24 hours.
- *Bladder diary*: records the times of micturitions and voided volumes, incontinence episodes, pad usage, and other information such as fluid intake, degree of urgency, and degree of incontinence.

It is useful to ask the patient to make an estimate of liquid intake in a 24-hour period. Consumption of significant quantities of water-containing foods (vegetables, fruit, and salads) should be taken into account. The time at which any diuretic therapy is taken should be marked on the chart or diary.

The following measurements can be abstracted from FVCs and bladder diaries using the 2002 ICS definitions<sup>40</sup>:

- *Daytime frequency* is the number of voids recorded during waking hours and includes the last void before sleep and the first void after waking and rising in the morning.
- *Nocturia* is the number of voids recorded during a night's sleep: each void is preceded and followed by sleep.
- *24-Hour frequency* is the total number of daytime voids and episodes of nocturia during a specified 24-hour period.
- *24-Hour production* is measured by collecting all urine for 24 hours. This is usually commenced after the first void produced after rising in the morning and is completed by including the first void produced after rising the following morning. *Polyuria* is defined as the measured production of more than 2.8 L of urine in 24 hours in adults. It may be useful to look at output over shorter time frames.<sup>41</sup>

- *Nocturnal urine volume* is defined as the total volume of urine passed between the time the patient goes to bed with the intention of sleeping and the time of waking with the intention of rising. Therefore, it excludes the last void before going to bed but includes the first void after rising in the morning. *Nocturnal polyuria* is present when an increased proportion of the 24-hour output occurs at night (normally during the 8 hours while the patient is in bed). The nighttime urine output excludes the last void before sleep but includes the first void of the morning. The normal range of nocturnal urine production differs with age, and the normal ranges remain to be defined. Therefore, nocturnal polyuria is present when greater than 20% (young adults) to 33% (>65 years) is produced at night. Hence, the precise definition is dependent on age.
- *Maximum voided volume* is the largest volume of urine voided during a single micturition and is determined from the FVC or bladder diary. The term “functional bladder capacity” is no longer recommended by the ICS, because “voided volume” is a clearer and less confusing term, particularly if qualified (e.g., “maximum voided volume”). If the term “bladder capacity” is used, in any situation, it implies that this has been measured in some way, if only by abdominal ultrasonography. In adults, voided volumes vary considerably.

In OAB /DO, the patient has reduced variable volumes of urine during the day. The nighttime volumes and the first void on waking in the morning are often larger and of normal quantity.<sup>42</sup>

In a recent study, the authors correlated the patients' symptoms of frequency, urgency, nocturia, and urge incontinence with the parameters on the bladder diary. They found that frequency and urgency symptoms were associated with a higher 24-hour frequency, lower maximum volume voided, and lower mean voided volume.<sup>43,44</sup>

There has been wide variation in the number of days over which the patient is complete a bladder diary, ranging from 1 day to 2 weeks, with 7 days probably being the previous “gold standard.” A recent study by Schick and coworkers indicated that a 4-day chart in women is as reliable as a 7-day chart. They suggested that a 4 day chart optimizes patients' compliance without compromising the diagnostic value of the FVC.<sup>45</sup>

It is advised that a simple FVC with the additional recording of incontinent episodes, pad usage, and overall assessment of fluid intake be used for routine clinical use. In a research setting, urinary diaries may add significant additional information, allowing a more complete evaluation of novel therapies.<sup>45</sup>

### Quality of Life Assessment

Severe OAB is a disabling condition that may render the patient housebound to avoid the embarrassment of leakage episodes. Assessing the severity and the impact of the symptoms on the patient's daily activity is an essential part of evaluating these patients. OAB symptoms can have an effect on the psychological, occupational, and sexual function of the patient.<sup>46</sup> In the study by Milsolm and colleagues, 67% of women with OAB reported that their symptoms had a deleterious effect on daily living.<sup>26</sup> The OABqol is a quality-of-life questionnaire that is specifically designed to assess the effect of OAB on the patients' life.<sup>47</sup>

### Physical Examination

In addition to the general examination, there are a number of other essential components in the examination of patients with OAB:

*Abdominal examination* after voiding in an effort to detect a palpable bladder or abnormal masses.

*Focused neurologic examination*, in particular of the lower limbs, looking for any focal signs that might suggest a neurologic cause for OAB. Patients with a history suggestive of possible neurogenic OAB require a more extensive neurologic examination.

*Rectal examination* to assess anal tone, pelvic floor function, and the consistency of stool as a sign of constipation.

*External genitalia and perineal examination* allows inspection of the skin (e.g., atrophy, excoriation) or any abnormal anatomic features. In addition, the area should be tested for normal sensation

*Vaginal examination* to assess pelvic organ prolapse, with the patient bearing down, and pelvic floor function as described in the ICS report on Pelvic Organ Prolapse.<sup>48</sup> Pelvic floor muscle function can be qualitatively defined by the tone at rest and the strength of a voluntary or reflex contraction (strong, weak, or absent) or by a validated grading system (e.g., modified Oxford scale).<sup>49</sup> A pelvic muscle contraction may be assessed by visual inspection, palpation, electromyography, or perineometry. Factors to be assessed include strength, duration, displacement, and repeatability. Changes due to lack of estrogen should also be noted

### Simple Investigations

#### Urinalysis

Because UTI is a readily detected and easily treatable cause of LUTS, urine testing is highly recommended. Patients with UTI often suffer from frequency and have urgency to pass urine, with nocturia and sometimes urge incontinence that mimics OAB. Therefore, all patients with OAB should have their urine tested to exclude UTI. Testing may range from examination of urine in a clear glass container, to dipstick testing, to urine microscopy.

#### Estimation of Postvoid Residual Urine

In patients with suspected voiding dysfunction, the postvoid residual urine (PVR) estimation is part of the initial assessment. The result is likely to influence management; for example, in patients with neurologic disorders. PVR can be estimated by noninvasive methods such as the standard ultrasound scan or hand-held bladder scan, or invasively with the use of a urethral catheter; the latter method has the advantage of taking a clean specimen of urine for microbiologic testing.

### Urinary Tract Imaging

Routine imaging of the urinary tract in patients with OAB symptoms is not recommended. However, if the history or the initial assessment indicate a complex problem or is suspicious for an associated pathology, then imaging could be used to exclude it. To start with, an ultrasound scan or plain radiographic study should be used.

Imaging of the lower urinary tract is recommended in those women with suspected lower tract or pelvic pathology (e.g., bladder stone, pelvic mass).

Imaging of the upper urinary tract is recommended only in specific situations, including

- Neurogenic UI (e.g., myelodysplasia, spinal cord trauma)
- Incontinence associated with significant PVR
- Coexistent loin or kidney pain
- Severe pelvic organ prolapse, not being treated
- Suspected extraurethral UI
- Hematuria

### Invasive Investigations

Invasive investigations are used only after the initial workup has failed to make the diagnosis.

#### Endoscopy

Flexible or rigid cystoscopy has a limited role in patients with pure symptoms of OAB unless other pathology is suspected. Hence, endoscopy is recommended in the following situations:

- When initial testing suggests other pathologies, such as microscopic hematuria (possibility of bladder tumor)
- When pain or discomfort occurs in a patient with OAB (suggesting a possible intravesical lesion)

#### Urodynamics

There is some controversy in regard to the use of urodynamic testing in patients with LUTS, particularly those with OAB, based on several issues:

- Urodynamics is an invasive test with possible side effects, mainly UTI.
- The test is uncomfortable and could be embarrassing for the patient.
- The test has a considerable false-negative rate.

Urodynamic evaluation is recommended in the following situations:

- Before invasive treatments
- After treatment failure
- As part of a long-term surveillance program in neurogenic OAB
- In "complicated incontinence"

The aims of routine urodynamic evaluation are

- The detection of detrusor overactivity
- The assessment of urethral competence during filling
- The determination of detrusor function during voiding
- The assessment of outlet function during voiding
- The measurement of residual urine

It is recommended that routine urodynamic evaluation should consist of

- Filling cystometry (with provocation, and tailored to the individual patient's requirements)
- Voiding cystometry

The symptom combinations of OAB are suggestive of urodynamically demonstrable DO, which is characterized by involuntary detrusor contractions during bladder filling that may be spontaneous or provoked. Provocative maneuvers are defined as techniques used during urodynamics in an effort to provoke detrusor overactivity, such as rapid filling, use of cooled or acid medium, postural changes, and hand washing.

DO incontinence is incontinence caused by an involuntary detrusor contraction. In a patient with normal sensation, urgency is likely to be experienced just before the leakage episode. ICS recommends that the terms "motor urge incontinence" and "reflex incontinence" should no longer be used, because they have no intuitive meaning and are often misused.

In everyday life, the patient attempts to inhibit detrusor activity until he or she is in a position to void. Normally, after the aims of the filling study have been achieved and the patient has a desire to void, the "permission to void" is given. That moment is indicated on the urodynamic trace, and all detrusor activity before this point of "permission" is defined as "involuntary detrusor activity."<sup>40</sup>

Normal detrusor function allows bladder filling with little or no change in pressure. No involuntary phasic contractions occur despite provocation. There is no lower limit for the amplitude of an involuntary detrusor contraction, but confident interpretation of low-pressure waves (amplitude <5 cm H<sub>2</sub>O) depends on "high-quality" urodynamic technique. The phrase "which the patient cannot completely suppress" has been deleted from the old definition.

#### Classification of Detrusor Overactivity

DO can be phasic or terminal, idiopathic or neurogenic, symptomatic or asymptomatic. There are certain patterns of DO:

- *Phasic DO* is defined by a characteristic wave form and may or may not lead to UI. Phasic detrusor contractions are not always accompanied by any sensation, or they may be interpreted as a first sensation of bladder filling or as a normal desire to void.
- *Terminal DO* is defined as a single, involuntary detrusor contraction, occurring at cystometric capacity, that cannot be suppressed and results in incontinence, usually leading to bladder emptying (voiding). This is a new ICS term; it is typically associated with reduced bladder sensation; for example, in the elderly stroke patient, when urgency may be felt as the voiding contraction occurs. However, in patients with complete spinal cord injury, there may be no sensation whatsoever.

DO may also be qualified, when possible, according to cause:

- *Neurogenic DO* is the term used when there is a relevant neurologic condition; it replaces the term "detrusor hyperreflexia."
- *Idiopathic DO* is the term used when there is no defined cause; it replaces the term "detrusor instability."

The terms "detrusor instability" and "detrusor hyperreflexia" were both used as generic terms, in the English speaking world and in Scandinavia, before the first ICS report in 1976. As a compromise, they were allocated to idiopathic and neurogenic overactivity, respectively. Because there is no real logic or intuitive meaning to the terms, the ICS believes they should be abandoned.

Other patterns of DO are seen, such as the combination of phasic and terminal DO and the sustained high-pressure detrusor contractions seen in patients with spinal cord injury when attempted voiding occurs against a dyssynergic sphincter.

## CONCLUSIONS

Patients with OAB symptoms should be assessed systematically, should be investigated according to treatment intentions, and

# PATHOPHYSIOLOGY OF OVERACTIVE BLADDER

*William D. Steers and Adam P. Klausner*

The term *overactive bladder* (OAB) refers to the symptom complex of urgency, usually with frequency, and nocturia, with or without urge urinary incontinence. However, this definition, supported by the International Continence Society subcommittee on terminology,<sup>1</sup> is based on expert opinion and fails to account for causation or pathophysiology. Initially limited to the idiopathic condition, the term OAB has been used to describe the described constellation of symptoms regardless of their etiology. The term has gained widespread acceptance by the nonmedical community as well as health care professionals. Furthermore, there has been a dramatic increase in awareness of OAB because of marketing strategies focused on patient-directed advertising of pharmaceutical products. This chapter reviews the causes of OAB and describes possible linkages with other conditions that may provide insight into its pathogenesis. By shedding light on the pathophysiology of OAB, we hope to highlight new targets for therapeutic intervention and directions for further investigation.

The bladder functions as a cohesive unit for the purpose of urine storage and elimination. Several disparate elements contribute in concert to yield normal bladder function. These elements include the detrusor muscle, the urothelium, the vascular supply, interstitial cells, and innervation. A balance between these elements is requisite for normal bladder function. General factors such as mechanical obstruction, inflammation, injury, and the psychological state of the host can alter this balance and lead to OAB (Fig. 18-1). Specific etiologic entities of known importance in the pathophysiology of OAB, such as urinary tract infections, interstitial cystitis, benign prostatic obstruction, spinal cord injury, transitional cell carcinoma, and anxiety disorders, can be viewed as distinct “perturbations” that affect one or more of these elements. The end result is often the symptom complex known as OAB.

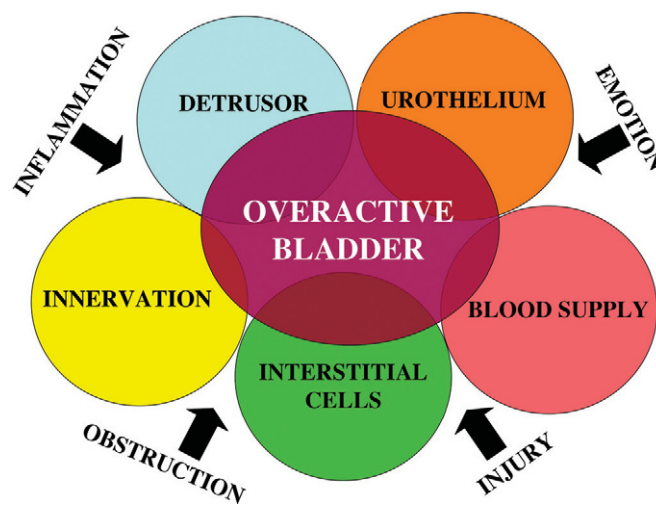

Experimental data continue to reveal that, with time, an alteration in one cell type often leads to changes in other cell types. Therefore, a single explanation for the pathophysiology of OAB is unlikely.

## EPIDEMIOLOGY

A detailed review of the epidemiology of OAB is beyond the scope of this review. However, a few key points are worth mentioning. The first is that the prevalence of OAB has generally been underestimated, because many studies have been limited to patients with incontinence, which is only one subset of OAB. The second is that, contrary to popular belief, the prevalence of OAB is similar in men and women. The third is that OAB is a chronic condition that adversely affects the quality of life.

Several well-done, large-scale studies have attempted to provide solid epidemiologic data for OAB. In a European study spanning six nations, telephone interviews of subjects older than 40 years of age were used to determine OAB prevalence. In this study, OAB was defined as urinary frequency greater than eight times per day and urgency, with or without urge incontinence. Using this definition, the prevalence of OAB was found to be 16.6%.<sup>2</sup> Symptoms increased with advancing age and, surprisingly, were of similar prevalence in men (15.6%) and women (17.4%). In addition, 40% of those who met criteria for OAB had never sought medical care for this condition. Of the 60% who had spoken to a physician, only 27% were currently taking medication to control their symptoms.

In an OAB prevalence study conducted in the United States, strikingly similar results were found. The overall prevalence of OAB was 16.0% in men and 16.9% in women.<sup>3</sup> Based on the combined results of these works, a reasonable estimate for the prevalence of OAB is approximately 17% of the adult female population. These studies highlight the relatively high prevalence of OAB, the substantial degree of underreporting, and the possibility of poor treatment efficacy. Although the epidemiology of OAB is complex, these numbers emphasize the dramatic social and economic impact of this condition.

**Figure 18-1** Diagram showing intrinsic and extrinsic factors that may contribute to the pathophysiology of overactive bladder (OAB). Substantial overlap between factors suggests that a single etiology for OAB is unlikely.

## CONTRIBUTORS TO OVERACTIVE BLADDER

### Role of the Detrusor Muscle

Most experimental research pertaining to OAB, urge incontinence, and detrusor overactivity (DO) has relied on increased detrusor contractions on cystometry as a surrogate for this disorder. Insight into urgency is lacking. In addition, the clinical findings that almost a quarter of patients with OAB and urge incontinence do not demonstrate DO on urodynamic testing<sup>4</sup> and, conversely, that almost a quarter of asymptomatic men and women demonstrate DO suggest that this symptom complex may not universally affect the detrusor per se.<sup>5-7</sup> This observation may explain in some patients the lack of efficacy of drugs such as antimuscarinics that target receptors on the detrusor.

### Autonomous Activity

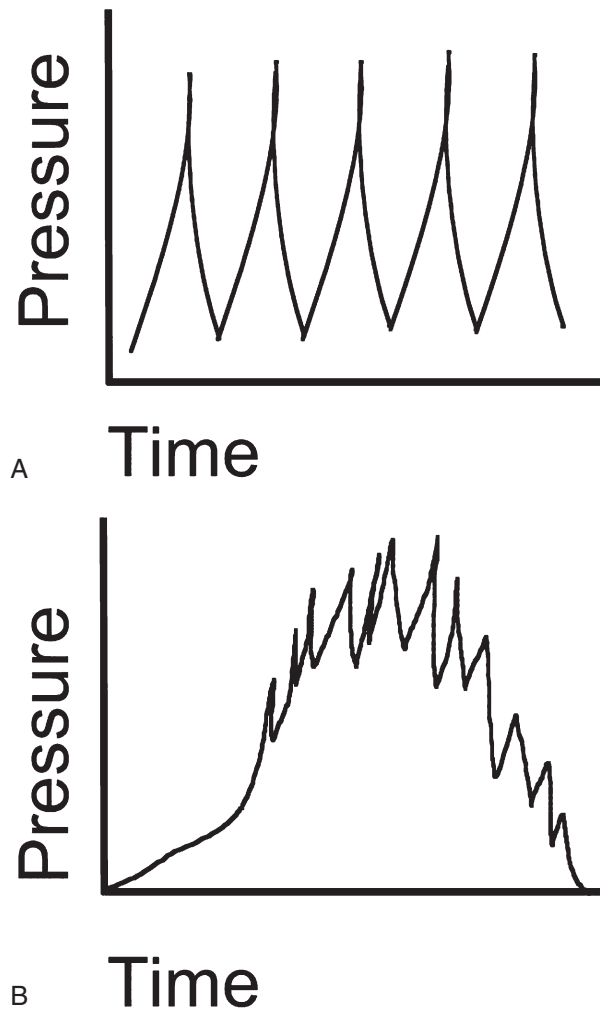

New research in detrusor physiology has added to our understanding of how this muscle contracts in a coordinated fashion. In a study by Gillespie and colleagues,<sup>8</sup> two distinct types of detrusor muscle activity were identified—phasic activity and global contractions (Fig. 18-2). During phasic activity, small regions of the detrusor muscle undergo localized “stretches” that are associated with phasic increases in bladder pressure. The investigators found that these phasic responses were triggered by low-dose muscarinics, low-dose nicotincs, and low-frequency nerve stimulation. In contrast, during global contractions, most of the bladder smooth muscle is involved. These global contractions were triggered by high-dose muscarinics and high-frequency nerve stimulation and were unresponsive to nicotincs. Immunohistochemistry confirmed the presence of two distinct smooth muscle cell populations. A thin layer of cells was found to reside just beneath the bladder mucosa. A larger layer was found to comprise the bulk of the detrusor. The authors postulated that the thin, submucosal layer may be responsible for autonomous pacemaker activity in the bladder, and the remaining detrusor may be responsible for the classically understood parasympathetic nerve–stimulated bladder contraction.

### Interstitial Cells

Interstitial cells with spontaneous pacemaker activity have been found in gut smooth muscle. In the gut, these pacemaker cells, known as interstitial cells of Cajal (ICCs), have been identified by their immunohistochemical (Kit-positive) and morphologic (presence of dendritic processes) properties. The search for these cells in the bladder dome has been prompted by research showing bladder electrical waves that start at the dome and propagate in a caudad fashion.<sup>9,10</sup> Shafik and coworkers<sup>9</sup> identified cells with these characteristics in bladder strips harvested from cystectomy specimens obtained from patients with bladder cancer. ICC cells were found to exist in isolation or in interconnected networks in the bladder dome of all specimens. The authors suggested that changes in the number or functionality of this cell population may be important in motility disorders involving the bladder.

### Electrical Properties of the Detrusor

Tissue from unstable bladder shows enhanced spontaneous contractile activity. This has been documented in human bladder strips from obstructed unstable bladders<sup>11,12</sup> and from those with neuropathy.<sup>13</sup> However, depending on the etiology of OAB, important differences exist. In both idiopathic DO and obstruction, bladder strips demonstrate increased sensitivity to

**Figure 18-2** Comparison of phasic and global bladder contractions. **A**, During phasic contractions, localized stretches lead to short, nonsustained bursts of increased bladder pressure. **B**, During global contractions, the majority of detrusor muscle is involved, and a sustained rise in bladder pressure is observed.

**Table 18-1** Electrical Properties of the Detrusor Muscle in Overactive Bladder (OAB)

Property	Idiopathic OAB	OAB of Obstruction
Spontaneous activity	↑	↑
KCl <sup>-</sup> sensitivity	↑	↑
Response to electrical stimulation	↓	↓
Response to muscarinics	Normal	↑

potassium chloride and reduced response to electrical stimulation.<sup>11,12,14,15</sup> However, strips from obstructed bladders appear to be supersensitive to muscarinic agonists, whereas strips from bladders with idiopathic DO do not demonstrate this response (Table 18-1).<sup>11,12</sup>

Increased electrical coupling has been identified in bladders with OAB. Gap junctions are believed to be important in the

**Figure 18-3** Mechanism of overactive bladder (OAB) initiated by local distortions (LD) in the bladder wall. In the normal bladder (*left*), lack of coupling limits the spread of activity initiated by LD. In OAB (*right*), increased coupling allows LD to propagate. Accordingly, in the setting of increased coupling, LD could lead to involuntary contractions.

electrical coupling of detrusor smooth muscle cells. In a study by Haferkamp and associates,<sup>16</sup> increased gap junction expression was identified by testing for the gap junction marker, connexin-43. Biopsy specimens from patients with neurogenic DO were compared to control specimens obtained from women with pure stress urinary incontinence. Connexin-43 RNA expression was determined by using a polymerase chain reaction method. A statistically significant increase in connexin-43 RNA was found in specimens from patients with neurogenic DO. These results suggest that increased electrical coupling via heightened expression of gap junctions may be important in the pathophysiology of certain forms of OAB.

One theory of OAB is based on the observation<sup>17</sup> that localized distortions of the bladder wall occur during filling. These distortions are probably activated by sporadic populations of low-threshold postganglionic parasympathetic neurons. In the normal detrusor, poor coupling between smooth muscle bundles would limit the spread of this activity, and only a localized distortion of the bladder wall would occur. However, in the setting of increased coupling, as seen in OAB, localized distortions would spread throughout the bladder (Fig. 18-3). In this scenario, intravesical pressure would rise, and involuntary contractions might occur.

### Morphologic Changes

Morphologic changes in the structure of the detrusor muscle have also been identified in the setting of OAB. Patchy denervation of muscle bundles can be identified. Furthermore, areas of reduced innervation become infiltrated with connective tissue, and, after complete denervation, smooth muscle cell hypertrophy occurs.<sup>18</sup> At the ultrastructural level, detrusor muscle that demonstrates OAB contains protrusion junctions and ultra-close abutments between myocytes. This ultrastructural pattern is not typically present in normal detrusor muscle and may represent an additional mechanism through which increased electrical coupling in OAB might occur (Table 18-2).<sup>19</sup>

**Table 18-2** EMorphologic Changes in the Detrusor Muscle in Overactive Bladder (OAB)

Cellular Level	Ultrastructural Level
Connective tissue infiltration	Increased protrusion junctions
Smooth muscle cell hypertrophy	Increased ultra-close myocyte abutments
Patchy denervation	Increased gap junctions (connexin-43)

### Role of the Urothelium

The previous notion of the urothelium as an inert, impermeable barrier has been challenged in recent years. New research focuses on the urothelium as a biologically active layer that functions as a luminal sensor. In the bladder, the presence of afferent nerve terminals just beneath the urothelium highlights the importance of this sensory communication. One theory to explain the presence of OAB symptoms is that urothelial signals may lead to heightened sensitivity of submucosal afferents. Accordingly, isolated sensitization of submucosal afferents would trigger symptoms of urgency. Further sensitization of submucosal afferents would then lead to enhanced smooth muscle coupling, and urgency with associated unstable detrusor contractions might ensue. Signaling most likely occurs through mediators such as nitric oxide,<sup>20-22</sup> neurokinin A,<sup>23,24</sup> and adenosine triphosphate (ATP).<sup>25,26</sup> These mediators are released by the urothelium in response to low urinary pH, high urinary potassium, and increased urinary osmolality. Furthermore, urothelial signaling is probably a dynamic process. In studies by Sun and colleagues, the presence of increased urinary ATP, as seen in conditions of OAB such as interstitial cystitis, was associated with increased ATP production from stretched urothelial cells (Fig. 18-4).<sup>25-27</sup> Identification of feed-forward processes such as these may

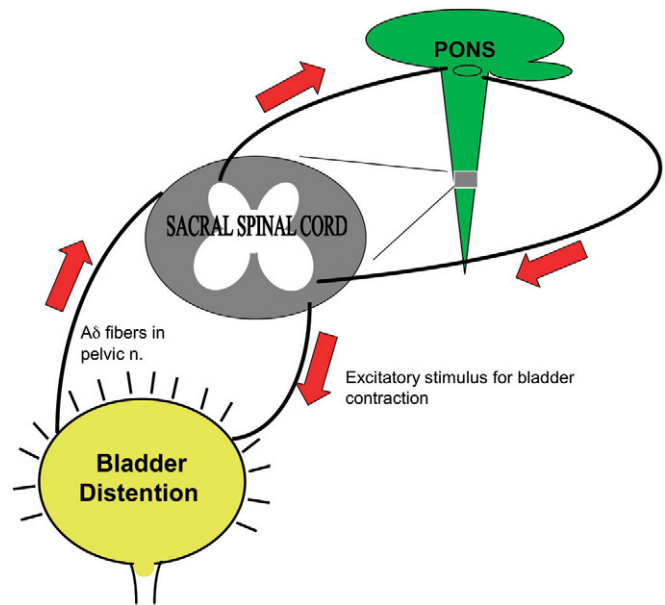

**Figure 18-4** Mechanism of overactive bladder (OAB) initiated by feed-forward stimulation of afferent nerve terminals through adenosine triphosphate (ATP) signaling, based on work from Sun and colleagues.<sup>25-27</sup> In this model, urinary ATP leads to increased ATP release from stretched urothelial cells. ATP then stimulates additional afferent nerve terminals by binding to the purinergic receptor,  $P_{2X}$ . As a result, new afferent fibers are “turned on,” a condition that could lead to the occurrence of OAB.

help to explain the self-sustaining nature of many forms of OAB.

### Role of Blood Flow

Research demonstrates that reduction in blood flow is related to the level of bladder decompensation.<sup>28</sup> OAB in the elderly is associated with various changes in the bladder, including reduced compliance, ultrastructural changes of detrusor myocytes, and ischemia.<sup>29,30</sup> Reduced blood flow to the bladder triggers a cascade of events that include apoptosis of smooth muscle cells and damage to intrinsic bladder nerves. Importantly, nerve tissue is far more sensitive to ischemic damage than detrusor muscle itself, and damage that occurs to nerve tissue is generally irreversible. In the setting of OAB associated with obstruction, damage and degeneration of the intrinsic bladder nerves is a common finding. Hypertrophy of detrusor myocytes is also prevalent, and this creates increased metabolic demand on the cells and the surrounding nerve tissue. Therefore, the effects of reduced blood flow, coupled with increased metabolic demand, can produce an anoxic environment and lead to increased neuronal death.<sup>31</sup>

In an animal model of bladder outflow obstruction, high-pressure urination was associated with prolonged periods of detrusor ischemia. This ischemic state may play a role in the metabolic and structural changes in smooth muscle and nerve tissues found in the setting of OAB.<sup>32</sup> The effects of acute ischemia have also been studied. Bratslavsky and colleagues<sup>33</sup> produced complete ischemia to the bladder for up to 18 hours. Strips of bladder were then harvested and tested in organ bath experiments. The bladder strips showed altered contractile responses to a variety of stimulants, and the most pronounced alteration was seen with electrical field stimulation. In another model, bilateral iliac artery injury was created to produce a state of chronic bladder ischemia. When tested urodynamically, animals with severe ischemia were found to have reduced bladder contractility and evidence of bladder decompensation. Animals with moder-

**Figure 18-5** Neural circuitry involved in micturition. In response to bladder distention, mechanosensitive afferent nerve terminals in the bladder wall are stimulated. Signals ascend in the spinal cord via a spinobulbospinal pathway. In the brainstem, the pontine micturition center coordinates processing of ascending and descending signals. The excitatory motor stimulus exits the sacral cord via the pelvic nerve and leads to detrusor contraction.

ate ischemia were found to have DO only.<sup>34</sup> Again, this highlights the point that ischemia may contribute to the pathophysiology of OAB.

### Role of Innervation

Voiding occurs as the result of a spinobulbospinal micturition reflex that is initiated by afferents from the bladder and culminates in efferent outflow via the pelvic nerve (Fig. 18-5). Micturition may be initiated by three events: bladder distention triggering mechanoreceptive afferents, autonomous myogenic activity activating afferents in the detrusor, and urothelial/interstitial cell interaction with chemosensitive or mechanoreceptive suburothelial afferents. In many instances, DO has been attributed to activation of a micturition reflex. It is not difficult to envision that the key symptom of urgency may be caused by activation of afferents that is consciously perceived but insufficient for micturition. A threshold for afferent firing is determined by the balance between myogenic, urothelial, and interstitial cell factors that are designed to limit the spread of inadvertent neural impulses and neural mechanisms that are designed to ensure the efficient transmission of impulses across synapses. In response to injury or disease, it has been postulated that either the trigger for firing is changed, the type of fiber is altered, or the threshold for firing is lowered. Any of these hypothetical scenarios could manifest as a sensation of fullness or precipitate detrusor contractions at lower bladder volumes. The abnormal sensation of urgency may derive from a change in the stimulus or in the type of afferents that are activated. Plasticity in afferents may be a protective mechanism whereby a noxious stimulus or injury facilitates the elimination of toxins and potentially shortens the duration of disease processes.

### Neuroplasticity

*Neuroplasticity* is the term that describes the mechanisms whereby the nervous system changes in response to injury or disease. Unfortunately, these mechanisms may continue long after the elimination of the inciting events. As an example, neuroplasticity may occur in women with chronic bladder infections to promote the rapid elimination of urinary bacteria in times of active infection. However, in a subset of these women, symptoms of urinary frequency and urgency may continue even in the absence of active bacterial infection. These women are said to have idiopathic DO or simply OAB. A comprehensive understanding of why this occurs (e.g., ATP release) and to whom (e.g., genomic predisposition) simply does not exist. Ongoing research in this area is critical and will undoubtedly result in the identification of novel therapeutic strategies in the upcoming decade.

Currently, researchers have focused on the role of neurotrophic factors in bladder neuroplasticity. In this regard, molecular triggers for changes in sensory nerve inputs from the bladder or neural transmission directly in the central nervous system could involve nerve growth factor (NGF) or other neurotrophins such as brain-derived neurotrophin factor (BDNF), glia-derived neurotrophin factor (GDNF), neurotrophin 3 and 4, and various cytokines. NGF has been shown to promote neuronal regrowth after injury and is important for the growth and sustenance of both sensory and sympathetic nerves.<sup>35,36</sup> In fact, elevations in NGF have been identified in patients with OAB, benign prostatic hyperplasia,<sup>37,38</sup> and interstitial cystitis.<sup>39</sup>

Neuroplasticity resulting in symptoms of OAB occurs in experimental animals after spinal cord injury or urethral obstruc-

tion. In these situations, a size increase in both sensory and motor neurons to the bladder has been found.<sup>40,41</sup> The transmission time of the micturition reflex becomes shorter after spinal cord injury.<sup>42,43</sup> At the neuronal level, significant reorganization occurs. The micturition pathway changes from a spinobulbosacral loop to a network that is mainly spinal. In addition, unmyelinated sensory C fibers, which are silent in the normal state, become active and contribute to the reduced micturition threshold noted after spinal cord injury (Fig. 18-6).

In humans, the ice water test provides evidence for neuroplasticity associated with both obstruction and neurogenic DO. This test involves instillation of ice-cold water or saline into the bladder. In normal subjects, the instillation of cold fluid does not stimulate bladder contractions. However, in patients with bladder outlet obstruction and neurogenic DO, bladder contractions are triggered. The explanation for this disparate response is that cold-sensitive C fibers are silent in the normal state and become active in various conditions associated with OAB.<sup>44,45</sup> Additional evidence for C-fiber neuroplasticity is demonstrated by the occasional clinical efficacy of capsaicin<sup>46</sup> and resiniferatoxin<sup>47</sup> in the amelioration of OAB. These neurotoxins selectively block C fibers.<sup>46</sup> Therefore, they likely act to suppress the heightened C-fiber activity that occurs in many forms of OAB.

Capsaicin, an ingredient found in chile peppers that is responsible for their hot or pungent taste, acts as a neurotoxin to selectively desensitize C-fiber afferents.<sup>48</sup> As described earlier, C-fiber neurons are typically silent in the normal bladder but become active in many conditions that result in neurogenic DO. Capsaicin and the more potent resiniferatoxin have been used for

**Figure 18-6** Neuroplasticity. Simplified view of several nerve growth factor (NGF)-mediated processes that are probably involved in neuroplasticity associated with overactive bladder (B) compared with the normal bladder (A). These mechanisms include changing from high-threshold, tetrodotoxin (TTX)-resistant Na<sup>+</sup> currents to low-threshold, TTX-sensitive Na<sup>+</sup> currents in bladder afferent neurons (*top insets*); changing from inactive, small size C-fiber neurons to active, hypertrophic C-fiber neurons (*middle insets*); and changing from a long duration, spino-bulbo-spinal reflex to a short duration spinal reflex (*bottom insets*).

several years in clinical trials in patients with DO. The success of this C fiber–directed therapy highlights the importance of activated C-fiber afferent neurons as a key element in the pathophysiology of neurogenic DO.

### Spinal Cord Injury

After spinal cord injury, neurogenic DO often occurs. The exact sequence of molecular events leading to this clinical picture remains unknown. However, it is clear that, after spinal cord injury, C-fiber afferents in the bladder develop increased mechanosensitivity. Cell bodies of these afferents located in dorsal root ganglia become hypertrophied.<sup>49</sup> Furthermore, patch clamp experiments demonstrate that expression of sodium (Na<sup>+</sup>) channels shifts from the high-threshold, tetrodotoxin-resistant type channel to the low-threshold, tetrodotoxin-sensitive type channel.<sup>50,51</sup> Because conductances via Na<sup>+</sup> and potassium (K<sup>+</sup>) channels are crucial to neuronal excitability, the ability of disorders to alter these channels, possibly through cytokines and neurotrophins, may underlie the mechanism of OAB in conditions ranging from spinal cord injury and bladder outlet obstruction to inflammation. In fact, such plasticity in channel function or expression could mediate the reduction in firing threshold for chemo/thermo/mechano-sensitive afferents demonstrated in OAB. Therefore, Na<sup>+</sup> and K<sup>+</sup> channels are attractive targets for OAB therapy.

The presence of these changes in neuron morphology and electrophysiology suggests that transport of signals from the injured spinal cord to nerve terminals in the bladder or vice versa must be occurring in the setting of spinal cord injury. NGF and GDNF have been investigated in this regard. Indeed, NGF is associated with hypertrophy of cell bodies of bladder afferents seen in various forms of OAB.<sup>40,41</sup> In addition, experimental blockage of NGF in the setting of spinal cord injury prevents the occurrence of DO. GDNF may also be important in the setting of spinal cord injury, because a small population of bladder C-fiber neurons responds only to GDNF and are unresponsive to NGF.<sup>52</sup>

### Role of Obstruction and Inflammation

In the setting of mechanical obstruction of the bladder outlet, symptoms of OAB are frequently present. This is most commonly seen in men with bladder outlet obstruction due to prostatic enlargement. However, women with functional obstruction of the bladder neck or mechanical obstruction due to trauma or surgery can display similar symptomatology. Insight into the pathophysiology of OAB can be gleaned from urodynamic studies in patients who present with persistent lower urinary tract symptoms after surgical resection of the prostate. These studies demonstrate that persistent symptoms are related more to DO than to recurrent or residual bladder outlet obstruction.<sup>53,54</sup>

The explanation for this persistent symptomatology is that the effects of bladder outlet obstruction are not purely mechanical. Rather, obstruction causes enhancement of a facilitory spinal reflex mediated by C-fiber afferent bladder nerves. Evidence for this reflex is seen in the positive response of patients with bladder outlet obstruction to the ice water test. Again, the presence of involuntary contractions after instillation of ice-cold water into the bladder demonstrates an activated C-fiber reflex. In addition, bladder outlet obstruction triggers heightened expression of growth-associated protein-43, a phosphoprotein whose expression is induced in the setting of axonal sprouting and neuronal

remodeling.<sup>55</sup> New spinal circuits may arise after bladder outlet obstruction, and failure to revert to a normal voiding pattern after obstruction is relieved suggests that these new circuits can sometimes persist.

NGF probably plays an important role in the activation of these de novo circuits after bladder outlet obstruction. Levels of NGF are elevated in obstructed bladders of humans and experimental animals.<sup>56</sup> In animal models of bladder outlet obstruction, blockade of NGF prevents the activation of C-fiber reflexes, and DO does not occur. Importantly, the rise in NGF precedes the development of neuronal hypertrophy and the clinical development of OAB. This suggests that NGF is involved in the initiation of the obstruction-induced neuroplastic process.

Likewise, NGF is also increased in the setting of bladder inflammation. This increase is seen in both the urine and the bladder tissue itself. It has been identified in animal models of experimental bladder inflammation and also in patients with interstitial cystitis.<sup>39,57,58</sup> Inflammation of the bladder results in enlargement of cell bodies of bladder afferent nerves, a finding that is seen in other forms of OAB and that is associated with increased expression of NGF. Changes in the neurons within the spinal cord have also been identified in the setting of bladder inflammation. After experimental inflammation of the bladder induced by mechanical irritation or chemically by systemic treatment with cyclophosphamide, neurons in the lumbosacral spinal cord displayed increased expression of FOS, a nonspecific marker for neuronal activation.<sup>59,60</sup>

These findings suggest that inflammatory stimuli within the bladder trigger changes in afferent nerve endings. These changes are then communicated to cell bodies that reside in dorsal root ganglia and ultimately are relayed to spinal cord neurons and to higher-order neurons in the brain. NGF is probably an important mediator in this signaling process. However, the exact cascade of molecular events remains unknown, and elaboration of this cascade will certainly lead to the identification of novel targets for pharmacologic intervention in OAB.

### Role of Psychological Factors

#### Depression

In 1978, Stone and colleagues<sup>61</sup> first documented the association of psychiatric symptoms and voiding dysfunction. Subsequent researchers noted this association specifically for disorders of idiopathic DO and urge incontinence<sup>62,63</sup> and suggested that these voiding symptoms might be psychosomatic in nature. Chiverton and Judd<sup>64</sup> found a higher incidence of depression among women with urinary incontinence compared with women in the general population. Zorn and coworkers<sup>65</sup> performed a case-control study in which 115 consecutive patients presenting to an incontinence clinic were compared with 80 continent controls. Patients with incontinence had significantly higher scores on the Beck Depression Inventory and reported a history of depression more frequently. Interestingly, when stratified by type of incontinence, patients with stress incontinence and those with urge incontinence due to obstruction or neurogenic causes did not demonstrate these differences. However, 60% of patients with idiopathic urge incontinence reported a history of depression, compared with only 17% of continent control patients. In addition, a history of depression often preceded the development of urine loss, suggesting that incontinence or OAB symptoms per se did not cause depression. Recently, several large cross-sectional studies

examined the association of depression and incontinence. Dugan and colleagues<sup>66</sup> found a strong association in elderly patients. Nygaard and colleagues<sup>67</sup> performed a cross-sectional survey study of almost 6000 women comparing incontinence with depressive symptoms. After adjusting for medical morbidity, functional status, and demographic variables, women with severe incontinence or mild to moderate incontinence were 80% and 40% more likely, respectively, to have depression than continent women.

One possible explanation for an association between depression and OAB or urge incontinence may be altered central transmitter function, especially monoamines, in certain areas of the brain that influence micturition. Recently, our group and others<sup>68</sup> identified a significant increased relative risk for OAB and urge incontinence in postpartum women with severe depression (“baby blues”), compared with nondepressed cohorts. Postpartum depression may herald future depressive episodes that are associated with altered serotonin function. This association is intriguing and is consistent with animal studies demonstrating that lowered serotonin induces urinary frequency and intermicturition contractions on cystometry.<sup>69</sup>

### *Anxiety and Panic Disorders*

Melville and coworkers<sup>70</sup> examined the association of incontinence and panic disorder in a prospective study of 218 consecutive women presenting to a urogynecology clinic with a diagnosis of urinary incontinence. All patients underwent a history, physical examination, multichannel urodynamics to assess the type of incontinence and completed validated instruments to diagnose psychiatric disorders and disease-specific quality-of-life effects. Overall, 11% of patients with urge incontinence or mixed incontinence suffered from panic disorder, compared with 0% of patients with stress incontinence. After adjusting for potential confounding variables such as medical comorbidities, marital status, and age, patients with urge incontinence were found to be 9.2 times more likely than those with stress incontinence to have a panic disorder. Patients with mixed incontinence were found to be 13.5 times more likely to have a panic disorder than patients with stress incontinence. Furthermore, Weissman and associates<sup>71</sup> identified a potential genetic syndrome in which families manifest both panic disorder and urinary frequency. Using genetic linkage analysis, they identified a clinical syndrome in certain families with panic disorder that included voiding dysfunction, migraine headaches, mitral valve prolapse, and hypothyroid conditions. The association of this mental condition with seemingly unrelated medical conditions prompted the authors to advocate for more extensive clinical evaluation of patients with

psychiatric conditions, in order to identify this type of phenotypic clustering.

Some investigators have found that patients with anxiety and panic disorders may simply experience greater “bother” from their symptoms. For this reason, they might present more frequently for medical evaluation. Watson and coworkers<sup>72</sup> performed a prospective study on women with symptoms of incontinence presenting for urodynamics testing. The 48-hour pad test and the Hospital Anxiety and Depression (HAD) scale were administered. Patients with high anxiety scores had statistically significant lower mean urine loss on the 48-hour pad test (44 versus 97 mL) compared with patients without high anxiety scores. The investigators concluded that anxious patients present with a lesser degree of incontinence than nonanxious patients. However, most data appear to support the notion that anxiety and panic disorders are significant risk factors for OAB and urge incontinence.

These clinical associations are consistent with laboratory investigations showing that anxiety models such as the spontaneously hypertensive rat exhibit urinary frequency and intermicturition contractions on cystometry.<sup>38</sup> Central neurotransmitters that activate the stress response (e.g., corticotropin-releasing factor) also increase bladder activity. Conversely, corticotropin-releasing factor antagonists reduce bladder activity in certain animal models of OAB.<sup>73</sup>

## CONCLUSIONS

The pathophysiology of OAB is diverse and involves an interplay between urothelial, myogenic, and neurogenic mechanisms. Ultimately, the ability to effectively combat the symptoms of OAB depends on success in identifying the underlying mechanisms in each affected patient. Unique therapeutic strategies targeting individual pathologies can then be crafted. In the future, the use of bioimaging modalities such as positron emission tomographic (PET) scanning or functional, local blood oxygen level–dependent (fBOLD) magnetic resonance imaging (MRI); risk factor or hazard scoring; genetic profiling; and molecular techniques will allow clinicians to better categorize patients and individualize therapy. As advances are made in molecular medicine, clinical applications in the treatment of OAB will evolve. However, more effective treatments for this pervasive, costly, and debilitating condition can be achieved only by the pursuit of translational research aimed at a comprehensive understanding of the pathophysiology of OAB.

# BEHAVIORAL MODIFICATION AND CONSERVATIVE MANAGEMENT OF OVERACTIVE BLADDER

*Alain P. Bourcier*

Millions of people throughout the world are affected by overactive bladder (OAB) syndrome, a serious condition that can have dramatic personal and social costs. Symptoms of OAB increase with age and are slightly more common in women. The median prevalence of incontinence in women has been reported as varying from 14% to 40.5%; using the definition of the International Continence Society (ICS), it is 23.5%. In women, urge and mixed incontinence accounted for a median relative share of 51% of cases.

These estimates have varied based on the differing methodologies of the studies and the previously uncertain definition of OAB. OAB is characterized by the ICS as a syndrome encompassing urgency (with or without urge incontinence), usually with frequency and nocturia.<sup>1</sup> OAB syndrome is a well-recognized complex of symptoms that is usually suggestive of detrusor overactivity but can also be caused by urethrovaginal dysfunction of another type.

According to the ICS,<sup>1</sup> urgency, with or without urge incontinence, usually with frequency and nocturia, can be described as OAB syndrome, urge syndrome, or urgency-frequency syndrome. Lower urinary tract symptoms are the subjective indicator of a disease or change in condition as perceived by the patient, caregiver, or partner. In this context, urgency is the complaint of a sudden compelling desire to pass urine that is difficult to defer, increased daytime frequency is the complaint of voiding more than to seven times a day, and nocturia is the complaint of awakening one or more times at night to void. Urge incontinence is characterized by a strong desire to void coupled with an involuntary loss of urine.<sup>2</sup> OAB patients are likely to require long-term or even lifelong therapy to control their symptoms. Patients with OAB symptoms are at elevated risk for other conditions that increase their use of health care resources. Common patient reactions to OAB symptoms and incontinence are embarrassment, frustration, anxiety, depression, and fear of odor from urine leakage.<sup>2</sup>

Nonpharmacologic approaches include education and explanation of normal lower urinary tract structure and function, lifestyle changes, toileting programs, bladder retraining, and pelvic muscle training or rehabilitation. Behavior modification, which involves learning new skills and strategies for preventing urine loss and other symptoms, has a growing body of clinical research.

### LIFESTYLE INTERVENTIONS

Behavior modification is a treatment option for persons with urinary incontinence (UI) and OAB. Changing a patient's behav-

ior, environment, or lifestyle can mitigate or reduce symptoms (urine leakage or incontinence, urgency, frequency, and nocturia).

The interventions include lifestyle changes: cessation of smoking, weight reduction, elimination of dietary bladder irritants, adequate fluid intake, bowel regulation, moderation of physical activities, and exercises. Lifestyle changes and behavior modification are integral to clinical management of UI and OAB. In the United States, therapies have been combined to include interventions called behavioral treatments.

Behavioral interventions are a group of therapies used to modify stress, urge, or mixed UI by changing the patient's bladder habits or by teaching new skills. The interventions include lifestyle changes, toileting programs (e.g., habit training, prompted voiding), bladder retraining, and pelvic muscle training or rehabilitation (using methods such as biofeedback, vaginal weights, and electrical stimulation). Although research showing the effectiveness of changes in certain lifestyle behaviors on UI, urgency, and frequency may not be conclusive, many health care providers frequently recommend alterations in lifestyle and behavior.

### Smoking

Increased intra-abdominal pressure may promote the development of UI and urinary urgency, particularly in women. This increased pressure exists with conditions that include pulmonary diseases such as asthma, emphysema, and chronic coughing such as seen in smokers.<sup>3</sup> Smoking, in particular, increases the risk of developing all forms of UI, and especially stress urinary incontinence (SUI); the level of risk depends on the number of cigarettes smoked. There may be several causes of the increased risk of SUI in smokers. Compared with nonsmokers, smokers have stronger, more frequent, and more violent coughing, which may lead to earlier development of damage to the urethral sphincteric mechanism and vaginal supports.<sup>4</sup> Violent and frequent prolonged coughing can increase downward pressure on the pelvic floor, causing repeated stretch injury to the pudendal and pelvic nerves. In addition, elements of tobacco products may have antiestrogenic hormonal effects, which may influence collagen synthesis. Nicotine contributes to large phasic bladder contractions, as shown in animal studies through the activation of purinergic receptors; nicotine seems to affect the human bladder similarly.<sup>5</sup> There may also be an association between nicotine and increased detrusor contractions. Bump and McClish<sup>6</sup> showed that women who previously smoked had a 2.2-fold increased incidence, and

those who currently smoked had a 2.5-fold increased incidence of SUI. The risk of UI in women caused by cigarette smoking was estimated to be 28%. This study indicated that the risk of genuine SUI is positively correlated with both the current intensity of cigarette consumption and the degree of lifetime exposure to cigarette smoking. The increased prevalence of SUI in smokers is independent of other risk factors such as older age, parity, obesity, and hypoestrogenism. Smoking habits indicate that smoking can cause symptoms of urge incontinence and urgency and frequency.<sup>3</sup> Nuotio and colleagues<sup>7</sup> showed a correlation between smoking and urinary urgency in a population-based survey of 1059 women and men aged 60 to 89 years. Smokers were more likely to report incontinence than nonsmokers. In a survey of 2128 middle-aged and elderly men who smoked or formerly smoked, Koskimaki and colleagues showed an increased risk of lower urinary tract symptoms.<sup>8</sup>

### Obesity

Obesity is an independent risk factor for the development of SUI and mixed UI in women.<sup>9,10</sup> Excessive body weight, specifically measured by sagittal abdominal diameter, affects bladder pressure. The SUI that occurs with obesity may be secondary to increases in intra-abdominal pressure on the bladder and greater urethral mobility. Also, obesity may impair blood flow or nerve innervation to the bladder. A woman with a body mass index (BMI) of 29 or less is considered to be of normal or low weight; a woman with a BMI of 30 or greater is obese.<sup>3</sup> Elia and associates<sup>9</sup> reported on 540 women who responded to a questionnaire and whose BMI status was obtained. The association between BMI and UI was statistically significant. Poor personal hygiene in obese women may lead to an infectious process. Mommsen and Foldspang found a relationship between SUI and an increased BMI.<sup>11</sup> Roe and Doll<sup>12</sup> reported on 6139 (53% response rate) respondents to a postal survey on incontinence status. Significantly more respondents with UI had a higher mean BMI when compared with continent respondents. This association was more prevalent in women than men. Brown and colleagues<sup>13</sup> studied 2763 women who completed questionnaires about prevalence and type of incontinence as part of a randomized trial of hormone therapy. A higher BMI and higher waist-to-hip ratio were found to be predictors of SUI and also of mixed UI when the major component was stress. This study found that the prevalence of at least weekly SUI increased by 10% for every 5 units of increased BMI. At this time, there is little information on whether weight loss resolves incontinence in women who are moderately obese. Obese women should lose weight before surgery to improve the technical ease, increase the durability, and decrease the failure rate of the surgery.<sup>14</sup> Maintaining normal weight through adulthood may be an important factor in the prevention of UI. Given the high prevalence of both incontinence and obesity in women, weight reduction should be recommended as part of the conservative management and behavior modification for obese women with UI.<sup>3</sup>

### Dietary Habits

#### Fluid Management

Patients with UI and OAB symptoms may subscribe to either restrictive or excessive fluid intake behaviors. It is important to teach the patient that adequate fluid intake is necessary to elimi-

nate irritants from the bladder and prevent UI.<sup>3</sup> Surveys of community-residing elders report self-care practices that include the self-imposed restrictions of fluid intake because of fears of UI, urinary urgency, and urinary frequency.<sup>15</sup> Adequate fluid intake is very important for older adults, who already have a decrease in their total body weight and are at increased risk for dehydration. Institutionalized patients are chronically dehydrated, because most require assistance to eat and drink. Although drinking less liquid does result in less urine in the bladder, the smaller amount of urine may be more highly concentrated and irritating to the bladder mucosa. In addition, inadequate fluid intake is a risk factor for constipation, another problem common in older adults. Nygaard and Linder<sup>16</sup> surveyed teachers and questioned their voiding habits at work, allotted breaks, and bladder complaints including urinary tract infections and incontinence. Teachers who drank less while working to decrease their voiding frequency had a twofold higher risk of urinary tract infection than those who did not report self-imposed fluid restriction. There was no association between urinary tract infection and either voiding infrequently at work or mean number of voids at work. Fitzgerald and colleagues<sup>17</sup> surveyed women who worked for a large academic center. Of the 1113 women surveyed, 232 (21%) reported UI at least monthly.

Incontinent women were significantly older and had a higher BMI than continent women. The strategies used by women in this study to avoid urinary symptoms included limiting fluids and avoiding caffeinated beverages. The recommended daily fluid intake is 1500 mL, but many believe that a more appropriate intake is 1800 mL to 2400 mL per day.<sup>3</sup> To be adequately hydrated, older patients must consume at least 1500 to 2000 mL per day of liquids.<sup>18</sup> It is suggesting by the renal physicians, that a total fluid intake of 24 mL/kg/day in a temperate climate is appropriate to normal requirements, and of course there are variations depending on factors such as amount of exercise or presence of air-conditioning at home.<sup>19</sup>

#### Influence of Bladder Irritants

The type of fluid or food is important. Caffeine is a xanthine derivative, a natural diuretic and bladder irritant. It acts similarly to thiazide diuretics. Caffeine is a central nervous system stimulant that reaches peak blood concentrations within 30 to 60 minutes after ingestion and has an average half-life of 4 to 6 hours.<sup>3</sup> Caffeine can cause a significant rise in detrusor pressure, leading to urinary urgency and frequency after caffeine ingestion.<sup>20</sup> Caffeine has an excitatory effect on the detrusor muscles.<sup>21</sup> Caffeine is found in liquids such as sodas (e.g., Pepsi, Coca-cola) and foods and candy that contain milk chocolate (e.g., 7 mg in 10 ounces of milk chocolate). Carbonated drinks that are identified as “caffeinated colas” have been associated with an increased risk of SUI.<sup>22</sup>

Alcohol also has a diuretic effect. Alcohol causes a release of antidiuretic hormone from the posterior pituitary.<sup>20</sup> Anecdotal evidence suggests that elimination of dietary factors such as artificial sweeteners (aspartame) and certain foods (e.g., highly spiced foods, citrus juices, tomato-based products) may promote continence.<sup>3,23,24</sup> Arya and colleagues<sup>25</sup> found that women ( $n = 20$ ) with higher caffeine intake (361 to 607 mg per day) had a 2.4-fold increased risk for detrusor instability than women ( $n = 10$ ) with a low caffeine intake (110 to 278 mg per day). There was also a correlation between current smoking and caffeine intake.

Bryant and coworkers<sup>26</sup> conducted a prospective randomized trial of persons with symptoms of urgency, frequency, and urge

UI who routinely ingested 100 mg or more of caffeine per day. Both groups were taught bladder training, but the intervention group was also instructed to reduce caffeine intake to less than 100 mg/day. Significant improvement in urgency (61% decrease), in voiding frequency (35% decrease), and in urine leakage (55% decrease) was seen in the treatment group compared to baseline. Even though current research is not conclusive, patients with UI and OAB should be assessed for amount of caffeine intake. They should be advised about the possible adverse effects caffeine may have on the detrusor muscle and the possible benefits of reduction of caffeine intake.<sup>3,27</sup> They also should be instructed to switch to caffeine-free beverages and foods or to eliminate them and see if urinary urgency and frequency decrease. If they continue to consume caffeine, clients with incontinence and OAB should take no more than 100 mg/day to decrease urgency and frequency.

### *Nutrient Composition of the Diet*

Storage symptoms can affect quality of life and activities of daily living and have large resource implications for both the individual and the health service. Clinically, a number of foods and drinks are thought to have adverse or beneficial effects on certain urinary symptoms. However, little scientific evidence exists, and no studies have investigated the association between nutrient intake and urinary storage symptoms. The origin of detrusor overactivity may be neurogenic, with a variety of neurologic causes<sup>28</sup>; some of these may be related to diet, such as neuropathies resulting from vitamin B<sub>12</sub> deficiency.<sup>29,30</sup> Another proposed pathologic mechanism is myogenic bladder overactivity,<sup>31</sup> possibly due to ischemia. Associations with diseases such as stroke and diabetes<sup>32</sup> suggest that OAB may be linked to a number of systemic conditions related to nutrition. In an earlier publication, Dallosso and colleagues<sup>33</sup> reported possible dietary associations with OAB in terms of food groups and individual food items and showed that lower intakes of three food groups (vegetables,  $P < .02$ ; chicken,  $P < .005$ ; breads,  $P < .001$ ) were independently associated with increased risks of OAB onset. A higher intake of vitamin D was significantly associated with reduced risk of OAB onset ( $P = .008$ ). There was some evidence of a trend toward decreased risk of onset with increasing vitamin D intake: those in the 4th quintile were 0.51 times less likely to experience OAB onset, compared with the lowest intake quintile (95% confidence interval: 0.34 to 0.78).

Evidence for an association between diet and the OAB symptom syndrome would be valuable in understanding its etiology. In a very recent study, Dallosso and associates<sup>34</sup> investigated prospectively the association between the nutrient composition of the diet and the onset of OAB. A random sample of community-dwelling women aged 40 years or older was studied. Baseline data on urinary symptoms and diet were collected from 6371 women using a postal questionnaire and food frequency questionnaire. Follow-up data on urinary symptoms were collected from 5816 of the women in a postal survey 1 year later. Logistic regression was used to investigate the association of diet (daily intakes of energy, macronutrients, and micronutrients) with 1-year incidence of OAB. There was evidence that three nutrients may be associated with OAB onset. Higher intakes of vitamin D ( $P = .008$ ), protein ( $P = .03$ ), and potassium ( $P = .05$ ) were significantly associated with decreased risks of onset. Although overall the associations with vitamin B<sub>6</sub> and niacin were not significant ( $P = .08$  and  $P = .13$ , respectively), there was some evidence of a decreased risk of onset with higher intakes. This study

was the first to consider an association between the nutrient composition of the diet and OAB onset, and it provided some evidence that lower intakes of a number of nutrients may be associated with an increased risk of OAB onset. The association was strongest for vitamin D. Further studies are needed using additional validated indicators of OAB status and diet to confirm the associations found.

The observed associations of a number of nutrients with OAB onset present an overall pattern of low intake levels associated with increased risk of onset, possibly suggesting that general inadequacy of the diet may be an important factor. Although clinical deficiencies of protein and vitamins are very uncommon in Western countries, suboptimal levels of intake may be important.<sup>35</sup> Comparisons with the literature are difficult, because the only published work on diet and urinary symptoms comes from studies looking at prostatic enlargement in men, defined either clinically<sup>36,37</sup> or by reporting of symptoms.<sup>38</sup>

The Dallosso study<sup>34</sup> results suggested that low intake levels of certain micronutrients may be associated with increased risk of OAB onset, the most significant association being with vitamin D. Vitamin D and its metabolites are steroid hormones and have many important functions. Low vitamin D status is involved in the pathogenesis of several chronic diseases. Muscle wasting is a symptom of osteomalacia, the clinical condition resulting from vitamin D deficiency in adults, and muscle atrophy has been described histopathologically in type II fibers. The potential role of vitamin D in the function of the detrusor muscle needs to be considered. Because it is produced phytochemically in the skin by exposure to ultraviolet light, the level of dietary intake is not usually very important. Apart from the elderly and other at-risk groups, there is no recommended level of vitamin D intake in the United Kingdom.

This study<sup>34</sup> also provided some evidence that lower intake levels of the B vitamins niacin and B<sub>6</sub> may be associated with OAB onset. Bread and chicken are sizeable sources of niacin in the diet,<sup>39</sup> and lower intake levels of both of these food groups showed an association with greater onset of OAB in our earlier analysis.<sup>33</sup> Niacin is involved in energy metabolism and is essential for normal functioning of various systems of the body, including the central nervous system. However, the literature also reports strong associations with folate and vitamin B<sub>12</sub>; this suggests that the B<sub>6</sub> association with homocysteine may be due to the fact that the three vitamins share the same food sources.<sup>40</sup> Potassium is very widespread in the diet, and a low intake is rare, sometimes occurring in people with bizarre or extremely low energy intakes. Potassium depletion in the body never results solely from an inadequate intake and is always associated with abnormal losses from the body. The largest sources in the diet are fruit and vegetables (30%) and refined grains (21%)<sup>41</sup>; in our earlier analysis, high intakes of vegetables and breads were associated with a reduced risk of OAB onset. A high potassium intake is generally considered an indicator of a "good quality diet," mainly because of its association with high fruit and vegetable content. The associated reduced risk of OAB onset could therefore be related to some aspect of a "healthy diet."

### *Dietary Changes with Improvement of Defecation*

Lubowski and colleagues<sup>42</sup> reported that denervation of the external anal sphincter and pelvic floor muscles (PFMs) may occur in association with a history of excessive straining on defecation. Many believe that, if these are lifetime habits, they may have a cumulative effect on pelvic floor and bladder function. There is

very little research that assesses the effect of regulating bowel function on incontinence and OAB. Spence-Jones and colleagues<sup>43</sup> found that straining excessively at stool was significantly more common in women with SUI and in women with prolapse than in women who experienced neither condition. Moller and coworkers<sup>44</sup> reported an almost uniform positive association between straining at stool and constipation and lower urinary tract symptoms in women ( $N = 487$ ) 40 to 60 years of age. Moller believed that chronic constipation and repeated straining efforts induce progressive neuropathy in the pelvic floor. Because research suggests that chronic constipation and straining may be risk factors for the development of incontinence and OAB, self-care practices that promote bowel regularity should be an integral part of any treatment program.<sup>3</sup>

Treatment of elderly patients can significantly improve lower urinary tract symptoms, which include urgency and frequency.<sup>45</sup> Suggestions to reduce constipation include the addition of fiber to the diet, increased fluid intake, regular exercise, external stimulation, and establishment of a routine defecation schedule. Improved bowel function can also be achieved by determining a schedule for bowel evacuation so that the client can take advantage of the “call to stool,” or the urge to defecate. The schedule should be determined by the client’s bowel elimination pattern and previous time pattern for defecation. Dougherty and colleagues<sup>46</sup> conducted a randomized, controlled trial that incorporated reduction of caffeine consumption, adjustments in the amount and timing of intake of fluids, and dietary changes to promote bowel regularity, which were termed “self-monitoring activities.” Women in the intervention group also received bladder training and biofeedback-assisted pelvic muscle exercises. A total of 218 women with stress, urge, or mixed UI were randomized, and 178 completed one or more follow-ups. At 2 years, the intervention group’s UI severity had decreased by 61%. Self-monitoring and bladder training accounted for most of the improvement.

Epidemiologic research has revealed several factors associated with UI in women, the most commonly reported being age, pregnancy, and childbirth. Risk factors that may be modifiable have not been investigated to the same extent. Inadequate control for confounding factors is a weakness of several studies, and many investigations have been performed in selected populations. The aim of one large population-based study<sup>47</sup> was to evaluate the role of smoking and other modifiable lifestyle factors potentially associated with UI in women. A total of 27,936 women completed the incontinence part of the questionnaire. For the 6876 incontinent women (24.6 %), a severity index was calculated based on the answers regarding frequency and amount of leakage, and the incontinence was categorized as slight, moderate, or severe. The incontinence was also classified into three different subtypes: stress, urge, and mixed UI. The participating women answered additional questions about many other topics, including smoking habits; intake of alcohol, tea, and coffee; and amount of physical activity. BMI was derived from the measurements of height and weight ( $\text{kg}/\text{m}^2$ ) at the screening station. Proportions were used to describe the univariate relationship between UI and the ordered variables. Where relevant, possible interaction or confounding was evaluated by stratified table analyses and logistic regression. Logistic regression analyses were used to adjust for confounding and to establish the factors independently associated with the outcome, and odds ratios (ORs) were the effect measure.

Effects were denoted as strong if the ORs were 1.8 or greater and weak if they were between 1.2 and 1.7. In all logistic regression analyses, women without incontinence served as the reference group. All analyses were performed separately for each of the different outcomes under investigation: any incontinence (all incontinent women), severe incontinence, and the different subtypes. The crude analyses showed that the prevalence of any UI increased with increasing age and increasing BMI. Former smokers reported incontinence more frequently than did current or never smokers. An increasing intake of tea and coffee seemed to be associated with a higher prevalence of incontinence, whereas the inverse relationship was true for intake of alcoholic beverages. The crude prevalences also suggested an association between physical activity and any incontinence.

The prevalence of severe incontinence and of the different subtypes of incontinence varied in a pattern parallel to that for any incontinence, according to the factor in question. When smoking status was explored, there was no association between any incontinence and former or current smoking of less than 20 cigarettes a day, but there was an increased and significant OR for both former and current smoking of 20 cigarettes or more daily. The effect was stronger for severe incontinence. For the different subtypes of incontinence, smoking status showed a weak and significant association only with mixed incontinence. Increasing BMI was strongly associated with any UI, with severe symptoms and with all subtypes. An increasing amount of low-intensity physical activity was related to slightly lowered odds for any incontinence, severe incontinence, and both SUI and mixed types of incontinence. High-intensity physical activity showed only weak and insignificant associations to either of the outcomes. Daily tea drinkers had an increased risk for incontinence. The intake of tea was weakly associated with all three types, although not significantly for the urge type. Coffee had no effect on any incontinence and a weak but significant negative effect on severe incontinence and severe mixed type. The intake of alcohol showed no association with any of the outcomes under analysis.

Hannestad and colleagues<sup>47</sup> found that former and current smoking was associated with incontinence only for those who smoked more than 20 cigarettes per day. Severe incontinence was weakly associated with smoking regardless of number of cigarettes. The association between increasing BMI and incontinence was strong and was present for all subtypes. Increasing amounts of low-intensity physical activity had a weak and negative association with incontinence. Tea drinkers had raised risk for all types of incontinence. No important effects of high-intensity activity or of intake of alcohol or coffee were found. This study was designed to describe associations, and accordingly no conclusions could be drawn regarding causality. It remains for future research to establish whether modification of associated lifestyle factors alters the prevalence of incontinence. Nevertheless, strategies to discourage women from smoking should be implemented. At the very least, women should be educated on the relationship between smoking, UI, and OAB.<sup>3</sup>

#### Physical and Occupational Stressors: Sports and Fitness Activities

Another lifestyle behavior associated with triggering of SUI in young, healthy women is physical exertion. This is more common than health care professionals estimated, and it is one of the chief

complaints in the younger female population. Physically active women are more likely than sedentary women to experience incontinence, and the problem is most common in high-impact sports, such as running and basketball, because repetitive bouncing can increase abdominal pressure and transmit the impact to the bladder. Because SUI occurs during physical exertion, we could say that this condition represents a major problem for females participating in fitness programs or sports activities.

Regarding the problem of PFMs, there are two contradicting theories about female athletes and the strength of their PFM.<sup>48</sup> The first theory is to consider that general physical activities strengthen all the body muscles, including the pelvic floor, and female athletes could have a strong pelvic musculature. The second theory is that heavy activities with repetitive pressure on the pelvic floor support may overload the pelvic floor and weaken these muscles over time. The PFMs play a major role in the continence control system. The speed and strength of PFM contractions may be one of the main causes.<sup>49</sup> During stressful situations (physical exertion, strain), the levator ani muscles pull the vesical neck upward, and the urethra is compressed against a supportive layer composed of the endopelvic fascia and the anterior vaginal wall. The theory of Petros and Ulstem, with their prediction that defects of the vagina or its supporting ligaments adversely affect the dynamics of the pelvic floor and the ability of interacting forces to coordinate closing of the urethra, is another explanation of the SUI associated with physical activities.<sup>50</sup> The high intra-abdominal pressure and/or weakness or nonfunctioning of the levator ani leads to loss of support of the bladder neck and urethra. These two parameters represent the mechanical hypothesis in the pathophysiology of SUI related to sports. Because of the rigidity of the abdominal wall, the pelvic diaphragm cannot play its role of “shock absorber.” Prevalence of SUI in young female athletes and women who exercise ranges from 8% to 47%.

Nygard and associates<sup>51</sup> studied the relationship between exercise and incontinence. A self-administered questionnaire assessed the prevalence of both exercise and incontinence in 326 regularly exercising women (mean age, 38.5 years) attending private gynecologic offices. Eighty-nine percent exercised at least once a week, with an average practice of three times per week for 30 to 60 minutes per session. Researchers found that 47% of regularly exercising women reported some degree of incontinence. In another study<sup>52</sup> involved a group of 156 nulliparous, elite college varsity female athletes (mean age, 19.9 years), who were asked to fill out a questionnaire about the occurrence of UI during participation in their sport and during activities of daily life. Overall, 40 athletes (28%) reported urine loss while participating in their sport. Activities most likely to provoke incontinence included jumping (basketball), running, and making impact on the floor as gymnasts do with dismounting or after flips.

Bourcier and Juras<sup>53</sup> studied SUI in sports and fitness activities in 59 women, whom they divided into two groups: group I ( $n = 28$ ) represented female athletes, and group II ( $n = 31$ ) represented women who practiced sports on a regular basis. In group I, the mean age was 25.5 years (range, 21 to 29) and mean parity was 0.5 (range, 0 to 1); in group II, mean age was 28 years (range, 23 to 32), and mean parity was 1 (range, 0 to 2). The degree of SUI was defined as severe (dripping incontinence on exercising), moderate (incontinence with heavy lifting, running), or mild (incontinence in jumping). In the athlete group, the prevalence

of SUI symptoms was 7% for severe, 24% for moderate, and 33% for mild incontinence. Bourcier and coworkers<sup>48</sup> studied the relationship between physical activity and incontinence. A self-administered questionnaire assessed the prevalence of both exercise and incontinence in two groups of patients; 480 women (group I; mean age, 48.5 years) with no regular practice of sports and 120 women (group II; mean age, 28 years) who practiced sports on regular basis ( $>5$  hr/wk) were investigated. The investigators reported that urine loss in group I was related to sneezing or coughing in 87% of the women; in group II, urine loss was related to running or tennis in 38% and aerobics in 35%.

The purpose of the study by Larsen and Yavorek<sup>54</sup> was to determine the prevalence of UI and to assess the stages of pelvic support in a population of nulliparous, physically active college students at the United States Military Academy. This was an observational study of 143 female cadets. Cadets in the freshman and sophomore classes were asked to participate in an ongoing study comparing UI and pelvic organ support before and after attending military jump school. The results were as follows. Overall, the group of women were found to be very physically active, with 69.2% (99/143) exercising four or more times per week and 91.6% (131/143) working out three or more times. Additionally, 49.7% (60/131) of those exercising spent 60 minutes or more per session. Running was the most common form of exercise, with 77.6% (111/143) running for at least part of their workout. Of the women examined, 50.3% (72/143) were found to be at pelvic prolapse stage 0 and 49.7% (71/143) at stage I. A total of 18.8% (27/143) women who reported recurrent incontinence, with the largest percentage (44%) being SUI by history. The conclusion of the authors was that 50% of nulliparous cadets had stage I prolapse on standardized pelvic support examination, primarily in the anterior compartment. A small percentage admitted to incontinence at the time of examination. This study indicates that trauma from physical activity might cause pelvic support defects that could predispose women to incontinence problems later in life.

Because the percentage of women who exercise and participate in sports is increasing, it is important to determine what effect this increase has on pelvic support. Jorgensen and coworkers<sup>55</sup> reported that Danish nursing assistants, who are exposed to frequent heavy lifting, were 1.6-fold more likely to undergo surgery for pelvic organ prolapse or UI than women in the general population. Fitzgerald and colleagues<sup>17</sup> surveyed women who worked for a large academic center. Of the 1113 women surveyed, 21% ( $n = 232$ ) reported UI at least monthly. Incontinent women were significantly older and had a higher BMI than continent women. Women in this study used self-care practices such as using absorbent products or limiting fluids.

Several studies have reported on the relationship between UI and military training and activities. Women in the military have physically demanding roles, and the presence of UI can interfere with lifestyle as well as ability to perform assigned duties. Sherman and associates<sup>56</sup> found that 27% ( $N = 450$ ) of U.S. female army soldiers (average age, 28.5 years) experienced problematic UI, with 19.9% saying they leaked significantly during training tests. However, only 5.3% felt that urine leakage had a significant impact on their regular duties. This may be due to the fact that 30.7% of women stated that they took precautions such as voiding before training, wearing “extra-thick” pads, and limiting fluid intake. A very disturbing finding in this study was that 13.3% of women restricted fluid intake while participating in strenuous

field training. A third study<sup>57</sup> looked at women flying in high-performance combat aircraft. Aircrews who fly in high-gravity aircraft perform an M-1 maneuver, which is a modified Valsalva with an isometric contraction of the lower extremities. This movement may place women pilots at risk for urine loss due to increased intra-abdominal pressure and increased gravity load. Results of a questionnaire of aircrew ( $N = 274$ ) indicated that 26.3% had experienced urine loss at some time. However, pilots did not have higher UI rates than women in other positions (e.g., navigators, weapon systems operators). In this study, as in others, crew position, history of vaginal delivery, and age were found to be significant risk factors.<sup>3</sup>

The data from these studies demonstrate that UI is not rare among young women. We think that young incontinent women need an appropriate treatment to prevent the possible worsening of symptoms, and it seems logical to develop strategies for screening those with high risk factors.<sup>58</sup> We assume that UI is a female disease with much higher prevalence than medical literature has demonstrated and with a surprisingly high prevalence in groups of physically active women.<sup>48,53</sup> Based on our current knowledge of the effect of pelvic floor muscle training (PFMT), we recommend that specific training pelvic programs be proposed as the first choice of treatment. The perineal blockage technique and the Knack technique appear to be effective adjunctive modalities for pelvic floor rehabilitation and can be proposed for active women.<sup>48,53</sup> The impact of carefully instructed pelvic floor exercises on sports incontinence has not been as beneficial as that in a normal female population.

## BLADDER RETRAINING AND PELVIC FLOOR MUSCLE EXERCISES

### Bladder Retraining

No single treatment modality should be considered the first choice of treatment in the management of either the unstable bladder or the urge syndrome. Bladder retraining, sometimes termed bladder drill, is a noninvasive treatment modality that has been used not only for these two conditions but also for mixed incontinence and even SUI.<sup>59</sup> It has been widely studied over the last 20 to 25 years, although little scientific work has been published recently. An excellent review of the subject is available in the Cochrane Library.<sup>60</sup> Bladder retraining is a form of behavioral therapy in which a patient with an intact nervous system “relearns” to inhibit a detrusor contraction or a sensation of urgency. Such behavioral therapies include biofeedback, hypnotherapy, and acupuncture. There are good reasons why behavioral methods or therapies may be of value in idiopathic urge syndromes. Although these have been a subject of review,<sup>59,61</sup> they can be summarized as follows:

- A strong emotive event in a patient's life may be the initial trigger for urinary symptoms.
- Patients with detrusor instability have a higher neuroticism score on formal testing than do patients with genuine SUI.
- There is relationship between detrusor instability and hysterical personality trait.
- Patients with detrusor instability are more likely to have psychosexual problems than patients with genuine SUI.
- Other behavioral forms of therapy, such as hypnosis, are effective methods of treatment.

- Treatment is itself associated with a strong placebo effect, which has been estimated at between 4% and 47% in clinical trials.

A frequently used treatment regimen<sup>59</sup> can be broken into the following components:

- Exclude pathology.
- Explain the condition to the patient.
- Explain the treatment and its rationale to the patient.
- Instruct the patient to void at set times during the day, for instance, every hour. The patient must not void between these times; she must wait or be incontinent.
- The voiding interval is increased by increments (of perhaps 30 minutes) after the initial goal is achieved, and the process is then repeated.
- The patient should have a normal fluid intake.
- The patient should keep her own input and output chart. The increasing volumes of urinary output at increasing intervals act as a reinforcement reward.
- The patient should receive praise and encouragement on reaching her daily targets.

Typical results note that up to 90% of patients become continent, although there is a relapse rate up to 40% within 3 years of treatment. Such relapses could be treated by reinstatement of a retraining program.

Most patients with a urodynamically demonstrable unstable bladder who were rendered symptom free also became stable on urodynamic assessment.<sup>59</sup> Several studies have compared bladder retraining regimens with pharmacologic treatment. Further studies have addressed the issue of supplementing bladder retraining with drug treatment. Although the data from such studies are currently limited, there is no evidence so far that supplemental drug therapy is superior to bladder retraining alone.<sup>59,61</sup> Therefore, bladder retraining appears to be equal or superior to drug treatment and may have greater long-term benefits.

There are numerous areas for future study. There is a lack of consistency in bladder retraining programs. There is a need not only to evaluate an optimal program but also, most importantly, to identify the optimal increment in both the voiding interval and the rate at which the voiding interval is iterated after attainment of each stage of the regimen. A shorter initial voiding interval, for instance, may be necessary for women with more intense frequency or with less confidence. There is clearly a popular benefit from widespread treatment in a community as opposed to treatment of a small number of patients in hospital, but there is a need to determine the optimal supervision in the community. There is a need for comparison between bladder retraining and other physical interventions. There are limited data, for instance, comparing bladder retraining with PFMT, estrogen replacement, and electrical stimulation. Bladder retraining is an effective treatment for women with urge, stress, or mixed UI. It is not yet clear whether the urodynamic diagnosis specifically affects the likelihood of success. There is a lack of consistency in bladder retraining programs, and an optimal regimen needs to be identified. However, it is possible that regimens will need to be tailored to the individual patient.<sup>59</sup> Bladder retraining appears to have benefits similar to those of drug treatment; it does not appear to be benefited by supplementary drug treatment; and it may have greater long-term benefits than drug therapy. Bladder retraining appears to be largely free of adverse effects and is acceptable to patients.<sup>59</sup>

**Figure 19-1** Pelvic floor muscle strength is important to the control of urge incontinence. Patients are taught “urge strategies” to prevent loss of urine. The goal is to challenge the urgency by using pelvic floor muscles to inhibit the involuntary detrusor contraction; this is accomplished by rapidly contracting the pelvic floor muscles and taking a deep breath. Pabd: Intra-abdominal pressure; Pdet: Detrusor pressure; Pves: Intra vesical pressure; SSUE: External Striated Urethral Sphincter; PFM: Pelvic Floor Muscles.

### Pelvic Floor Muscle Exercises

The role of the PFMs in urge incontinence is less clear. Therapy is usually based on improving PFM function—in particular, the ability to sustain a contraction—and then using the improved muscle function in a bladder retraining program. Reflex inhibition of a detrusor contraction may be possible by producing a voluntary contraction of the striated muscles of the pelvic floor and activating the perineodetrusor inhibitory reflex, as described by Mahony and colleagues.<sup>62</sup> PFM exercises are also used for the treatment of OAB. The rationale behind the use of PFMT to treat urge incontinence is the observation that electrical stimulation of the pelvic floor inhibits detrusor contractions. The aims of this approach are to inhibit detrusor muscle contraction by voluntary contraction of the PFMs when the patient has the urge to void and to counteract the fall in urethral pressure or urethral relaxation that occurs with an involuntary detrusor contraction.<sup>63</sup> It has been suggested that reflex inhibition of detrusor contractions may accompany repeated voluntary PFM contraction or maximum contractions (Fig. 19-1).

### Clinical Results: Bladder Retraining and Pelvic Floor Muscle Exercises

Berghmans and associates<sup>64</sup> recently reviewed the literature concerning the effectiveness of pelvic floor exercises for the treatment of OAB and concluded that, although bladder retraining seems to yield some benefit, the available data are insufficient to fully evaluate the efficacy of this strategy. Conservative treatment

of women with UI, specifically PFMT and bladder retraining, is recognized as effective therapy.<sup>65</sup> Only three published reports of a single-session group education were identified, but none assessed improvement of pelvic floor contraction strength, an expected outcome of PFMT, or lengthening of intervoid interval, an expected outcome of bladder retraining.<sup>66-68</sup>

Frequency-volume charts (FVCs) are an important tool in the investigation of patients with lower urinary tract dysfunction, because they provide the ability to study lower urinary tract function during normal daily activities. The information obtained by FVCs is currently limited to the number of voidings, the voided volumes, the distribution of voidings between daytime and nighttime, the registration of episodes of urgency and leakage, and the number of incontinence pads used. Little research has been done to incorporate a sensory evaluation into these charts. However adequate sensation of bladder filling is important for proper bladder function. Currently, sensory information related to bladder filling is mainly deduced from cystometric studies in which the patient is catheterized and, in case of conventional cystometry, the bladder is artificially filled. To what extent these factors confound the sensory evaluation remains unknown. De Wachter and Wyndaele<sup>69</sup> studied whether FVCs can be used as a noninvasive tool for sensory evaluation. Furthermore, they studied the agreement between sensory data derived from these charts and data obtained during conventional cystometry. Fifteen healthy female, nulliparous students, without urologic history, between 18 and 24 years old, were asked to fill out a 3-day FVC during normal daily activities. They noted the time and volume of each micturition and scored the grade of perception of bladder fullness according to predefined grades before each micturition. All volunteers also underwent a conventional cystometric bladder filling at 30 mL/min and were asked to describe all sensations related to bladder filling. They also correlated these sensations to the same predefined grades of perception of bladder fullness that were used on the FVCs. Data from this pilot study showed that the information obtained from FVCs can be extended beyond just recording “classic” parameters such as voided volumes: these charts can be used as a noninvasive, inexpensive tool to evaluate sensations of bladder filling during normal daily activities. Moreover, sensory data deduced from FVCs show good agreement with sensory data from cystometric bladder filling. Because the largest proportion of the micturitions was made without a desire to void in the healthy female population we studied, the distribution of sensation-related micturitions may provide a new parameter to study bladder behavior. Including a sensory evaluation into FVCs and evaluating the distribution between sensation-related and non-sensation-related micturitions may improve the power of these charts to discriminate among different pathologies. The use of these “sensation-related FVCs” is currently being investigated in groups of incontinent patients.<sup>64</sup>

In a randomized controlled trial, Sampselle and colleagues<sup>70</sup> examined changes in pelvic floor contraction strength and intervoid interval at 12 months after intervention in women who attended a single group teaching session followed up with a single brief individual visit. They further examined the treatment group’s knowledge of PFMT and bladder training as well as technique and adherence. Volunteers who qualified from telephone screening were randomly assigned to a control (no treatment) group or to a treatment group that received the behavioral modification program. Both groups underwent clinical baseline screening and evaluation of pelvic floor contraction strength (measured by palpation of pressure and displacement), as well as

documentation of intervoid interval (measured by a 3-day voiding diary). The treatment group received a 2-hour classroom presentation of the anatomy and physiology of continence, with an explanation of the rationale and verbal instruction in PFMT and bladder training. This was followed in 2 to 4 weeks with an individualized evaluation to test knowledge (measured by response to eight multiple-choice items), technique (measured by palpation), and adherence (measured by report of practice). Brief additional instruction in PFMT and bladder training was provided as needed. Follow-up was by phone and mail every 3 months except at the 12th month, when all participants underwent a final clinical examination.

A total of 195 control and 164 treated participants completed the study.<sup>70</sup> In the treatment group, mean knowledge at 2 to 4 weeks after instruction was 87% for PFMT and 89% for bladder training. Palpation of PFMT technique revealed that 65% of participants needed no further instruction, and 32% required brief individual instruction (approximately 5 minutes); 3% were unable to demonstrate effective PFM contraction techniques after individual instruction and were excluded from the study. With respect to adherence, participants in the behavioral modification program were encouraged to practice PFMT every day throughout the 12-month postinstruction period. At the 3-month data point, 82% of participants reported practicing PFMT two to three or more times per week. At 12 months, the treatment group demonstrated significant increases in pelvic floor contraction pressure ( $P = .0008$ ) and displacement ( $P < .0001$ ), compared with controls. Intervoid interval also was significantly lengthened for those in the treatment group compared with the control group ( $P < .0001$ ). A regression model that adjusted for UI level at baseline and other covariants, including race, age, and education, revealed a treatment group effect that was significant at  $P < .0001$  for each of the three outcomes (i.e., pelvic floor contraction pressure, displacement, and intervoid interval). The authors concluded<sup>70</sup> that this randomized controlled trial of the effectiveness of group teaching of behavioral therapies followed by brief individual instruction as needed demonstrated positive effects on knowledge, technique, and adherence. The significant 12-month outcome differences between treatment and control groups provided evidence that this was an effective method to teach these behavioral therapies.

Clearly, the necessary knowledge and skills were imparted to enable women to perform PFMT and bladder training at levels that resulted in significant differences in pelvic floor contraction strength and lengthened intervoid interval. The greater efficiency of instruction when provided to groups rather than individually warrants further study to document cost-effectiveness outcomes.

## BIOFEEDBACK THERAPY

Biofeedback can be defined as the use of monitoring equipment to measure internal physiologic events, or various body conditions of which the person is usually unaware, to develop conscious control of body processes. Biofeedback uses instruments to detect, measure, and amplify internal physiologic responses to provide the patient with feedback concerning those responses.<sup>71,72</sup>

The most common modalities of biofeedback involve electromyography (EMG), manometry, thermal measurement, electroencephalography (EEG), electrodermal feedback, and respiration

rate. The instruments include sensors (EMG, pressure sensors) for detecting and measuring the activity of anal or urinary sphincters and PFMs, and techniques also have been developed to measure activity of the detrusor muscle for treatment of UI. A major reason for high interest in biofeedback is that the patient is actively involved in treatment. Biofeedback has now gained several potential applications for urologic conditions, having been successfully used for patients with urologic disorders such as detrusor instability.

Biofeedback is a very specific treatment that can restore bladder control by teaching patients to modulate the mechanisms of continence. Also, behavioral therapy can be used in combination with pharmacologic therapy to provide an excellent response with minimal side effects.<sup>73</sup>

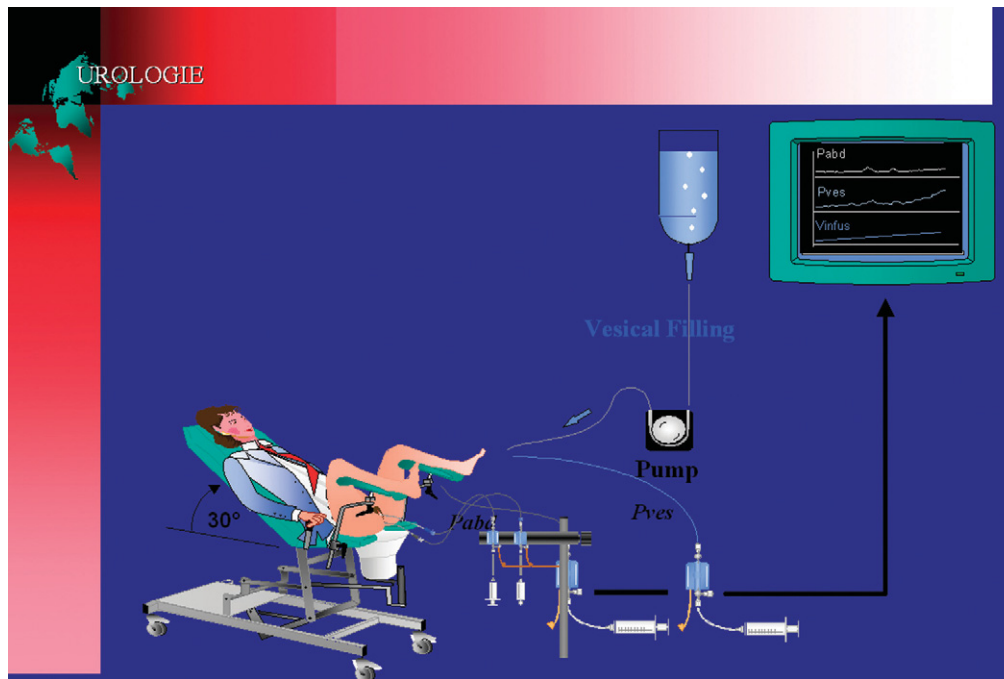

For biofeedback to be useful, several conditions must be met. There must be a readily detectable and measurable response (e.g., bladder pressure, PFM activity), and there must be a perceptible cue (e.g., the sensation of urgency) that indicates to the patient when control should be performed. Of particular importance is the patient's ability to modify bladder function through operant conditioning. In the application of biofeedback to the treatment of UI, the concepts of neurophysiology of voiding and learning and conditioning are combined to accomplish the clinical objective of voluntary control of bladder function.<sup>74,75</sup>

### Cystometric Biofeedback

During cystometry, bladder pressure readings are available to the patients and may provide a mechanism for feedback that allows them to acquire better control. An overactive detrusor contraction with imperative urge should be inhibited before it escalates. Cystometric biofeedback is used to teach the patient how to recognize and inhibit detrusor contractions. Other authors have described similar methods.<sup>76</sup>

The original technique for biofeedback in the management of idiopathic detrusor instability was described by Cardozo and colleagues.<sup>77</sup> After an initial explanation, the patient's detrusor pressure was measured cystometrically and recorded on a chart recorder. A voltage-to-frequency converter was connected to the detrusor pressure strain-gauge amplifier. This emitted an auditory signal rather like a siren. Alternatively, for patients who exhibited confusing rectal contractions during the treatment sessions, the auditory feedback could be transferred to the intravesical-pressure strain gauge. The gain and frequency range were adjusted to suit the individual patient, but once a baseline tone was decided upon, the note emitted through the loudspeaker increased in pitch as the detrusor pressure rose and decreased as it fell. A mirror was positioned in such a way that the patient could observe the detrusor (or intravesical) pressure tracing. Female patients attended four to eight 1-hour sessions, during which the bladder was filled two or three times with 0.9% saline prewarmed to body temperature. When detrusor contractions occurred, they could be heard and seen, and these signals were associated with the symptoms of urgency and urge incontinence.

The women were instructed to attempt to control the pitch of the auditory signal by deep breathing, general relaxation, tightening certain muscle groups, or any other means they found helpful. As patients learned to control their detrusor pressure during supine cystometry, provocative maneuvers such as erect cystometry, laughing, coughing, and running the water taps were employed.<sup>78</sup> Burgio and colleagues<sup>79</sup> used a similar technique of bladder biofeedback in a behavioral training program for older

**Figure 19-2** During cystometric biofeedback, bladder pressure readings are available to the patient and may provide feedback that allows the patient to acquire better control. The rectal catheter measures and subtracts the intra-abdominal pressure. When detrusor contraction occurs, it can be seen on the screen. The patient is requested to produce a voluntary pelvic floor contraction when she feels the strong urge to void. Pabd (*top*): Intra-abdominal pressure; Pves (*middle*): Intra-vesical pressure.

men and women with urge incontinence. During training sessions, patients observed bladder pressure during retrograde filling and practiced keeping bladder pressure low. Cystometric biofeedback requires the use of a transurethral bladder catheter and a rectal pressure monitor for suppression of the uninhibited contractions (Fig. 19-2). The bladder catheter measures increases in intravesical pressure indicative of uninhibited contractions. The rectal catheter measures and subtracts the intra-abdominal pressure. Artificial filling of the bladder is necessary for this technique of biofeedback and represents more accurately the conditions under which continence must be achieved during regular daily activities. Although this concept appears to be clinically relevant, filling of the bladder requires catheterization, with its associated discomfort and a small degree of risk. Such therapy could be proposed using urodynamics equipment with the biofeedback included.

### Pelvic Floor Muscle Biofeedback

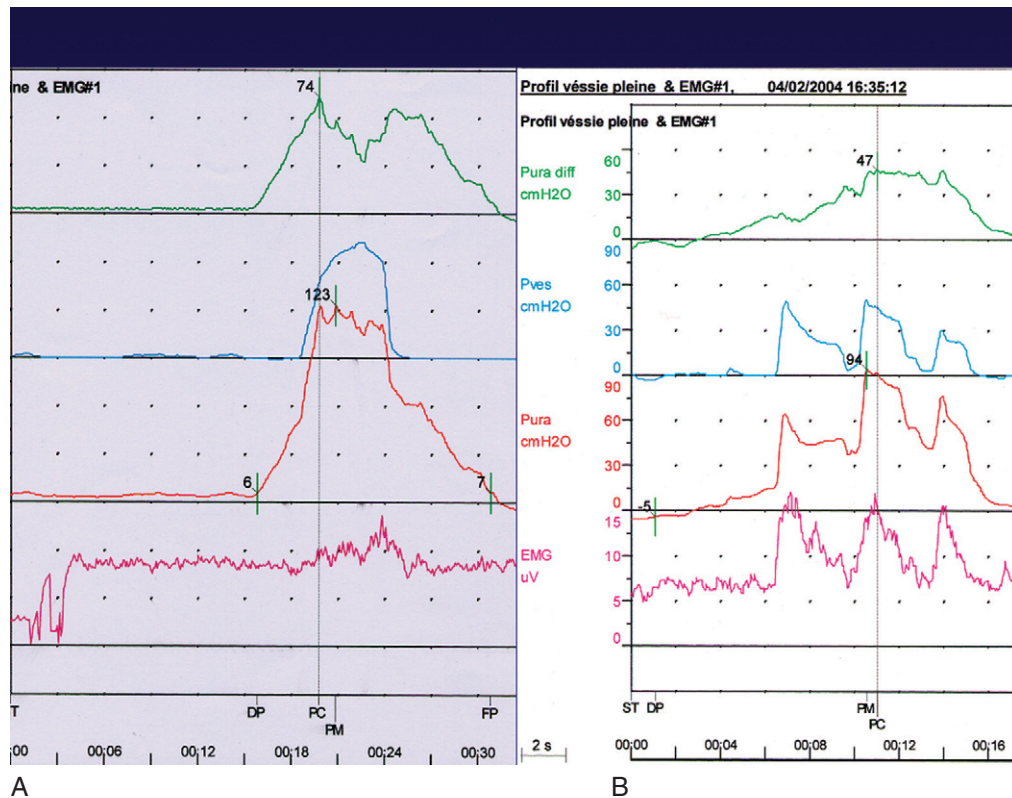

The three common signal sources (bladder pressure, anal sphincter pressure, and vaginal EMG) are significantly altered by increases in intra-abdominal pressure. Simultaneous measurement of abdominal activity should be done with all biofeedback therapy techniques. Intra-abdominal pressure can be measured easily using an internal rectal balloon. Electromyographic activity of the rectus abdominis muscles can be determined by surface electrodes. The abdominal muscle activity is displayed via two active electrodes placed 3 cm apart just below the umbilicus. A ground electrode is placed on a convenient bony prominence, such as the iliac crest.<sup>73,80,81</sup> Myographic biofeedback training has a twofold purpose: to increase the activity of weak muscle groups and to promote relaxation of spastic or tense muscles. Biofeed-

back equipment has become sophisticated, and there are two basic types designed to suit the setting in which biofeedback is implemented: the outpatient clinic, where the patient is trained using a comprehensive clinic system, and the individual's home, where a smaller unit is used, generally on a more frequent basis. Abdominal muscle activity should be monitored simultaneously with PFMs so that patients can learn to contract the PFMs selectively. These measurements can be accomplished through a two-channel system.

Another approach to biofeedback for UI<sup>79,82</sup> combines bladder pressure and pelvic floor musculature biofeedback in a procedure that provides simultaneous visual feedback of bladder, external anal sphincter, and intra-abdominal pressures. Using two-channel biofeedback (one with surface electrodes and one using an internal rectal balloon), patients are taught to contract and relax the PFMs selectively without increasing bladder pressure or intra-abdominal pressure.

The initial step in treatment is to help the patient identify the PFMs. It is important to test contractility and to know how the patient contracts the PFMs when instructed to squeeze around the examining fingers. Very often, the contraction is performed incorrectly (Fig. 19-3). Instead of lifting up with the muscles, the patient is observed to be bearing down, which is counterproductive because it increases intra-abdominal pressure and therefore bladder pressure.<sup>82-84</sup> This response has been referred to as a "reversed perineal command"<sup>79,82,85</sup> or a "paradoxical perineal command." The frequency of such incorrect contraction is about 22% in women after childbirth, and it decreases to about 10% in women in the perimenopausal period. Bump and colleagues<sup>86</sup> reported that 50% of women were unable to perform a voluntary PFM contraction after brief verbal instruction, and as many as 25% mistakenly performed a Valsalva maneuver. This type of

**Figure 19-3** Recording of electromyographic (EMG) surface activity of pelvic floor muscles (*bottom*), urethral pressure (*middle*), and vesical pressure (*top*) during a hold maneuver. The graphs demonstrate abnormal voluntary perineal contractions. **A**, Paradoxical Perineal Command: Instead of lifting up the anus and vagina in drawing up, the patient is observed to be bearing down or pushing, which is counterproductive because it increases intra-abdominal pressure and therefore bladder pressure. From bottom to top, three tracings: Surface EMG of Pelvic floor muscles activity (*bottom*); Urethral pressure Profile (*second*); Vesical Pressure (*third*); Differential pressure: Urethral Pressure minus Vesical Pressure (*top*). **B**, Co-contraction of abdominal muscles. Some patients use antagonist muscles when contracting the pelvic floor. From bottom to top, four tracings: Surface EMG of Pelvic floor muscles activity (*bottom*); Urethral Pressure Profile (*second*); Vesical pressure (*third*); Differential pressure: Urethral Pressure minus Vesical Pressure (*top*).

improper PFM activity needs to be identified and eliminated as soon as possible.

It seems clear that patients who bear down in this way must be identified before being asked to practice Kegel exercises at home, or the efforts will be futile. In addition, such maneuvers might increase vaginal wall descent or worsen UI by increasing intra-abdominal pressure. Except for the group of patients who are unable to perform a proper voluntary pelvic floor contraction, it seems very rare to perform a voluntary pelvic floor contraction without a co-contraction of the abdominal muscles. Research suggests that it is not possible to maximally contract the PFM without co-contraction of transverse abdominal muscle (*transversus abdominis*). Contraction of this muscle can be observed as a pulling in of the abdominal wall with no movement of the pelvis. During the initial biofeedback session, it is also common to observe patients perform pelvic muscle contractions accompanied by contraction of synergistic muscles such as adductors (pressing the knees), or gluteal muscles (squeezing the buttocks). This natural substitution of the stronger muscles for the weakened or minimally perceived motor response can also have negative consequences.

An instrumentation system allows multiple measurements and modalities to be displayed on a monitor and stored in a computer database. Feedback must be relevant in order to enhance learning and to focus on agonist (*levator ani*) and antagonist (*abdominal*) muscles. Patients should be able to recognize that the proper muscles are being used appropriately. Therapy is

first concentrated on inhibition of the antagonist muscles and decreasing the activity of surrounding muscles while increasing the response of the agonists. Because the aim of performing the contraction is to contract the PFMs correctly, the proprioceptive signals generated by the substituting muscles can easily be misinterpreted as originating from the pelvic floor rather than from the strong antagonist muscles. When the substituting muscles contract, their afferents can mask low-intensity sensory signals that may be generated by the weakened PFMs. This faulty maneuver perpetuates the substitution pattern and delays the development of increased awareness of the isolated PFMs. During the initial session (Fig. 19-4), this pattern occurs quite often as the patient attempts to contract her PFMs by moving the upper part of the abdomen, even rising off the table.

When the patient is instructed to relax the abdominal muscles or the surrounding muscles (*adductors/gluteal*), substitution of the interfering muscles may be detected by the biofeedback equipment. An abdominal substitution pattern used when attempting to “hold back” leads to a false maneuver of pushing down, which causes a rise in intra-abdominal pressure. With such recruitment, the contraction would only maximize a rise of intra-abdominal pressure, resulting in an increase in EMG abdominal signals.

To minimize inappropriate tensing, it is helpful to train patients to keep these muscles relaxed when trying to prevent urine loss. For this purpose, patients are instructed to breathe evenly and to relax abdominal muscles. During the training

**Figure 19-4** The initial step in treatment is to help the patient identify the pelvic floor muscles. During the session, the patient needs to be comfortably installed with legs slightly apart and abducted. Patient is instructed to breathe evenly and to relax abdominal muscles.

sessions, the patient is also asked to place one hand on her lower abdomen to palpate the faulty abdominal contraction.

Biofeedback therapy provides the patient with better volitional control over skeletal muscles such as levator ani and urinary sphincter, heightened sensory awareness of the pelvic floor area, and decreased muscle antagonist contractions. PFM strength and control are also important to the control of urge incontinence.<sup>79,82</sup> Patients with urge incontinence are taught “urge strategies” to prevent loss of urine during detrusor contractions. Patients with urge incontinence typically report that they rush to the toilet when they experience a sensation of urgency to void. Voluntary PFM contraction to control urge has been shown to be effective in the management of urge incontinence.<sup>79,82,87,88</sup> Godec and colleagues<sup>89</sup> inhibited reflex contraction of the detrusor muscle with an electrically stimulated contraction of the PFM. Reflex inhibition of detrusor contractions may accompany repeated voluntary pelvic floor contractions.<sup>90</sup> Patients are taught a more effective pattern of responding to urgency. They are told not to rush to the toilet, because this movement increases abdominal pressure on the bladder, increasing the likelihood of incontinence. Instead, they are encouraged to pause, sit down if possible, practice relaxing, and contract the PFMs maximally several times in an effort to diminish urgency, inhibit detrusor contraction, and prevent urine loss. When urgency subsides, they then proceed at a normal pace to the toilet.<sup>79,82,87</sup> Multichannel systems (Figs. 19-5 and 19-6) allow pressure and EMG measurements as well as abdominal measurements, thereby providing the clinician with multiple methods of biofeedback.

### Clinical Results

Many studies have demonstrated that treatment with biofeedback reduces incontinence. The data show clearly that the treatments are safe and effective, and they yield high levels of patient satisfaction. Cardozo and colleagues<sup>91</sup> reported a study of 34 women between the ages of 16 and 65 years treated by bladder biofeedback. They were given an average of 5.4 sessions of cystometric biofeedback. Female patients were treated in 4- to 8-hour

sessions at weekly intervals, during which the bladder was filled two to three times using 0.9% saline prewarmed to body temperature. A total of 87% were cured or improved subjectively and 60% objectively. No patient’s condition was worsened by biofeedback. The six patients who failed to improve had severe detrusor instability, with detrusor contractions greater than 60 cm H<sub>2</sub>O and a cystometric capacity of less than 200 mL. They found it impossible to inhibit detrusor activity. One of them was later found to have multiple sclerosis. Patient follow-up proved difficult, but of 11 women who were initially cured or improved, 4 remained completely cured and 2 had undergone surgery. These long-term results seem disappointing, but all the patients in the group had previously failed drug therapy.<sup>92</sup>

Millard and Oldenburg<sup>93</sup> used bladder training, bladder biofeedback, or a combination of both to treat 59 women with frequency, nocturia, urgency, and urge incontinence. The women underwent urodynamic testing, which revealed detrusor instability alone in 38 women, detrusor instability and sphincter incompetence in 6, sensory urgency in 12, and sensory urgency and sphincter incompetence in 3. All patients were initially hospitalized for 5 to 14 days and then assigned to either a Frewen-type bladder training program or a weekly outpatient biofeedback program. Millard and Oldenburg stated that “biofeedback was undoubtedly the most useful of the techniques.”<sup>55</sup> They claimed a 74% rate of cure or major improvement for patients with detrusor instability. None of the patients with detrusor instability and urethral incompetence was cured, although three of them improved, with conversion to stable cystometry. Of the women with sensory urgency, 92% benefited. It is difficult to see how biofeedback could have helped them, because their symptoms could not have been associated with cystometric changes. We think that patients were using their inhibition skills to abort detrusor contractions and give themselves enough time to reach the bathroom; it is difficult to separate components of treatment (bladder retraining, biofeedback).

Kjolseth and colleagues<sup>94</sup> assessed the outcome of biofeedback therapy (bladder filling with visual stimuli) in 15 children (6 to 12 years of age) and 7 adults (aged 20 to 50 years) with cystometrically proven detrusor instability. Detrusor pressure was visually conveyed to the patient during repeated bladder fillings.

Patients were instructed to inhibit detrusor pressure incrementally by tensing the pelvic floor musculature. None of the children was completely cured, but nine showed a marked decrease in the number or extent of symptoms. Two children showed moderate improvement, and for four children the treatment failed. One adult was completely cured, two showed moderate improvement, and four remained the same. None of these patients was converted to stable bladder.

In an uncontrolled study, Burgio and colleagues<sup>79,82</sup> demonstrated an 88% reduction in incontinence episodes in elderly men with urge incontinence who participated in an average of four 30-minute biofeedback training sessions. O’Donnell and Doyle<sup>95</sup> treated 20 male patients (>65 years old) with urge incontinence using 1-hour sessions twice weekly for 5 weeks. The mean number of incontinence episodes was decreased from 5.1 to 2.0 per day after treatment. Burns and colleagues<sup>96,97</sup> conducted a randomized clinical trial of vaginal EMG biofeedback in the treatment of SUI or mixed UI.<sup>9</sup> As part of this trial, older women (>55 years old) were assigned to 8 weeks of biofeedback-assisted PFMT. A no-treatment control group contained 38 subjects. Biofeedback combined with daily practice resulted in a mean 61% reduction in frequency of urine losses; this was not significantly better than

**Figure 19-5** The unit used by the patient at home could be connected the stationary device. (Courtesy of HMT Inc.)

training without biofeedback, which resulted in a mean 59% reduction of incontinence. Both results were significantly better than the mean 9% increase in incontinence demonstrated by the control group.

Because the mechanisms of urge incontinence are in some ways different from the mechanisms for SUI, the role that biofeedback plays in treating these conditions may be different as well. The contribution of biofeedback in the treatment of urge incontinence was examined in a randomized study of 20 older men and women with persistent urge incontinence.<sup>98</sup> Patients who were trained without biofeedback responded as well to treatment as those trained with bladder-sphincter biofeedback. Later, a larger randomized controlled trial corroborated this finding. Burgio and colleagues<sup>82,88</sup> studied 222 older women with predominantly urge incontinence. Patients were randomly assigned to behavioral training with biofeedback, behavioral training without biofeedback, or behavioral training with a self-help booklet. Instead of biofeedback, training was done with verbal feedback based on vaginal palpation. Patients in the biofeedback group showed a 63% reduction of incontinence, which was not significantly different from the 69% reduction in the verbal feed-

back group. These findings indicate that careful training with verbal feedback is as effective as biofeedback in the first-line treatment of urge incontinence, and that biofeedback can be reserved for those cases in which women cannot successfully identify their muscles. Stein and colleagues evaluated the long-term effectiveness of transvaginal or transrectal EMG biofeedback in 28 patients with stress and urge incontinence.<sup>99</sup> Sixty percent of the patients had detrusor instability, as demonstrated by urodynamics. Biofeedback successfully treated 5 (36%) of 14 patients with SUI and 9 (43%) of 21 with urge incontinence. The treatment response was durable throughout follow-up, from 3 to 36 months, in all of the responding patients. The authors concluded that biofeedback is a moderately effective treatment for stress and urge incontinence and should be offered to patients as a treatment option.

PFMT with biofeedback is also effective for treatment of predominantly urge incontinence. Burgio and colleagues<sup>82,87</sup> conducted a randomized clinical trial to compare biofeedback-assisted behavioral training with drug therapy (oxybutynin chloride) for treatment of urge incontinence in ambulatory, community-dwelling older women. A volunteer sample of 197 older women (55 to 92 years of age) was evaluated. Subjects were randomized to four sessions (8 weeks) of biofeedback-assisted behavioral treatment, drug treatment, or a placebo control condition. Daily bladder diaries were completed by patients before, during, and after treatment. Behavioral training, which resulted in a mean 80.7% improvement, was significantly more effective than drug treatment (mean, 68.5% improvement;  $P = .009$ ). Similarly, a larger proportion of subjects in the behavioral group achieved at least 50% and 75% reductions of incontinence ( $P = .002$  and  $P = .001$ , respectively). Although the values for full recovery of continence (100%) followed a similar pattern, the differences were not statistically significant ( $P = .07$ ). Several secondary outcome measures were used to assess the patients' perceptions of treatment. On every parameter, the behavioral group reported the highest perceived improvement and satisfaction with treatment progress ( $P < .001$ ).

Wyman and colleagues compared the efficacy of bladder training, PFM exercise with biofeedback-assisted instruction, and combination therapy in women with genuine SUI and in those with detrusor instability.<sup>100</sup> This was a large randomized clinical trial with three treatment groups. Women with incontinence ( $N = 204$ : 145 with SUI and 59 with urge incontinence due to instability) received a 12-week intervention program, including six weekly office visits and six weekly mail or telephone contacts. They were followed up immediately and after 3 months. The combination therapy group had significantly fewer incontinent episodes, better quality of life, and greater treatment satisfaction immediately after the therapy. No differences between groups were observed at the 3-month follow-up. The authors concluded that combination therapy consisting of bladder training and PFMT with biofeedback had the greatest immediate efficacy in the management of female UI.

## ELECTRICAL STIMULATION

### Basic Principles and Mechanism of Action

Electrical currents are applied therapeutically to stimulate muscle contraction, usually through activation of nerves that supply muscles. Electrical stimulation was first used in the management

of UI in 1952, when Bors<sup>101</sup> described the influence of electrical stimulation on the pudendal nerves, and in 1963, when Caldwell<sup>102</sup> developed electrodes that were permanently implanted into the pelvic floor and controlled by radiofrequency.

Godec and associates<sup>103</sup> first described the use of nonimplanted stimulators specifically for bladder inhibition. Initial work in animals indicated the potential of this therapy, and early clinical experience in Europe supported its likely efficacy. Much confusion surrounds electrical stimulation, and some is the result of inconsistent nomenclature. Commonly used terms include "functional electrical stimulation" and "neuromuscular electrical stimulation." Further confusion has arisen because of the wide range of stimulators, probes, and applications used.

Electrical stimulation is an effective treatment for urge incontinence. This technique uses natural pathways and the micturition reflexes, and its efficacy relies on a preserved reflex arc, with complete or partial integrity of the PFM innervation.<sup>104</sup> Based on animal experiments, direct stimulation of afferent or efferent fibers appears to be the most important mechanism to enhance the reflex response.

The mechanism of electrical stimulation for urge incontinence is a reflex inhibition of detrusor contraction. Bladder inhibition is accomplished through three mechanisms<sup>105,106</sup>:

1. Activation of afferent fibers within the pudendal nerve by activation of the hypogastric nerve at low intravesical pressure, corresponding to the filling phase
2. Direct inhibition of the pelvic nerve within the sacral cord at high intravesical pressure
3. Supraspinal inhibition of the detrusor reflex

In principle, defective control of the urinary bladder, resulting in urge incontinence, is caused by a central nervous dysfunction that affects central inhibitory control of the micturition reflex. Appropriate electrical stimulation may restore the inhibition effect.<sup>107</sup> Threshold intensity varies inversely with fiber diameter.

Any pulse configuration can provide nerve activation, and many stimulation waveforms have been used to cause neural excitation.<sup>105,107</sup> These include biphasic capacitively coupled pulses, monophasic square pulses, biphasic square pulses, and monophasic capacitively coupled spike pulses. Pulse durations ranged from 0.08 milliseconds up to 100 milliseconds but the most common used pulse duration is 0.2 milliseconds. To minimize electrochemical reactions at the electrode-mucosa interface, biphasic or alternating pulses are recommended.<sup>108</sup> The effects of electrical stimulation on detrusor inhibition are optimal with different stimulation parameters: 10 to 20 Hz. The sacral afferent nerves, particularly the autonomic nerves of the pelvic organs, are poorly myelinated (A $\delta$ ) or unmyelinated (C) fibers, which conduct current at a slow rate of 5 to 20 Hz. Thus, in the treatment of bladder instability and hyperreflexia, low-frequency stimulation is applied to the pudendal nerve afferents through probes. In both forms of electrical stimulation, the frequencies are chosen based on the clinical diagnosis. In mixed incontinence, two strategies are used. One strategy involves the use of a compromise setting of approximately 20 Hz; the other involves delivering both low-frequency and high-frequency stimuli.<sup>109</sup> Low frequencies (1 to 5 Hz) generate twitch contractions, allowing little sustained tension to develop in the muscle. Slow-twitch muscle fibers have a natural firing rate of 10 to 20 Hz, whereas fast-twitch fibers fire at 30 to 60 Hz.

Treatment of chronic lower urinary tract dysfunction can be challenging and difficult. Behavioral and medical therapies in

**Figure 19-7** Transcutaneous electrical stimulation of the peripheral nerves may facilitate inhibition of detrusor activity, with specific parameters: intensity of 5 to 8 V, frequency of 10 Hz, and pulse width of 5 to 20 msec. Transcutaneous posterior nerve stimulation is performed with a needle inserted 5 cm cephalad to the medial malleolus.

patients with urge incontinence often result in unsatisfactory outcomes, leaving the patient with refractory incontinence no other option but surgery (e.g., bladder transection phenolization, clam-ileocystoplasty).<sup>110</sup> To sidestep surgery, electrostimulation offers an alternative for therapy-resistant urge incontinence. During the past decades, electrical stimulation of the bladder, sacral roots, and pudendal nerves has been explored with varying success. However, these treatments involve technical problems, high cost, or low patient compliance because of the discomfort associated with treatment procedures.<sup>111-113</sup>

Transcutaneous electrical nerve stimulation (TENS) of the S3 segment is a useful alternative in patients with detrusor instability.<sup>114</sup> Okada and coworkers stimulated thigh muscles and observed clinical improvement for several weeks to months.<sup>115</sup> However, TENS therapy can induce skin irritation and allergy at the stimulation site due to chemical and mechanical irritation. Consequently, other stimulation approaches have been explored. Research has focused on the effect of stimulation of afferent nerves in the lower limb. In cat experiments, Lindstrom and Sudsuang demonstrated detrusor inhibition through stimulation of the myelinated afferents of the hip adductor muscles.<sup>116</sup> Inspired by acupuncture points over the tibial and peroneal nerves, McGuire and Zhang applied TENS to these nerves to treat bladder overactivity. They reported restoration of bladder control in a small group of patients.<sup>117</sup> Stoller proposed percutaneous posterior tibial nerve stimulation (PTNS) for treatment of bladder and pelvic floor dysfunction.<sup>118</sup> In this multicenter study, PTNS was used for the treatment of symptoms related to bladder overactivity. The posterior tibial nerve is a mixed nerve, containing motor and sensory nerve fibers. Correct placement of the needle electrode induces a motor and sensory response (Fig. 19-7). Centrally, the posterior tibial nerve projects to the sacral spinal cord in the same area where bladder projections are found (i.e.,

the sacral micturition center and the nucleus of Onuf). These are most probably the areas where the therapeutic effect of neuromodulation of the bladder through PTNS takes place.

PTNS has a clear carry-over effect: 30 minutes of stimulation induces a lasting beneficial effect. In cat experiments, a 5-minute stimulation of afferent nerves resulted in more than 1 hour of bladder inhibition.<sup>119</sup> Perhaps some kind of learned behavior is activated by intermittent stimulation such as PTNS. This supposition suggests that higher regions within the cortical central nervous system are also involved. Furthermore, in rats, PTNS exerted its influence on FOS expression, suggesting neuromodulating action.<sup>120</sup> In addition, activation of endorphin pathways at sites within the spinal cord could affect detrusor behavior.<sup>121</sup> Parallel to the gate control theory for pain, it can be suggested that stimulation of large somatic fibers modulates or inhibits the thinner afferent A $\delta$  or C fibers, thus decreasing the perception of urgency.<sup>122</sup>

### Clinical Practice and Selection of Patients

Different types of electrical stimulation (see Figs. 19-4 and 19-5) include office therapy and the home treatment program.<sup>123,124</sup> Office therapy is also called the outpatient program or in-clinic treatment. With this approach, a stationary device with a wide range of electrical parameters is used in the office or clinic under the control of the therapist. The system can be modified to suit the needs of each patient. Devices with microcomputers allow the caregiver to change the stimulation parameters (e.g., waveform, pulse width, frequency) based on patient history and urodynamic data.

Many probes are available (Fig. 19-8), including a standard two-ring vaginal probe; an intra-anal probe; and a two-channel vaginal and anal insertion probe. Special conditions that affect the choice of probe include the following:

- Vaginal size (depth of 4 to 12 cm) and shape (e.g., atresia or gaping vagina)
- Vaginal angle (10 to 45 degrees) and quality of the levator ani (thin or thick fibers)
- Type and degree of vaginal wall descent

Accurate assessment of individual anatomic differences allows the therapist to select the appropriate electrodes to obtain the most effective results. Low frequencies (10 to 20 Hz) are used for urge incontinence. Some stimulators have controls that are used to adjust frequency, duty cycle, and timing. The stimulus and intensity of the current are also adjustable, and all of these systems allow easy graduation in the intensity of contraction.

Therapeutic stimulation is recommended for women with UI who have undergone unsuccessful PFMT as a first-line treatment.<sup>125,126</sup> Pelvic floor electrical stimulation is one of the non-surgical approaches when treating UI. The stimulation decreases detrusor contractions in cases of OAB. Electrical stimulation must be performed in conjunction with a bladder drill and biofeedback.

The main contraindications to electrical stimulation are as follows:

1. Demand heart pacemakers
2. Pregnancy, if the risk of pregnancy exists
3. Postvolume residual (PVR) greater than 100 mL
4. Obstruction of the urethra, a fixed and radiated urethra, or a heavily scarred urethra

**Figure 19-8** Many probes are available with special conditions that affect the choice of probe. **A**, A probe designed specifically for patients with a wide vaginal hiatus (*top left*). **B**, The reference electrode is inserted in the middle of the vaginal probe (*top right*). **C**, During a severe relaxation of the pelvic floor or an important defect of levator ani muscles, the “finger” probe is used (*bottom left*). The patient is in lithotomy position with a one leg well supported while the therapist stimulates one side of the pubococcygeal portion of the levator ani with the “finger probe,” which is a two channel probe. **D**, An anal probe with the reference electrode inserted in the middle (*bottom right*).

5. Bleeding
6. Urinary tract infection or vaginal discharge
7. Complete peripheral denervation of the pelvic floor
8. Severe genital prolapse with complete eversion of the vagina

There are a few strict contraindications,<sup>1,2,6,7</sup> and there is general agreement that a patient with pelvic floor disorder associated with other conditions<sup>4,5,8</sup> will not respond to treatment. Although patients with severe genital prolapse are poor candidates, mild prolapse is not a significant problem. Many patients will not accept treatment with vaginal or anal probes because of ethical and religious beliefs. These concerns must be taken into account before this therapy is advocated. This issue is especially relevant when home treatment is being considered, because some patients will not agree to insert the device themselves, and some will refuse this type of treatment altogether. Functional, anatomic, and attitudinal barriers are more common in frail elderly people. Cognitively or functionally impaired subjects require a participating caregiver. In the elderly, home care treatment could be performed by a nurse or a physical therapist.

Patients with mild to moderate incontinence are the best candidates for this treatment, regardless of age. Because of the slight discomfort and embarrassment that may occur during stimulation, motivated patients of any age are the best candidates for this therapy. For unmotivated patients, another technique may be recommended, such as PTNS or electromagnetic stimulation.

In PTNS, the posterior tibial nerve is stimulated. This nerve closely relates to pelvic nerves for bladder and perineal floor; therefore, a retrograde stimulation of S3 roots and of sacral spinal

cord can be obtained. Several studies on the effects of this treatment on OAB syndrome have been published.<sup>127,128</sup> TENS of acupuncture points (see Fig. 19-7) may be used to inhibit detrusor activity. Surface electrodes are placed bilaterally over both tibial nerves or both common peroneal nerves.<sup>129</sup> Percutaneous stimulation of peripheral S2 and S3 afferents by way of the posterior tibial nerve modulates unstable detrusor activity. PTNS<sup>130</sup> is performed with a 34-gauge needle inserted 5 cm cephalad to the medial malleolus. TENS of the peripheral nerves may facilitate inhibition of detrusor activity with specific parameters, such as intensity of 5 to 8 V, frequency of 2 to 10 Hz, and pulse width of 5 to 20 msec.

### Clinical Results

One major problem in reviewing the literature on incontinence is the lack of data on the pretreatment status of patients, particularly when noninvasive forms of therapy are studied.<sup>131</sup> The interpretation of data may be limited because patients often are not classified urodynamically. Nonimplanted stimulators are effective in treating UI: overall, an improvement or cure rate of approximately 50% is common. No serious morbidity is reported with this type of therapy. Side effects that are common with drug therapy (e.g., anticholinergics,  $\alpha$ -adrenergics) do not occur with electrical stimulation.

Eriksen and Eik-Nes<sup>132</sup> performed a study of chronic stimulation with a dual vaginal-anal electrode in 55 patients. They found an initial response rate of 68%, with 47% of the overall group becoming dry. The objective response was an improved stress

profile. Kralj<sup>133</sup> studied the influence of the type of idiopathic urge incontinence on the efficient outcome of treatment with acute maximal electrical stimulation. Eighty-eight female patients were divided into a motor urge group ( $n = 40$ ) and a sensory group ( $n = 48$ ). Both groups underwent vaginal stimulation for 20 minutes. Of the 40 patients in the motor urge group, 55% were cured and 20% showed improvement, whereas 25% showed no change. Of the 48 patients in the sensory group, 87.5% were cured and 12.5% showed improvement.

Bent and associates<sup>134</sup> conducted a study of 45 patients with genuine SUI ( $n = 14$ ), detrusor instability ( $n = 10$ ), or mixed incontinence ( $n = 21$ ) and assessed the applicability of electrical stimulation and patient response to short-term electrical home therapy. Treatment was administered for 15 minutes twice daily for 6 weeks. Treatment consisted of biphasic stimulation at 20 Hz for urge incontinence and at 50 Hz for genuine SUI. The ratio of the duty cycle was 2 seconds "on" and 4 seconds "off." Subjective results showed improvement in 71% of patients with genuine SUI, 70% of patients with urge incontinence, and 52% of patients with mixed incontinence. The pressure-transmission ratio improved in four patients, and urethral pressure profiles improved in five patients with genuine SUI. Bladder capacity during cystometry improved in only one patient with detrusor instability.

Bourcier and Juras<sup>135</sup> conducted a study to establish the effectiveness of two different modalities: home treatment, consisting of treatment for 20 minutes twice daily for a 6-week period, and office therapy, consisting of twice-weekly treatment administered in the clinic for an average of 12 sessions. Of the 95 patients included in the study, 50 received home treatment and 45 received office therapy. Twelve patients had undergone a hysterectomy, and six had previously undergone colposuspension. All were evaluated with urodynamic tests. Patients with urge incontinence received biphasic capacity-coupled pulses with a continuous current of 20 Hz at a pulse width of 0.75 msec. Patients with genuine SUI received biphasic square pulses of 50 Hz at a pulse width of 1 msec. Current intensity was 0 to 90 mA or 0 to 24 V. During the first follow-up period (3 months), 71% of patients in the office therapy group reported subjective improvement, as did 51% of patients in the home treatment group. During the late follow-up period (6 months), 85 patients were studied (7 patients in the home treatment group and 3 in the office therapy group withdrew). Of the patients who participated in late follow-up, 47 were in the office therapy group (28 patients with genuine SUI and 19 with urge incontinence) and 38 were in the home treatment group (23 patients with genuine SUI and 15 with urge incontinence). The cure rate was approximately 50%. This study showed that both office therapy and home treatment are effective forms of treatment for patients with genuine SUI or urge incontinence. In addition, this treatment has no side effects. The results showed a higher degree of improvement with office therapy than with home treatment. The number of patients who did not continue physiotherapy was much higher in the group with urge incontinence (43%) than in the group with genuine SUI (15%). Patients with urge incontinence had less motivation to continue with therapy and also had a higher degree of psychological factors (e.g., chronic depression, psychosomatic disturbances, hysterical personality), which included reluctance to cooperate actively with treatment.

Many factors (e.g., age, severity of incontinence) are less crucial than previously thought, but the single factor that is consistently associated with positive outcome is greater motivation

and/or compliance with the intervention.<sup>136</sup> Brubaker and colleagues<sup>137</sup> compared electrical stimulation with sham electrical stimulation in women with urodynamically proven detrusor instability and found a significant reduction in detrusor overactivity in the electrical stimulation group only. This prospective double-blind, randomized control trial included 121 women who had genuine SUI ( $n = 60$ ), urge incontinence ( $n = 28$ ), or mixed incontinence ( $n = 33$ ). The study had two groups: a treated group ( $n = 61$ ) and a placebo-controlled group ( $n = 60$ ) with sham electrical stimulation. Patients underwent 8 weeks of treatment. Electrical stimulation was administered twice daily for 20 minutes with a vaginal probe at 20 Hz, a pulse duration of 0.1 msec, and a duty cycle of 2 seconds "on" and 4 seconds "off." The output was 0 to 100 mA; in the placebo group, sham electrical stimulation was characterized by no current in patient circuit. Objective cure was reported in 49% of patients in the treatment group who had detrusor instability, but no change was observed in patients with genuine SUI in either group. The authors found no significant change in the number of women who had genuine SUI on urodynamic testing at 2 months.

In a prospective multicenter study,<sup>138</sup> 35 patients with complaints of urge incontinence underwent 12 weekly sessions of PTNS at one of five sites in the Netherlands and one site in Italy. FVCs and I-QoL and SF-36 questionnaires were completed at 0 and 12 weeks. Success was analyzed by using subjective and objective criteria. Overall subjective success was defined as the willingness to continue treatment, whereas objective success was defined as a significant decrease (to <50%) in total number of leakage episodes. Twenty-two patients (63%) reported a subjective success. Twenty-four patients (70%) showed a 50% or greater reduction in total number of leakage episodes. Sixteen (46%) of these patients were completely cured (i.e., no leakage episodes) after 12 sessions. Quality-of-life parameters improved significantly. The authors concluded that PTNS is an effective, minimally invasive option for treatment of patients with complaints of urge incontinence, because improvement was seen in subjective as well as objective parameters.

One of the latest studies compared the three different approaches of conservative treatment: PFMT, biofeedback-assisted PFMT, and electrical stimulation (ES) in the management of OAB in women.<sup>139</sup> Exclusion criteria included pregnancy, deafness, neurologic disorders, diabetes mellitus, use of a pacemaker or intrauterine device, genital prolapse greater than stage two of the ICS grading system, residual urine volume 100 mL or greater, and urinary tract infection. Inclusion criteria included age between 16 and 75 years, symptoms and/or signs of OAB for more than 6 months, frequency of voiding eight or more times per day, and urgency of voiding one or more times per day. After the calculation of sample size, which disclosed that the total sample size should be at least 102 women, randomization of the eligible participants into the three treatment groups was performed. Initial assessment included a detailed medical history, a pelvic examination in the dorsal lithotomy position, a 1-hour pad test, and a filling and voiding cystometry, as well as a 4-day 24-hour FVC. Other assessments were evaluation of PFM strength using internal digital assessment according to the Oxford grading system and measurement of vaginal pressure with a balloon probe connected to a pressure transducer, as well as the Kings Health Questionnaire. The interventions included a PFMT program, an EMG-based biofeedback-assisted PFMT program with an intravaginal probe accompanied by a home program, and an electrical stimulation program using a biphasic symmetric

probe current with a frequency of 10 Hz, a pulse width of 400 milliseconds, and a duty cycle of 5 sec “on” and 10 sec “off.”

The treatment period consisted of 12 weeks. Patients also returned twice a week to the physiotherapy unit for mentoring of their progress. The treatment protocol for the biofeedback-assisted PFMT and electrical stimulation groups was conducted twice a week at the physiotherapy unit. The main outcome measures were post-treatment PFM strength, the record of the FVC, and the Kings Health Questionnaire. A total of 137 women with clinically proven OAB were recruited for the study; 120 subjects were randomly allocated to the three different treatment groups after 17 women were excluded for various reasons. Another 17 women dropped out during the treatment, leaving 34 women in the PFMT group, 34 in the biofeedback-assisted PFMT group, and 35 in the electrical stimulation to complete the study. Significant differences were noted between the biofeedback-assisted PFMT and electrical stimulation groups and also between the electrical stimulation and PFMT groups in specific gravity ( $P = 0.22$  and  $P = .003$ , respectively) and the number of subjects in menopause ( $P = .025$  and  $P = .001$ , respectively). A significant difference in parity ( $P = .01$ ) was also noted between the electrical stimulation and PFMT groups. With regard to PFM strength, compared to the electrical stimulation group, the biofeedback-assisted PFMT group and the PFMT group both showed significant post-treatment versus pretreatment improvements in scale of power ( $P = .001$  and  $P = .001$ , respectively), time of fast contraction ( $P = .007$  and  $P = .012$ , respectively), and degree of vaginal pressure ( $P = .001$  and  $P = .001$ , respectively). However, between the biofeedback-assisted PFMT and PFMT groups there were no significant pretreatment or post-treatment differences in these three variables. Based on comparison of the main outcome measures, either biofeedback-assisted PFMT or PFMT resulted in significantly better PFM strength and better quality of life than electrical stimulation and therefore was more effective than electrical stimulation in the management of OAB in women.

## CONCLUSION

Although adjunctive therapies are useful because they may actively involve the patient in treatment, a combination of behavioral and pharmacologic approaches to the OAB syndrome offers the greatest chance of success.<sup>140</sup> Bladder training is a modification of bladder drill that is conducted more gradually on an outpatient basis and has resulted in significant reduction of incontinence in older, community-dwelling women. Multicomponent behavioral training is another form of behavioral treatment that includes PFM exercises. Patients may learn strategies to inhibit bladder contraction using PFM contraction and other suppression strategies.<sup>19</sup> Biofeedback is a treatment methodology that has considerable potential application for urogynecologic conditions and represents an important consideration in the initial treatment of UI for women of all ages. Further, it may be used to help relieve symptoms such as urge incontinence, detrusor instability, and irritative symptoms. Biofeedback-assisted training may be used as a conservative first-line therapy for urge or mixed incontinence, either alone or in combination with other behavioral or pharmacologic therapy.

Correction of continence with electrical stimulation has been achieved with various techniques, with results showing bladder inhibition. Electrical stimulation is indicated for patients who are not strongly motivated to perform pelvic floor exercises and for those with weak PFM activity. As the use of electrotherapy grows due to advances in technology, it is necessary that health care professionals carefully analyze innovative applications and demand a demonstration of the efficacy of this therapy.

Behavioral treatments are effective in only half of patients with OAB syndrome. It is not yet clear whether these approaches should be the first-line treatment for all patients with OAB syndrome or whether they should be used in conjunction with anticholinergic agents. In addition, it is not yet known which behavioral therapies are most appropriate for various subgroups of patients with OAB.<sup>141</sup>

# DRUG TREATMENT OF URINARY INCONTINENCE IN WOMEN

*Alan J. Wein and M. Louis Moy*

The lower urinary tract has two basic functions: the storage and emptying of urine. The physiology and pharmacology of micturition have been described by many qualified authors, each of whom has reported his or her own particular concept of the neuroanatomy, neurophysiology, and neuropharmacology of the smooth and striated muscle structures involved; of the peripheral, autonomic, and somatic neural factors; and of the spinal and supraspinal influences that are necessary for normal function.<sup>1-5</sup> Although there are significant disagreements about the finer details, it is important to realize that exact agreement about neuromorphology, neurophysiology, and neuropharmacology is not necessary for an understanding of the pharmacologic principles and applications involved in drug-induced alterations of voiding function and dysfunction. Despite such disagreements, “experts” would agree that, for the purposes of description and teaching, urinary continence requires, first, accommodation of increasing volumes of urine at a low intravesical pressure and with appropriate sensation; second, a bladder outlet that is closed at rest and remains so during increases in intra-abdominal pressure; and third, absence of involuntary bladder contractions (IVCs), including non-neurogenic and neurogenic detrusor overactivity (DO).

As a result of advances in understanding of the neuropharmacology and neurophysiology of the lower urinary tract, effective pharmacologic therapy now exists for the management of urinary incontinence. Because of the number of drug therapies available along with the varying quality and quantity of studies performed using them, the International Consultation on Incontinence has assessed many of the available agents for voiding dysfunction and made recommendations regarding their use (Table 20-1).

This chapter summarizes the pharmacologic treatments available for female urinary incontinence within this functional classification. As an apology to others in the field whose works have not been specifically cited in this chapter, it should be noted that citations have generally been chosen primarily because of their review or informational content, or sometimes for their controversial nature, and not because of originality or initial publication on a particular subject.

## CLINICAL UROPHARMACOLOGY OF THE LOWER URINARY TRACT

### Some Useful Concepts

Clinical uropharmacology of the lower urinary tract is based primarily on an appreciation of the innervation and receptor content of the bladder and its related anatomic structures. The targets of pharmacologic intervention in the bladder body, base, or outlet include nerve terminals that alter the release of specific

neurotransmitters, receptor subtypes, cellular second-messenger systems, and ion channels identified in the bladder and urethra. Peripheral nerves and ganglia, spinal cord, and supraspinal areas are also sites of action of some agents discussed. Because autonomic innervation and receptor content are ubiquitous throughout the human body’s organ systems, there are no agents in clinical use that are purely selective for action on the lower urinary tract. The majority of side effects attributed to drugs facilitating bladder storage or emptying are collateral effects on organ systems that share some of the same neurophysiologic or neuropharmacologic characteristics as the bladder.

**Table 20-1 International Consultation on Incontinence Assessments of Pharmacotherapy for Voiding Dysfunction, 2004**

Drug	Level*	Grade <sup>†</sup>
<b>Antimuscarinics</b>		
Tolterodine	1	A
Trospium	1	A
Darifenacin	1	A
Solifenacin	1	A
Propantheline	2	B
Atropine, hyoscyamine	3	C
<b>Drugs with mixed actions</b>		
Oxybutynin	1	A
Propiverine	1	A
Dicyclomine	3	C
Flavoxate	2	D
<b>Antidepressants</b>		
Imipramine	3	C
<b>Vasopressin analogues</b>		
Desmopressin	1	A
<b>β-Adrenergic receptor agonists<sup>‡</sup></b>		
Baclofen	3	C
Capsaicin	2	C
Resiniferatoxin	2	C
Botulinum toxin	2	B

\*Levels: 1—systematic reviews, meta-analyses, good-quality randomized controlled clinical trials; 2—randomized controlled trials, good-quality prospective cohort studies; 3—case-controlled studies, case series; 4—expert opinion.

<sup>†</sup>Grades: A—based on level 1 evidence (highly recommended); B—consistent level 2 or 3 evidence (recommended); C—level 4 studies or “majority evidence” (optional); D—evidence inconsistent or inconclusive (no recommendation possible).

<sup>‡</sup>Class includes terbutaline, salbutamol, and clenbuterol.

Generally speaking, the simplest and least hazardous form of treatment should be tried first. A combination of therapeutic maneuvers or pharmacologic agents can sometimes be used to achieve a particular effect, especially if their mechanisms of action are different and their side effects are not synergistic. At the outset it should be noted that, in our experience, although great improvement often occurs with rational pharmacologic therapy, a perfect result (restoration to “normal” status) is seldom, if ever, achieved.

### Facilitation of Urine Storage

The pathophysiology of failure of the lower urinary tract to fill with or to store urine adequately may be secondary to problems related to the bladder, the outlet, or both.<sup>6</sup> DO can be expressed as discrete IVCs or as reduced compliance with or without phasic contractions. It may manifest symptomatically as overactive bladder (OAB) syndrome, a syndrome of urgency that may be associated with frequency and nocturia. IVCs are most commonly associated with inflammatory or irritating processes in the bladder wall or with bladder outlet obstruction, or they may be idiopathic. Decreased compliance during filling may be secondary to the sequelae of neurologic injury or disease but may also result from any process that destroys the elastic or viscoelastic properties of the bladder wall. Purely sensory urgency may result from inflammatory, infectious, neurologic, or psychological factors, or it may be idiopathic. A fixed decrease in outlet resistance may result from degeneration of or damage to innervation of the structural elements of the smooth or striated sphincter or from neurologic disease or injury, surgical or other mechanical trauma, or aging. Classic stress urinary incontinence (SUI) or genuine SUI in women implies a failure of the normal transmission of increases in intra-abdominal pressure to the area of the bladder neck and proximal urethra due to changes in the anatomic position of the vesicourethral junction and proximal urethra during increases in intra-abdominal pressure (hypermobility). The pathophysiology of SUI may also involve a decrease in the reflex striated sphincter contraction, which occurs with a number of maneuvers that increase intra-abdominal pressure. Treatment of abnormalities related to the filling or storage phase of micturition are directed toward inhibiting bladder contractility, increasing bladder capacity, decreasing sensory input during filling, or increasing outlet resistance, either continuously or only during abdominal straining.

## DECREASING BLADDER CONTRACTILITY

### Anticholinergic Agents

Physiologic bladder contractions are thought to be primarily triggered by acetylcholine-induced stimulation of postganglionic parasympathetic muscarinic cholinergic receptor sites on bladder smooth muscle.<sup>1,5</sup> Atropine and atropine-like agents should depress normal bladder contractions and IVCs of any cause.<sup>6-8</sup> In patients taking such agents, the volume accumulated before the first IVC is generally increased, the amplitude of the IVC is decreased, and the maximum bladder capacity is increased. However, although the volume and pressure thresholds at which an IVC is elicited may increase, the “warning time” (the time between perception of an IVC about to occur and its occurrence)

and the ability to suppress an IVC are not increased. Therefore, urgency and incontinence still occur unless such therapy is combined with a regimen of timed voiding or toileting. McGuire and Savastano<sup>9</sup> reported that atropine increased both the compliance and the capacity of the neurologically decentralized primate bladder.<sup>10</sup> However, the effect of pure antimuscarinics in those who exhibit only decreased compliance has not been well studied. Outlet resistance, at least as reflected by urethral pressure measurements, does not seem to be clinically affected by anticholinergic therapy.

Although antimuscarinic agents can produce significant clinical improvement in patients with IVCs and associated symptoms, only partial inhibition results. In many animal models, atropine only partially antagonizes the response of the whole bladder to pelvic nerve stimulation and of bladder strips to field stimulation, although it does completely inhibit the response of bladder smooth muscle to exogenous cholinergic stimulation. Of the theories proposed to explain this phenomenon, termed *atropine resistance*, the most attractive and most commonly cited is the idea that a portion of the neurotransmission involved in the final common pathway of bladder contraction is nonadrenergic noncholinergic (NANC)—that is, it occurs secondary to a release of a transmitter other than acetylcholine or noradrenaline.<sup>1,2,5</sup> Although the existence of atropine resistance in human bladder muscle is by no means agreed on, this concept is the most common hypothesis invoked to explain clinical difficulty in abolishing IVCs with anticholinergic agents alone, and it is also used to support the rationale of treatment of such types of bladder activity with agents that have different mechanisms of action. Brading<sup>11,12</sup> and Andersson<sup>5</sup> both discussed the difficulty of evaluating apparently conflicting data in the literature with respect to atropine resistance. Brading<sup>12</sup> stated that the size of the atropine-resistant component varies markedly among species and, in a given preparation, also depends on the frequency of nerve stimulation. Andersson<sup>5</sup> stated that “most probably normal human detrusor muscle exhibits little atropine resistance,” but that this does not exclude its existence in morphologically or functionally abnormal bladders.

At least five different genetically established muscarinic subtypes ( $M_1$  through  $M_5$ ) exist, as determined by cloning experiments<sup>13</sup>; the cholinergic muscarinic receptor genes are designated *CHRM1* through *CHRM5*. The protein products of the  $M_1$  through  $M_4$  subtypes have been defined pharmacologically with the use of receptor subtype agonists and antagonists.<sup>5,14,15</sup> A physiologic role for the product of the  $M_5$  coding region remains undefined.<sup>15</sup> Pirenzepine (a selective muscarinic blocker) was originally used to subdivide muscarinic receptors into  $M_1$  and  $M_2$  categories; using this subclassification, detrusor muscarinic receptors were classified as the  $M_2$  type.<sup>5,16,17</sup> On further analysis of the  $M_2$  receptor population, a small proportion of glandular  $M_2$  receptors were found which could represent the pharmacologic type responsible for muscarinic agonist-induced contractions. This subtype is now called the  $M_3$  receptor.<sup>5,14</sup> Although it appears that the majority of the muscarinic receptors in human smooth muscle, including bladder, are of the  $M_2$  subtype,<sup>18</sup> in vitro data indicate that most smooth muscle contraction, including that of the urinary bladder, is mediated by the  $M_3$  receptor subtype.<sup>18,19</sup> Muscarinic receptor subtyping becomes important when considering the possibility of pharmacologically selecting (and blocking) those receptors responsible for urinary bladder smooth muscle contraction while minimally affecting other muscarinic receptor sites throughout the body. Ideally, this approach

would effectively treat the underlying problem (DO) while eliminating the unpleasant systemic side effects of most nonspecific antimuscarinic agents (e.g., dry mouth, constipation, blurred vision), which, in many cases, are worse than the problem they are treating and result in patient noncompliance.

### Specific Drugs

Propantheline bromide is the classically described oral agent used for producing an antimuscarinic effect in the lower urinary tract. The usual adult oral dose is 15 to 30 mg every 4 to 6 hours, although higher doses are often necessary. Propantheline is a quaternary ammonium compound that is poorly absorbed after oral administration. No available oral drug has a direct *in vitro* antimuscarinic binding potential that is closer to that of atropine than propantheline bromide.<sup>20,21</sup> There is a surprising lack of valuable data on the effectiveness of propantheline for the treatment of bladder overactivity. As Andersson pointed out,<sup>8</sup> anticholinergic drugs in general have been reported to have both great and poor efficacy for this indication. Zorzitto and colleagues<sup>22</sup> concluded that propantheline bromide administered orally in doses of 30 mg four times a day to a group of institutionalized incontinent geriatric patients had marginal benefits that were outweighed by the side effects. Blaivas and colleagues,<sup>7</sup> on the other hand, increased the dose of propantheline (up to 60 mg four times a day) until incontinence was eliminated or side effects precluded further use and obtained a complete response in 25 of 26 patients with IVCs. Differences in bioavailability, selective drug delivery, receptor selectivity, receptor density, atropine resistance, pathophysiology, susceptibility to dose-limiting side effects, and mental status are all potential factors that could explain such disparate results. The Agency for Health Care Policy and Research (AHCPR) Clinical Practice Guidelines<sup>23</sup> listed five randomized controlled trials for propantheline, in which 82% of the patients were women. The percentage of cure was listed as ranging from zero to 5%, reduction in urge incontinence from zero to 53%, side effects from zero to 50%, and dropouts from zero to 9% (all figures refer to overall percentage minus percentage on placebo).

Atropine is reported to be available in a 0.5-mg tablet, although we have yet to find it. Atropine and all related belladonna alkaloids are well absorbed from the gastrointestinal tract. Atropine is said to have almost no detectable central nervous system (CNS) effects at clinically used doses.<sup>24</sup> It has a half-life of about 4 hours.

Scopolamine is another belladonna alkaloid marketed as a soluble salt. It has prominent central depressive effects at low doses, probably because of its greater penetration (compared with atropine) through the blood-brain barrier. Transdermal scopolamine has been used for treatment of IVCs.<sup>25</sup> The "patch" provides continuous delivery of 0.5 mg daily to the circulation for 3 days. Cornella and associates,<sup>26</sup> however, reported poor results with this dosage in 10 patients with DO: only 2 patients showed a positive response; 1 showed a slight improvement, and the drug was discontinued in 8 patients because of side effects. Side effects were related to the CNS (ataxia, dizziness) and included blurred vision and dry mouth. A double-blind placebo-controlled study using transdermal scopolamine was performed on 20 patients with DO: after a 14-day treatment period, the 10 patients randomized to transdermal scopolamine treatment showed statistically significant improvements in frequency, nocturia, urgency, and urge incontinence compared with the placebo group; no adverse effects of the therapy were reported.<sup>27</sup> A

double-blind placebo study on the effects of transdermal scopolamine in patients who had undergone suprapubic prostatectomy was performed to investigate its use in the treatment or prevention of pain, IVCs, urgency, and bladder pressure rises of 15 cm H<sub>2</sub>O. No statistical differences were found.<sup>28</sup> In our experience of treating IVCs with this method, results were very erratic, and skin irritation with the patch was a problem for some patients. Because of the fixed dose, caution should be exercised in the use of the patch in elderly and young patients.

Hyoscyamine and hyoscyamine sulphate are reported to have anticholinergic actions and side effects similar to those of other belladonna alkaloids. Hyoscyamine sulphate is available as a sublingual formulation, a theoretical advantage, but controlled studies of its effects on bladder overactivity are lacking. Glycopyrrolate is a synthetic quaternary ammonium compound that is a potent inhibitor of both M<sub>1</sub> and M<sub>2</sub> receptors but has a preference for the M<sub>2</sub> subtype.<sup>29</sup> It is available in both oral and parenteral preparations; the latter is commonly used as an antisialagogue during anesthesia. An anticholinergic agent with a significant ganglionic-blocking action as well as such action at the peripheral receptor level might be more effective in suppressing bladder contractility. Although methantheline has a higher ratio of ganglionic blocking to antimuscarinic activity than does propantheline, the latter drug seems to be at least as potent in each respect, clinical dose for dose. Methantheline does have similar effects on the lower urinary tract, and some clinicians still prefer it over other anticholinergic agents. Few solid data are available regarding its efficacy.

The potential side effects of all antimuscarinic agents include inhibition of salivary secretion (dry mouth), blockade of the ciliary muscle of the lens to cholinergic stimulation (blurred vision for near objects), tachycardia, drowsiness, and inhibition of gut motility. Those agents that possess some ganglionic-blocking activity may also cause orthostatic hypotension and erectile dysfunction at high doses (at which nicotinic activity becomes manifest). Antimuscarinic agents are contraindicated in patients with narrow-angle glaucoma and should be used with caution in patients with significant bladder outlet obstruction, because complete urinary retention may be precipitated.

A lack of selectivity is a major problem with all antimuscarinic compounds, because they tend to affect parasympathetically innervated organs in the same order; in general, larger doses are required to inhibit bladder activity than to affect salivary, bronchial, nasopharyngeal, and sweat secretions. Several new receptor antagonists with varying degrees of specificity for the lower urinary tract show some promise in decreasing the side effect profiles of this class of medications without compromising efficacy.

Tolterodine and its primary metabolite, PNU-200577,<sup>30</sup> have shown some selectivity for bladder tissue over salivary tissue in *in vitro* and *in vivo* studies in the anesthetized cat.<sup>31,32</sup> These tissue-selective effects do not appear to be related to muscarinic receptor subtype selectivity<sup>30,31</sup> but may be the result of differential affinities of the receptors in the salivary gland and detrusor muscle for tolterodine compared with oxybutynin. Although it appears that the binding affinity of tolterodine and oxybutynin to muscarinic receptors in the urinary bladder (in the guinea pig) are very similar, the affinity of tolterodine for muscarinic receptors in the parotid gland is eight times lower than that of oxybutynin.<sup>33</sup> Tolterodine is available in two formulations: an immediate-release (IR) form (2 mg twice daily) and an extended-release (ER) form (2 mg or 4 mg once daily).

In a pilot study in 12 healthy men, tolterodine was shown to have a greater objective and subjective effect on bladder function than on salivation.<sup>34</sup> Jonas and colleagues<sup>35</sup> looked at the urodynamic effects of tolterodine in a multicenter, randomized, double-blind, placebo-controlled study: 242 patients were enrolled and treated over a 4-week period with 1 or 2 mg tolterodine or placebo twice daily. Compared with placebo, 2 mg tolterodine (but not 1 mg) produced statistically significant improvements in mean volume to first IVC (from 141 to 230 mL in the 2-mg group, 142 to 210 mL in the 1-mg group, and 140 to 181 mL in the placebo group), mean maximal strength of IVC (52 to 37 cm H<sub>2</sub>O, 41 to 35 cm H<sub>2</sub>O, and 47 to 40 cm H<sub>2</sub>O in the three groups, respectively), and maximal cystometric capacity (272 to 316 mL, 276 to 294 mL, and 264 to 268 mL, respectively). The proportion of adverse effects in the treated groups, compared with placebo, was not statistically significant; however, dry mouth, the most common event, was reported in 9% of treated patients, significantly less than the 50% incidence reported in the literature for other commonly used anticholinergic preparations.<sup>36</sup> Furthermore, the dry mouth was classified as “severe” by only 1% of patients. At higher doses, the incidence of side effects of tolterodine may be more significant and may approach that of other commonly used anticholinergic drugs.

Rentzhog and colleagues<sup>37</sup> noted that, at a dose of 2 mg or less, the incidence of adverse effects (including dry mouth) due to tolterodine was comparable to that of placebo (2/13 patients in the placebo group versus 9/51 patients in the tolterodine group reported dry mouth); however, when the dose of tolterodine was increased to 4 mg, a substantial increase in the incidence of dry mouth occurred (9/16 patients). Overall, it appears that tolterodine is safe and efficacious for the treatment of DO. A favorable side-effect profile exists at lower doses (less effect on salivary glands), which may diminish in a dose-dependent fashion.

There have been several randomized controlled studies documenting the effectiveness of tolterodine in reducing micturition frequency and incontinence episodes.<sup>38,39</sup> There have also been comparative trials comparing it to other agents.

The Overactive Bladder: Judging Effective Control and Treatment (OBJECT) trial performed by Appell and colleagues<sup>40</sup> compared tolterodine IR 2 mg twice daily to oxybutynin ER 10 mg daily. This was a randomized, double blind, parallel-group study that included 378 patients with OAB. Patients were treated for 12 weeks. The outcome measures included number of episodes of urge incontinence, total incontinence, and micturition frequency. The study showed oxybutynin ER to be significantly more effective than tolterodine in each of the outcome measures when adjusted for baseline. The most common adverse event was dry mouth, which was reported by 28% and 33% of those taking oxybutynin ER and tolterodine IR, respectively. Rates of other adverse events including CNS side effects were generally low and comparable between the two groups.

In the Overactive Bladder: Performance of Extended Release Agents (OPERA) study, Diokno and colleagues<sup>41</sup> compared tolterodine ER 4 mg daily to oxybutynin ER 10 mg daily in 790 women with OAB symptoms. This too was a randomized, double-blind study with a duration of 12 weeks. Patients kept 24-hour voiding diaries to document the number of incontinence episodes (primary outcome), total incontinence, and micturition frequency at weeks 2, 4, 8, and 12. Improvements in weekly urge incontinence episodes were similar between the two treatment groups. Oxybutynin ER was more effective in reducing micturition frequency, and 23.0% of women taking it reported no epi-

sodes of urinary incontinence, compared with to 16.8% of women taking tolterodine ER. Dry mouth was more common in the oxybutynin ER group, with both groups having similar discontinuation rates. The conclusions were that the two drugs had similar reductions in weekly urge incontinence and total incontinence episodes. Those taking oxybutynin ER had more dry mouth, but the tolerability between the two drugs was comparable.

In the Antimuscarinic Clinical Effectiveness Trial (ACET), Sussman and Garely<sup>42</sup> performed an open-label trial in patients with OAB comparing tolterodine ER 2 mg or 4 mg to oxybutynin ER 5 mg or 10 mg. A total of 1289 subjects participated in the study. After 8 weeks, 70% of patients taking tolterodine ER 4 mg perceived an improved bladder condition, compared with about 60% in the other groups. There were fewer withdrawals from the study in the tolterodine ER 4 mg group (12%) than in either the oxybutynin ER 5 mg group (19%) or the oxybutynin 10 mg group (21%). Patients taking tolterodine ER 4 mg reported significantly less dry mouth than those taking oxybutynin ER 10 mg. Although the findings suggest that tolterodine ER 4 mg may have improved clinical efficacy and tolerability compared with oxybutynin ER 10 mg, the open-label design of this study makes for a less convincing conclusion.

Zinner and colleagues<sup>43</sup> performed a 12-week randomized, double-blind, placebo-controlled study to evaluate the efficacy, safety, and tolerability of tolterodine ER in treating OAB symptoms in older ( $\geq 65$  years) and younger ( $< 65$  years) patients. Objective measures by micturition diaries as well as subjective measures were evaluated. There were significant improvements among patients taking tolterodine ER in micturition chart variables, compared with placebo. There were no age-related differences. Dry mouth was the most common adverse event in both arms. No CNS or cardiac events were seen. Tolterodine ER appeared to be well tolerated by both age groups.

Freeman et al<sup>44</sup> presented a secondary analysis of a double-blind, placebo-controlled study looking at the effects of tolterodine ER 4 mg on the symptoms of urinary urgency in patients with OAB. A total of 772 patients with eight or more micturitions per 24 hours and urge incontinence ( $\geq 5$ /week) were randomized to drug or placebo therapy and treated for 12 weeks. Efficacy was assessed by using patient perception evaluations. Patients taking tolterodine ER 4 mg had a greater improvement in urgency (44% versus 32%) and bladder symptoms (62% versus 48%) than those taking placebo. Patients taking tolterodine ER 4 mg were also significantly more likely to hold their urine after experiencing urgency.

Recently, several pharmacologic agents have been approved by the Food and Drug Administration (FDA) for use in the United States. Darifenacin, a tertiary amine, is a selective muscarinic M<sub>3</sub> receptor antagonist. Its theoretical advantage is its ability to selectively block the M<sub>3</sub> receptor, which is the most important subtype in bladder contraction, and thereby decrease the adverse events related to blockade of other muscarinic subtypes.

Darifenacin has been studied in several randomized controlled studies. Haab and colleagues performed a multicenter, randomized, double-blind, placebo-controlled study comparing darifenacin 3.75 mg, 7.5 mg, 15 mg, and placebo once daily.<sup>45</sup> The treatment period was 12 weeks. Using an electronic voiding diary, patients recorded daily incontinence episodes, micturition frequency, volume voided, frequency and severity of urgency, incontinence episodes necessitating a change of clothing or pads, and nocturnal awakenings due to bladder symptoms. The

7.5- and 15-mg doses of darifenacin had a quick onset of action, with significant improvements over placebo being seen at week 2. The clinical parameters in which the treatment arm were significantly better than placebo included improvements in micturition frequency, bladder capacity, frequency of urgency, severity of urgency, and number of incontinence episodes. No significant change occurred in nocturnal awakening due to bladder symptoms. The most common side effects seen were mild-to-moderate dry mouth and constipation. No patients withdrew from the study due to dry mouth, and the discontinuation rate due to constipation was rare (0.9% for darifenacin versus 0.6% for placebo). The CNS and safety profile were similar for darifenacin and placebo.

An analysis of the pooled data from phase 3 trials was performed by Chapple and associates.<sup>46</sup> A total of 1059 patients (85% female) with symptoms of urgency, urge incontinence, and frequency were randomized into three arms: darifenacin 7.5 mg, darifenacin 15 mg, or placebo daily for 12 weeks. Once again, patient voiding diaries were maintained electronically. The parameters monitored included incontinence episodes, frequency and severity of urgency, micturition frequency, and volume voided. Compared to baseline, there was a significant dose-related decrease in the number of incontinence episodes per week, with darifenacin 7.5 mg reducing episodes by 8.8, and darifenacin 15 mg reducing episodes by 10.6 per week. Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinent episodes requiring a change of clothing or pads were seen, as well as an increase in bladder capacity. Although the most common side effect was dry mouth, this led to few discontinuations (darifenacin 7.5 mg, 0.5%; darifenacin, 15 mg, 2.1%; placebo, 0.3%), and the incidence of CNS and cardiovascular adverse events was similar to placebo.

Cardozo and colleagues<sup>47</sup> performed a study to determine the effects of darifenacin on “warning time,” or the ability of the medication to allow patients to postpone micturition once urge was sensed. This was a multicenter, randomized, double-blind, placebo-controlled study with a 2-week treatment phase of darifenacin 30 mg daily or placebo. Darifenacin treatment resulted in a significant increase in the mean warning time (median increase, 4.3 minutes) compared with placebo. Overall, 47% of darifenacin-treated subjects and 20% of those receiving placebo achieved a greater than 30% increase in mean warning time. Although this study used a higher than usual dose of therapeutic agent and the treatment period was short, it was the first to evaluate changes in warning time. This effect may be particularly germane to patients with severe symptoms of urgency and urge incontinence.

Solifenacin (YM-905) is a tertiary amine, once-daily antimuscarinic. It is well absorbed from the gastrointestinal tract and undergoes significant hepatic metabolism by the cytochrome P450 enzyme system. There have been several large trials examining the effects of solifenacin.

Chapple and colleagues performed a multinational study comparing various doses of solifenacin (2.5, 5, 10, and 20 mg) to tolterodine IR 2 mg twice daily and placebo<sup>48</sup> in patients with OAB. A total of 225 patients were treated for 4 weeks and monitored for an additional 2 weeks. To be included in the study, all patients had to have at least eight micturitions in 24 hours and one episode of incontinence or one episode of urgency daily, as recorded by a 3-day voiding diary. Micturition frequency was the primary outcome. In patients treated with solifenacin, there was

a statistically significant reduction in micturition frequency for those taking 5, 10, or 20 mg. This was not seen in the other two arms of the study. Additionally, these doses of solifenacin, when compared with placebo, resulted in a significant increase in volume voided and a reduction in episodes of frequency and incontinence. The onset of action was rapid, occurring at 2 weeks, the earliest follow-up point in the study. Discontinuation rates were similar among the various treatments except for solifenacin 20 mg, which was higher. The 5- and 10-mg doses of solifenacin had a lower rate of dry mouth than tolterodine did.

Another dose-ranging, placebo-controlled study of solifenacin 2.5 to 20 mg, was performed by Smith and colleagues in the United States.<sup>49</sup> The treatment duration was 4 weeks, with 2 weeks of follow-up. There was a significant reduction in micturition frequency in the solifenacin 10-mg and 20-mg groups, compared with placebo. The onset of efficacy was seen at 7 days, with continued improvement at 28 days. Significant increases in volume voided were seen in those taking 5, 10, or 20 mg of solifenacin. The 10 mg solifenacin dose also had a significant decrease in incontinent episodes.

There were four phase 3 trials to evaluate efficacy, safety, and tolerability of solifenacin in adult patients with OAB. The primary outcome in all the studies was 24-hour micturition frequency. Secondary outcomes included change in number of urgency and incontinence episodes and mean volume voided.

Chapple and colleagues<sup>50</sup> performed a multicenter, randomized, placebo-controlled and tolterodine-controlled study. Subjects were treated for 12 weeks with solifenacin 5 mg daily, solifenacin 10 mg daily, tolterodine IR 2 mg twice daily, or placebo. Both doses of solifenacin resulted in a significant decrease in urgency episodes at 24 hours, compared with placebo, but tolterodine did not. In the solifenacin group, there was a significant decrease in incontinence episodes; and the mean number of voids in 24 hours was significantly lower in all three active treatment arms. As with most antimuscarinics, the most common side effect was dry mouth, occurring in 14% in the solifenacin 5 mg group and in 21.3% of the solifenacin 10 mg group.

Cardozo and colleagues<sup>51</sup> performed a multicenter randomized, placebo-controlled study comparing solifenacin 5 mg and 10 mg once daily with placebo. They found that both of the doses significantly improved frequency compared with placebo. Solifenacin was also better than placebo in improving urgency, increasing volume voided, and decreasing incontinence episodes over 24 hours. The reduction in urgency was slightly greater than 50% for both doses of solifenacin, whereas placebo resulted in a reduction of 33%. The percentage increases in voided volume per micturition were 25.4%, 29.7%, and 11% for solifenacin 5 mg, 10 mg, and placebo, respectively. The percentage decreases in overall incontinence episodes were 60.7%, 51.9%, and 27.9%, respectively. Only a small percentage of patients (2% to 4%) did not complete the study due to adverse events, which were comparable in all groups. The incidence of dry mouth was 2.3%, 7.7%, and 23.1% in placebo, solifenacin 10 mg, and solifenacin 20 mg groups, respectively. There were no changes in electrocardiographic parameters.

Two double-blind trials of solifenacin were performed<sup>52</sup> in the United States, in which a total of 1208 patients participated. Findings included a reduction in the number of micturitions per 24 hours, a decrease in the number of incontinence and urgency episodes per 24 hours, and an increase in the volume voided per micturition. Among patients who were incontinent at baseline, a significant percentage of those taking solifenacin became

continent, compared to those taking placebo (53% versus 31%, respectively).

### Musculotropic Relaxants

Musculotropic relaxants affect smooth muscle directly at a site that is metabolically distal to the cholinergic or other contractile receptor mechanism. Although the agents discussed in this section do relax smooth muscle *in vitro* by papaverine-like (direct) action, all have also been found to possess variable anticholinergic and local-anesthetic properties. There is still some uncertainty about how much of their clinical efficacy is due only to their atropine-like effect. If, in fact, any of these agents do exert a clinically significant inhibitory effect that is independent of antimuscarinic action, a therapeutic rationale exists for combining them with a relatively pure anticholinergic agent.

Oxybutynin chloride is a moderately potent anticholinergic agent that has strong independent musculotropic relaxant activity as well as local-anesthetic activity. The recommended oral adult dose is 5 mg three or four times a day; side effects are antimuscarinic and dose-related. Initial reports documented success in depressing neurogenic DO,<sup>53</sup> and subsequent reports documented success in inhibiting other types of bladder overactivity as well.<sup>8</sup> A randomized double-blind, placebo-controlled study comparing 5 mg oxybutynin three times a day with placebo in 30 patients with DO was carried out by Moisey and colleagues: 17 of 23 patients who completed the study with oxybutynin had symptomatic improvement, and 9 showed evidence of urodynamic improvement, mainly an increase in maximum bladder capacity.<sup>54</sup> Hehir and Fitzpatrick<sup>55</sup> reported that 16 of 24 patients with neuropathic voiding dysfunction secondary to myelomeningocele were cured or improved (17% dry, 50% improved) with oxybutynin treatment; average bladder capacity increased from 197 to 299 mL with oxybutynin compared to 218 mL with placebo, and maximum bladder filling pressure decreased from 47 to 37 cm H<sub>2</sub>O with oxybutynin versus 45 cm H<sub>2</sub>O with placebo. In a prospective randomized study of 34 patients with voiding dysfunction secondary to multiple sclerosis, Gajewski and Awad<sup>56</sup> found that 5 mg oral oxybutynin three times a day produced a good response more frequently than 15 mg propantheline three times a day; they concluded that oxybutynin was more effective in the treatment of neurogenic DO secondary to multiple sclerosis. Holmes and associates<sup>57</sup> compared the results of oxybutynin and propantheline in a small group of women with DO. The experimental design was a randomized crossover trial with a patient-regulated variable-dose regimen. This kind of dose-titration study allows the patient to increase the drug dose to whatever she perceives to be the optimum ratio between clinical improvement and side effects—an interesting way of comparing two drugs while minimizing differences in oral absorption. Of the 23 women in the trial, 14 reported subjective improvement with oxybutynin as opposed to 11 with propantheline. Both drugs significantly increased the maximum cystometric capacity and reduced the maximum detrusor pressure on filling. The only significant objective difference was a greater increase in the maximum cystometric capacity with oxybutynin. The mean total daily dose of oxybutynin tolerated was 15 mg (range, 7.5 to 30 mg), and that of propantheline was 90 mg (range, 45 to 145 mg).

Thuroff and colleagues<sup>58</sup> compared oxybutynin with propantheline and placebo in a group of patients with symptoms of instability and either neurogenic and non-neurogenic DO. Oxy-

butynin (5 mg three times a day) performed best, but propantheline was used at a relatively low dose (15 mg three times a day). The incidence of side effects was higher for oxybutynin at approximately the level of clinical and urodynamic improvement. The mean grade of improvement on a visual analogue scale was higher for oxybutynin (58.2%) than for propantheline (44.7%) or placebo (43.4%). Urodynamic volume at the first IVC increased more with oxybutynin (51 mL, versus 11.2 mL for propantheline and 9.7 mL for placebo), as did the change in maximum cystometric capacity (80.1, 48.9, and 22.5 mL, respectively). Residual urine volume also increased more (27.0, 2.2, and 1.9 mL, respectively). The authors further subdivided their overall results into the categories of excellent (>75% improvement), good (50% to 74%), fair (25% to 49%), and poor (<25%). Results for treatment with oxybutynin were 42% excellent, 25% good, 15% fair, and 18% poor. The authors concluded that their 67% rate of good or excellent results compared favorably with those reported in seven other oxybutynin series in the literature (some admittedly poorer studies included), which ranged from 61% to 86%. The results of propantheline treatment generally ranked between those of oxybutynin and placebo but did not reach significant levels over placebo in any variable. Subdivision of propantheline results into excellent, good, fair, and poor categories yielded percentages of 20%, 30%, 14%, and 36%, respectively. The 50% ratio of good or excellent results were consistent with those achieved in six other propantheline studies reported in the literature (30% to 57%). Although this study was better than most in the literature, it did have drawbacks, and anyone using it in a meta-analysis would be well advised to read it and the other cited studies very carefully.

Zeegers and colleagues<sup>59</sup> reported on a double-blind, prospective, crossover study comparing oxybutynin, flavoxate, emepromium, and placebo. Although there was a high dropout rate (19 of 60 patients) and the entry criteria were vague (frequency, urgency, urge incontinence), the results, scored as 5 (excellent overall effect) to 1 (no improvement) by both patient and physician, were combined into a single number. The percentages of results in categories 3 to 5 for the agents used were oxybutynin, 61%; placebo, 41%; emepromium, 34%; and flavoxate, 31%. The results of the first treatment gave corresponding percentages of only 63%, 29%, 18% (probably reflecting eight dropouts due to side effects), and 44%, respectively.

Ambulatory urodynamic monitoring and pad weighing were used to assess the effects of oxybutynin on DO by Von Doorn and Zwiers.<sup>60</sup> The 24-hour average frequency of IVCs decreased from 8.7 to 3.4; the maximum contraction amplitude decreased from 32 to 22 cm H<sub>2</sub>O, and the duration of the average IVC decreased from 90 to 60 seconds. However, the daily micturition frequency did not change (11 to 10), nor did the amount of urine lost—findings the authors tried to minimize by pointing out that some patients also had sphincteric incontinence and that, during treatment, there may have been a higher fluid intake.

The AHCPR guidelines<sup>23</sup> list six randomized controlled trials for oxybutynin; 90% of patients were women. The percentage of cure was listed as ranging from 28% to 44%, reduction in urge incontinence from 9% to 56%, side effects from 2% and 66%, and dropouts from 3% to 45% (all figures refer to overall percentage minus percentage on placebo). There were some negative reports on the efficacy of oxybutynin. Zorzitto and colleagues<sup>61</sup> came to conclusions similar to those resulting from their study of propantheline in a double-blind placebo-controlled trial conducted in 24 incontinent geriatric institutionalized patients:

oxybutynin 5 mg twice a day was no more effective than placebo with scheduled toileting in treating incontinence in this type of population with DO. An incontinence profile was used to assess results, and the only significant difference noted was an increase in residual urine volume (from 159 to 92 mL). Ouslander and colleagues<sup>62</sup> reported similar conclusions in a smaller study of geriatric patients, and in an accompanying article they concluded simply that the drug is safe for use in the elderly at doses of 2.5 to 5 mg three times a day.<sup>62,63</sup>

An ER form of oxybutynin is available that releases the active compound over a period of 24 hours. Aside from the ease of once-daily administration, the potential benefit of the ER formulation is that stabilization of serum levels throughout the day should lower the incidence of side effects.<sup>64</sup> Another theoretical advantage may be that less absorption occurs in the proximal portion of the gastrointestinal tract which drains into the portal system, so there is less first-pass metabolism.

IR and ER oxybutynin were compared in a multicenter randomized, double-blind trial of 106 patients, all of whom had previously responded to IR oxybutynin.<sup>65</sup> For patients currently taking anticholinergic therapy, after a 1-week washout period, a dose-titration schedule was used to reach the maximum allowable dose (20 mg IR or 30 mg ER daily), or to the dose at which no urge urinary incontinence (UUI) episodes occurred over the course of 2 days (as measured from a diary) or until a dose was reached with intolerable side effects (at which point, the final dose was decreased by 5 mg). Thirteen patients discontinued therapy during the trial, four because of anticholinergic events. Overall, similar efficacy was noted for both formulations of oxybutynin in overall number of episodes (27.4 to 4.8 for ER and 23.4 to 3.1 for IR), in the percentage decrease in weekly UUI episodes (84% for ER and 88% for IR), and in overall incontinence episodes (urge, stress, and mixed). The number and proportion of patients achieving continence was also similar between the groups (41% for ER, and 40% for IR). Curiously, voiding frequency increased in both groups, with a statistically significant percentage increase of voiding frequency in patients receiving the ER compared with those receiving the IR formulation (54% versus 17%;  $P < .001$ ). Anticholinergic side effects were noted in both groups. Dry mouth was the most frequent symptom, occurring in a majority of patients. Dry mouth was reported as moderate or severe by 25% and 46% of patients receiving the ER and IR formulations, respectively ( $P = .03$ ). Other anticholinergic side effects were reported with similar frequency in the ER and IR groups: somnolence (38% versus 40%), blurred vision (28% versus 17%), constipation (30% versus 31%), dizziness (28% versus 38%), impaired urination (25% versus 29%), nervousness (25% versus 23%), and nausea (19% versus 17%).

In an open-label trial<sup>66</sup> with 256 patients (23.4% of whom were taking an anti-incontinence medication at baseline and switched over to oxybutynin ER for the study), oxybutynin ER reduced the number of incontinence episodes per week from 18.8 at baseline to 2.8 at the end of the study (83.1% reduction); 31% of patients remained free of UUI throughout the study. A 14.7% reduction in voiding frequency was noted on therapy compared with baseline, as measured from the voiding diary. Dry mouth was reported by 58.6% of patients; 23.0% reported moderate or severe dry mouth. Only 1.6% of patients discontinued therapy because of dry mouth. Overall, 7.8% of patients discontinued therapy because of adverse events, of which nausea, dry mouth, and somnolence were most frequent.

Topical application of oxybutynin and other agents to normal or unstable bladders has been suggested and implemented.<sup>67</sup> This conceptually attractive form of alternative drug administration, delivered by periodic intravesical instillation of either liquid or timed-released pellets, awaits further clinical trials and the development of preparations specifically formulated for this purpose. Several nonrandomized, unblinded and non-placebo-controlled studies have demonstrated the efficacy of this therapy in a variety of patients with neurogenic bladders, showing statistically significant improvements in cystometric capacity, volume at first IVC, bladder compliance, and overall continence.<sup>68-70</sup>

Madersbacher and Jilg reviewed the intravesical usage of 5 mg of oxybutynin dissolved in 30 mL distilled water in 13 patients with complete suprasacral cord lesions who were on clean intermittent catheterization.<sup>71</sup> Of the 10 patients who were incontinent, 9 remained dry for 6 hours. For the group, the changes in bladder capacity and maximum detrusor pressure were statistically significant. Some of the more interesting data were given in a figure showing plasma oxybutynin levels for a group of patients in whom administration was intravesical or oral. The level achieved after an oral dose rose to 7.3 mg/mL within 2 hours and then precipitously dropped to slightly less than 2 mg/mL at 4 hours. After intravesical administration, the level rose gradually to a peak of about 6.2 mg/mL at 3.5 hours, but at 6 hours it was still greater than 4 mg/mL and at 9 hours it was still between 3 and 4 mg/mL. From these data, it is unclear whether the intravesically applied drug acted locally or systemically.

In a later study, Madersbacher and Knoll<sup>72</sup> administered oxybutynin intravesically and then, 1 week later, gave oxybutynin orally to six patients with neurogenic bladders in order to study the pharmacokinetics of the drug and investigate the pharmacologic properties responsible for its clinical effects. Serum drug levels were correlated with urodynamic effects 20 minutes and 2 hours after administration of the drug. The authors concluded that the main effect of intravesical oxybutynin was a result of systemic absorption; however, a secondary direct local effect (smooth muscle relaxation or topical anesthetic effect) could not be excluded.

Weese and colleagues<sup>73</sup> reported use of a similar dose of oxybutynin (5 mg in 30 mL sterile water) to treat 42 patients with IVCs for whom oral anticholinergic therapy had failed (11 patients) or who had intolerable side effects (31 patients): 20 had neurogenic DO, 19 had non-neurogenic DO, and 3 had bowel or DO after augmentation. The drug was instilled two or three times each day for 10 minutes by catheter. Nine patients (21%) withdrew from the study because they were unable to tolerate clean intermittent catheterization or to retain the solution properly, but there were no reported side effects. Of the patients (33) who were able to follow the protocol, 18 (55%) reported at least a moderate subjective improvement in incontinence and urgency. Nine patients became totally continent and experienced complete resolution of their symptoms; 18 patients improved and experienced a decrease of 2.5 pads per day. There were no urodynamic data. Follow-up ranged from 5 to 35 months (mean, 18.4 months).

The lack of side effects prompted some speculation about the mechanism of drug action: one possibility was simply a more prolonged rate of absorption; another was a decreased pass through the liver and therefore a decrease in metabolites, the hypothesis being that perhaps the metabolites and not the primary compound are responsible for the side effects.

Enzelsberger and associates<sup>74</sup> reported on the use of intravesical oxybutynin in the treatment of DO in 52 women. In the only published randomized, double-blind, placebo-controlled study of this intravesical administration, patients received once-daily intravesical oxybutynin (20 mg in 40 mL sterile water) or placebo for 12 days. The results revealed statistically significant differences in first desire to void (from 95 mL before treatment to 150 mL after treatment), cystometric capacity (205 to 310 mL), maximal pressure during filling (16 to 9 cm H<sub>2</sub>O), daytime frequency (7.5 to 4), and nocturia (5.1 to 1.8). Side effects were similar in the treated and placebo groups (17% versus 10%, respectively). For unexplained reasons, 19 of 23 patients in the treated group continued to have symptomatic relief after termination of the study.

In an increasing effort to maintain or improve the efficacy of oxybutynin while minimizing its side effects, the use of transdermal oxybutynin has been investigated. In one study,<sup>75</sup> the daily-dose patch significantly reduced the number of weekly incontinence episodes while reducing average daily urinary frequency by increasing the average voided volume. Dry mouth rates were similar to those reported with placebo (7% versus 8.3%). A recent study<sup>76</sup> comparing transdermal oxybutynin and oxybutynin IR demonstrated equivalent reduction in incontinent episodes but significantly less dry mouth with the patch (38% versus 94%). In a third study,<sup>77</sup> transdermal oxybutynin was compared to placebo and tolterodine ER. The two drugs had similarly significant reduced daily incontinence episodes and increased voided volume, but tolterodine ER was associated with a higher rate of antimuscarinic adverse events. The major side effect for transdermal oxybutynin was pruritus at the application site in 14% and erythema in 8.3% of patients.

Dicyclomine hydrochloride is also reported to exert a direct relaxant effect on smooth muscle in addition to an antimuscarinic action.<sup>78</sup> An oral dose of 20 mg three times a day in adults has been reported to increase bladder capacity in patients with neurogenic DO.<sup>79</sup> Beck and coworkers<sup>80</sup> compared the use of 10 mg dicyclomine, 15 mg propantheline, and placebo three times a day in patients with DO<sup>81</sup>: the rates of cure or improvement were 62%, 73%, and 20%, respectively. Awad and associates<sup>82</sup> reported that 20 mg dicyclomine three times a day caused resolution or significant improvement in 24 of 27 patients with IVCs.

Flavoxate hydrochloride has a direct inhibitory action on smooth muscle but very weak anticholinergic properties.<sup>83</sup> In cats, at least, there is some evidence that flavoxate may also have central effects on the inhibition of the micturition reflex in addition to its effects on the relaxation of smooth muscle.<sup>84</sup> Clinical studies addressing the efficacy of flavoxate in the treatment of DO have been mixed. Milani and colleagues<sup>85</sup> performed a double-blind, crossover study comparing flavoxate 1200 mg/day with oxybutynin 15 mg daily in 41 women with idiopathic motor or sensory urgency, using clinical and urodynamic criteria. The two drugs had similar efficacy, with flavoxate having fewer side effects. However, Briggs and colleagues<sup>86</sup> reported that this drug had essentially no effect on non-neurogenic DO in an elderly population, an experience that coincides with the laboratory effects obtained by Benson and associates.<sup>87</sup> There were few reported side effects. Although the efficacy of flavoxate compared with other agents in this group has not been proven, a short clinical trial may be worthwhile.

Trospium and propiverine are classified as predominantly antispasmodic agents (smooth muscle relaxants) with some anti-

cholinergic effects as well. Although both drugs have been used in Europe for years, trospium chloride has been recently approved by the FDA and is now available for use in the United States. It is a quaternary amine and has limited ability to cross the blood-brain barrier, therefore in theory leading to minimal cognitive dysfunction.<sup>88-90</sup> Trospium has no selectivity for a muscarinic subtype.

Several randomized controlled trials have shown the beneficial effects of trospium<sup>91,92</sup> in both neurogenic and non-neurogenic DO.<sup>93-97</sup> Stohrer and colleagues performed a multicenter, placebo controlled, double-blind study to determine the effects of trospium on urodynamic parameters in patients with neurogenic DO secondary to spinal cord injury.<sup>91</sup> Patients were randomized to either trospium 20 mg twice daily or placebo for 3 weeks. The treatment group showed an increase in maximum cystometric capacity, decreased maximal detrusor pressure, and increased compliance. No such effects were seen in the placebo group. A similar study by Madersbacher and coworkers<sup>92</sup> compared the use of trospium and oxybutynin in the treatment of neurogenic DO. The two medications appeared to have equal effects, but those patients taking trospium had fewer side effects.

The effectiveness of trospium in the treatment of non-neurogenic DO has also been well documented. Allouis and colleagues<sup>93</sup> performed a randomized, double-blind, placebo-controlled study in 309 patients with non-neurogenic DO. The treatment group received trospium 20 mg twice daily, and the study length was 3 weeks. They found a significant increase over placebo in volume at first involuntary detrusor contraction and in maximum bladder capacity. Cardozo and colleagues<sup>94</sup> also performed a randomized, placebo-controlled, double-blind study in patients with non-neurogenic DO. A total of 208 patients participated in the study and were given placebo or trospium 20 mg twice daily for 2 weeks. They similarly found an increase in volume at which the first involuntary detrusor contraction took place as well as an increase in maximum cystometric capacity.

In a study comparing the efficacy of trospium 20 mg twice daily with tolterodine 2 mg twice daily and placebo in patients with urodynamically proven DO, Junemann and colleagues found trospium to be significantly more effective in decreasing the frequency of micturition than either tolterodine or placebo.<sup>95</sup> Trospium was also found to cause a greater reduction in the number of incontinence episodes and produced similar rates of dry mouth as tolterodine.

Halaska and associates<sup>96</sup> performed a long-term tolerability and efficacy study comparing trospium 20 mg twice daily and oxybutynin 5 mg twice daily in patients with DO. Patients were treated for 52 weeks. Urodynamic studies were performed at baseline, 26 weeks, and 52 weeks, and patient voiding diaries were also kept at baseline, 2, 26, and 52 weeks. A significant increase in mean maximum cystometric capacity was found, with 92 mL at 26 weeks and 115 mL at 52 weeks in the trospium group. No other significant difference in urodynamic parameters was noted between the two treatment groups. Voiding diaries revealed a decrease in frequency, frequency of incontinence, and urgency episodes in both groups. At least one adverse event occurred in patients (64.8% and 76.6% in the trospium and oxybutynin groups, respectively). The most common side effect in both groups was dry mouth. Overall, the two drugs were comparable in efficacy in improving urinary symptoms, but trospium had a better benefit-risk ratio than oxybutynin due to better tolerability.

In a large multicenter, placebo controlled, randomized, parallel study, Zinner and colleagues, from the Trospium Study Group,<sup>97</sup> compared the effects of trospium 20 mg twice daily and placebo in patients with OAB and urge incontinence. The study length was 12 weeks, with the primary end points being a change in the mean number of voids and a change in urge incontinent episodes in a 24-hour period. Other variables, such as mean volume per void, urge severity, diurnal and nocturnal micturition episodes, and onset of action, were also examined. Compared with placebo, trospium produced a significant reduction in the mean frequency of toilet voids and in urge incontinent episodes. A significant increase in volume voided and decrease in urge severity and diurnal frequency were also seen. The effects were seen after 1 week of treatment and were maintained throughout the remainder of the study. Once again, the most common side effect was dry mouth, occurring in 21.8% of patients, followed by constipation in 9.5% and headache in 6.5%. Similar results were confirmed by Rudy and colleagues<sup>98</sup> in a large multicenter study in the United States that included 658 patients.

Propiverine is a musculotropic smooth muscle relaxant with anticholinergic activity. It is rapidly absorbed and has a high first-pass metabolism.<sup>99</sup> Thuroff and associates<sup>100</sup> reviewed nine randomized studies on a total of 230 patients and found reductions in frequency and micturitions per 24 hours of 30% and 17%, respectively. There was a 77% subjective improvement, and side effects were found in 14% of the patients. In a study by Stohrer and colleagues,<sup>101</sup> superiority of propiverine over placebo was documented in patients with neurogenic DO. In controlled trials comparing propiverine, flavoxate, and placebo or propiverine, oxybutynin, and placebo,<sup>102</sup> they confirmed the efficacy of propiverine and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin.

Madersbacher and colleagues<sup>103</sup> compared the tolerability and efficacy of propiverine (15 mg three times daily), oxybutynin (5 mg twice daily) and placebo in 366 patients with urgency and urge incontinence in a randomized, double-blind, placebo-controlled clinical trial. The urodynamic efficacy of propiverine was similar to that of oxybutynin, but the incidence and severity of dry mouth was less. Dorschner and colleagues<sup>104</sup> performed a double-blind, multicenter, placebo-controlled randomized study to test the efficacy and cardiac safety of propiverine in elderly patients with urgency, urge, or mixed incontinence. There were 98 patients with a mean age of 68 years who received propiverine 15 mg or placebo three times daily for 4 weeks. Propiverine resulted in a significant reduction in micturition frequency and a decrease in incontinence episodes. The adverse events were very low. Therefore, propiverine appears to have an acceptable side effect profile and reasonable efficacy.

### Calcium Antagonists

The role of calcium as a messenger in linking extracellular stimuli to the intracellular environment is well established, including its involvement in excitation-contraction coupling in striated, cardiac, and smooth muscle.<sup>1,5</sup> Interference with calcium inflow or intracellular release is a very potent potential mechanism for bladder smooth muscle relaxation.

Nifedipine has been shown to be an effective inhibitor of contraction induced by several mechanisms in human and guinea pig bladder muscle.<sup>8,105</sup> It has also been shown to block completely the noncholinergic portion of the contraction produced

by electrical field stimulation in rabbit bladder.<sup>106</sup> Nifedipine more effectively inhibited contractions induced by potassium than those induced by carbachol in rabbit bladder strips, whereas terodiline, an agent with both calcium-antagonistic and anticholinergic properties, had the opposite effect. However, terodiline did cause complete inhibition of the response of rabbit bladder to electrical field stimulation. At low concentrations, terodiline has mainly an antimuscarinic action, whereas at higher concentration a calcium-antagonistic effect becomes evident. Experiments *in vitro* appeared to show that these two effects were at least additive with regard to bladder contractility. Other experimental studies confirmed the inhibitory effect of the calcium antagonists nifedipine, verapamil, and diltiazem on a variety of experimental models of the activity of spontaneous and induced bladder muscle strips and whole bladder preparations.<sup>101,108</sup> Andersson and colleagues<sup>109</sup> showed that nifedipine effectively (and with some selectivity) inhibited the nonmuscarinic portion of the contraction of rabbit detrusor strips, whereas verapamil, diltiazem, flunarizine, and lidoflazine caused a marked depression of both the total and the nonmuscarinic part of contraction, suggesting that differences exist between various calcium-channel blockers with respect to their effects, at least on electrically induced bladder muscle contraction. These results were used as support for the view that, even if “atropine-resistant” contractions in rabbit and human bladder had different causes, combined muscarinic-receptor and calcium-channel blockade might offer a more effective way of treating bladder overactivity than the single-mechanism therapies currently available.

A number of clinical studies on the inhibitory action of terodiline on bladder overactivity have shown clinical effectiveness.<sup>110</sup> In a double-blind crossover study of 12 women with motor urge incontinence, Ekman and colleagues<sup>111</sup> reported increases in bladder capacity and the volume at which sensation of urgency was experienced in all but one of the patients treated with terodiline, whereas placebo treatment had no objective or subjective effect. Peters<sup>112</sup> reported the results of a multicenter study that ultimately included data from 89 patients (from an original 128) and compared terodiline and placebo in women with motor urge incontinence. The daily dose in this study was 12.5 mg in the morning and 25 mg at night. The authors concluded that terodiline was more effective than placebo but noted that this improvement was much more apparent on subjective than on objective assessment of cystometric and micturition data; 63% of patients preferred terodiline, regardless of treatment sequence. Although statistically significant objective differences between terodiline and placebo were recorded, they were not very impressive. Tapp and colleagues<sup>113</sup> reported on a double-blind placebo-controlled study that used a dose-titration technique and included 70 women with urodynamically proven DO and bladder capacities of less than 400 mL. Of the 34 women in the terodiline group, 62% considered themselves improved, and 38% were unchanged; of the 36 women in the placebo group, 42% considered themselves improved, 47% unchanged, and 11% worse—a statistically significant response in favor of terodiline with regard to the improvement percentage. Micturition variables of daytime frequency, daytime incontinence episodes, number of pads used, and average voided volumes were statistically changed in favor of terodiline, but the absolute changes were relatively small (e.g., a change in daytime incontinence episodes among patients taking placebo from 2.5 to 1.9 per day, as opposed to a reduction from 3.7 to 1.6 for those taking terodiline). Urodynamic data, although showing a trend in favor of terodiline in each parameter, showed

no statistically significant differences in any category. Side effects were noted in a large number of patients and with equal frequency in both groups after the dose-titration phase. However, the incidence of anticholinergic side effects was higher in the drug group: 29% of the terodiline group and 11% of the placebo group spontaneously complained of a dry mouth, and 20% of the terodiline group but none of the placebo group complained of blurred vision. The AHCPR guidelines<sup>23</sup> list seven randomized controlled trials for terodiline; 94% of patients were women. The percentage of cure was listed as ranging from 18% to 33%, reduction in urge incontinence from 14% to 83%, side effects from 14% to 40%, and dropouts from 2% to 8% (all figures refer to overall percentage minus percentage on placebo).

Terodiline also exhibited an inhibitory effect on experimental neurogenic DO in the rabbit whole-bladder model, suggesting a possible role for local administration as well.<sup>114</sup> Terodiline is almost completely absorbed from the gastrointestinal tract and has a low serum clearance. The recommended dosage in adults is 25 mg twice a day, reduced to an initial dose of 12 mg twice a day in geriatric patients. The half-life is approximately 60 hours. Abrams<sup>110</sup> logically proposed, on this basis, a once-daily dose but emphasized the necessity of dose titration for each patient.

The common side effects seen with calcium antagonists (hypotension, facial flushing, headache, dizziness, abdominal discomfort, constipation, nausea, rash, weakness, and palpitations) have not been reported in larger initial clinical studies with terodiline, its side effects consisting primarily of those consequent on its anticholinergic action. However, questions have been raised about the occurrence of a rare arrhythmia (torsades de pointes) among patients taking terodiline simultaneously with antidepressants or antiarrhythmic drugs.<sup>116,117</sup> Stewart and colleagues<sup>118</sup> reported a prolongation of the QT and QTc (corrected QT) intervals and a reduction in heart rate among elderly patients taking 12.5 mg terodiline twice a day; these effects were apparent after 1 week but not after 1 day of therapy. These investigators also reported polymorphic ventricular tachycardia in four patients (three older than 80 years of age) receiving the drug. They advised avoidance of the drug in patients with cardiac disease requiring cardioactive drugs, in those with hypokalemia, and in combination with other drugs that can prolong the QT interval, such as tricyclic antidepressants or antipsychotics. After other reports of apparent cardiac toxicity, the drug was voluntarily withdrawn by the manufacturer pending the results of further safety studies. The studies conducted for approval by the FDA were likewise voluntarily halted by the manufacturer pending the results of further safety studies.

Other calcium-antagonist drugs have not been widely used to treat voiding dysfunction. A bladder-specific membrane calcium channel is not known to exist, and there is no agent that specifically blocks intracellular calcium release only in bladder smooth muscle cells. Available information does not suggest that systemic therapy with calcium antagonists is an effective way to treat DO.

### Potassium Channel Openers

Potassium channel openers relax various types of smooth muscle, including the detrusor, by increasing potassium efflux, resulting in membrane hyperpolarization.<sup>8</sup> Hyperpolarization reduces the opening probability of ion channels involved in membrane depolarization, and excitation is reduced. Andersson<sup>119</sup> summarized studies showing that, in isolated human and animal detrusor

muscle, potassium channel openers reduced spontaneous contractions and contractions occurring in response to electrical stimulation, carbachol, and low (but not high) external potassium concentrations. There are some suggestions that bladder instability—at least that associated with intravesical obstruction and detrusor hypertrophy—may be secondary to supersensitivity to depolarizing stimuli. Theoretically, then, potassium channel openers might be an attractive alternative for the treatment of DO in such circumstances without inhibiting the normal voluntary contractions necessary for bladder emptying.<sup>120</sup>

Pinacidil is a compound that, in a concentration-dependent fashion, inhibits not only spontaneous myogenic contractions but also contractile responses induced by electrical field stimulation and carbachol in isolated human detrusor<sup>121</sup> and in normal and hypertrophied rat detrusor muscle. However, a preliminary study of this agent in a double-blind, crossover format produced no effects on symptoms in nine patients with DO and bladder outlet obstruction.<sup>122</sup> Nurse and associates<sup>123</sup> reported on the use of cromakalim, another potassium channel opener, in 17 patients who had refractory DO or neurogenic DO or had stopped other drug therapy because of intolerable side effects. Six (37.5%) of 16 patients who completed the study showed a decrease in frequency and an increase in voided volume. Long-term observation was not possible, because the drug was withdrawn owing to reported adverse effects of high doses in animal toxicology studies. Levromakalim (the pharmacologically active enantiomer of cromakalim) was administered intravenously to six patients with high spinal cord lesions and reflex micturition<sup>124</sup>; other than an increase in the duration of the detrusor contraction, no other urodynamic parameters associated with the neurogenic DO were significantly affected. Levromakalim resulted in a rapid and significant drop in blood pressure which precluded studies at a higher dose. Overall, potassium channel openers are not at present very specific for the bladder and are more potent in relaxing other tissues—hence, their potential utility in the treatment of hypertension, asthma, and angina. If tissue-selective potassium-activator drugs can be developed, they may prove very useful for the treatment of detrusor instability, irritable bowel syndrome, and epilepsy.<sup>125</sup> Intravesical use has also been suggested<sup>124,125</sup> as a method of potentially eliminating some of the intolerable systemic side effects that limit the clinical utility of these agents.

Side effects of pinacidil have been studied best; they include headache, peripheral edema (in 25% to 50% of patients and dose-related), weight gain, palpitations, dizziness, and rhinitis. Hypertrichosis and symptomatic T-wave changes have also been reported (30%). Fewer data are available on cromakalim, which can produce dose-related headache but rarely edema.<sup>119</sup>

### Prostaglandin Inhibitors

Prostaglandins are ubiquitous compounds that have a potential role in the excitatory neurotransmission to the bladder, the development of bladder contractility or tension occurring during filling, the emptying contractile response of bladder smooth muscle to neural stimulation, and even the maintenance of urethral tone during the storage phase of micturition, as well as the release of this tone during the emptying phase. Downie and Karmazyn<sup>126</sup> suggested a different type of contractile influence of prostaglandins on detrusor muscle. They found that mechanical irritation of the epithelium of rabbit bladder increased basal tension and spontaneous activity in response to electrical stimu-

lation and that these responses, related to the intensity of the irritative trauma, were mimicked by prostaglandins. The effect was significantly reduced by pretreatment of the epithelium, but not the muscle, with prostaglandin synthetase inhibitors. Andersson<sup>8</sup> suggested a possible sensitization of sensory afferent nerves by prostaglandins, increasing afferent input at a given degree of bladder filling and contributing to the triggering of IVCs at a small bladder volume. Therefore, there are many mechanisms whereby prostaglandin synthetase inhibitors might decrease bladder contractility in response to various stimuli; however, objective evidence that such effects can occur is scant.

Cardozo and colleagues<sup>127</sup> reported on a double-blind placebo study of the effects of 50 mg flurbiprofen (a prostaglandin synthetase inhibitor) given three times a day on 30 women with DO. They concluded that the drug did not abolish IVCs or abnormal bladder activity but did delay the intravesical pressure rise to a greater degree of distention. Of these patients, 43% experienced side effects—primarily nausea, vomiting, headache, indigestion, gastric distress, constipation, and rash. Cardozo and Stanton<sup>128</sup> reported symptomatic improvement in patients with detrusor instability who were given indomethacin in doses of 50 to 200 mg daily, but this was a short-term study with no cystometric data, and the drug was compared only with bromocriptine. The incidence of side effects was high (19 of 32 patients), although no patient had to stop treatment because of them. Numerous prostaglandin synthetase inhibitors exist, most of which belong in the category of nonsteroidal anti-inflammatory drugs. It should be remembered that these drugs can interfere with platelet function and contribute to excess bleeding in surgical patients; some may also have adverse renal effects.<sup>129</sup>

### **β-Adrenergic Agonists**

The presence of β-adrenoceptors in human bladder muscle has prompted attempts to increase bladder capacity with β-adrenergic stimulation. Such stimulation can cause significant increases in the capacity of animal bladders, which contain a moderate density of β-adrenoceptors.<sup>1</sup> Studies *in vitro* show a strong dose-related relaxant effect of β<sub>2</sub>-agonists on the bladder body of rabbits but little effect on the bladder base or proximal urethra. Terbutaline, in oral doses of 5 mg three times a day, was reported to have a “good clinical effect” in some patients with urgency and urgency incontinence but no significant effect on the bladders of neurologically normal humans without voiding difficulty.<sup>130</sup> Although these results are compatible with those seen in other organ systems (e.g., β-adrenergic stimulation causes no acute change in total lung capacity in normal humans but does favorably affect patients with bronchial asthma), there are few adequate studies of the effects of β-adrenergic stimulation in patients with DO. Lindholm and Lose<sup>131</sup> used 5 mg terbutaline three times a day in eight women with motor urge incontinence and seven with sensory urge incontinence. After 3 months of treatment, 14 patients claimed to have experienced beneficial effects, and 12 became subjectively continent. In six of eight cases, the detrusor became stable on cystometric examination. The volume at first desire to void increased in those patients with originally unstable bladders, from a mean of 200 mL to 302 mL, but the maximum cystometric capacity did not change. Nine patients had transient side effects, including palpitations, tachycardia, or hand tremor, and in three of them the side effects continued but were acceptable to the patient. The drug was discontinued in one patient because of severe adverse symptoms.

Gruneberger,<sup>132</sup> in a double-blind study, reported that clenbuterol produced a good therapeutic effect in 15 of 20 patients with motor urge incontinence. Unfavorable results of β-agonist usage for bladder overactivity were published by Castleden and Morgan<sup>133</sup> and by Naglo and associates.<sup>134</sup> As yet there have been no controlled clinical trials on the treatment of OAB with β<sub>3</sub>-agonists.

### **Tricyclic Antidepressants**

Many clinicians have found that tricyclic antidepressants, particularly imipramine hydrochloride, are useful for facilitating urine storage, both by decreasing bladder contractility and by increasing outlet resistance. These agents have been the subject of extensive and highly sophisticated pharmacologic investigation to determine the mechanisms of action responsible for their varied effects.<sup>135-137</sup> Most data have been accumulated as a result of trying to explain the antidepressant properties of these agents and consequently involve primarily CNS tissue. Although the results, conclusions, and speculations based on the data are extremely interesting, it should be emphasized that it is essentially unknown whether they apply to, or have relevance for, the lower urinary tract. In varying degrees, all of these agents have at least three major pharmacologic actions: they have central and peripheral anticholinergic effects at some (but not all) sites; they block the active transport system in the presynaptic nerve ending that is responsible for the reuptake of the released amine neurotransmitters noradrenaline and serotonin; and they are sedatives, an action that occurs presumably on a central basis but is perhaps related to antihistaminic properties (at H<sub>1</sub> receptors, although they also antagonize H<sub>2</sub> receptors to some extent). There is also evidence that these agents desensitize at least some α<sub>2</sub>- and some β<sub>2</sub>-adrenoceptors. Paradoxically, they also have been shown to block some α- and serotonin-1 receptors. Imipramine has prominent systemic anticholinergic effects but only a weak antimuscarinic effect on bladder smooth muscle.<sup>138,139</sup> However, it does have a strong direct inhibitory effect on bladder smooth muscle that is neither anticholinergic nor adrenergic.<sup>136,140,141</sup> This may be the result of a local-anesthetic-like action at the nerve terminals in the adjacent effector membrane, an effect that seems to occur also in cardiac muscle,<sup>142</sup> or it may be caused by an inhibition of the participation of calcium in the excitation-contraction coupling process.<sup>138,140</sup> Akah<sup>143</sup> provided supportive evidence in the rat bladder that desipramine, the active metabolite of imipramine, depresses the response to electrical field stimulation by interfering with calcium movement (perhaps not only extracellular calcium movement but also internal translocation and binding). Direct evidence suggesting that the effect of imipramine on noradrenaline reuptake occurs in lower urinary tract tissue as well as in brain tissue was provided by Foreman and McNulty<sup>144</sup> in the rabbit. In addition, they described a significantly greater but similar effect of tomoxetine in the bladder and urethra in this model. Tomoxetine inhibits noradrenaline reuptake selectively, whereas imipramine has a nonselective effect. This fact suggests a potential new clinical approach to the use of more selective and potent reuptake inhibitors for the treatment of incontinence. In attempting to correlate clinical effects with mechanisms of action, one might also postulate a β-receptor-induced decrease in bladder body contractility if peripheral blockade of noradrenaline reuptake does occur there owing to the increased concentration of β-receptors compared with α-adrenoceptors in that area. An enhanced α-adrenergic effect in the smooth muscle of the bladder base and proximal

urethra, where  $\alpha$ -receptors outnumber  $\beta$ -receptors, is generally considered the mechanism whereby imipramine increases outlet resistance.

Clinically, imipramine seems to be effective in decreasing bladder contractility and increasing outlet resistance.<sup>145-148</sup> Castleden and colleagues<sup>148</sup> began therapy in elderly patients with DO with a single 25-mg nighttime dose of imipramine, which was increased every third day by 25 mg until the patient was continent or had side effects or a dose of 150 mg was reached. Six of 10 patients became continent; in addition, among those who underwent repeated cystometry, bladder capacity increased by a mean of 105 mL and bladder pressure at capacity decreased by a mean of 18 cm H<sub>2</sub>O. Motor unit potential increased by a mean of 30 cm H<sub>2</sub>O. Although our subjective impression<sup>146</sup> was that the bladder effects became evident only after days of treatment, some patients in the Castleden series became continent after only 3 to 5 days of therapy. Our usual adult dose for treatment of voiding dysfunction is 25 mg four times a day; less-frequent administration is possible because of the drug's long half-life. Half of that dose is given in elderly patients, in whom the drug half-life may be prolonged. In our experience, the effects of imipramine on the lower urinary tract are often additive to those of atropine-like agents; consequently, a combination of imipramine and an antimuscarinic or an antispasmodic is sometimes especially useful for decreasing bladder contractility.<sup>146</sup> If imipramine is used in conjunction with an atropine-like agent, it should be noted that the anticholinergic side effects of the drugs may be additive.

It has been known for many years that imipramine is relatively effective for the treatment of nocturnal enuresis in children. Doses for this condition range from 10 to 50 mg daily. It is not known whether the mechanisms of drug action in this situation are the same as those for decreasing bladder contractility. Korczyn and Kish<sup>149</sup> presented evidence that the mechanism of the antineuritic effect differs from that of the peripheral anticholinergic effect and the drug's antidepressant effect. The antineuritic effect occurs soon after initial administration, whereas the antidepressant effects usually take 2 to 4 weeks to develop.

Doxepin is another tricyclic antidepressant that has been found (in rabbit-bladder strips *in vitro*) to be more potent than other tricyclic compounds with respect to antimuscarinic and muscolotropic relaxant activity.<sup>142</sup> Lose and colleagues,<sup>150</sup> in a randomized, double-blind, crossover study of women with IVCs and frequency, urgency, or urge incontinence, found that this agent caused a significant decrease in control over nighttime frequency and incontinence episodes, as well as a near-significant decrease in urine loss (by the pad-weighting test) and in the cystometric parameters of first sensation and maximum bladder capacity. The dose of doxepin used was either a single 50-mg bedtime dose or this dose plus an additional 25 mg in the morning. The number of daytime incontinence episodes decreased in both doxepin and placebo groups, and the difference was not statistically significant. Doxepin treatment was preferred by 14 patients, whereas 2 preferred placebo and 3 had no preference. Of the 14 patients who stated a preference for doxepin, 12 claimed that they became continent during treatment and 2 claimed improvement; the 2 patients who preferred placebo also claimed improvement. The AHCPR guidelines<sup>23</sup> combine results for imipramine and doxepin, citing only three randomized controlled trials, with an unknown percentage of women patients. The percentage of cure was listed as 31%, reduction in urge incontinence as ranging from 20% to 88%, and side effects as

ranging from zero to 70% (all figures refer to overall percentage minus percentage on placebo).

When the tricyclic antidepressants are used in the generally larger doses employed for antidepressant effects, their most frequent side effects are those attributable to their systemic anticholinergic activity.<sup>135,136</sup> Allergic phenomena, including rash, hepatic dysfunction, obstructive jaundice, and agranulocytosis, may also occur but are rare. CNS side effects may include weakness, fatigue, parkinsonian effects, fine tremors (noted mostly in the upper extremities), a manic or schizophrenic picture, and sedation, probably from an antihistaminic effect. Postural hypotension may also be seen, presumably due to selective blockade (a paradoxical effect) of  $\alpha_1$ -adrenoceptors in some vascular smooth muscle. Tricyclic antidepressants may also cause excess sweating of obscure origin and a delay in orgasm or orgasmic impotence, the cause of which is likewise unclear. They may also produce arrhythmias and can interact in deleterious ways with other drugs; therefore, caution must be observed when using these drugs in patients with cardiac disease.<sup>135</sup> Whether cardiotoxicity will prove to be a legitimate concern in patients receiving smaller doses (i.e., smaller than those used for treatment of depression) for lower urinary tract dysfunction remains to be seen, but it is a matter of potential concern. Consultation with a patient's physician or cardiologist is always helpful before such therapy is instituted in questionable situations. The use of imipramine is contraindicated in patients receiving monoamine oxidase inhibitors because severe CNS toxicity can be precipitated, including hyperpyrexia, seizures, and coma. Some potential side effects of antidepressants may be especially significant in the elderly, specifically weakness, fatigue, and postural hypotension. If imipramine or any of the tricyclic antidepressants is to be prescribed for the treatment of voiding dysfunction, the patient should be thoroughly informed about the fact that this is not the usual indication for this drug and that potential side effects exist. Reports of significant side effects (severe abdominal distress, nausea, vomiting, headache, lethargy, and irritability) after abrupt cessation of high doses of imipramine in children suggest that the drug should be discontinued gradually, especially in patients receiving high doses.

### Botulinum Toxin

Botulinum toxin (BTX), is a presynaptic inhibitor of acetylcholine release and the release of other neurotransmitters and therefore decreases muscle contractility. It can be administered in the bladder by cystoscopic injection directly into the detrusor muscle. This produces a chemical denervation that is reversible after about 6 months. Of the seven subtypes of botulinum toxin that have been identified, botulinum A toxin (BTX-A) is the most commonly used, with botulinum B toxin (BTX-B) being the next most commonly used.

There have been some open-label and a few double-blind studies reporting its use in the treatment of neurogenic and idiopathic DO. Preliminary studies using BTX-A look promising, but for the use of BTX-B is too early to tell. Schurch<sup>151</sup> evaluated the use of BTX-A in patients with neurogenic DO secondary to spinal cord injury who were on intermittent catheterization. The study was prospective but nonrandomized. Twenty-one patients received 200 to 300 U of BTX-A. At 6 weeks, 17 of 19 patients were completely continent and could decrease or stop oral agents for their DO. The two who did not improve were given the lower dose of BTX-A (200 U). Urodynamics also demonstrated an

increase in mean bladder capacity, increased postvoid residual, and a decrease in maximum voiding pressure. In some of the patients, the improvements were still durable out to 36 weeks.

Reitz and colleagues from Europe describe the European experience with BTX-A.<sup>152</sup> This retrospective study examined the data on 200 patients with neurogenic DO. At 12 weeks, there was a significant increase in the mean maximum cystometric bladder capacity, postvoid residual, and compliance. A majority of the patients could reduce or discontinue their anticholinergic medications. Data at 36 weeks revealed continued improvement.

Two studies studied the use of BTX for the treatment of non-neurogenic DO. Rapp and colleagues<sup>153</sup> performed BTX-A intradetrusor injections in 35 patients (29 women and 6 men) with frequency, urgency, and/or urge incontinence. They used 300 U of BTX-A injected transurethraly into 30 different sites within the bladder. There was a significant decrease in the scores recorded by the Incontinence Impact Questionnaire and Urinary Distress Inventory short forms. Overall, 60% of patients reported a slight to complete improvement in symptoms. Improvement was seen for at least 6 months. Dykstra and associates<sup>154</sup> used escalating doses of BTX-B in a similar cohort of patients; 14 of 15 patients reported decreased frequency of urination and subjective improvement. BTX does appear to be a promising new therapy for facilitating bladder storage. Further placebo-controlled studies need to be carried out to appreciate its true efficacy and to determine the optimal dosages and locations of injections.

### Dimethyl Sulfoxide

Dimethyl sulfoxide (DMSO), a naturally occurring organic compound used as an industrial solvent for many years, has multiple pharmacologic actions (membrane penetration, anti-inflammatory, local analgesic, bacteriostatic, diuretic, cholinesterase inhibitor, collagen solvent, vasodilator) and has been used for the treatment of arthritis and other musculoskeletal disorders. The formulation for human intravesical use is a 50% solution. Sant<sup>155</sup> summarized the pharmacology and clinical usage of DMSO and tabulated good-to-excellent results in 50% to 90% of collected series of patients treated with intravesical instillations for interstitial cystitis. However, DMSO has not been shown to be useful in the treatment of neurogenic or non-neurogenic DO, nor in any patient with urgency or frequency without interstitial cystitis.

### Polysynaptic Inhibitors

Baclofen is an agent that decreases outlet resistance secondary to striated sphincter dyssynergia. It is also capable of depressing neurogenic detrusor overactivity resulting from spinal cord injury.<sup>156</sup> Taylor and Bates,<sup>157</sup> in a double-blind crossover study, reported that baclofen was very effective in decreasing both day and night urinary frequency and incontinence in patients with idiopathic DO. Cystometric changes were not recorded, however, and considerable improvement was also obtained in the placebo group. The intrathecal use of baclofen for treatment of DO is a potentially exciting area, and further reports are awaited.

### Other Potential Agents

Nitric oxide (NO) is hypothesized to be a mediator of the non-adrenergic, noncholinergic relaxation of the outlet smooth

muscle that occurs with bladder contraction.<sup>5</sup> Evidence exists that it is also involved in relaxation of bladder body smooth muscle,<sup>158</sup> and this provides interesting fodder for speculation: Is relaxation impaired in some types of overactivity, and can NO analogues or synthetase stimulators be developed as agents to inhibit detrusor contractility? Glyceryl trinitrate releases NO in vivo and achieves its cardiovascular effects by relaxing vascular smooth muscle. Although the ubiquity of NO might seem to mitigate its potential use in treating bladder overactivity (unless more organ-specific substrates or receptors are found), randomized controlled trials should be conducted.

Soulard and colleagues<sup>159</sup> described the effects of JO1870 on bladder activity in the rat. This non-anticholinergic probable opioid agonist increased bladder capacity and threshold pressure responsible for micturition in a dose-dependent fashion, raising the possibility of the use or development of opioid agonists with selectivity for receptors involved in the micturition reflex.

Constantinou<sup>160,161</sup> described the effects of thiphenamil hydrochloride on the lower urinary tract in healthy female volunteers and in those with detrusor incontinence. This drug was said to be a “synthetic antispasmodic.” In a randomized controlled trial, based on diary records from 14 patients with DO, it was reported that voiding frequency per day decreased significantly (from 10.3 to 8.0 times), but placebo values were not given. Daily incontinence episodes decreased in nine analyzable patients, from 2.3 to 1.6 (not significant; placebo values not given), with pad dryness (rated on a scale of 0 to 4) improving from 1.6 to 1.2 (significant, but again no placebo data were given). Objective urodynamic results (in 16 patients) showed no flowmetry changes, no changes in bladder capacity, some increase in first sensation of fullness, and a significant decrease in detrusor voiding pressure (from 46.1 to 31.9 cm H<sub>2</sub>O), compared with placebo. The data and interpretation in this article are confusing, especially because the study of healthy volunteers showed no urodynamic differences except an increase in maximum flow rate (from 16.9 to 27.7 mL/sec) at a drug dose of 800 mg. The most that can be said about the clinical use of thiphenamil is that, now a question has been raised, it needs to be addressed by further, “cleaner” studies with internally consistent results.

### INCREASING BLADDER CAPACITY BY DECREASING SENSORY (AFFERENT) INPUT

#### Vanilloids: Capsaicin and Resiniferatoxin

Decreasing afferent input peripherally is the ideal treatment for both sensory urgency and DO in a bladder with relatively normal elastic or viscoelastic properties, in which the sensory afferents constitute the first limb in the abnormal micturition reflex. Maggi has written extensively about this type of treatment, specifically with reference to the properties of capsaicin.<sup>162-164</sup> Capsaicin is an irritant and algogenic compound obtained from hot red peppers that has highly selective effects on a subset of mammalian sensory neurons, including polymodal receptors and warm thermoreceptors.<sup>165</sup> Capsaicin produces pain by selectively activating polymodal nociceptive neurons by membrane depolarization and opening a cation-selective ion channel, which can be blocked by ruthenium red. Repeated administration induces desensitization and inactivation of sensory neurons by several mechanisms. Sys-

temic and topical capsaicin produce a reversible antinociceptive and anti-inflammatory action after an initially undesirable analgesic effect. Local or topical application blocks C-fiber conduction and inactivates neuropeptide release from peripheral nerve endings, accounting for local antinociception and reduction of neurogenic inflammation. Resiniferatoxin (RTX) is an analogue of capsaicin and is approximately 1000 times more potent for desensitization than capsaicin,<sup>166</sup> but it is only a few hundred times more potent for excitation.<sup>167</sup> Systemic capsaicin produces antinociception by activating specific receptors on afferent nerve terminals in the spinal cord; spinal neurotransmission is subsequently blocked by a prolonged inactivation of sensory neurotransmitter release. With local administration (intravesical), the potential advantage of capsaicin is a lack of systemic side effects. The actions are highly specific when the drug is applied locally: the compound affects primarily small-diameter nociceptive afferents, leaving the sensations of touch and pressure unchanged, although heat (but not cold) perception may be reduced; motor fibers are not affected. The effects are reversible, although it is not known whether initial levels of sensitivity are regained.

Maggi<sup>164</sup> reviewed the therapeutic potential of capsaicin-like molecules. Capsaicin-sensitive primary afferents (CSPAs) innervate the human bladder, and intravesical instillation of capsaicin into human bladder produces a concentration-dependent decrease in first desire to void, decreased bladder capacity, and a warm burning sensation. Maggi<sup>162</sup> used doses of 0.01, 1.0 and 10  $\mu\text{mol/L}$ , administered in ascending order at intervals of 10 to 15 minutes as constant infusions of 20 mL/min until micturition occurred. Five capsaicin-treated patients with "hypersensitive disorder" reported either a complete disappearance of symptoms (four patients) or marked attenuation of symptoms (one patient), beginning 2 to 3 days after administration and lasting for 4 to 16 days; after that time, the symptoms gradually reappeared but were no worse.<sup>164</sup> Fowler and colleagues<sup>169</sup> found that considerably higher doses (up to 1 to 2 mmol/L for 30 minutes) were necessary to produce an effect in humans<sup>170</sup> however, they reported that bladder control improved within 2 days, and the improvement lasted for 3 to 6 months. Lower doses (0.1 to 100  $\mu\text{mol/L}$ ) produced "no long-lasting benefit." In a later study, Fowler and colleagues<sup>171</sup> administered intravesical capsaicin to 14 patients with DO and intractable urinary incontinence, 12 of whom had known spinal cord disease. A single intravesical instillation of 1 or 2 mmol/L capsaicin produced a response in nine patients (all of whom had spinal cord disease), with four of these patients having only a "partial" response and five patients having complete and durable (3 weeks to 6 months) responses, defined as complete continence on intermittent catheterization. Among the nine patients who responded to treatment, mean bladder capacity increased from 106 to 302 mL and maximum detrusor pressure decreased from 54 to 36 cm H<sub>2</sub>O. There were no long-term adverse effects from the therapy.

Similar results were noted by Das and colleagues,<sup>172</sup> who treated seven patients with neurogenic bladders with four increasing doses of intravesical capsaicin over a period of several weeks (100  $\mu\text{mol/L}$ , 500  $\mu\text{mol/L}$ , 1 mmol/L, and 2 mmol/L). Only five of seven patients were able to complete the therapy, owing to the discomfort induced by the instillation. Of these five patients, three had symptomatic and urodynamic improvement. Geirsson and associates<sup>173</sup> treated 10 patients with traumatic spinal cord injury and neurogenic bladder with 2 mmol/L intravesical capsaicin; urodynamic improvement (decreased voiding pressure

and increased bladder capacity) was noted in 9 of the 10 patients at 6 weeks. Subjective improvement was noted in 4 patients at 2 to 7 months after therapy, 2 of whom became continent. All 10 patients had no improvement or a worsening of symptoms during the first 1 to 2 weeks after instillation. Adverse reactions included severe burning on instillation in those patients with partial spinal lesions, precipitation of autonomic dysreflexia in several other patients, and gross hematuria in four patients. Chandiramani and colleagues<sup>174</sup> were able to reduce significantly the short-term toxicity (triggering of involuntary detrusor contractions) and discomfort of intravesical capsaicin therapy by pretreatment with an instillation of 2% topical lidocaine. Pretreatment with lidocaine did not alter the therapeutic efficacy of the capsaicin.

An efferent function of CSPAs is the release of neurotransmitters from the peripheral endings of these sensory neurons, such as tachykinins and calcitonin gene-related peptide.<sup>162</sup> These neurotransmitters can produce events collectively known as neurogenic inflammation, which can include smooth muscle contractions, increased plasma protein extravasation, vasodilatation, mast cell degranulation, facilitation of transmitter release from nerve terminals, and recruitment of inflammatory cells. This is another reason why intravesical capsaicin could theoretically be useful in treating the pain and related problems of interstitial cystitis and certain types of bladder overactivity that originate in primary afferents.

The peripheral terminals of CSPAs form a dense plexus just below the bladder urothelium, and fibers penetrating the urothelium come into contact with the lumen. This location, combined with their peculiar chemosensitivity, permits CSPAs to detect "backflow" of chemicals across the urothelium, which is thought to occur during conditions leading to breakdown of the "barrier function" of the urothelium.<sup>164</sup> If the "barrier" theory or "leaky urothelium" theory of the pathogenesis of the interstitial cystitis is true for some or many of the patients with this condition, the CSPAs in such patients may be stimulated by urine constituents' leaking back across the urothelium; under these circumstances, a local release of neuropeptides may well contribute to the production of neurogenic inflammation. If this is so, as Maggi suggested,<sup>164</sup> a local treatment leading to desensitization of CSPAs would be doubly advantageous. With capsaicin, however, excitation precedes desensitization, somewhat limiting the potential for therapy in humans. A preferable analogue would produce the latter action while reducing or eliminating the former. Last, Maggi<sup>164</sup> discussed the possible long-term disadvantages of such therapy as related to the potential physiologic roles (trophic or protective) of CSPAs and their secretions in response to stimulation.

RTX has been shown to be beneficial in several studies.<sup>175-179</sup> de Seze and colleagues compared the efficacy and tolerability of nonalcohol capsaicin (1 mmol/L) and RTX (100 nmol/L) in 10% alcohol in a randomized, double-blind, parallel group study in 39 spinal cord-injured patients with neurogenic DO. Follow-up was 3 months. On day 30, similar clinical and urodynamic improvements were found—in 78% and 83% of patients receiving capsaicin and 80% and 60% of those receiving RTX. The benefit remained in two thirds of the two groups after 3 months. There was no difference in side effects between the two groups.

Overall, intravesical capsaicin and RTX treatment may be a promising therapy for DO, and possibly for sensory dysfunction of the lower urinary tract; however, many problems exist. Optimal

dosage, method and timing of delivery, and optimum delivery vehicle (diluent) remain unclear. The patients most likely to respond to this therapy are not yet defined, and randomized placebo-controlled studies to determine overall efficacy have not yet been performed. Finally, discomfort and triggering of involuntary bladder activity with instillation and postinstillation gross hematuria may be problematic.

## INCREASING OUTLET RESISTANCE

### $\alpha$ -Adrenergic Agonists

The bladder neck and proximal urethra contain a preponderance of  $\alpha$ -adrenergic receptor sites, which, when stimulated, produce smooth muscle contraction.<sup>1,2,5</sup> The static infusion urethral pressure profile is altered by such stimulation, producing an increase in motor unit potential and maximum urethral closure pressure (MUCP).  $\alpha$ -Adrenergic stimulants generally increase outlet resistance to a variable degree but are most often limited by their potential side effects, including blood pressure elevation, anxiety and insomnia due to stimulation of the CNS, headache, tremor, weakness, palpitations, cardiac arrhythmias, and respiratory difficulties. All such agents should be used with caution in patients with hypertension, cardiovascular disease, or hyperthyroidism.<sup>180</sup>

The use of ephedrine to treat SUI was mentioned as early as 1948.<sup>178</sup> Ephedrine is a noncatecholamine sympathomimetic agent that enhances release of noradrenaline from sympathetic neurons and directly stimulates both  $\alpha$ - and  $\beta$ -adrenoceptors.<sup>154</sup> The oral adult dosage is 25 to 50 mg four times a day. Some tachyphylaxis develops in response to its peripheral actions, probably as a result of depletion of noradrenaline stores. Pseudoephedrine, a stereoisomer of ephedrine, is used for similar indications and carries similar precautions. The adult dosage is 30 to 60 mg four times a day, and the 30-mg dose form is available in the United States without prescription. Diokno and Taub<sup>181</sup> reported a "good-to-excellent" result in 27 of 38 patients with sphincteric incontinence treated with ephedrine sulphate. Beneficial effects were most often achieved in those with minimal-to-moderate wetting; little benefit was achieved in patients with severe SUI. A dose of 75 to 100 mg norephedrine chloride has been shown to increase motor unit potential and MUCP in women with SUI.<sup>182</sup> At a bladder volume of 300 mL, motor unit potential rose from 82 to 110 cm H<sub>2</sub>O, and MUCP from 63 to 93 cm H<sub>2</sub>O. The functional profile length did not change significantly. Obrink and Bunne,<sup>183</sup> however, noted that 100 mg norephedrine chloride given twice a day did not improve severe SUI sufficiently to offer it as an alternative to surgical treatment. They further noted in their group of 10 patients that the MUCP was not influenced at rest or with stress at low or moderate bladder volumes. Lose and Lindholm<sup>184</sup> treated 20 women with SUI with norfenefrine, an  $\alpha$ -agonist, given as a slow-release tablet: 19 patients reported reduced urinary leakage, and 10 reported no further SUI. MUCP increased in 16 patients during treatment, the mean rise being from 53 to 64 cm H<sub>2</sub>O. It is interesting and perplexing that most patients reported an effect only after 4 days of treatment. This delay is difficult to explain on the basis of drug action, unless one postulates a change in the number or sensitivity of  $\alpha$ -adrenoceptors.

The group at Kolding Hospital in Denmark has published three other articles of note on the use of norfenefrine for sphinc-

teric incontinence, with interesting results. Forty-four patients with SUI were randomized to treatment with norfenefrine (15 to 30 mg three times a day) versus placebo for 6 weeks.<sup>185</sup> Subjectively, 12 (52%) of 23 of the norfenefrine group reported improvement, as opposed to 7/21 (33%) of the placebo group—a difference that was not significant. Continence was reported by six (26%) norfenefrine patients and three (14%) placebo patients (not significant). Judged by a stress test, seven patients in each group became continent; 11 (48%) of 23 improved both subjectively and objectively in the norfenefrine group, as did 5/21 (24%) of the placebo group ( $P = .09$ ). MUCP increased significantly (from 50 to 55 cm H<sub>2</sub>O in the norfenefrine group, but also from 55 to 65 cm H<sub>2</sub>O in the placebo group). Although the patients were said to have "genuine SUI," 5 of 12 patients with "urge incontinence" were reported cured with norfenefrine, and 4 of 7 with placebo.

Diernoës and associates<sup>186</sup> reported on the results of a 1-hour pad test in 33 women with either SUI or combined SUI and urgency treated with 30 mg norfenefrine three times a day. Leakage of more than 10 g was required for entry into the study. Subjective improvement was reported by 10 patients (30%). Continence as shown by pad test was found in six patients (18%). Pad tests were graded on a scale of 1 to 4. At 12 weeks, 20 patients (61%) had improved by at least one grade ( $P < .05$ ), but at 3 weeks the number was 13 (39%; not significant).

Lose and colleagues<sup>187</sup> studied 44 women scheduled for operation for SUI who were treated with 15 to 30 mg norfenefrine three times a day versus placebo for 3 to 4.5 months and were then evaluated for outcome after a median observation period of 30 months. The description and categorization of results were somewhat confusing, but the results were interesting. Originally, 23 patients were allocated to the norfenefrine group and 21 to placebo. Results were categorized as follows: cured or much improved with no further treatment wanted; underwent surgery for relief; wanted medical therapy reinstated; uncertain about what kind of treatment they wanted; used pads or pelvic floor exercises. At the end of a 6-week initial treatment period and re-evaluation, patients whose initial treatment had had no effect at all were crossed over to the other group. It is obvious that a powerful placebo effect occurred, for reasons unknown, and therefore caution must be exercised in the evaluation of all modalities of therapy for sphincteric (and detrusor) incontinence.

Phenylpropanolamine (PPA) hydrochloride shares the pharmacologic properties as ephedrine and is approximately equal in peripheral potency while causing less central stimulation.<sup>188</sup> It is available in tablets of 25 or 50 mg and in 75-mg timed-release capsules and is a component of numerous proprietary mixtures marketed for the treatment of nasal and sinus congestion (usually in combination with an H<sub>1</sub> antihistamine) or as appetite suppressants. Using doses of 50 mg three times a day, Awad and associates<sup>189</sup> found that 11/13 women and 6/7 men with SUI were significantly improved after 4 weeks of therapy. MUCP increased from a mean of 47 to 72 cm H<sub>2</sub>O in patients with an empty bladder and from 43 to 58 cm H<sub>2</sub>O in patients with a full bladder. Using a capsule containing 50 mg PPA, 8 mg chlorpheniramine (an antihistamine), and 2 mg isopropamide (an antimuscarinic), Stewart and colleagues<sup>190</sup> found that, of 77 women with SUI, 18 were "completely cured" with one sustained-release capsule; 28 patients were "much better," six were "slightly better," and 25 were "no better." In 11 men with SUI after prostatectomy, the numbers in the corresponding categories were 1, 2, 1, and 7. The

formulation of Ornade has now been changed, and each capsule of drug contains 75 mg PPA and 12 mg chlorpheniramine. Collste and Lindskog<sup>191</sup> reported on a group of 24 women with SUI who were treated with PPA or placebo with crossover after 2 weeks. Severity of SUI was graded 1 (slight) or 2 (moderate). Average MUCP overall increased significantly with PPA compared with placebo (from 48 to 55 cm H<sub>2</sub>O versus 48 to 49 cm H<sub>2</sub>O). This was a significant difference in grade 2 but not in grade 1 patients. The average number of leakage episodes per 48 hours was reduced significantly overall for PPA patients but not for placebo patients (5 to 2 versus 5 to 6). This was significant for grade 1 but not for grade 2 patients. Subjectively, 6 of 24 patients thought that both PPA and placebo were ineffective. Among the 18 patients (of 24) who reported a subjective preference, 14 preferred PPA and 4 preferred placebo. Improvements were rated subjectively as good, moderately good, or slight. Improvements obtained with PPA were significant compared with those for placebo for the entire population and for both groups separately. The AHCPR guidelines<sup>23</sup> reported eight randomized controlled trials with PPA 50 mg twice a day for SUI in women. The percentage cure was listed as ranging from zero to 14%, reduction in incontinence from 19% to 60%, side effects from 5% to 33%, and dropouts from zero to 4.3% (all figures refer to overall percentage minus percentage on placebo).

Some authors have emphasized the potential complications of PPA. Mueller<sup>192</sup> reported on a group of 11 patients who had significant neurologic symptoms (acute headache, psychiatric symptoms, or seizures) after taking "look-alike pills" thought to contain amphetamines but actually containing PPA. Baggioni and associates<sup>193</sup> emphasized the possibility of blood pressure elevation, especially in patients with autonomic impairment. Lasagna<sup>194</sup> pointed out that previously reported blood pressure elevations occurred with a product that differed from American PPA and probably contained a different and much more potent isomer. He noted that, although a huge volume of PPA has been consumed in the form of decongestants and anorectic medications, the world literature has reported only a minimum number of possible toxic reactions, most of which involved excessively high doses in combination medications. Liebson and colleagues<sup>195</sup> found no cardiovascular or subjective adverse effects with doses of 25 mg three times a day or with a 75-mg sustained-release preparation in a population of 150 healthy normal volunteers. Blackburn and colleagues,<sup>196</sup> in a larger series of healthy subjects using many over-the-counter formulations, concluded that a statistically significant but clinically unimportant pressor effect existed during the first 6 hours after administration of PPA and that this was greater with sustained-release preparations. Caution should still be exercised in individuals known to be significantly hypertensive and in elderly patients, in whom pharmacokinetic function may be altered.

Midodrine is a long-acting  $\alpha$ -adrenergic agonist that is reported to be useful in the treatment of seminal emission and ejaculation disorders after retroperitoneal lymphadenectomy. Treatment with 5 mg twice a day for 4 weeks in 20 patients with SUI produced a cure in 1 and improvement in 14 patients.<sup>197</sup> The MUCP rose by 8.3%, and the planometric index of the continence area on profilometry increased by 9%. The actions of imipramine have already been discussed. On a theoretical basis, an increase in urethral resistance might be expected if, indeed, an enhanced  $\alpha$ -adrenergic effect at this level resulted from an inhibition of noradrenaline reuptake. However, as mentioned previ-

ously, imipramine also causes  $\alpha$ -adrenergic blocking effects, at least in vascular smooth muscle. Many clinicians have noted improvement in patients treated with imipramine primarily for bladder overactivity but who had in addition some component of sphincteric incontinence. Gilja and colleagues<sup>198</sup> reported a study of 30 women with SUI who were treated with 75 mg imipramine daily for 4 weeks: 21 women subjectively reported continence, and the mean MUCP for the group increased from 34.06 to 48.23 cm H<sub>2</sub>O.

Although some clinicians have reported spectacular cure and improvement rates with  $\alpha$ -adrenergic agonists and agents that produce an  $\alpha$ -adrenergic effect in the outlet of patients with sphincteric urinary incontinence, our own experience coincides with those who report that such treatment often produces satisfactory or some improvement in mild cases but rarely total dryness in patients with severe or even moderate SUI. Nevertheless, a clinical trial, when possible, is certainly worthwhile, especially in conjunction with pelvic floor physiotherapy or biofeedback.

### **$\beta$ -Adrenergic Antagonists and Agonists**

Theoretically,  $\beta$ -adrenergic blocking agents might be expected to "unmask" or potentiate an  $\alpha$ -adrenergic effect, thereby increasing urethral resistance. Gleason and colleagues<sup>199</sup> reported success in treating certain patients with SUI with propranolol, using oral doses of 10 mg four times a day; the beneficial effect became manifest only after 4 to 10 weeks of treatment. Cardiac effects occur rather promptly after administration of this drug, but hypotensive effects do not usually appear as rapidly, although it is difficult to explain such a long delay in onset of the therapeutic effect on incontinence on this basis. Kaisary<sup>200</sup> also reported success with propranolol in the treatment of SUI. Although such treatment has been suggested as an alternative to  $\alpha$ -agonists in patients with sphincteric incontinence and hypertension, few, if any, subsequent reports of such efficacy have appeared. Others have reported no significant changes in urethral profile pressures in normal women after  $\beta$ -adrenergic blockade.<sup>201</sup> Although 10 mg four times a day is a relatively small dose of propranolol, it should be recalled that the major potential side effects of the drug are related to the therapeutic  $\beta$ -blocking effects. Heart failure may develop, as well as an increase in airway resistance, and asthma is a contraindication to its use. Abrupt discontinuation may precipitate an exacerbation of anginal attacks and rebound hypertension.<sup>188</sup>

$\beta$ -Adrenergic stimulation is generally conceded to decrease urethral pressure, but  $\beta_2$ -agonists have been reported to increase the contractility of fast-contracting striated muscle fibers (extensor digitorum longus) from guinea pigs and to suppress that of slow-contracting fibers (soleus).<sup>202</sup> Clenbuterol, a selective  $\beta_2$ -agonist, has been reported to potentiate, in a dose-dependent fashion, the field stimulation-induced contraction in isolated periurethral muscle preparation in the rabbit. The potentiation was greater than that produced by isoprenaline and was suppressed by propranolol. Kishimoto and colleagues<sup>203</sup> reported an increase in urethral pressure with clinical use of clenbuterol and speculated on its promise in the treatment of sphincteric incontinence. Although the differential effects on the smooth and striated musculature of the outlet and even on different fiber types of the striated sphincter may be functionally antagonistic, one

should not ignore the possibility of an augmentative effect on outlet resistance by a drug such as clenbuterol under certain physiologic conditions. Other  $\beta_2$ -agonists are salbutamol and terbutaline.

### Duloxetine

Duloxetine, a combined serotonin- and norepinephrine-reuptake inhibitor, increases sphincteric muscle activity during the filling and storage phase of micturition in the model of the irritated bladder in the cat. This relatively new pharmacologic agent has been used clinically as an antidepressant.<sup>204</sup> In a study of its effects on the lower urinary tract in the cat, Thor and Katofiasc<sup>205</sup> noted that duloxetine significantly increased bladder capacity (probably through a CNS effect) and also enhanced external urethral sphincter activity with no effect on sphincter activity during voiding.

To date, there have been several randomized controlled studies documenting the effects of duloxetine in the treatment of SUI. Dmochowski and colleagues<sup>206</sup> enrolled 683 patients in a double-blind, placebo-controlled study comparing duloxetine 40 mg twice daily to placebo. There was a significantly greater decrease in incontinence episode frequency in the duloxetine group (50%) compared with the placebo group (27%), as well as improvement in quality of life. The improvements with duloxetine were associated with significant increases in the voiding interval (20 minutes versus 2 minutes) compared to placebo. The discontinuation rate was higher in the duloxetine group (24%) than with placebo (4%), and discontinuation was most frequently due to nausea (6.4%), which was usually transient.

Similar results were reported by Millard<sup>207</sup> and van Keerebroek<sup>208</sup> in investigations of the effects of duloxetine in the treatment of SUI outside the United States. At present time, this medication is not indicated for the treatment of SUI in the United States.

### Estrogens

Although estrogens were recommended for the treatment of female urinary incontinence as early as 1941,<sup>201</sup> there is still controversy concerning their use and the benefit-risk ratio for this purpose. Numerous clinical studies exist, but there has been little consistency in methodology, many of the studies have been observational, different formulations of estrogens have been tested, and the data can be conflicting. In some cases, raw data seem to have been ignored in favor of statistics; however, as always, there is no lack of opinions.

Significant work has been done on the effects of estrogenic hormones on the lower urinary tract. Hodgson and associates<sup>209</sup> reported that the sensitivity of the rabbit urethra to  $\alpha$ -adrenergic stimulation was estrogen dependent. Levin and coworkers<sup>209,210</sup> showed that parenteral estrogen administration can change the autonomic receptor content and the innervation of the lower urinary tract of immature female rabbits, increasing the response to  $\alpha$ -adrenergic, muscarinic, and purinergic stimulation in the bladder body, but not in the base, and significantly increasing the number of  $\alpha$ -adrenergic and muscarinic receptors in the bladder body but not in the base. Other work<sup>5</sup> showed a decrease in muscarinic receptor density after estradiol treatment of mature female rabbits and either no change or a decreased detrusor response to cholinergic and electrical stimulation. Levin and

coworkers<sup>211</sup> concluded that pregnancy induced an increase in the purinergic and a decrease in the cholinergic responses of the rabbit bladder to field stimulation, and Tong and colleagues<sup>212</sup> reported a decrease in the  $\alpha$ -adrenergic response of the mid-part and base of the bladder of pregnant as opposed to virgin rabbits. Larsson and associates<sup>213</sup> reported that estrogen treatment of the isolated female rabbit urethra caused an increased sensitivity to noradrenaline. The mechanism was postulated to be related to a more than twofold increase in the  $\alpha$ -adrenergic receptor number. Callahan and Creed<sup>214</sup> reported that pretreatment with estrogen of oophorectomized dogs and wallabies did increase sensitivity of urethral strips to  $\alpha$ -adrenergic stimulation, but that this did not occur in the rabbit or guinea pig. Bump and Friedman<sup>215</sup> reported that sex hormone replacement with estrogen, but not testosterone, enhanced the urethral sphincter mechanism in the castrated female baboon by effects that were unrelated to skeletal muscle. They added that these effects might be related not just to changes in the urethral smooth musculature but to changes in the urethral mucosa, submucosal vascular plexus, and connective tissue.

Estrogens have been considered in the treatment for SUI because the urethra has four estrogen-sensitive layers that may play a role in maintaining a positive urethral pressure. These layers are the epithelium, the vasculature, the connective tissue, and the musculature.

Two meta-analyses have shed some light on the use of estrogen therapy in the treatment of SUI. In the first, a report by the Hormones and Urogenital Therapy Committee, the use of estrogens to treat all causes of incontinence in postmenopausal women was examined.<sup>216</sup> Of 166 articles reviewed, there were only 6 controlled and 17 uncontrolled series. Although there was a subjective improvement in UI, when an objective parameter (amount of urine loss) was examined, there was no significant change. Maximum urethral closure pressure was also increased in one study. In a second study, by Sultana and Walters,<sup>217</sup> estrogens were found to be not efficacious in the treatment of SUI. The authors did, however, believe estrogens might be useful in the treatment of urgency and urge incontinence. Estrogen alone may not be effective treatment for urinary incontinence, but in combination with other therapies, both pharmacologic and pelvic floor exercises, it may be more efficacious and useful.

Estrogen therapy certainly seems to be capable of facilitating urinary storage in some postmenopausal women. Whether this effect is related just to changes in the autonomic innervation, receptor content, or function of the smooth muscle or to changes in estrogen-binding sites<sup>218</sup> or in the vascular or connective tissue elements of the urethral wall has not been settled. After menopause, urethral pressure parameters normally decrease slightly<sup>219</sup>; although this change is generally conceded to be related in some way to decreased estrogen levels, it is still largely a matter of speculation whether the actual changes occur in smooth muscle, blood circulation, supporting tissues, or the "mucosal seal mechanism." Versi and associates<sup>220</sup> described a positive correlation between skin collagen content (which does decline with declining estrogen status) and parameters of the urethral pressure profile, suggesting that the estrogen effect on the urethra may be predicted, at least in part, by changes in the collagen component.

Beisland and colleagues<sup>221</sup> carried out a randomized, open, comparative, crossover trial in 20 postmenopausal women with urethral sphincteric insufficiency. Both oral PPA, 50 mg twice a

day, and estriol vaginal suppositories, 1 mg daily, significantly increased the MUCP and the continence area on profilometry. PPA was clinically more effective than estriol, but not sufficiently so to obtain complete continence. However, with combined treatment, eight patients became completely continent, nine were considerably improved, and only one remained unchanged. Two patients dropped out of the study because of side effects. Bhatia and colleagues<sup>222</sup> used 2 g of conjugated-estrogen vaginal cream daily for 6 weeks in 11 postmenopausal women with SUI; six were cured or improved significantly. Favorable response was correlated with increased closure pressure and increased pressure transmission. Negative effects from estrogen alone on SUI were reported by Walter and colleagues,<sup>223</sup> Hilton and Stanton<sup>224</sup> and Samsioe and associates;<sup>225</sup> however, in each of these studies, urge symptomatology was favorably affected. In a review article, Cardozo<sup>226</sup> concluded that “there is no conclusive evidence that oestrogen even improves, let alone cures, stress incontinence,” although it “apparently alleviates urgency, urge incontinence, frequency, nocturia and dysuria”.

Kinn and Lindskog<sup>227</sup> described the results of treatment of 36 postmenopausal women with SUI with oral estriol and PPA, alone or in combination, in a double-blind trial after a 4-week run-in period with PPA. Although some of the data are difficult to interpret, the authors concluded that PPA alone and PPA plus estriol raised the intraurethral pressure and reduced urinary loss by 35% (significant) in a standardized physical strain test. Leakage episodes and amounts were significantly reduced by estriol and PPA given separately (28%) or in combination (40%); the authors found no evidence of a synergistic effect but did indicate that an additive effect was present. Walter and colleagues<sup>228</sup> completed a complicated but logical study of 28 postmenopausal women with SUI (out of 38 original subjects). After 4 weeks of a placebo run-in, patients were randomized to oral estriol or PPA alone for 4 weeks and then to combined therapy for 4 weeks. In the group that sequentially received placebo, PPA, and PPA/estriol, the percentages reporting cure or improvement, respectively, were 0% and 13%, 13% and 20%, and 21% and 14%. In the group receiving placebo, estriol, and estriol/PPA, the corresponding percentages were 0% and 0%, 14% and 29%, and 64% and 7%. Objective parameters showed the following: the number of leak episodes per 24 hours in patients treated with PPA first showed a 31% decrease (from ~3 to 2) compared with placebo ( $P < .003$ ). For those treated with estriol first, the change was not significant (-1.5 to 0.8). Combined treatment produced a mean decrease of 48% compared with placebo. There was a greater effect with estriol/PPA than with PPA/estriol. Pad weights (in grams in a 1-hour test) decreased significantly with PPA alone (~27 to 6 g), but there was no difference between PPA and PPA/estriol. Estriol alone significantly decreased pad weights (~47 to 15 g). Although estriol/PPA was not significantly different, there was further numerical loss, from ~15 to 3 g. The overall conclusions were that estriol and PPA are each effective in treating SUI in postmenopausal women and that, on the basis of the subjective data, combined therapy is better than either drug alone. This conclusion was substantiated by a significant decrease in the number of leak episodes among those patients to whom estriol was given before PPA but was not confirmed statistically by pad-weighting tests.

Confusing the data on the potential benefits of estrogen is a recent study by Hendrix and colleagues.<sup>229</sup> They reviewed data from 27,347 postmenopausal women participating in the Women's Health Initiative, which was a double blind, random-

ized, placebo-controlled study of menopausal hormone therapy, to assess the effects of hormonal therapy on stress, urge, and mixed incontinence. Depending on the presence or absence of a uterus, patients were treated with placebo, 0.625 mg/day of conjugated equine estrogen (CEE), or a combination of 0.625 mg/day CEE and 2.5 mg/day of medroxyprogesterone acetate (MPA). They evaluated 23,296 women whose urinary incontinence symptoms were known. They found that menopausal hormonal therapy increased all types of urinary incontinence, with SUI being the most common, in women who were continent at baseline after 1 year of use. For those women with urinary incontinence at baseline, frequency worsened with both CEE alone and the combination of CEE and MPA.

Sessions and associates<sup>230</sup> reviewed the benefits and risks of estrogen-replacement therapy. Improvements in vasomotor symptomatology and osteoporosis prevention are well established. There is also substantial evidence of a decreased risk of cardiovascular disease, perhaps because of an effect on the lipid profile. There is little question, however, that unopposed estrogen use in those with an intact uterus increases the risk of endometrial cancer. Progestogen treatment exerts a protective effect, and daily administration of an estrogen and a progestogen provides an attractive alternative because of a lack of withdrawal bleeding (with sequential therapy) and consequent increased patient compliance. Whether progestogen administration adversely affects the results of estrogen treatment of SUI is unknown but must be considered. Progestogens may also cause mastalgia, edema, and bloating. It is concluded, further, that there is no evidence for an increase in thromboembolism or hypertension with estrogen replacement. Transdermal administration of estrogen avoids any theoretical problems associated with the first-pass effect through the liver with oral administration (alteration in clotting factors and increase in renin substrate). The evidence does suggest an association between breast cancer and estrogen replacement therapy, but only for those who have received such therapy for more than 15 years. A preventive role of progestogens in this regard is controversial, as is the dose of estrogen necessary to produce this effect. Grodstein and colleagues<sup>231</sup> looked at the relationship between long-term postmenopausal hormonal replacement therapy and overall mortality in a cohort of nurses over an 18-year period. Although they noted an overall lower risk of death (relative risk, 0.63) for active estrogen users compared with subjects who had never taken hormones, the apparent benefit decreased somewhat (relative risk 0.80) after 10 years of therapy owing to an increased mortality from breast cancer in the hormone-treated group.

As to the type of estrogen preparation preferred, transdermal administration seems to be as effective as oral, and subcutaneous implants appear to produce physiologic serum levels. Percutaneous and intramuscular estrogen seem to produce variable serum levels. Vaginal creams are said to produce variable serum levels but physiologic estradiol/estrone ratios.<sup>230</sup> We agree that “hands on” application to the “affected area” may have a psychological benefit as well, as suggested by Murray.<sup>232</sup> A unique new method for delivering vaginal estrogen involves a silicone ring with an estradiol-loaded core containing 2 mg of 17 $\beta$ -estradiol inserted into the vagina by the patient or the physician. A low, constant dose (5 to 10 g/24 hr) is delivered over a period of 90 days. This mode of administration not only is more acceptable to certain women<sup>233</sup> but also offers a more continuous delivery of estrogen to the affected tissues.<sup>234</sup>

## CIRCUMVENTING THE PROBLEM

### Antidiuretic Hormone–Like Agents

The synthetic antidiuretic hormone (ADH) peptide analogue desmopressin acetate (DDAVP; 1-desamino-8-D-arginine vasopressin) has been used for the symptomatic relief of refractory nocturnal enuresis in both children and adults.<sup>232,235</sup> The drug can be administered conveniently by intranasal spray at bedtime (in a dose of 10 to 40 µg) and effectively suppresses urine production for 7 to 10 hours. Its clinical long-term safety has been established by continued use in patients with diabetes insipidus. Normal water-deprivation tests, as described by Rew and Rundle,<sup>236</sup> indicate that long-term use does not cause depression of endogenous ADH secretion, at least in patients with nocturnal enuresis. Changes in diuresis during 2 months of treatment in an elderly group of 6 men and 12 women with increased nocturia and decreased ADH secretion were reported by Asplund and Oberg.<sup>237</sup> Nocturia decreased 20% (in milliliters) in men and 34% in women; the number of voids between 20:00 to 08:00 hours decreased from 4.5 to 4.3 in men and from 3.5 to 2.8 in women, but the drug was not given until 20:00 hours. At present, this novel circumventive approach to the treatment of urinary frequency and incontinence has been largely restricted to those with nocturnal enuresis and diabetes insipidus. The fact that the drug seems to be much more effective than simple fluid restriction alone for the former condition is perhaps explained by relatively recent reports suggesting a decreased nocturnal secretion of ADH by such patients.<sup>235</sup> Recently, suggestions have been made that

desmopressin might be useful in patients with refractory nocturnal frequency and incontinence who do not belong in the category of primary nocturnal enuresis. Kinn and Larsson<sup>238</sup> reported that micturition frequency “decreased significantly” in 13 patients with multiple sclerosis and urge incontinence who were treated with oral tablets of desmopressin and that less leakage occurred. The actual approximate average change in the number of voids during the 6 hours after drug intake was from 3.2 to 2.5.

A similar circumventive approach is to give a rapidly acting loop diuretic 4 to 6 hours before bedtime. This, of course, assumes that the nocturia is not caused by obstructive uropathy. A randomized, double-blind, crossover study of this approach using bumetanide in a group of 14 general practice patients was reported by Pedersen and Johansen.<sup>239</sup> Control nocturia episodes per week averaged 17.5; with placebo, this decreased to 12, and with bumetanide to 8. Bumetanide was preferred to placebo by 11 of 14 patients.

## CONCLUSIONS

There are more pharmacologic therapies available for the treatment of urinary incontinence in women than ever before. The treatments available are limited by their efficacy and their side effects. Continued investigation and a greater understanding of the pathophysiology of urinary incontinence will certainly lead to improvements in treatment of this highly prevalent condition.

# PHARMACOLOGIC NEUROMODULATION

Raymond R. Rackley and Patrick J. Shenot

## INTRAVESICAL CAPSAICIN AND RESINIFERATOXIN

### Anatomy and Function of the Uroepithelium

The internal surface of the urinary bladder is lined with transitional epithelium. Three distinct layers of the uroepithelium have been described.<sup>1</sup> Large umbrella cells form the superficial lining of the bladder urothelium. The permeability barrier of the urothelium is maintained in this stratum by tight junctions that prevent the paracellular passage of urinary solutes across this outer layer into the bloodstream. Umbrella cells are associated with a group of crystalline protein plaques called uroplakins that also contribute to the permeability barrier of the urothelium. Beneath the umbrella cell layer is the intermediate layer of moderately sized cells and a basal layer of small cells.<sup>2</sup> In the bladder, suburothelial afferent fibers form a dense plexus that innervates both the detrusor itself and the basal layer of the urothelium.<sup>3</sup> These afferent fibers are critical for sending sensory input to the central nervous system. The uroepithelium was once thought to serve only as a passive barrier to the contents of the bladder, but there is a growing body of evidence that confirms reciprocal communication between the neuronal system and the uroepithelium. This implies that the uroepithelium may play a significant role in regulating bladder activity via a number of neuron-like properties that modulate bladder sensory function and may represent a potential novel therapeutic target for pharmacologic intervention for bladder dysfunction.

### Afferent Innervation of the Urinary Bladder

Normal storage of urine is dependent on spinal reflex mechanisms that activate somatic and sympathetic pathways to the bladder outlet and detrusor muscle as well as tonic inhibitory pathways that suppress parasympathetic excitatory activity leading to detrusor relaxation and bladder filling. Micturition requires efferent nerve input to the bladder from the spinal cord as well as afferent input from the bladder to central nervous system. Sensory information, including the sensations of bladder fullness and pain, is conveyed to the spinal cord via afferent fibers in the pelvic and hypogastric nerves. The most important afferents controlling the micturition process are the small myelinated A $\delta$  fibers, which transmit signals mainly from mechanoreceptors that detect wall tension and bladder fullness, and unmyelinated C fibers, which detect noxious signals and initiate painful sensations.<sup>4-6</sup> At other sites in the body, such as the skin and mucous membranes, C-fiber afferents transmit nociceptive information into the central nervous system and modulate various reflex responses to noxious stimuli such as hot temperatures (see later discussion).

After suprasacral spinal cord injury, there is significant reorganization of micturition reflexes that leads to the emergence of primitive spinal bladder reflexes triggered by C-afferent neurons. Afferent C-fiber activation may also occur in infectious or irritative conditions in the bladder and serve to facilitate or trigger voiding. This may be viewed as a defense mechanism to eliminate bladder irritants or bacteria. Bladder wall C fibers may be responsible for afferent signals that trigger detrusor overactivity (DO). As specific C-fiber neurotoxins, capsaicin and resiniferatoxin (RTX), its ultrapotent analogue, may be used to study and treat lower urinary tract dysfunction.<sup>7,8</sup>

### Vanilloid Pharmacology

Current pharmacologic treatment of the overactive bladder relies on partially blocking the efferent parasympathetic innervation to the detrusor with anticholinergic drugs. These drugs often have troublesome side effects and are often used in doses insufficient to provide significant clinical benefit. The afferent pathways of the voiding reflex may be targeted by intravesical instillation of drugs with relative selectivity for sensory nerves. Capsaicin and RTX are potent neurotoxins that desensitize these C-fiber afferent neurons, which may be responsible for signals that trigger DO.

Hot peppers have been eaten and used by humans since pre-historical times.<sup>9</sup> Hogeny, in 1878, reported that the pungent and irritant action of capsicol, an extract of *Capsicum*, is mediated by sensory nerves.<sup>10</sup> Capsaicin and its ultrapotent analogue, RTX, collectively belong to class of neurotoxic agents referred to as vanilloids. RTX is isolated from some species of *Euphorbia*, a cactus-like plant. These compounds are characterized by a terminal homovanilloid moiety that interacts with a specific membrane receptor (Fig. 21-1) The action of vanilloid compounds on sensory neurons is mediated via interaction of the homovanilloid moiety with the vanilloid receptor TRPV1 (transient receptor potential V1 or VR1 receptor), a nonspecific, heat-gated cation channel that mediates the influx of calcium and sodium, resulting in depolarization of nociceptive afferents to initiate a nerve impulse passing through the dorsal root ganglion into the central nervous system.<sup>11,12</sup> Vanilloid receptors are expressed not only by small unmyelinated C fibers but also by uroepithelial cells themselves.

As intracellular calcium levels rise, voltage-sensitive calcium channels are first activated leading initially to local transmitter release, and then inhibited, serving to block the very same response. Noxious temperatures are also sensed via this mechanism, explaining the characteristic sensation of heat that is experienced when eating chili peppers.<sup>13</sup> Therefore, capsaicin mimics the action of physiologic/endogenous stimuli that activates the “nociceptive pathway.” At the molecular level, nociception is carried out by ion channels or receptors.

**Figure 21-1** Chemical composition of capsaicin and its ultrapotent analogue, resiniferatoxin. These compounds are characterized by a terminal homovanillyl moiety that interacts with a specific membrane receptor.

Both capsaicin and RTX cause initial excitation of sensory neurons with a subsequent lasting refractory state termed desensitization. Jancso discovered that, after a period of initial intense excitation of sensory neurons, animals treated with capsaicin become unresponsive to noxious chemical stimuli and fail to develop inflammation.<sup>14,15</sup> A large number of studies have since confirmed this finding and established capsaicin as a useful agent for the study of sensory neuron function.<sup>16</sup>

### Vanilloid Potency

The Scoville heat unit scale is commonly used commercially to compare the potency of pepper strengths. Wilbur Scoville, in 1912, calibrated the potency of peppers by extracting capsaicin in alcohol and diluting it until pungency was first detected after placing a drop on his tongue.<sup>17</sup> This technique has since been standardized using high-pressure liquid chromatography (HPLC). In fact, if all known peppers were measured using this technique, their scale of pungency would range from 1 Scoville unit, for the bell pepper, to as much as 300,000 units for the habanero pepper. Pure capsaicin has a Scoville heat unit score of 16 million, and RTX registers at 16 billion Scoville heat units, which is 1000 times the potency of capsaicin (Table 21-1).

### Sensitization (Acute Excitatory Effects)

On first contact with capsaicin, afferent neurons are invariably stimulated, and there seems to be no apparent difference whether the drug is applied to the peripheral or central endings or to the cell bodies of sensory neurons. Administration of vanilloids to peripheral nerve endings results in depolarization and discharge of action potentials, which in turn evokes a characteristic burning sensation via stimulation of C-fiber polymodal nociceptors. Acute activation of the sensory neurons via the vanilloid receptor TRPV1 results initially in depolarization and transmitter (peptide) release with eventual neuronal degeneration.<sup>18,19</sup>

**Table 21-1** Heat Level Comparisons

Pepper or Derivative	Scoville Value
Sweet Italian bell	0-1
Pepperoncini	100-500
Jalapeno	1000
Cayenne	30,000-50,000
Thai	50,000-100,000
Jamaican hot	100,000-200,000
Habanero	100,000-300,000
Pure capsaicin	16,000,000
Resiniferatoxin (RTX)	16,000,000,000

### Desensitization (Secondary Neurotoxic Effects)

After vanilloid-induced stimulation of primary afferent neurons, excitation subsides and the neurons become unresponsive to further applications of drug. Capsaicin desensitization is characterized by long-lasting, reversible suppression of sensory neuron activity.<sup>20</sup> The rate and duration of desensitization is related to the dose and time of exposure to capsaicin and the time interval between consecutive dosings.<sup>7,21</sup>

Although C-fiber neurons have well-described afferent functions, they probably have important efferent functions as well, including local release in the periphery of substance P, neurokinin A, calcitonin gene-related peptides (CGRP), and other neuropeptides that directly and indirectly produce tissue inflammation.<sup>22-25</sup> Desensitization of capsaicin-sensitive nerve fibers is associated with eventual depletion of transmitter neuropeptides.<sup>26,27</sup>

### Clinical Results of Intravesical Capsaicin

#### Hypersensitivity Disorders

Because capsaicin and RTX selectively activate sensory C fibers that convey information about noxious stimuli to the central nervous system, the use of intravesical capsaicin or RTX for interstitial cystitis and other types of sensory or inflammatory bladder conditions is logical.

Maggi and coworkers reported the clinical urologic application of intravesical capsaicin.<sup>28</sup> Intravesical instillation of capsaicin (0.1 to 10  $\mu\text{mol/L}$ ) in six patients with bladder hypersensitivity produced a concentration-related reduction of the first desire to void, bladder capacity, and pressure threshold for micturition. All patients reported disappearance or marked attenuation of their symptoms for a few days after capsaicin application. In three other patients, intravesical instillation of the vehicle (0.1% ethanol in saline) alone did not produce significant cystometric changes nor modify the symptomatology, suggesting that capsaicin-sensitive nerves exist in the human bladder. A second series using intravesical capsaicin, a randomized, placebo-controlled trial in patients with bladder hypersensitivity, confirmed the beneficial effect of intravesical instillation of capsaicin on voiding parameters but did not confirm improvement in pain score after capsaicin treatment compared with placebo.<sup>29</sup>

Although intravesical capsaicin has been proposed as a treatment option for interstitial cystitis, its utility has not been widely explored. One small pilot study of intravesical capsaicin in five patients with interstitial cystitis, using criteria of the National

Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), demonstrated subjective improvement in both symptom and pain score in four of them.<sup>30</sup>

### Neurogenic Detrusor Overactivity

Fowler and associates reported the first clinical experience with capsaicin in neurologically impaired patients with intractable incontinence due to multiple sclerosis and spinal cord injury.<sup>31,32</sup> After a single intravesical instillation of capsaicin (1 to 2 mmol/L) for 30 minutes, 10 of 14 patients exhibited an improved bladder capacity for up to 9 months without toxicity. Similar findings were noted in small studies in other patients with neurogenic DO.<sup>33,34</sup>

De Ridder and associates described the long-term outcome of intravesical capsaicin instillation in 79 patients with spinal cord disease and treatment-resistant urinary incontinence.<sup>35</sup> Repeated intravesical instillation of intravesical capsaicin (1 to 2 mmol/L in 30% ethanol) was effective, and the benefit persisted for up to 3 to 5 years. In patients with phasic detrusor hyperreflexia, complete continence was achieved in 44%, satisfactory improvement occurred in 36%, and treatment failure was observed in 20%. Clinical benefit from a single instillation lasted 3 to 6 months and was repeated in some patients with similar improvement. There was no clinical or urodynamic improvement in patients treated with the ethanol vehicle alone, and there were no reported long-term complications.

There have been only a few reported randomized, placebo-controlled studies of capsaicin in patients with neurogenic DO. The results of these trials have been mixed. Wiart and colleagues reported that a single intravesical instillation of 1 mmol/L capsaicin resulted in clinical improvement with significant regression of urine leakage episodes and urgency compared with those receiving vehicle (30% ethanol) alone.<sup>36</sup> These findings were supported by a later study in a similar population.<sup>37</sup> A third placebo-controlled crossover study of 12 patients by Petersen and associates showed no benefit for intravesical capsaicin treatment therapy in patients with neurogenic DO.<sup>38</sup>

### Resiniferatoxin

RTX is an ultrapotent capsaicin analogue present in the latex of a cactus-like plant, *Euphorbia resinifera*.<sup>19,39</sup> It mimics most biologic characteristics of capsaicin with approximately 1000-fold higher potency and minimal initial acute excitatory effects.<sup>9</sup> There are significant differences in biologic response between RTX and capsaicin. RTX and capsaicin show striking differences in relative potencies to excite and desensitize primary sensory neurons. In most cases, when RTX and capsaicin differ in potency of a particular biologic end point, the response is such that RTX preferentially causes desensitization whereas capsaicin administration leads to profound excitation.<sup>19</sup>

Intravesical RTX in concentrations as low as 100 nmol/L induced full desensitization, whereas a capsaicin concentration of 1 mmol/L was required to induce the same effect.<sup>40-42</sup> In addition, 100 nmol/L RTX solutions were much less irritating to bladder afferents than 1 mmol/L capsaicin solutions. RTX-induced desensitization may occur at concentrations so low that no noxious effect is elicited. Because of its potency and unique property of preferential desensitization, there has been much interest in the application of RTX therapy for patients with interstitial cystitis and DO.

### Clinical Results of Intravesical Resiniferatoxin

#### Interstitial Cystitis

The positive findings of a number of small pilot studies evaluating the efficacy of capsaicin in interstitial cystitis logically led to interest in the use RTX in the treatment of interstitial cystitis, a poorly understood condition. Most of these studies were poorly controlled, but one small, placebo-controlled study did suggest that RTX was effective in the treatment of urinary frequency, urgency, and pelvic pain.<sup>43</sup> A recent, relatively large randomized, double-blind, placebo-controlled trial of a single dose of 0.01 to 0.10  $\mu\text{mol/L}$  RTX found that it was not effective in improving overall symptoms, pain, urgency, frequency, nocturia, or voided volume during 12 weeks of follow-up.<sup>44</sup>

#### Neurogenic Detrusor Overactivity

The first clinical use of RTX in patients with neurogenic DO was reported by Cruz and colleagues in 1997.<sup>40</sup> They treated seven patients with intravesical instillation of 50 to 100 nmol/L RTX dissolved in 100 mL solution of 10% alcohol. Itching or mild discomfort were the only symptoms evoked in four patients during the first minutes of the treatment. Temporary exacerbation of bladder symptoms, as seen during the first 1 to 2 weeks after capsaicin administration, did not occur. In five of the seven patients, urinary frequency decreased by 33% to 58%, and this effect was detected as soon as the first day after treatment. Three patients were incontinent and became dry on most days. Improvement was sustained for up to 3 months, the longest follow-up period available. Four patients had urodynamic improvement, with a rise in maximum cystometric capacity from 50% to 900% of pretreatment cystometric capacity.

Lazzeri and colleagues reported using intravesical RTX (10 nmol/L) in eight normal patients and seven patients with overactive bladder.<sup>42</sup> RTX did not decrease the volume required to elicit the first desire to void and did not produce warm or burning sensations at the suprapubic or urethral level during infusion in normal subjects. Mean capacity increased significantly in patients with overactive bladder immediately after instillation but was not significantly increased after 4 weeks. There was no significant improvement in bladder capacity in the overall group, but two patients with detrusor hyperreflexia did improve urodynamically in conjunction with clinical improvement in frequency, nocturia, and incontinence episodes.

Although the results of several small studies suggested that intravesical RTX may have a role in the treatment of refractory neurogenic detrusor overactivity, its efficacy has not been conclusively confirmed in any randomized controlled trials.<sup>45-48</sup> RTX has been demonstrated to adsorb to polyethylene, polyvinylchloride, and latex (but not silicone or glass) catheters and containers. These materials were used in some of these studies, possibly leading to lower than expected drug delivery, thereby confounding the results obtained.<sup>49</sup>

A double-blind, randomized, controlled study comparing the efficacy and tolerability of RTX to capsaicin demonstrated significant clinical improvement in approximately two thirds of patients with neurogenic DO for 90 days after treatment with either agent.<sup>50</sup> Patients in the capsaicin arm were treated with capsaicin dissolved in a novel glucidic solvent, whereas the RTX used in this study was diluted in 10% ethanol. There were no significant differences in regard to incidence, nature, or duration of side effects in capsaicin- versus RTX-treated patients, suggesting the importance of considering the role of vehicle solvent

when interpreting the efficacy and tolerance of vanilloid instillation.

RTX has also been compared with intravesical injections of botulinum A toxin (BTX-A) into the detrusor muscle in patients with spinal cord injury and refractory DO.<sup>51</sup> With both treatments, there was a significant reduction in mean catheterization and episodes of incontinence and a significant increase in mean first involuntary detrusor contraction and in mean maximum bladder capacity at 6, 12, and 24 months after therapy. Both RTX and BTX-A resulted in beneficial clinical and urodynamic results, with reduction of DO and restoration of urinary continence in most patients. BTX-A injection, however, provided better clinical and urodynamic benefits than intravesical RTX.

### Non-neurogenic Detrusor Overactivity

Enthusiasm for intravesical RTX as a treatment for neurogenic DO has led to its investigation as a potential therapy for non-neurogenic detrusor overactivity. RTX instillation may delay or suppress involuntary detrusor contractions and increase mean maximal cystometric capacity for at least 90 days.<sup>52</sup> Relatively modest improvements in clinical symptoms were noted in several studies of patients with non-neurogenic DO in this population.<sup>53-55</sup> To date, there has been no well-controlled randomized trial.

### Technique of Intravesical Capsaicin and Resiniferatoxin Administration

Neither capsaicin nor RTX is currently approved for routine clinical intravesical use. Insertion of a small silicone urethral catheter with balloon occlusion of the bladder neck is recommended. Care must be taken to avoid contact with polyethylene, polyvinylchloride, or latex which may result in a diminished effective administered dose. Intravesical lidocaine is commonly instilled before drug administration. Although a 1% to 2% lidocaine solution is most commonly used, there is evidence that 4% lidocaine may improve tolerability.<sup>44</sup>

Capsaicin has typically been used as a 1- to 2-mmol/L solution dissolved in 30% ethanol in saline. RTX is administered as a 0.05- to 0.10- $\mu$ mol/L solution in 10% ethanol. Both agents are usually left in the bladder for approximately 30 minutes.

### Conclusions for Intravesical Capsaicin and Resiniferatoxin

Intravesical instillation of vanilloid agents appears to be a promising therapy for the treatment of neurogenic and non-neurogenic DO. These agents may be used to directly target sensory nerves on the afferent limb of the voiding reflex without systemic side effects. Numerous studies have demonstrated improvement in lower urinary tract symptoms with minimal long-term complications. Despite more than a decade of experience with these neurotoxic agents, however, the true efficacy of these compound has not been clearly defined. RTX, which appears to have efficacy similar to capsaicin but with fewer side effects, holds greater promise as a safe, effective treatment for DO. Prospective randomized, placebo-controlled studies are necessary to truly define the role of intravesical vanilloid therapy in the management of overactive bladder.

## BOTULINUM TOXIN

Discovered by Professor Pierre Emile van Ermengem of Ellezelles in 1897, BTX is a neurotoxin produced by the gram-positive, rod-shaped anaerobic bacterium, *Clostridium botulinum*.<sup>56</sup> Although seven immunologically distinct antigenic subtypes of BTX have been isolated (A, B, C1, D, E, F, and G), only types A and B are available for use clinically. BTX-A, known as BOTOX in the United States and DYSPORT in the United Kingdom, is more potent and has a longer duration of action than type B, which is known as MyoBloc in the United States and NeuroBloc in Europe.<sup>57</sup>

BTX exerts its effects by binding to the peripheral cholinergic terminals and inhibiting the release of acetylcholine at the neuromuscular junction. As a result, a flaccid paralysis ensues. There are four steps involved in this process: binding, translocation, cleavage, and inhibition of neurotransmitter release.<sup>57</sup> BTX is made within the bacterial cytosol and is released as a 150-kd polypeptide chain. Proteolytic cleavage results in a heavy chain (100 kd) and a light chain (50 kd), which are linked by heat-labile disulfide bonds. Neither chain can exert neurotoxicity independently. The heavy chain is responsible for binding to the nerve terminal at the neuromuscular junction. The light chain, which is internalized by endocytosis, actively cleaves a specific site on the protein complex responsible for docking and release of vesicles containing neurotransmitters into the neuromuscular junction.<sup>58</sup> By cleaving protein receptors within the nerve terminals, BTX prevents the normal vesicular transport and release of acetylcholine from the motor nerve terminals into the neuromuscular junction.

Based on histologic evidence, recovery of chemodenervation occurs after 3 to 6 months. This is thought to be the result of turnover of the presynaptic molecules and nerve sprouting from the nerve terminal, forming a new functional synapse. Affected nerve terminals do not degenerate, and axonal sprouting and formation of new synaptic contacts can recover function. The time required to recover function after BTX paralysis depends on the subtype of toxin used and the type of nerve terminal.<sup>57</sup> Chemodenervation lasts between 3 and 6 months when BTX is injected near the neuromuscular junction of skeletal muscle and considerably longer (up to 1 year) when it is injected near the autonomic neurons of smooth muscle.<sup>57,58</sup>

### Applications in Urology

BTX was first approved by the Food and Drug Administration (FDA) in 1989 for use in people with strabismus and blepharospasm.<sup>56</sup> Since then, its use has been extended to cervical dystonia, cosmesis, hypersecretory disorders, and overactive muscle disorders. Although it is not an FDA-approved use, BTX has been used in urology to treat neurogenic and non-neurogenic DO, detrusor-sphincter dyssynergia (DSD), motor and sensory urgency, and, more recently, chronic pain syndromes.

### Detrusor Overactivity

The use of BTX in neurogenic DO was pioneered by Schurch and colleagues in 2000.<sup>59</sup> BTX-A (200 or 300 units) was injected into the trigone of 21 spinal cord-injured patients with DO and urge incontinence managed with clean intermittent catheterization. At 6 weeks, 17 of 19 patients were completely continent. Urody-

dynamic evaluation revealed significant increases in mean filling volume, maximum cystometric capacity, and postvoid residual urine and a decrease in detrusor voiding pressure. In the 11 patients available for follow-up at 16 and 36 weeks, improvements in bladder function and urodynamic parameters persisted. Similarly, significant increases were noted in cystometric bladder capacity, reflex volume, and bladder compliance, and there was a decrease in mean voiding pressures, in a retrospective multicenter European study of 200 patients with neurogenic DO.<sup>60</sup> More recently, Schurch and coworkers compared two different doses of BTX-A in a double-blinded, multicentered, randomized, placebo-controlled study of 59 patients with neurogenic DO.<sup>61</sup> Over 24 weeks, there was a rapid and sustained reduction in the number of incontinence episodes, an increase in maximum cystometric capacity, and a decrease in mean detrusor pressure. In a study of 66 patients with neurogenic DO, Grosse and associates examined the effect of repeat detrusor injections of BTX-A. After each BTX-A injection, cystometric capacity and reflex volume increased significantly while the number of reflex contractions decreased significantly from baseline.<sup>62</sup> Repeat injections were as effective as the first injection, indicating no evidence of drug resistance.

Given the benefits of BTX in patients with neurogenic DO, its use has been expanded to patients with idiopathic DO. Dykstra and colleagues conducted a pilot dose-escalation study of BTX-B in 15 women with idiopathic DO. All but one patient reported decreased urgency, decreased frequency, and no incontinence.<sup>63</sup> Although the degree of response was similar for all doses, the duration of response was dose-dependent, with the greatest duration seen at 100-150 units. Rapp and associates looked at the effect of BTX-A on 35 patients with urgency, frequency, and urge incontinence using the Incontinence Impact Questionnaire (IIQ-7) and the Urogenital Distress Inventory (UDI-6).<sup>64</sup> At 3 weeks, the mean IIQ-7 and UDI-6 scores decreased significantly. Overall, 60% of patients experienced improvement in voiding symptoms.

#### *Overactive Bladder without Detrusor Overactivity*

In a recent article, Schulte-Baukloh and colleagues examined the effect of 300 units of BTX-A administered by combined bladder and external sphincter injections in women who had overactive bladder symptoms without urodynamic DO.<sup>65</sup> In all cases, the patient's condition was refractory to anticholinergics, biofeedback, and neuromodulation. Significant reductions were noted in daytime frequency, nocturia, and pad use at 3 and 6 months. Maximal bladder capacity increased by 20% at 3 months. Significant improvements were also noted in the UDI-6 and Symptom Impact Index (SII) scores, and no side effects, such as urinary retention, were noted. The authors attributed their low rate of urinary retention to injection of low doses (50 to 75 units) of BTX-A into the external sphincter muscle.

#### *Detrusor Sphincter Dyssynergia*

The most widespread application of BTX for urethral conditions is for external sphincter dyssynergia.<sup>58</sup> Dykstra and colleagues, in 1988, were the first to use BTX for treatment of DSD.<sup>66</sup> In a study of 11 patients with spinal cord injuries and DSD, they injected BTX-A into the external urethral sphincter. The majority of patients showed signs of sphincter denervation on electromyography. Urethral pressure profiles and postvoid residual volumes were decreased. The largest series assessing the effect of BTX-A

on patients with spinal cord injury and DSD was conducted by Schurch and associates in 1996.<sup>67</sup> Three different protocols, using two different formulations of BTX-A toxin, were studied in 24 patients. Eighty-seven percent of patients (21/24) had improvements in urodynamic parameters regardless of the protocol or formulation used. Complete disappearance of DSD was noted in 8 of 21 patients, while mean maximum urethral pressure during DSD decreased by 48%, mean duration of DSD decreased by 47%, and mean urethral sphincter pressure decreased by 20%. More recently, de Seze and coworkers, in a randomized, double-blinded, lidocaine-controlled study of 13 spinal cord-injured patients with DSD, found that BTX significantly reduced postvoid residuals and maximal urethral pressures at 1, 7, and 30 days when compared with lidocaine.<sup>68</sup>

#### *Urinary Retention and Voiding Dysfunction*

Several studies have looked at the role of BTX-A injections into the external urethral sphincter in patients with voiding dysfunction and urinary retention. Phelan and colleagues, in a prospective study of 21 patients with voiding dysfunction, injected 80 to 100 units of BTX-A into the external urethral sphincter.<sup>69</sup> After the BTX-A injection, all but one patient were able to void spontaneously, and all but two discontinued catheterization. Kuo looked at the clinical effects and urodynamic parameters of 50 units of BTX-A in 103 patients with various types of lower urinary tract dysfunction.<sup>70</sup> Overall, 84.5% of patients had decreases in maximum voiding pressure, maximal urethral closure pressure, and postvoid residual. Indwelling urethral catheters and clean intermittent catheterization were discontinued in 87% of patients.

#### *Pelvic Pain, Chronic Prostatic Pain, and Interstitial Cystitis*

Although several studies have begun to explore the use of BTX-A in the treatment of pelvic pain, the direct mechanism of action by which BTX produces an antinociceptive effect is unknown. Animal studies have shown that, in addition to blocking acetylcholine release from motor neurons, BTX also inhibits the release of neurotransmitters involved in sensory pathways. BTX has been shown to inhibit the release of substance P and glutamate, neuropeptides involved in sensory and nociceptive pathways.<sup>71</sup> A more recent study looked at the effect of intravesical BTX-A on the release of CGRP in an acetic acid-induced rat bladder pain model. CGRP, a capsaicin-sensitive neuropeptide that has a role in regulation of micturition and mediation of painful bladder sensation, was found to be reduced in animals that received intravesical BTX-A.<sup>72</sup> This finding suggests that BTX inhibits CGRP release, thereby suppressing bladder pain.

Clinically, the literature on BTX in the treatment of pelvic pain syndromes is limited. Zermann and associates performed transurethral perisphincteric injection of BTX-A into 11 men with chronic prostatic pain.<sup>73</sup> Nine of the 11 patients reported subjective pain relief, with an average decrease in pain on a visual analogue scale from 7.2 to 1.6. Postinjection urodynamics showed decreases in functional urethral length, urethral closure pressure, and postvoid residual and increases in peak and average flow rates. Jarvis and coworkers conducted a pilot study evaluating the effect of BTX-A injection into the levator ani of 12 women with chronic pelvic pain and pelvic floor hypertonicity.<sup>74</sup> Under conscious sedation, women were injected with 40 units of BTX-A into the puborectalis and pubococcygeus bilaterally. Pelvic floor manometry showed a 37% reduction in resting pressure at week

4 and a 25% reduction at week 12. Significant improvements were noted in quality of life, dyspareunia, nonmenstrual pelvic pain, and dyschesia, but these changes were not statistically significant.

Three studies have looked at the antinociceptive effect of BTX on patients with interstitial cystitis. The first study, conducted at the Cleveland Clinic Foundation, retrospectively evaluated the effect of two treatment protocols on 10 patients meeting the NIDDK criteria for interstitial cystitis. The first five patients received submucosal injections, and the second five received intravesical instillations. Neither group showed statistically significant changes in subjective or objective outcome measures.<sup>58</sup> In the second study, Smith and colleagues injected the detrusor of 13 female patients with refractory interstitial cystitis.<sup>75</sup> Overall, 69% of patients noted subjective improvement. Statistically significant improvements were noted in the Interstitial Cystitis Symptom Index and the Interstitial Cystitis Problem Index, as well as daytime frequency, nocturia, and pain. On urodynamic testing, statistically significant improvements were noted in first desire to void and maximum cystometric capacity. In the third study, by Kuo, involved eight women and two men with chronic interstitial cystitis; five patients were injected with 100 units of BTX-A suburothelially into 20 sites, and an additional 100 units was injected into the trigone in the other five patients.<sup>76</sup> Therapeutic outcomes, including functional bladder capacity, number of daily urinations, bladder pain, and urodynamic changes, were compared between baseline and 3 months after treatment. The clinical result of suburothelial BTX injection was disappointing. None of the patients was symptom-free, and only a limited improvement in bladder capacity and pain score was achieved in two patients.

### Dosage

Although most institutions use between 100 and 300 units of Botox per treatment, the optimal dosage has yet to be established. Recent studies have examined the effects of various dosing regimens in patients with both neurogenic and non-neurogenic DO. For example, Schurch and colleagues conducted a double-blinded, randomized, placebo-controlled study evaluating the efficacy of two doses of BTX-A (200 versus 300 units) in 59 patients with neurogenic urinary incontinence.<sup>61</sup> Both groups demonstrated significant decreases in number of incontinent episodes per week, maximum detrusor pressure during bladder contractions, and number of hyperreflexic detrusor contractions. Both groups experienced significant improvements in Incontinence Quality of Life (I-QOL) total scores which were maintained throughout the 24-week study. There were no statistically significant differences in any of the objective or subjective measures between the patients who received 200 units of BTX and those who received 300 units. Further studies continue to define the optimal dosage of BTX for various treatment conditions.

### Injection Techniques

#### Bladder

For bladder injections, this procedure is typically performed in the outpatient setting. With the patient in the lithotomy position, 100 mL of 2% lidocaine solution is instilled into the bladder and allowed to dwell for 15 to 20 minutes to take effect.<sup>58</sup> In females, a 23-Fr rigid cystoscope with an injection needle (a 23-gauge

needle on a 5-Fr injection sheath) is inserted through the urethra. In males, the flexible cystoscope is used along with a flexible injection needle. Depending on the institution and clinical trial, the bladder is typically injected with 100 to 300 units of BTX-A. We typically use one vial of BTX-A that contains 100 units and dilute the dried toxin in 10 mL of injectable saline, yielding a final concentration of 10 units/mL. Approximately 30 bladder injections, each ~0.33 mL, are made into the detrusor muscle, avoiding extravasation into the bladder serosa. Injection sites vary depending on whether the trigone-sparing technique is used (Fig. 21-2). If the trigone-sparing technique is used, the 30 injections are distributed between the bladder base and lateral walls, sparing the trigone. If the trigone is injected, six injections, or 20% of the total volume, is made into the trigone. Proponents of trigonal injection argue that patients will have a better clinical response if the BTX is placed in the trigone, an area of greater nerve density. However, opponents argue that trigonal injection could result in distal ureteral paralysis and subsequent ureteral reflux. To date, this theoretical concern has not been observed clinically.

#### Urethral

The urethra can be injected in one of two ways, cystoscopically or periurethrally.<sup>58</sup> The first method involves localization of the external sphincter using the rigid cystoscope and a 23-gauge needle on a 5-Fr injection sheath. Between 100 and 200 units of BTX-A is injected into the sphincter under direct vision equally

Figure 21-2 Mapping of bladder injections.

at the 3, 6, 9, and 12 o'clock positions. In women, an alternative periurethral technique can be performed easily via a small-gauge spinal needle.

### Adverse Events and Contraindications

Side effects of BTX are rare in urologic applications. Not only are the injections localized with little systemic absorption, but the doses used are well below the presumed fatal dose in a 70-kg man.<sup>57</sup> Additionally, patients should be warned about the possibility of urinary retention after BTX treatment, secondary to detrusor hypocontractility. The rates of urinary retention after BTX-A vary from 0% to 50%, depending on injection technique; determining the postvoid residual before injection may aid in determining the proper amount of toxin and method of injection. In a recent study of seven patients, Schulte-Baukloh and colleagues reported no episodes of urinary retention.<sup>65</sup> They attributed this result to injection of the external sphincter muscle with 50 to 75 units of BTX-A after completion of the bladder injections. Kuo recently reported a seven-fold increase in postvoid residual, with 50% of patients requiring temporary clean intermittent catheterization after suburothelial injection of BTX-A.<sup>77</sup> These data suggest that suburothelial injections of BTX-A may have a more profound effect on detrusor contractility or sensation than detrusor injections do.

In nonurological cases, repeated injections of BTX-A caused immune responses in fewer than 5% of patients. Patients undergoing repeated injections are at risk of forming neutralizing antibodies that may interfere with the efficacy of BTX therapy.<sup>58</sup> Therefore, the use of other BTX serotypes which are not known to cause immune reactions, such as BTX-C, is being investigated.<sup>57</sup> Currently, new formulations of BTX-A and the timing cycle of repeated injections appear to have eliminated this concern. In

patients receiving BTX injections for cervical dystonia, spacing the injection cycles a minimum of 12 weeks apart has drastically reduced the formation of neutralizing antibodies.<sup>58</sup>

Contraindications to BTX injection include preexisting neuromuscular disease, such as myasthenia gravis, Eaton-Lambert syndrome, or amyotrophic lateral sclerosis (Lou Gherig disease).<sup>57,58</sup> BTX should also be avoided in patients who are breastfeeding, pregnant, or using agents that potentiate neuromuscular weakness, such as aminoglycosides. Patients should be informed that some formulations of BTX include stabilizers such as albumin that are derived from human blood; this fact may be of religious or cultural significance to some.

### Conclusions for Botulinum Toxin Therapy

BTX therapy is emerging as an alternative therapeutic option in patients with debilitating chronic urologic conditions such as DSD, neurogenic or non-neurogenic DO, and pelvic pain syndromes. Given its low side effect profile and long duration of action (6 to 12 months), BTX offers an attractive alternative to conservative medical therapy and invasive surgery. Limited but growing clinical experience has revealed that temporary chemodenervation with reduction or loss of neuronal activity at the target organ may be achieved with minimal risk. This highly favorable risk-benefit ratio in urology is derived from the clinical ability to effectively treat an end-organ condition with controllable site-specific delivery (e.g., subcutaneous, intramuscular, or instillation) combined with high affinity for toxin uptake by the peripheral nerves. Although many questions remain regarding the optimal use of this minimally invasive option for urologic applications, the opportunity for expanding indications will provide urologists with increasing options for addressing difficult challenges in voiding dysfunction.

# SACRAL NEUROMODULATION INTERVTIM FOR THE TREATMENT OF OVERACTIVE BLADDER

*Steven W. Siegel and Sarah E. Moeller*

Urinary incontinence and voiding dysfunction are common conditions affecting the quality of life of millions of men and women. In the case of those with overactive bladder (OAB), anticholinergic medications, behavioral interventions, and pelvic floor re-education are appropriate initial treatments, but often these are not able to control symptoms comfortably or sufficiently, and other options must be considered. Sacral neuromodulation has gained increased acceptance as a standard of care for these patients.<sup>1</sup> This chapter presents a detailed description of the therapy, including possible mechanism of action, patient selection, surgical technique, troubleshooting, and outcomes assessment for symptoms of OAB, including urge incontinence and urinary frequency and urgency.

## HOW SACRAL NEUROMODULATION WORKS

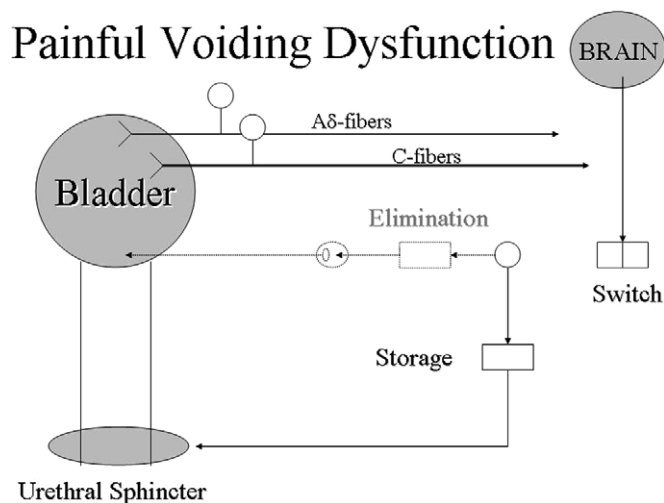

The observation that sacral nerve stimulation (SNS) may reduce or eliminate symptoms of voiding dysfunction implies that the conditions so affected are neuromuscular in nature. A simple concept is that the pathologic state represents an imbalance of reflexes between the bladder, sphincter, and pelvic floor, and that sacral neuromodulation improves or restores the balance. The fact that the same treatment may be effective for symptoms of OAB and retention implies that the therapy is modulating the central nervous system at the level where switching between bladder emptying and storage occurs (Fig. 22-1).<sup>2</sup> This fits with the observations that the impact of neuromodulation may be immediate and that it is usually reversed on therapy withdrawal. Anticholinergic drugs work at the efferent limb of the voiding reflex, inhibiting detrusor activity by receptor blockade. This approach may be ineffective if the underlying disorder represents an upregulation of pelvic visceral afferent input or a destabilization of the switch at the level of the dorsal horn or pons. Sacral neuromodulation is likely to exert its influence via modulation of afferent pathways at multiple possible levels (Box 22-1).<sup>3-20</sup> Because sacral root stimulation evokes a motor movement of the pelvic floor, it is also likely that manipulation of the guarding reflex is an essential mechanism of action. If the guarding behavior is coordinated or decreased, voiding may be facilitated; if it is increased, appropriate storage may be promoted. Symptoms of incontinence or voiding dysfunction may represent an alteration of the pelvic neuromuscular environment that changes pelvic organ function as opposed to a disorder of the organs per se, and neuromodulation is a method of altering the environment to promote normal function.

## Indications and Patient Selection

SNS was approved by the U.S. Food and Drug Administration (FDA) for intractable urge incontinence in 1997, and for urgency-frequency and nonobstructive urinary retention in 1999. Later, the labeling was changed to include “overactive bladder” as an appropriate diagnostic category. Patients from these groups are appropriate for SNS if they have chronic symptoms that significantly affect quality of life and if conservative treatments have been unsuccessful.<sup>1,21</sup>

## Overactive Bladder

The OAB syndrome represents a mixed group of disorders with a common set of voiding behaviors, including urinary urgency-frequency and urge incontinence. In most instances, the cause is deemed idiopathic. Certainly, a behavioral component or pelvic floor muscle dysfunction is commonly present. There frequently is evidence of pelvic floor muscle spasticity on examination and on urodynamic study. The urodynamic study may or may not demonstrate uninhibited detrusor contractions. There may have been a triggering event, such as a pelvic surgery (e.g., surgery for

**Figure 22-1** Micturition reflex pathways as outlined by de Groat. Note that the Aδ fibers and C fibers provide afferent signaling to the brain as the bladder fills. The brain, in turn, signals spinal pathways, resulting in a “turning off” of the guarding reflex, relaxation of the external urethral sphincter, contraction of the detrusor, and voluntary voiding of urine.

### Box 22-1 Possible Mechanisms of Sacral Nerve Stimulation

- Inhibits postganglionic nerve terminals<sup>4-6</sup>
- May inhibit primary afferents presynaptically<sup>7,8</sup>
- May affect pudendal afferents that transmit somatic and visceral neurochemical signaling<sup>9-11</sup>
- Inhibits spinal tract neurons involved in the micturition reflex<sup>12-15</sup>
- May suppress guarding reflexes indirectly by turning off bladder afferent input to internal sphincter sympathetic or external urethral sphincter interneurons<sup>8,16,17</sup>
- May activate bladder efferents to stimulate voiding while simultaneously turning off excitatory pathway to urethra<sup>18-20</sup>

stress incontinence) or trauma. As a rule, patients who are appropriate candidates for SNS are neurologically normal and have no structural abnormality of the bladder (e.g., scarring from radiation therapy, diverticulum).

#### Neurogenic Disorders

Patients with defined neurologic abnormalities such as multiple sclerosis or partial cord injury may also benefit, but studies in this population of patients have been few. When faced with the alternative of an indwelling catheter or urinary diversion, it may be reasonable to consider a diagnostic trial of SNS. Patients with disorders such as peripheral neuropathy, a cord lesion, multiple sclerosis, parkinsonism, or myelodysplasia are not ideal candidates. Patients with multiple sclerosis, for example, were excluded from the original trials leading to FDA approval of SNS because of the potential for the underlying condition to change.<sup>22</sup> If this were to have occurred, the effectiveness of the therapy might have been called into question by the FDA. However, we know that SNS does help patients who have multiple sclerosis,<sup>23</sup> and, in some cases, it may be the most appropriate option.

#### Interstitial Cystitis and Pelvic Pain

Interstitial cystitis is not an FDA-approved indication for SNS, but one could define a set of symptoms characteristic of interstitial cystitis as “urinary frequency and urgency with pelvic pain.” If a diagnostic label based on objective voiding behaviors is used, patients with interstitial cystitis may readily fit into the approved diagnostic criteria. Although isolated symptoms of pelvic floor muscle dysfunction, pelvic pain, and/or bowel dysfunction are not indications for the therapy, they are commonly present in patients who are otherwise candidates for SNS and frequently improve along with the urinary complaints if the therapy is otherwise successful.<sup>24-29</sup> Patient selection for SNS remains empiric. A key is to think of voiding dysfunctions in terms of voiding behaviors and pelvic floor muscle function, rather than organ-based labels. Patients with intractable urinary frequency, urgency, and urge incontinence should be considered as prime candidates. Evidence of high-tone pelvic floor muscle dysfunction may also be demonstrated on routine physical examination and on diagnostic studies such as pelvic floor electromyography.<sup>30</sup> A successful trial stimulation remains the best indicator for patient selection and should be used as a routine diagnostic test for patients with chronic, life-altering voiding complaints that

cannot be adequately resolved by medications or behavioral interventions.

#### Technique

Brindley and colleagues, Schmidt, and Tanagho were some of the first to describe electrode placement to treat urinary incontinence in humans. Brindley and colleagues treated paraplegic subjects with sacral anterior root stimulation starting in 1976.<sup>31</sup> Thirty of the 50 treated patients reported complete continence, and 26 of the 28 male patients were able to achieve penile erection with sacral root stimulation. Schmidt reported on placement technique for the neurostimulator electrode at the S3 or pudendal nerve level.<sup>32</sup> Pelvic pain symptoms improved by at least 50% in almost half of the patients.<sup>33</sup> In 1990, Tanagho reported that almost 70% of 31 urge-incontinent patients self-rated their symptom improvement as 50% or higher.<sup>34</sup> Since that time, the test stimulation, lead design, and surgical technique have been refined.

#### Staged Lead Implantation as Initial Trial

It is our preference to perform a staged implantation as the initial therapeutic trial. The benefits of this approach include the ability to place a potentially chronic lead under minimal anesthesia. The design of the chronic lead is useful in correct identification of the anatomic nerve pathway, due to its array of four contact points, which also allows for reprogramming of the site of stimulation during the trial. Use of minimal anesthesia during chronic lead implantation (monitored anesthesia care, or MAC) allows the patient to give sensory feedback during the positioning of the lead, which serves to increase the accuracy of site selection and decrease the risk of uncomfortable sensations with chronic use of the device. We typically conduct the staged lead implantation over a 1-month period, and if there is at least a 50% improvement of the target symptoms to justify the use of an implantable pulse generator (IPG), the patient can depend on the result of the trial phase to accurately predict how the permanent implant will function. It is our impression that this technique results in a lower rate of false-positives, which may occur if there is insufficient time to gauge the response. The more accurate placement of the potentially permanent lead should also result in a higher rate of appropriate patient selection and should decrease the need for later revision surgery.

#### Preoperative Preparation

The patient should have completed baseline diaries documenting the target voiding dysfunction and/or incontinence. These include specific quantification of urinary frequency, voided volumes per void, degree of urgency, number and severity of incontinence episodes per day, and number and type of pads used per day. We do not ask the patients to do a cleansing bath or shower. Patients are given a preoperative dose of cephazolin (Ancef), or if they are allergic to penicillin, gatifloxacin (Tequin).

#### Anesthesia

The patient's feedback during lead placement can be essential to the ultimate success of the therapy; therefore, MAC/local anesthesia is most appropriate for lead placement. This also allows for more immediate postoperative programming because of the quicker patient recovery. Developing a routine with the anesthesia team is critical to the ease and success of this procedure. Our anesthesiologists use a cocktail of propofol (Diprivan), fentanyl

**Figure 22-2** The patient is placed on a fluoro-friendly table that allows C-arm access under the pelvis for both anterior-posterior and lateral views. Chest rolls are placed to improve breathing, and a pillow or blanket supports the hips. Access to the feet is maintained out of the sterile field to allow monitoring of responses.

(Sublimaze), and midazolam hydrochloride (Versed). This allows for titration of the level of consciousness during the procedure. There is also a degree of amnesia as a result of the Versed. Some patients are comfortable with remaining alert throughout, whereas others, who may be more pain focused, need a higher level of sedation from the start. In rare instances, a general anesthetic is required due to issues such as sleep apnea or patient choice. If so, it is critical that only short-acting paralyzing agents be used to avoid obscuring pelvic muscle responses turning intraoperative stimulation.

#### Intraoperative Positioning and Preparation

Patients are placed on a fluoro-friendly table in a prone position (Fig. 22-2). Use of MAC/local anesthesia can aid in allowing the patient to assist in transfer and table positioning. Pillows are helpful under the pelvis and beneath the shins. The hips must be positioned so that a C-arm unit can be passed under the table in order to allow viewing of the sacrum in an anterior-posterior (AP) plane. The feet must remain uncovered to allow for direct observation during the procedure. Two chest rolls are also needed to aid with respiration. The lower back and buttocks are first wiped with alcohol and then painted with DuraPrep (3M) solution. This is allowed to dry completely before the skin is covered with an Ioban (3M). The use of alcohol/DuraPrep/Ioban allows for a quicker and more bactericidal preparation than a prolonged Betadine scrub and paint. When used in this fashion, the Ioban also sticks to the skin very snugly, preventing any direct exposure to the skin other than at the exact site of incision. This is initially placed smoothly over the lower back and sacral area and loosely over the buttocks. After first placement of the Ioban, the cheeks of the buttocks are gently pulled apart and released to allow the covering to dip into the buttocks crease. This provides for excellent visualization of the “bellows” response without risk of field contamination from colonic flora. The buttocks cheeks are not taped apart, because this adds little benefit in discerning a bellows response yet tends to tense-up and humiliate the patient.

#### Selecting the Appropriate Foramen

As a rule, the target foramen is either the right or left S3 level. In rare instances, S4 is best, and S2 is almost never appropriate for chronic stimulation. If the patient has a lateralizing pain component, that side is usually approached preferentially. If there is no

**Figure 22-3** An anterior-posterior view is obtained to determine the medial edge of the foramina. A marker is placed on the skin and moved to the edge, where a skin mark is made. The opposite edge is usually two fingerbreaths across from the first mark. All of the foramina line up along the same plane. Once these landmarks have been determined, a cross-table lateral view is used to determine the target foramina for needle placement.

lateralization, and if the surgeon is right-handed, we tend to choose the patient’s left side for lead placement and prefer to stand on the patient’s right side during the procedure. We therefore preferentially place the IPG in the right upper buttocks, with the lead on the left; this uses up an additional 2 cm of lead length, minimizing potential lead redundancy at the connecting site.

#### Local Anesthesia

Once the starting point has been estimated, the skin is anesthetized with 0.25% bupivacaine (Marcaine) to create a dime-sized wheal. The skin must exhibit a “peau d’orange” effect to achieve rapid anesthesia, and it is not necessary to infiltrate into the fat below the skin level. It may be necessary to numb the posterior sacral periosteum if the patient exhibits discomfort.

#### Positioning the Foramen Needle with the Use of Fluoroscopy

Fluoroscopy is needed to identify the target site. Initially, an AP view is obtained to determine the medial edge of the foramina (Fig. 22-3). A skin mark is made at this level on one side, and then, by estimating two fingerbreadths over, the second site is confirmed again with fluoroscopy and marked. An imaginary line parallel to the spine at the level of either mark is where the foramina lineup, and now the S3 level needs to be determined by a cross-table fluoroscopic view. On the cross-table lateral view (Fig. 22-4), the S2 level is readily identified as the point at which the sacroiliac joint fuses, forming a characteristic shadow. The first anterior protrusion or “hillock” from the surface of the sacrum below this shadow is typically S3. Next, a skin marker such as a mosquito clip is positioned in line with the medial edge of the foramina, and a cross-table view is obtained to determine

**Figure 22-4** The lateral view determines where to aim for needle placement. A skin marker is placed in the line of the foramina determined on the anterior-posterior view. The sacroiliac shadow (A) is usually where S2 is located, and S3 (C) is most often the first hillock below the sacroiliac shadow. Once the target foramen has been identified, it is possible to determine if the needle must be aimed more caudally (B) or more cranially.

the potential course of the foramen needle. It should always be oriented in a cephalocaudal direction, and it should come out as close as possible to the tip of the hillock. Depending on the estimated course of the needle, the marker may need to be moved up or down until appropriately positioned. After the skin is anesthetized and the needle is placed, another fluoroscopic view is obtained to determine whether the needle must be aimed more cranially or more caudally in order to point toward the hillock. The needle is then “walked” up or down along the line of the foramina, which was determined on the AP view, until it drops into the foramen. As the aim of the needle is adjusted up or down, it is important to pull it out and reinsert it, rather than torquing or bending it (see Fig. 22-4). Once the needle enters the foramen, the fluoroscope is used to gauge the depth. We start stimulating just anterior to the bony surface (point C in Fig. 22-4). This is the most consistent location of the sacral nerve ramus relative to the point of introduction. The foramen needle is then stimulated with the screening device to check sacral root responses (Table 22-1).

If responses are not appropriate at this level (i.e., consistent with S2 or S4), the point of introduction at the skin level is re-estimated to aim for the next hillock above or below the initial point of stimulation. If appropriate responses are elicited, the needle is advanced in increments along the relevant length of the permanent electrode (2 cm) to determine whether the foramen needle has paralleled the course of the nerve. If the response is lost on advancement of the needle and retesting, the needle should be pulled back toward the skin and reinserted through the foramen until a more appropriate position has been identified.

**Table 22-1** Anticipated Motor and Sensory Responses to Stimulation at S2, S3, and S4 Levels

Level	Motor Responses	Sensory Responses
S2	Bellows (inward movement of intergluteal fold) Clamp (anteroposterior pinching of the perineum or coccyx) Dorsiflexion of the foot, heel rotation, calf cramping	Genital
S3	Bellows Dorsiflexion of the great toe, bottom of the foot	Genital, perineal, anal
S4	Bellows	Anal

### Positioning the Tined Lead under Fluoroscopy

Once the course of the nerve has been fathomed using the foramen needle, the tined lead is deployed. A skin nick is made at the foramen needle insertion point, and the metal stylet is placed at the appropriate depth for either the 3- or 5-inch foramen needle. Next, the foramen needle is exchanged for a lead introducer sheath. The tip of the introducer sheath has a radiopaque marker, and the depth of this marker should be about 1 cm proximal to the anterior surface of the bone (Fig. 22-5A). Deploying the lead from this position allows it to release in the fatty plane surrounding the nerve, improving the chance that the lead will “catch the wave” and follow its course (see Fig. 22-5B). It is also very helpful to use the “ball-tipped” stylet, which is an accessory (Medtronic Accessory Kit), because it is softer than the one currently packaged with the lead and is less likely to force the electrode out of the proper plane. The ball-tipped stylet has a slight curve or “hockey stick” appearance to it, and it marries to the lead body at its most external point, allowing the tip to be steered under fluoroscopic guidance (Fig. 22-6).

When deployed properly, the lead should always point caudally to a slight degree (point B in Fig. 22-6) and never cephalad (point A in Fig. 22-6). Additionally, it should flip out laterally. This can be achieved by pointing the hockey stick “down and out” as it first enters the foramen. On the lateral fluoroscopic view, the spaces between the lead contact points (0 to 3) should appear closer together between the more distal sites, indicating that the lead is pointing away as it separates from the anterior surface of the bone. On the posterior-anterior view, the most ideal lead position should course out flat and laterally from the medial aspect of the foramen (Fig. 22-7). We always straddle the bone table with lead sites 3 and 2 (see Fig. 22-6). This allows for a consistent lead depth, prevents premature deployment of the tines, and provides a point of reference in the future. Once a satisfactory trajectory of the lead has been obtained, starting with the most distal contact (point 0), each site is stimulated and the threshold of response is measured. If each site elicits an appropriate response at a relatively low threshold, the position of the nerve has been appropriately paralleled by the lead. If not, the lead should be pulled back under fluoroscopic guidance until the tip is proximal to the end of the introducer sheath, and then reinserted under fluoroscopic control, watching to make sure it takes a different course. It is then retested at each contact point. The goal is to get all four contact points yielding an appropriate response at a similar, relatively low threshold. If this cannot be

A

B

**Figure 22-5 (A)** Once appropriate responses have been determined, the foramen needle is exchanged for the lead introducer sheath. This is placed under fluoroscopic control so that the radiopaque marker remains within the bone table about 1cm posterior to the anterior surface of the sacrum. This allows the lead to be deployed in the fatty plane through which the nerve travels **(B)**, and, combined with the use of the ball-tipped stylet, improves the chance that all four contact points will be in line with the nerve.

attained after several repositionings, it may be necessary to bend the lead/stylet to accentuate the hockey stick shape and redeploy it. If this is still unsuccessful, it may be necessary to start again with the foramen needle to map out a different course for the nerve. Once the ideal position has been determined, the tines are deployed by uncoupling the stylet and pulling it back under fluoroscopic guidance, as the position of contacts 3 and 2 are maintained relative to the anterior surface of the sacrum.

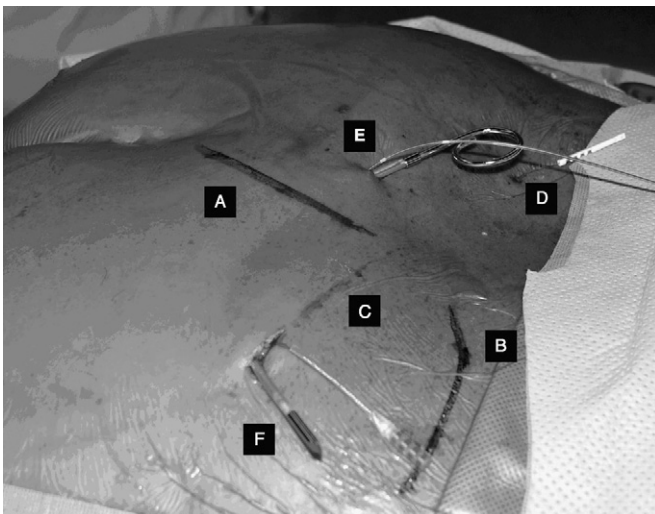

**Figure 22-6** Potential positions for lead deployment are shown. Aiming the ball-tipped stylet under fluoroscopic control allows repositioning if needed. Try to aim it down and out to begin with. Point A depicts the lead coursing cephalad, which is inappropriate, and may lead to S2 stimulation at the distal contact points. Position C is too caudal and may lead to S4 stimulation at the distal sites. The proximal contacts (2 and 3) may yield similar responses in all of the deployments. It is unlikely that all four sites would have the same stimulation thresholds in either position A or position C, because the lead is not following the course of a single nerve root. Position B is most ideal. Note how the contact points appear closer together distally, indicating that the lead is headed out laterally along the course of the nerve. All four sites should yield an S3-type response at low thresholds. The lead is deployed with contact sites 2 and 3 straddling the bone table. (Courtesy of Medtronic, Inc.)

#### Setting Up the Connection between the Lead and Lead Extension

We typically place the connection between the lead and lead extension in the anticipated site for the future IPG (Fig. 22-8). The lateral aspect of the future IPG incision is made at this time (point F on Fig. 22-8). The location is usually on the right side (because of where the surgeon stands), and the future IPG should be lateral to the lateral edge of the sacrum (point A on Fig. 22-8), below the posterior superior iliac crest (point B on Fig. 22-8). These landmarks are outlined with a marking pen, as is the future IPG incision location (point C on Fig. 22-8). Then, the tunneling device is placed from the lateral aspect of this incision across the patient's back to the furthest point away from the connecting incision that the tunneled sheath will allow (point C to point D on Fig. 22-8), minimizing the potential for infection. For the same reason, care should be taken to course the tunnel away from the lead insertion site over the sacrum (point D to point E on Fig. 22-8), so this usually means that the intended IPG incision is on a slant. Once the distance from the connecting incision to the lead extension skin exit point has been estimated, an

**Figure 22-7** Posterior-anterior view of sacrum. The right-sided lead is taking the most appropriate course laterally. This can be achieved by directing the tip of the lead/stylet “down and out” as it is inserted through the introducer sheath. Sometimes, it is helpful to accentuate the curve of the “hockey stick” if initial deployments do not adequately track with the nerve.

**Figure 22-8** The lateral edge of the sacrum (point A) and the posterior superior iliac crest (point B) are marked. The future site of the IPG incision (point C) is marked diagonally so that the implantable pulse generator may be placed in a plane of fat away from bony prominences. The course of the lead extension allows it to exit the skin at a safe distance from the lead (point D). The lead extension is tunneled using an uncurved tunneler, allowing for the maximum tunnel length (point C to point D). The tined lead is tunneled to the lateral aspect of the connecting incision using a curved trocar (point E to point F). This takes up some of the redundant lead length and also allows for the lead to be placed in a predictable position for future reference.

**Figure 22-9** The connection hub between the lead and lead extension electrode is placed in the subcutaneous fat underneath the middle portion of the potential implantable pulse generator (IPG) incision (*inset*). This allows for its immediate location during the second-phase procedure. The plastic sheath protecting the lead extension is grasped gently with a hemostat and escorted into the fat in the direction in which it was placed. Once it is in position, the hemostat is spread and released as the lead extension is gently pulled into place. At the next phase, the connecting incision can be reopened to allow for lead removal or extended medially to allow for IPG placement.

anesthetic skin wheal can be made at the lateral aspect of the future IPG incision and at the skin exit point. A 1- to 2-cm incision is made at the connection site, taking care to make it completely through the skin into fat, preventing the lead from getting caught too superficially. The tunneler is then placed about 2 cm deep to the skin from the lateral aspect of the incision, toward the preanesthetized exit point. As long as the tunneler is kept in the fatty tissue beneath the skin, there is little sensation or discomfort during this maneuver, and only the entry and exit points require local anesthesia. The sheath is left in place, and the lead extension can be pushed through it with fingers, or it can be escorted by reinserting the tunneler or the lead introducer stylet if necessary. Next, the lead is tunneled to the lower lateral aspect of the connecting incision. (point F on Fig. 22-8). Care must be taken to be sure the presacral incision is wide (usually 0.75 cm) and deep enough to allow the tunneler to be placed without harming the lead and also to make sure that the lead is in the fat below the skin, to prevent potential infection. We typically curve the tunneling device to cause the lead to sweep down and back up toward the lateral aspect of the connecting incision (point E to point F on Fig. 22-8). This maneuver “uses up” additional length of lead, preventing redundancy at the connection site. Once the lead is coupled to the lead extension, a straight clamp is placed on the tip of the plastic sleeve that extends out over the extension, and the lead is escorted in the direction of its pass into the subcutaneous fat just medial to the edge of the incision. The clamp is spread slightly and pulled away as tension is maintained at the lead extension exit site (Fig. 22-9).

This procedure sets up the connection at the medial aspect of the potential IPG site (see Fig. 22-9, *inset*), where it can readily be found for the next stage. If there is any redundancy of the lead, it is always looped in the fatty tissue inferior to the incision and usually will not be encountered at the next phase unless it is to

be removed. The procedure is completed by irrigating with antibiotic solution, achieving final hemostasis, and closing the connecting incision with subcutaneous Vicryl. The skin of both incisions is closed with staples to avoid encountering the knot of a running subcuticular closure in the connecting incision at the time of IPG implantation, because it could not be sterilized. Patients are discharged after programming, and they return in 1 week for staple removal and reprogramming as needed. A 1-month trial period is used routinely. This is helpful in making sure that programming is optimized and for evaluating the veracity of responses in terms of the target symptoms and secondary complaints such as pain and bowel dysfunction.

### Completion Phase

We schedule a completion phase procedure 4 weeks after the first stage. The exit site is draped out of the prepared field, with care to leave enough slack to allow pulling of the entire lead extension sleeve into the connecting incision. If symptoms have not been sufficiently improved, the lead is removed under MAC/local anesthesia by infiltrating the connecting incision with 0.25% Marcaine, opening the incision, and discovering the connection hub at the medial margin. It is pulled into the incision, and the lead extension electrode is cut. It will be removed completely at the end of the procedure, once the connecting incision has been closed and dressed. The lead is then pulled sharply from the connecting incision, and it usually comes without resistance. If it is pulled slowly, it tends to elongate and thin out, potentially increasing the risk of lead fracture. There is no risk of nerve injury if the lead is deployed as discussed, because the tines are all outside of the foramen. Finally, the connecting incision is closed loosely with staples to minimize the risk of infection.

### Implantation of the Pulse Generator

If there has been a sufficient improvement in the target symptoms to justify IPG implantation, this is done at the completion phase. The incision is marked with a marking pen, extending medially from the 1.5-cm connection incision toward the lead exit point. An area surrounding the intended incision is marked to estimate the space for the IPG and lead extension assembly. The entire area is infiltrated with 0.25% Marcaine, creating a skin wheal over the areas to be surgically dissected. The incision is then made, and hemostasis is carefully maintained to minimize the risk of hematoma formation. The connection between the lead and lead extension is identified; the extension is cut beyond the plastic sleeve, and then it is clamped at the sleeve, allowing the housing to remain as a protection against inadvertent cautery of the lead during creation of the pocket. A subcutaneous pocket is created using cautery and blunt dissection. This should be 2 cm beneath and parallel to the skin, just large enough to comfortably house the IPG and lead assembly. Once hemostasis has been assured, the remaining housing from the previous lead extension is removed from the lead and discarded. The wound is irrigated with antibiotic solution, and the IPG and lead extension are connected to the previously placed lead, taking care to keep the connection clean and dry and to avoid overtightening of the lead extension onto the lead. The device is positioned in the pocket with its noninsulated side (the side with writing) facing up, taking care to tuck the lead and extension behind the device. This step prevents superficial migration of the connection site and also potential lead injury if a revision surgery is ever needed. The incision is closed as described for the first phase.

Figure 22-10 Stimulation parameters.

### Programming

The goal of programming is to reproduce, with the permanent device, the same results achieved during the trial phase. This goal is greatly aided if the patient has had several weeks to test various bipolar electrode configurations with the external screening device and by the fact that the same electrode is used for the trial and permanent implantation phases when the staged trial is used. We typically do programming before discharge after outpatient placement of the IPG. The settings that were most successful during the trial phase are reproduced with the chronic device. Typical programming parameters for sacral neuromodulation include a rate of stimulation or frequency between 10 and 20 Hz and a pulse width between 180 and 240  $\mu$ sec (Fig. 22-10). (Note: the manufacturer recommends a rate of 10 to 14 Hz and a pulse width of 180 to 210  $\mu$ sec.<sup>35</sup>) The sensation of stimulation feels more like a thump at lower rates and like a flutter or buzz at higher rates. Rates of stimulation greater than 30 Hz are thought to be potentially harmful to peripheral nerves; the manufacturer more conservatively recommends not increasing the rate beyond 19 Hz.<sup>36</sup> Increasing the pulse width increases the pulse duration. Pulse widths greater than 270  $\mu$ sec are not recommended by the manufacturer.<sup>36</sup> The amplitude is variable, determined by patient comfort, and based on the proximity of the lead to the nerve, as determined during lead placement. Ideally, patients should feel paresthesias at thresholds lower than 4 V, which allows for longer battery life. The patient has the ability to increase or decrease the amplitude using the hand-held programmer; in our experience, there is little risk of injury when the patient is allowed to adjust the programmer over the full range of amplitudes. Reprogramming is needed if there is decreased efficacy over time or if the patient experiences diminished or uncomfortable stimulation. Programming is either unipolar or bipolar (Fig. 22-11). A unipolar configuration is any combination of electrodes with at least one negative electrode and with the case positive (case POS, electrode NEG). In a bipolar configuration, the current flows between one negative electrode and one positive electrode (e.g., electrode 1+, 2-, case off). A change in the active (negative) electrode changes the location of the stimulation pattern. For example, deep electrodes (3-) are typically felt more anteriorly, whereas shallow electrodes (0-) are typically felt more posteriorly.

## TROUBLESHOOTING

### Insufficient Benefit from the First Stage of Implantation

If patients do not document sufficient improvement from baseline symptoms (usually at least 50% improvement in target symptoms), they should not go on to an IPG implantation as a

**Figure 22-11** Lead electrode array and programming options.

next step. We are looking for a dramatic change in symptoms to justify the completion phase, and if there is only modest or minimal change, it is best to re-evaluate. This may require that a repeat trial phase stimulation be performed at a later date with an attempt to place the electrode on the opposite side or at another level. In our experience, bilateral stimulation has never been an adequate improvement when unilateral stimulation is not sufficiently successful. Because we would ordinarily consider a trial of SNS only in patients for whom both medical management and biofeedback have failed, further treatment options would include pudendal nerve stimulation, intravesical injection of botulinum toxin, or possible augmentation cystoplasty.

### Wound Infection

If wound infection occurs, it is necessary to remove all the implanted components. We are unaware of any successful reports of salvage procedures for these devices. If the presacral incision is not fluctuant, it usually does not have to be opened to remove the lead, which can be pulled from the IPG site. It is helpful to remove the capsule that may have formed around the IPG if it has been in place for a sufficient length of time. Wounds usually need to be left open and have to heal by secondary intention. We have had much quicker resolution of wound infections using closed-suction wound systems, and consultation with enterostomal therapy for these services has been a great benefit for our patients. We give a wound infection 3 or more months to resolve completely before considering reimplantation. This would typically be done as a single-stage implantation of both the lead and the device, providing there was a sufficient benefit from the previous implantation and the lead location can be successfully duplicated.

### Lack of Efficacy over Time

It is extremely important to be certain of the benefit from the trial phase stimulation. This is why we do a staged implantation as the trial procedure and give the patient a month before we move on to the next phase. Also, placing the lead under conscious sedation reduces the chance that stimulation will be uncomfortable for the patient. The care taken during lead placement—making every effort to identify the course of the nerve, and getting all four contact points in line with it, yielding typical responses at low thresholds—gives maximal flexibility for programming

afterward. These steps are all helpful in minimizing the need for a future revision. It is presumed that all combinations of unipolar and bipolar stimulation configurations have been tested. Also, it is helpful to check impedances using the programming device, because this may point to a lead fracture or another problem causing an open circuit (fluid in the connection site). An AP and lateral radiographic study may be helpful in defining a lead displacement or fracture, and having the films available from the original placement is useful for comparison. It may also be helpful to turn the device off completely, letting the patient experience his or her symptoms without the benefit of neuromodulation. This step often demonstrates that the symptoms are indeed controlled to a great degree, although perhaps not completely. If the patient decides that the therapy provides insufficient benefit once both devices have been placed, it may be necessary to do a staged trial at another foramen (most often S3 on the opposite side of the originally implanted lead) and then to compare the result of the implanted system to stimulation with the externalized lead and temporary stimulation device. If there is sufficient improvement, the new lead may be connected to the previously placed IPG as a second-stage completion. If SNS cannot control the symptoms even after revision, it may be reasonable to consider pudendal nerve stimulation (currently off-label) to salvage use of the device.

### Pain at the Implantation Site

If there is pain at the IPG site, it can often be improved by programming with bipolar settings. In rare instances, use of an anesthetic patch over the device or performance of a trigger point injection with local anesthesia provides relief. If the device is superficial or if it is over a bony prominence, it may need to be repositioned deeper or more lateral or inferior to the original site. On rare occasions, it is necessary to move the device to the opposite side. If repositioning is done, the previous IPG capsule needs to be excised or sufficiently scarified to minimize the risk of seroma accumulation.

### Need for Magnetic Resonance Imaging

As more patients undergo implantation and patients with neurologic conditions are included as candidates for treatment with this option, the likelihood that an occasional patient with an IPG will need a magnetic resonance imaging (MRI) study increases. There is evidence that MRI can be used safely in some patients with the Medtronic InterStim device.<sup>37</sup> These include instances in which the site to be studied is away from the pelvis, such as in the head or upper spine, and a smaller magnet (1.5 tesla) can be used, with an open device if possible. The implanted device must be turned off for the procedure, and the patient must be able to signal to the technician if discomfort develops during the scan. The patient must also be willing to sign a waiver releasing the radiologist from liability if there is damage to the device or other complications after the study.

## TREATMENT RESULTS

Treatment of OAB with SNS has been shown to be highly successful and enduring. Siegel and Catanzaro and their colleagues reported on patients who were observed 1.5 to 3 years after sacral neurostimulator implantation. At 3 years, 59% of 41 urinary

**Figure 22-12** Maintained clinical success rates (percentage reporting at least a 50% improvement compared with baseline) in urge-incontinent patients for average number of leaks per day.

**Figure 22-13** The percentage of patients with clinical success in average number of voids per day (at least 50% improvement compared with baseline) is shown for urgency-frequency patients at annual intervals after implantation.

urge-incontinent patients showed 50% or greater improvement in symptoms, including a significant reduction in the number of leakage episodes per day. Forty-six percent of patients reported being completely dry in their voiding diaries. At 2 years after implantation, 56% of the urgency-frequency patients showed at least a 50% reduction in the number of voids per day.<sup>21</sup>

This same cohort of patients was observed in an earlier study wherein patients were randomized to stimulated or nonstimulated groups. All patients who demonstrated a positive response to test stimulation were randomly divided into a stimulation group (25 patients) and a control group (26 patients). The SNS system was implanted into the stimulation group immediately after positive response to test stimulation and after 6 months in the control group. Patients were followed up at 1, 3, and 6 months, and then at 6-month intervals for up to 2 years after implantation. The number of daily voids, the volume voided per void, and the degree of urgency before voiding were assessed. Patients in the stimulation group reported statistically significant ( $P < .0001$ ) improvements in 6-month voiding diary results, including average number of daily voids (from  $16.9 \pm 9.7$  to  $9.3 \pm 5.1$ ), volume per void ( $118 \pm 74$  to  $226 \pm 124$  mL), and degree of urgency (rank of  $2.2 \pm 0.6$  to  $1.6 \pm 0.9$ ). Patients in the control group showed no significant changes in voiding parameters at 6 months. The stimulation group also reported significant improvements on quality-of-life questionnaires and water cystometry. When the neurostimulators were turned off in the stimulation group at 6 months after implantation, urinary symptoms returned to baseline values, negating the impact of any potential placebo effect. After the stimulators were turned back on, SNS was shown to be effective at 12 and 24 months after implantation.<sup>37</sup>

After FDA approval of electrical neurostimulation for the treatment of OAB, many of these same original (pre-approval) study patients were enrolled into a postmarket study. Additional

patients were also enrolled to ensure an adequate sample size. Both groups were monitored for 5 years after implantation to assess the long-term safety and efficacy of SNS for the treatment of urgency and urgency-frequency.<sup>38</sup> Successful clinical treatment of patients was defined as at least 50% improvement in voiding symptoms. The average age of the patients was 45 years, and 90% were female.

Sixty patients who had been diagnosed with urgency were monitored for 5 years after implantation. This group reported significant improvement ( $P < .05$ ) in average number of leaking episodes per day, number of heavy leakage episodes per day, average severity of leakages, and number of pads used per day (compared with baseline values) at every annual visit. By 5 years after implantation, the average number of leakages per day had decreased from 10 to 4 ( $P < .0001$ ), with 60% of patients classified as clinically successful at 5 years (Fig. 22-12). The average number of pads used per day dropped from 5 at baseline to 2 at 5-year follow-up ( $P < .0001$ ), with 68% deemed clinically successful, having at least 50% improvement in the number of pads used per day.

Eighteen patients with urgency-frequency were evaluated at baseline and annually for 5 years after implantation. This group reported an improvement in number of average number of voids per day, from 20 at baseline to 13 at 5-year follow-up ( $P = .002$ ). Clinical success was defined as at least 50% improvement in number of voids per day. At 4 years after implantation, there was a 50% clinical success rate in number of voids per day, and at 5 years the rate was 39% (Fig. 22-13). The average change in degree of urgency per day was also statistically significantly improved ( $P < .05$ ) compared with baseline at each annual visit, with the exception of the 1- and 5-year follow-up visits ( $P = .06$  and  $P = .10$ , respectively). The clinical success rates were 74% at 3 years, 64% at 4 years, and 56% at 5 years after implantation.

**Figure 22-14** The percentage of urgency-frequency patients with clinical success (at least 50% improvement compared with baseline) in average volume per void peaked at 2 years after implantation with 71.4% clinical success. Clinical success was maintained at a reasonably acceptable level (55.6%) at 5 years after implantation.

The volume voided per void was significantly improved at each annual follow-up visit ( $P = .004$ ), with the average volume improving from 101 to 202 mL at 5 years after implantation (Fig. 22-14). Clinical success for this measure (at least 50% improvement) was maintained long-term after SNS implantation. Results were reported as 68% clinical success at 3 years, 59% at 4 years, and 56% at 5 years.

### Safety

The long-term safety of SNS has been well characterized. In the same multicenter study<sup>38</sup> 42% of patients required surgical intervention for a device- or therapy-related adverse event that occurred by the time they reached 5 years after implantation. The most common surgical intervention was device explant and replacement (lead, extension, or neurostimulator), which occurred in 24% of patients throughout 5 years of follow-up. If these data are recategorized to include all device- or therapy-related events that did or did not include surgical intervention, the most frequently reported event was new pain or undesirable change in stimulation, occurring in 27% of all patients. Pain at lead or IPG implantation site related to the neurostimulator was the second most common reported event, occurring in 20% of patients. During this study, the tined lead was not used for the testing phase, because it was not approved for use by the FDA until 2002. The use of a tined lead in conjunction with the SNS system can significantly reduce the invasiveness of the procedure as well as the length and depth of the incision required, making it possible to complete the procedure under local anesthesia. The patient remains alert in order to provide sensory feedback that may facilitate more accurate lead placement, leading to fewer revisions and better, more comfortable positioning of the lead.

### CONCLUSIONS

SNS for intractable OAB symptoms has emerged as a standard of care and should be considered as an appropriate next step if

drugs, behavioral interventions, and pelvic floor rehabilitation have provided insufficient relief. The exact mechanism of action remains unknown, but modulation of afferent nerves at several levels and manipulation of the guarding reflex are key elements in restoring a more normal balance of reflexes among the bladder, sphincter, and pelvic floor muscles. The therapy is most appropriate for OAB patients who are without underlying neuropathology, but it has been successful for a range of problems, including interstitial cystitis, idiopathic nonobstructive urinary retention, neurogenic voiding dysfunction, and fecal incontinence. A key finding on preoperative assessment is evidence of high-tone pelvic floor muscle dysfunction. It is helpful to think of conditions of voiding dysfunction in terms of behaviors, instead of using organ-based labels, and to view the first phase or application of sacral neuromodulation as a test. Urinary diaries are essential to objectively document the target symptoms before, during, and after a therapeutic trial.

We prefer to go directly to a staged lead implantation as the initial trial phase, because it allows a sufficient length of time to evaluate the therapy for a given patient, and the results of the trial using the potentially permanent electrode will most closely predict the outcome once the chronic device has been implanted. Keys to successful lead implantation include performance of the procedure under MAC/local anesthesia, which allows the patient to give sensory feedback during lead placement. Care using fluoroscopy and use of the ball-tipped stylet are essential to identifying the level and course of the appropriate sacral nerve root. It is ideal to have as many contacts as possible yielding the same responses at low thresholds, to give the most flexibility with future programming of the device. The long-term effectiveness of sacral neuromodulation for intractable OAB has been documented, and the therapy continues to undergo further refinements with the hope of improved ease of use and suitability for a host of urologic disorders. Now that the role of neuromodulatory therapies for chronic voiding dysfunction is established, new devices and alternative stimulation targets will emerge, and they will need to be compared to sacral neuromodulation as the gold standard for this treatment modality.

# POSTERIOR TIBIAL NERVE STIMULATION FOR PELVIC FLOOR DYSFUNCTION

*Matthew R. Cooperberg and Marshall L. Stoller*

### SCOPE OF THE PROBLEM

Pelvic floor dysfunction (PFD) is a highly prevalent functional disorder, affecting both women and men, which may manifest in diverse clinical symptoms including urinary frequency, urgency with or without incontinence, and/or retention, as well as rectal incontinence and pelvic pain. Overactive bladder (OAB), a constellation of symptoms defined by “urgency, with or without urge incontinence, usually with frequency and nocturia,”<sup>1</sup> is one of the most common manifestations of PFD, and it the best-studied epidemiologically. OAB affects approximately 16.5% of adult men and women in population-based studies conducted in both the United States<sup>2</sup> and Europe.<sup>3</sup> Some 9.3% of women and 2.6% of men, respectively, suffer from OAB associated with urge incontinence.<sup>2</sup> These figures translate to an estimated 33 million affected adults in the United States alone, a prevalence similar to that of other major chronic conditions such as hypertension and heart disease.<sup>4</sup> The global costs of treating OAB are estimated at \$12 to \$17 billion per year, comparable to those attributed to pneumonia, osteoporosis, or arthritis.<sup>2,5</sup>

Pharmaceutical remedies for urinary complaints referable to PFD remain suboptimal due to a high incidence of side effects, relatively modest efficacy, poor patient compliance, and high long-term costs. Surgical procedures described to date do not work well for most cases of PFD featuring a prominent urge component; moreover, surgery may not be a suitable option for the many PFD patients who are elderly and faced with multiple medical comorbidities. Many studies using various measures have found that urge incontinence affects patients’ health-related quality of life (QOL) to a greater extent than does stress incontinence<sup>6-8</sup>; nevertheless, in part due to dissatisfaction with treatment alternatives and/or a public perception of unsatisfactory treatment outcomes, OAB often goes unrecognized and under-managed. In the United States, only 25% of OAB patients surveyed (40% of those with incontinence) had seen a physician for management of bladder symptoms in the past year.<sup>4</sup>

Urologists have long recognized PFD as a root source of diverse voiding complaints, but many patients with concomitant constipation would seek referral for treatment of constipation before a definitive evaluation for voiding dysfunction. Gastroenterologists, in turn, might advise patients to have their urinary problems corrected before offering a definitive opinion and treatment for constipation. Gynecologists faced with a patient with chronic pelvic pain and urinary or fecal continence issues may refer the patient for management of these problems before addressing the pain itself. In many cases, these apparently disparate problems are in fact interrelated manifestations of the common functional problem of PFD.

Recent reports have provided additional evidence for epidemiologic associations among urinary incontinence and other PFD-related complaints such as incontinence of flatus and/or feces and prolapse symptoms.<sup>9</sup> PFD probably also plays a significant role in the pathophysiology of female sexual disorders.<sup>10</sup> In recent years, novel approaches for the treatment of both OAB and other manifestations of PFD have been the subject of growing interest; one of the most promising such approaches is percutaneous neurostimulation as a means of modulation of the sacral outflow tract to the pelvic floor.

### PERCUTANEOUS NEUROMODULATION: RATIONALE AND THEORETICAL MECHANISM

Many groups over the past 20 years have focused efforts on stimulation of the S2 through S4 nerve roots at their origin from the sacral cord. Various techniques of central stimulation have been used successfully to treat OAB, pelvic pain, sphincteric incompetence, detrusor hyporeflexia, and idiopathic urinary retention.<sup>11</sup> Central sacral neuromodulation is successful for many patients with PFD<sup>12</sup> and has been shown to improve urinary function by both urodynamic and quality-of-life parameters.<sup>13</sup> This modality, however, has significant drawbacks. Placement of the stimulator is invasive: the system requires trial runs with percutaneous needles placed through the sacral foramina to access the cord for up to 1 week and ultimately requires a general anesthesia for permanent stimulator implantation. Among patients with a successful response to initial lead placement, as many as 20% to 51% do not enjoy similar long-term success with permanent implantation. Moreover, the complication rate varies from 22% to 43%, and up to 50% of patients receiving sacral neurostimulators eventually require reoperation.<sup>14</sup> Lead migration is a late complication that continues to limit the long-term efficacy of the central approach even in contemporary reports.<sup>15</sup>

Various approaches to minimally invasive neuromodulation have been tested, including perineal muscle stimulation for stress urinary incontinence; perineal nerve stimulation via the dorsal nerve of the penis for detrusor hyperreflexia; peripudendal percutaneous neural stimulation; and direct cutaneous stimulation of perineal, perianal, or perivaginal skin for the management of urge incontinence. The proliferation of these novel approaches to minimally invasive neuromodulation of the pelvic floor underscores the limitations of the more invasive central stimulation techniques. One of the most promising new approaches for multiple PFD-related complaints involves percutaneous posterior tibial nerve stimulation (PTNS).

The posterior tibial nerve is a mixed somatic/motor nerve containing fibers originating from spinal roots L4 through S3. These roots comprise the outflow of the sacral nerves, which modulate the somatic and autonomic nervous supply to the pelvic floor, innervating the bladder and urinary sphincter. Initial studies of potential approaches to peripheral neuromodulation of the sacral cord measured skin impedance at various points along the S2 and S3 dermatomes and identified a consistent area of high impedance above the medial malleolus. This area overlies the posterior tibial nerve and corresponds to the *sanyinjiao*, or Sp-6 (spleen-6) acupuncture point. In acupuncture practice, Sp-6 has been targeted for management of a variety of urinary complaints, as well as to stimulate labor and alleviate labor pain; traditional acupuncture at this point previously has been shown to produce transient improvements in urodynamic parameters.<sup>16</sup>

The precise mechanism by which neurostimulation, central or peripheral, exerts its influence on pelvic floor function remains unclear. In particular, conflicting data exist as to whether peripheral neurostimulation exerts a facilitative or inhibitory effect on urinary system neural pathways. Repetitive PTNS exerts a strong inhibitory effect on nociceptive spinothalamic tract neurons in primate studies, especially at high frequencies of stimulation, via activation of myelinated A $\delta$  fibers.<sup>17</sup> Primate data from the University of California at San Francisco (UCSF) demonstrated inhibition and even elimination of uninhibited bladder contractions during PTNS.<sup>18</sup> In a feline model, on the other hand, S2 stimulation induced excitatory bladder effects at lower amperage and complete bladder inhibition at higher intensities.<sup>19</sup> Peripheral afferent nerve stimulation in vivo abolished inappropriate detrusor contractions while leaving the normal micturition reflex intact. The therapeutic effect tended to increase with repetitive weekly treatments over 2 to 3 months.

One theory suggests that posterior PTNS results in improved blood flow to the pelvis. As yet unpublished data from UCSF, for example, found, among a cohort of five men with complete erectile dysfunction, that peripheral neurostimulation yielded an immediate doubling in cavernosal arterial diameter (from a mean of 3.8 mm to 7.5 mm) and velocity (from a mean 11 cm/sec to 20 cm/sec).

Another mechanistic hypothesis suggests that neurostimulation effects a change in the neurochemical environment along the sacral pathways. Chang and colleagues,<sup>20</sup> for example, studied expression of FOS protein, a marker for noxious stimulation of cell growth, in the rat spinal micturition center (L6-S2). Among normal animals, 0 to 4 cells per section at L6 were FOS-positive. After a standardized noxious insult to the rat bladder (1% acetic acid), FOS expression increased to a mean of 76 cells per section. A single 25-minute session of percutaneous neurostimulation at Sp-6 administered 1 hour before acetic acid infusion reduced FOS expression by 73%, to a mean of 20 cells per section.<sup>20</sup>

### EARLY EXPERIENCES WITH PERIPHERAL NEUROSTIMULATION

In 1983, McGuire and associates reported their “astonishingly good” results from transcutaneous tibial nerve stimulation (TTNS) applied via an adhesive electrode to 22 patients with a range of urologic diagnoses including detrusor instability, interstitial cystitis, radiation cystitis, and neurogenic bladder. Eight of 11 patients with detrusor instability were judged “dry” after

TTNS, as assessed by urodynamics and cystography; two patients with multiple sclerosis were “improved,” four of five neurogenic bladder patients were likewise “dry” and one “improved,” and four of six cystitis patients experienced some degree of improvement.<sup>21</sup> These early data, although not rigorously collected or reported, certainly indicated the potential utility of peripheral neurostimulation for bladder symptoms.

Based on experience with central neuromodulation both at UCSF<sup>12</sup> and elsewhere, and in the hope of reaching a larger patient population, the Stoller Afferent Nerve Stimulator (SANS) was introduced 4 years later, offering a method for PTNS that would be minimally invasive and less expensive.

The application of PTNS, like that of other neuromodulatory strategies, requires a cooperative patient with a morphologically intact urinary tract, a preserved sacral spinal reflex center, a low degree of peripheral denervation of the pelvic floor striated musculature, and the ability to void spontaneously or via self-catheterization without electrical stimulus.<sup>11</sup> Pretreatment testing mirrors the standard workup for refractory OAB symptoms and includes urinalysis and urine culture, formal urodynamic profiling, and cystoscopy to rule out foreign bodies or anatomic or urothelial abnormalities explaining the symptoms.

For each PTNS session, the patient sits in a frog-leg position, and solid 34-gauge needles are placed bilaterally, three fingerbreadths (6 cm) superior to the medial malleolus. The needles are advanced to a depth of approximately 4 cm, angling posterior to the tibia and about 30 degrees cephalad. The trajectory points toward a potential needle exit anterior to the fibula. A grounding electrode (e.g., an adhesive electrocardiogram pad) is also applied on each side, ipsilaterally overlying the medial calcaneus. Electrical stimulation is typically administered from a battery-powered generator, at an amplitude just beneath the sensory threshold of 0.5 to 10 mA, with a fixed pulse width of 200  $\mu$ sec and a fixed frequency of 20 Hz. Appropriate needle localization is verified by great toe plantar flexion or fanning of digits 2 through 5 in response to an initial higher amplitude stimulation. If the patient prefers, for increased comfort after the needles are applied, he or she may shift to a more comfortable position (i.e., out of frog-leg position), taking care not to dislodge the needles.

Continued stimulation is applied for 30 minutes, only on the side with the more pronounced response to the test pulse. However, both needles are left in situ during treatment. Sessions are repeated weekly for at least 10 to 12 weeks. Patients complete voiding and pain diaries; if they experience improvement in their symptoms, the frequency of therapy is tapered gradually to every 3 or 4 weeks. Some patients have been treated continuously for up to 10 years with sessions every 4 to 6 weeks, achieving sustained symptomatic relief but consistently experiencing relapse of symptoms when the SANS sessions are stopped for prolonged periods. Patients may experience transient discomfort at the initial skin puncture site, but there is minimal if any pain with needle advancement through the deeper tissues. No patient in our experience has complained of pain during the stimulation session.

In the initial UCSF experience over several years among 98 patients with urinary frequency, incontinence, and pelvic pain treated in weekly sessions for 12 weeks, diurnal frequency episodes fell from 19 to 8 per day, nocturia episodes from 5.5 to 2.5 per night, and pain from 6.9 to 1.9 on a scale of zero to 10. Among the 22 patients complaining primarily of urgency and urge incontinence, 80% had at least a 75% reduction in incontinence, and 45% were completely dry.<sup>22</sup>

## RECENT EVIDENCE

PTNS trials reported as of February 2005 are summarized in Table 23-1. Klingler and coworkers were the first European group to report results, having treated 15 OAB patients (11 women) with 12 weekly SANS sessions. They documented follow-up at a mean of 11 months. All patients enjoyed a reduction in pelvic pain (statistically significant reduction in visual analogue scale from a mean of 7.6 to 3.1). Mean diurnal frequency fell from 16.1 to 4.4 episodes, and nocturnal frequency from 8.3 to 1.4 episodes. Seven patients (47%) were considered to have complete responses ( $\leq 8$  voids/day,  $\leq 2$  voids/night, subjective “cure”); three (20%)

were improved (8 to 10 voids/day,  $>2$  voids/night, subjective “cure”); and five (33%) failed to respond ( $>10$  voids/day,  $>2$  voids/night, subjective “unchanged”). Significant increases were seen in bladder capacity measurements; maximum flow rate and maximum detrusor pressure decreased somewhat. This study is the only one to date to report cost data. SANS treatment for each patient cost €895 (US\$770), compared to €10,290 (US\$8849) for implantation of the Medtronic InterStim device.<sup>23</sup>

Three centers in the Netherlands collectively enrolled 49 patients (34 female, 15 male) over a 5-month period; 37 enrollees had OAB, and 12 had nonobstructive retention (detrusor hypocontractility urodynamically confirmed). Patients were treated

**Table 23-1 Trials of Percutaneous Tibial Nerve Stimulation**

First Author and Ref. No.	Year	Primary Symptoms	N	Criteria	Key Findings
Stoller <sup>22</sup>	1998	Frequency, incontinence, pelvic pain	98	Decrease in frequency, pain	Statistically significant improvement in diurnal and nocturnal frequency; 80% of patients had 75% reduction in incontinence
Klingler <sup>23</sup>	2000	OAB	15	Urgency, voiding diary, urodynamics, pelvic pain	$>50\%$ reduction in mean pelvic pain score; decrease in mean diurnal and nocturnal frequency from 16 and 4 episodes to 8 and 1 episodes, respectively
Govier <sup>29</sup>	2001	Refractory OAB	53	$>25\%$ reduction in diurnal/nocturnal voiding frequency	71% of patients met success criteria ( $P < .05$ )
Van Balken <sup>24</sup>	2001	OAB, nonobstructive retention	49	Frequency, nocturia, voided volumes, HRQOL	OAB patients: mean 17% reduction in frequency, 38% reduction in nocturia; increased voided volumes; improved HRQOL. Retention patients: modest, nonsignificant improvements in voided volumes and catheterization episodes
Vadoninck <sup>26</sup>	2003	OAB	90	Frequency, incontinence, HRQOL, urodynamics	Decrease in 24-hour frequency from 13 to 10 and in incontinence episodes from 5 to 2 daily; improved bladder capacity but no overall improvement in detrusor instability
Vandoninck <sup>25</sup>	2003	Urge incontinence	35	Incontinence episodes, frequency, nocturia, HRQOL, pad use	Median incontinence episodes per day reduced from 5 to 1; 16 patients completely dry; significant decreases in nocturia and pad use and improvements in HRQOL
Vandoninck <sup>27,28</sup>	2003	Nonobstructive urinary retention	39	Daily catheterizations, residual volume, voided volume, HRQOL	Decrease in mean catheterizations from 2.5 to 2.0 and in residual volume from 241 to 163 mL; improvements in HRQOL, especially incontinence-specific QOL.
Van Balken <sup>34</sup>	2003	Chronic pelvic pain	33	Visual analogue pain scale, HRQOL	$\geq 50\%$ reduction in pain score in 21% of patients, 25%-50% reduction in 18%; improved SF-36 scores
Shafik <sup>36</sup>	2003	Fecal incontinence	32	HRQOL questionnaire, rectometric parameters	Improvement in 78% of patients by fecal incontinence questionnaire
Congregado Ruiz <sup>45</sup>	2004	Frequency/urgency, urge incontinence	51	HRQOL, voiding diaries	Statistically significant improvements in frequency/urgency, HRQOL, and pain

HRQOL, health-related quality of life; OAB, overactive bladder; QOL, quality of life.

with 12 weeks of SANS. The results were positive and statistically significant<sup>24</sup> but considerably more modest than those reported by Klingler and colleagues.<sup>23</sup> Among the OAB cohort, diurnal frequency was reduced by an average of 2.8 episodes, to 16.5 times per day, and nocturnal frequency was reduced by 1 to 2.6 episodes per night. Voided volumes were also increased, and patients reported significant improvements in both general and incontinence-specific health-related QOL. Among the patients with retention, mean voided volumes increased slightly, and number of catheterizations decreased, but these findings were not significant.<sup>24</sup>

The same group later expanded to five sites in the Netherlands and one in Italy and has published three additional papers, focusing, respectively, on urge incontinence,<sup>25</sup> OAB,<sup>26</sup> and nonobstructive retention.<sup>27</sup> A total of 164 patients were treated. Vandoninck and coworkers reported the largest single cohort of patients treated with PTNS to date, accruing 90 consecutive OAB patients (67 female, 23 male) to 12 weekly stimulation sessions. The 24-hour frequency decreased from a mean of 13 to 10 episodes, leakage episodes decreased from a mean of 5 to 2 daily, and mean voided volume increased from 135 to 191 mL (all statistically significant results). Health-related QOL scores also improved significantly. Among 46 patients undergoing urodynamic profiling both before and after PTNS, mean cystometric bladder capacity increased from 243 to 340 mL. The proportion of patients with detrusor instability (70%) did not change, but the volume at which instability was triggered increased from 133 to 210 mL. Also of note, improvement in urodynamic parameters significantly predicted treatment success in terms of subjective improvement.<sup>26</sup>

Thirty-five patients (25 women) with documented urge incontinence received the same 12 weeks of PTNS and had, on average, more dramatic responses. The median baseline number of incontinence episodes was 5 per day. After treatment, this median fell to 1 episode per day, and 16 patients had no leakage episodes. Nocturia likewise decreased from a median of 2 to 1 per night, and pad use declined from a median of 3.5 daily to none. Health-related QOL once again improved. Thirty-one percent of these patients decreased their 24-hour voiding frequency to eight episodes or less. There was a trend toward greater likelihood of subjective improvement with increased stimulation intensity in terms of amperage.<sup>25</sup>

Finally, these authors accrued 39 patients (27 women) with chronic nonobstructive urinary retention to 12 weeks of PTNS. The mean number of catheterizations decreased from 2.5 to 2.0 per day, and the mean catheterized (residual) volume decreased from 241 to 163 mL; the total voided volume increased accordingly. Forty-one percent of patients had a 50% or greater reduction in catheterized volume. Seven patients reduced their catheterization frequency to once daily; two of these patients had no residual urine on frequency-volume charts, but no patient became consistently catheter-free. Once again, both overall and incontinence-specific health-related QOL increased significantly. Contrary to this group's experience with urge-incontinence patients, however, increased amperage in urinary retention patients *decreased* the likelihood of positive subjective success.<sup>27</sup> In a companion paper focusing on urodynamic findings in this cohort, the authors reported that, on multivariate analysis, four pretreatment urodynamic parameters—maximal detrusor pressure, maximal flow rate, bladder voiding efficacy, and bladder contractility index—predicted subjective success on PTNS, with an area under the curve of 0.73.<sup>28</sup>

In the United States, only one experience with PTNS has been reported to date. Govier and associates reported their results from a prospective, multicenter trial at five medical centers, including 53 patients (48 women, mean age 57 years) with OAB refractory to all standard treatments, which they treated with weekly bilateral SANS sessions. Eighty-nine percent of patients completed the 12-session study. Seventy-one percent of patients met the study goal of at least a 25% reduction in diurnal and/or nocturnal urinary frequency, with the mean reductions in diurnal, nocturnal, 24-hour, and excess (>10 episodes/day) frequency being 25%, 21%, 22%, and 70%, respectively (all  $P < .05$ ). On standardized questionnaires administered during the study, study participants reported a mean 35% improvement in urge incontinence episodes, a 30% improvement in pain, and a 20% improvement in incontinence-related QOL (all  $P < .05$ ). The authors did not report longer-term efficacy results. There were no serious adverse events. One patient each experienced moderate pain at the needle site, moderate right foot pain, and stomach discomfort; all of these symptoms resolved spontaneously.<sup>29</sup>

None of these studies examined either survey- or urodynamic-based *acute* effects of PTNS. One paper, however, reported on the acute urodynamic effects of TTNS in 44 patients with OAB. During stimulation, mean first involuntary detrusor contraction occurred at 232 mL of filling, compared with 163 mL at baseline. Maximum cystometric capacity likewise increased, from 221 to 277 mL. Only 50% of these patients had an acute positive response during stimulation in terms of either increased volume at first involuntary detrusor contraction or total cystometric capacity.<sup>30</sup>

#### PTNS FOR NONURINARY MANIFESTATIONS OF PELVIC FLOOR DYSFUNCTION

To date, PTNS has been studied primarily in patients with OAB, urge incontinence, and detrusor hypocontractility. However, increasing evidence supports the use of this modality for other indications referable to PFD, many of which have been previously validated in studies of central stimulation. Van Balken and coworkers treated 33 patients (22 male) who had chronic pelvic pain with 12 weeks of PTNS. Twenty-one percent of these patients experienced at least 50% improvement in pain as assessed by the visual analogue scale; an additional 18% experienced improvement of 25% to 50%. Among the 14 (42%) subjective responders (i.e., those who requested continued treatment), the mean pain score fell from 5.9 (range, 4.5 to 7.3) to 3.7 (range, 2.7 to 5.2). The authors also reported improvement in several domains of the Medical Outcomes Study Short Form-36 (SF-36), including role physical, physical functioning, pain, change of health, and overall score.<sup>31</sup>

Andrews and Reynard reported a single case of a patient with detrusor hyperreflexia resulting from a T8 spinal cord injury whose bladder capacity doubled, from 150 to 165 mL at baseline to 310 to 320 mL with PTNS.<sup>32</sup> Finally, Shafik and colleagues applied 4 weeks of PTNS treatment using the SANS device every other day to 32 patients (22 women) with fecal incontinence refractory to standard treatments, which was caused either by uninhibited rectal contractions (26 patients) or by anal sphincter relaxation (6 patients). They reported improvement in 78%; after treatment, eight patients relapsed, and six of these responded to repeated PTNS therapy.<sup>33</sup>

Further tangential evidence for the efficacy of PTNS in the management of nonurinary PFD symptoms can be found in

small studies of traditional acupuncture and acupressure treatments at the Sp-6 site. Acupuncture at this point has been shown to stimulate labor and to ameliorate labor pains<sup>34</sup>; acupressure has been used for symptoms of acute cystitis, and it was used successfully to alleviate the pain of primary dysmenorrhea in the majority of a cohort of young women.<sup>35</sup> For this latter indication, growing evidence supports the use of transcutaneous neurostimulation at Sp-6 and other sites for greater efficacy.<sup>36</sup>

## CONCLUSIONS AND FUTURE DIRECTIONS

In a recent review of various techniques of neurostimulation, central and peripheral, for bladder dysfunction, Van Balken and colleagues estimated the overall intent-to-treat success of these modalities at 30% to 50%.<sup>37</sup> Results achieved to date with PTNS should be considered in relation to anticholinergic medications, which constitute the “gold standard” treatment for many of the symptoms related to PFD.

In the largest trial to date of women with OAB, Swift and associates<sup>41</sup> reported on 417 women treated with extended-release tolterodine. They found a 53% reduction in incontinence episodes, from a mean of 3.2 to 1.5 per day, and a 16% drop in 24-hour frequency, from 10.8 to 9.0 voids. These results were statistically significantly better than those realized among the 410 women treated with placebo, whose incontinence episodes and 24-hour frequency fell by 30% and 12%, respectively. The results of Vandoninck and colleagues, described earlier, compare favorably, with a 60% reduction in incontinence episodes and a 23% drop in frequency.<sup>26</sup> The increase in mean voided volume was likewise higher with PTNS (from 135 to 191 mL, for a 41% increase)<sup>26</sup> and with tolterodine (from 141 to 179 mL, for a 26% increase) than with placebo (from 136 to 149 mL, for a 10% increase).<sup>41</sup> Although the PTNS studies were less rigorously designed and less powerful statistically than the larger pharmaceutical trials, it should be stressed that PTNS studies universally have been conducted among patients whose PFD symptoms are refractory to standard therapy, including oral anticholinergic medications; the results of PTNS might therefore be better still among unselected, treatment-naïve cohorts, who have yet to be treated with neurostimulation in the context of a published study.

Side effects of treatment are an important further consideration. Twenty-five percent of patients taking extended-release tolterodine complained of dry mouth, 40% of whom had moderate or severe symptoms. There was also a statistically significant increase in abdominal pain with extended-release tolterodine versus placebo (4.3% vs 1.7%).<sup>38</sup> In contrast, no major complications of PTNS have been reported in any of the studies published to date; indeed, even minor complications, such as persistent puncture site bleeding or pain, appear to be consistently rare. Puncture site infection has never been reported. PTNS may also be more cost-effective than chronic oral medication; Klinger reported a cost of \$770 for 12 weeks of PTNS and reported sustained improvement in voiding parameters at a mean of 11 months of follow-up.<sup>23</sup> By comparison, 11 months of tolterodine treatment would cost about \$1030.<sup>39</sup> Finally, if percutaneous neuromodulation fails, patients may still potentially benefit from central sacral neuromodulation; in pursuing a trial of PTNS, no bridges have been burned with respect to eligibility for or potential success of central stimulation. The principal advantages of PTNS are summarized in Box 23-1.

### Box 23-1 Key Advantages of Percutaneous Tibial Nerve Stimulation

- Efficacy is comparable to gold-standard pharmaceutical treatment.
- Nerve stimulation has a minimal side effect profile.
- The approach is cost-effective.
- PTNS does not preclude central neuromodulation or other treatments.

An implantable device currently under development, named the Urgent-SQ (Cystomedix, Andover, MN), combines the benefits of chronic, at-home therapy—currently offered only by the InterStim sacral stimulator—with the relatively low cost and minimal invasiveness of peripherally targeted neuromodulation. In an ongoing trial, patients with OAB, urge incontinence, and/or functional bladder retention who demonstrate successful responses to percutaneous neuromodulation will receive the Urgent-SQ implant, which consists of a small (<4 cm), round, implantable receiver incorporating an electrode placed under the perineurium of the posterior tibial nerve and a radiofrequency generator that can be worn externally on the lower leg (e.g., under a pant leg). The Urgent-SQ could be implanted with less morbidity than devices targeting the sacral cord; moreover, implantation in the ankle would be less emotionally challenging to patients than a device targeting the perineum or perirectal area, for example. This system would empower the patient to self-administer neurostimulation on an as-needed basis and to increase or decrease the frequency of treatment based on changes in his or her environment. Centrally placed neurostimulators are usually continuously activated, whereas PTNS has to date been administered intermittently. Whether continuous or intermittent stimulation is more effective in the context of a peripheral implantable device is unknown. In either case, however, an implantable device would certainly be expected to reduce the required frequency of physician visits.

A number of caveats must be raised with respect to the literature published to date on peripheral neuromodulation. Patient inclusion and exclusion criteria have been variable, as have been the metrics used to measure responses and the parameters to establish success. Published studies have reported wide variations in degrees of success, even when they used relatively objective measures such as diary-assessed frequency or incontinence episodes. A need clearly exists for randomized, sham-controlled trials using standardized, validated health-related QOL questionnaires in addition to diaries and urodynamic studies. Although urodynamics offers a measure of objectivity, it may not necessarily correlate with the health-related QOL outcomes most relevant to the patient. Sham-controlled trials could certainly be undertaken, with the “control” group treated either with needle placement but no stimulation or with needle placement and stimulation at a location removed somewhat from the properly targeted position; this was done successfully in at least one trial of transcutaneous neurostimulation.<sup>40</sup> Crossover designs would also be useful. Given the extremely good tolerability of PTNS, such trial designs should be ethically acceptable.

Peripheral neuromodulation is a technology still in the relatively early stages of development. How much additional benefit may be realized beyond 12 treatment sessions and the ultimate

durability of responses are among the questions about PTNS that have not yet been answered definitively. Although most research in the field has been reported only in the past few years, with few long-term data available, the results to date are exciting. Even if the initial response rates for PTNS are in fact lower than those for central neurostimulation, given the negligible risks and morbidity reported with PTNS, it would seem reasonable to offer this modality to all eligible patients, with those who do not respond remaining candidates for central sacral treatment. The anticipated availability of a peripherally implanted device offers the possibility of patient-controlled, chronic peripheral stimulation, which may produce even greater gains in the treatment of intractable PFD symptoms.

As described earlier, management of symptoms attributed to PFD already accounts for a large fraction of physician visits, with health care expenditures comparable to those of other major chronic ailments. Owing in large part to the aging of the population, demand for PFD management is expected to rise by an additional 45% over the next 30 years.<sup>41</sup> The high prevalence of undiagnosed PFD, discussed earlier, has left a large and growing reservoir of untreated patients, for whom the least invasive successful therapeutic modality would provide the best management. The ultimate standing of neuromodulation will be measured by its success in treating the diverse manifestations of PFD among those countless patients who need better options for improvement of their QOL.<sup>45</sup>

# PUDENDAL NERVE STIMULATION

*Richard C. Bennett and Kenneth M. Peters*

Pharmacotherapy is the mainstay of treatment for voiding dysfunction, but this modality of treatment has various degrees of effectiveness and is often associated with undesirable side effects. Alternatives to pharmacotherapy include pelvic floor exercises, biofeedback, and neuromodulation. Sacral nerve stimulation has been approved by the U.S. Food and Drug Administration (FDA) since 1997 for treatment of urinary urge incontinence, urgency, frequency, and refractory retention.

Contemporary sacral nerve root stimulation consists of implantation of a tined electrode in the S3 sacral foramen, with subsequent connection to an implantable pulse generator (IPG; InterStim, Medtronic, Minneapolis, MN). Sacral root neuro-modulation inhibits the micturition reflex through stimulation of spinal tract neurons and afferent pathways.<sup>1</sup> One limitation of the selection of S3 is that only one of the three afferent pathways inducing the inhibitory reflex is stimulated.

Selection of the pudendal nerve as a site of stimulation provides afferent stimulation of S2, S3, and S4. Afferent pudendal nerve stimulation can inhibit the micturition reflex, abolish uninhibited detrusor contractions, and increase bladder capacity in animals and humans.<sup>2-9</sup> Vodusek and colleagues<sup>5</sup> showed that detrusor contractions at low volumes of bladder filling were reduced or abolished by stimulating the dorsal penile or clitoral nerves transcutaneously in patients with spinal cord lesions. By stimulating the pudendal nerve close to the ischial spine using bipolar electrodes, Vodusek and coworkers<sup>5</sup> later reported electrical stimulation increased the micturition threshold and inhibited detrusor activity.

### ANATOMY OF THE PUDENDAL NERVE

The pudendal nerve originates from the S2, S3, and S4 sacral nerve roots. The main trunk of the pudendal nerve takes an extrapelvic course superficial to the coccygeus muscle. The main trunk passes over the ischial spine and enters Alcock's (pudendal) canal. In the upper half of the pudendal canal, the pudendal nerve gives rise to the inferior rectal nerve. The inferior rectal nerve exits the pudendal canal medially and extends motor and sensory branches. Motor branches innervate the levator ani, and the cutaneous branches innervate the perianal skin and the scrotum or labia. The inferior rectal nerve terminates in multiple branches to the external anal sphincter. At the end of the pudendal canal, the pudendal nerve gives rise to two branches, the perineal nerve and the deep dorsal nerve of the clitoris or penis. The deep dorsal nerve continues as a terminal branch to the penis or clitoris. The perineal nerve divides into the scrotal or labial branch and two muscular branches to the bulbocavernosus and the striated urethral sphincter.<sup>10,11</sup> The optimal point of pudendal nerve stimulation is at the level of the ischial spine, proximal to the branch points (Fig. 24-1).

### DEVICES AVAILABLE FOR PUDENDAL NERVE STIMULATION

The pudendal nerve can be stimulated on a chronic basis using a tined quadripolar lead (e.g., InterStim) or an implantable microstimulator (Bion, Advanced Bionics, Valencia, CA). Neither of these applications is FDA approved for pudendal stimulation. The development of a tined lead for sacral nerve stimulation allows implantation of the lead without suture fixation (Fig. 24-2). This feature makes it possible to deploy the lead at other sites, such as the pudendal nerve. The advantage is that the lead can be placed at the pudendal nerve by means of a posterior approach, externalized, and tested on an outpatient basis to assess the clinical response. If the patient demonstrates significant improvement in their voiding symptoms, a permanent IPG can be placed in a subcutaneous pocket in the upper buttock.

The Bion microstimulator is a miniature, self-contained, rechargeable, implantable neurostimulator that is designed as a platform technology and is intended to treat a wide variety of disorders through direct electrical stimulation. This device is approved in Europe for commercial use in pudendal nerve stimulation and is in clinical trials in the United States for urinary urge incontinence, urgency or frequency, and chronic headache. The fully integrated microstimulator contains a rechargeable battery, a radio transmitter, an antenna for bidirectional telemetry, a programmable microchip, and stimulating electrode. The implant is 28 mm long and 3.2 mm in diameter, and it has a mass of only 0.7 g (Fig. 24-3).

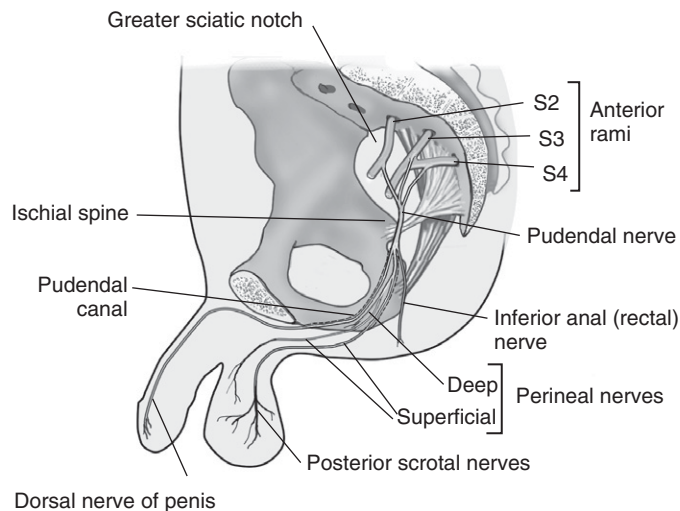

### PATIENT SELECTION

Chronic pudendal neuromodulation is not approved by the FDA for the treatment of voiding dysfunction. With appropriate informed consent, patients suffering from refractory voiding dysfunction, including urinary urgency, frequency, urge incontinence, and nonobstructive urinary retention, could be candidates for pudendal neurostimulation. Patients who had sacral nerve stimulation but did not respond may benefit from pudendal nerve stimulation. Other disease states that may be considered include interstitial cystitis and neurogenic bladder, including cases caused by partial spinal cord injury, multiple sclerosis, Parkinson's disease, and other neurologic disorders.

A complete voiding diary is paramount in the evaluation of the patient considering neuromodulation. The voiding diary evaluates the time of voids, voided volumes, incontinent episodes, urge scores, pain scores, bowel function, and catheterized volumes if in retention. This baseline information allows accurate postoperative evaluation of patient progress. Because these procedures can be done only "on protocol," appropriate Human

**Figure 24-1** Pudendal nerve anatomy.

**Figure 24-2** Tined quadripolar lead.

Investigation Committee approval is required, along with the patient's signature on an informed consent form.

## PROCEDURE

### Using the InterStim Tined Quadripolar Lead

#### *Preoperative Preparation and Patient Positioning*

Administer broad-spectrum intravenous antibiotics such as ampicillin and gentamycin. Place the patient in the prone position with appropriate padding and support. Provide light sedation with an agent such as Versed. Perform thorough Betadine preparation of the lower back, buttock, and anus. Place needle or patch electrodes at the external anal sphincter, and connect them to electromyographic device (Fig. 24-4). Use fluoroscopy to

**Figure 24-3** Bion microstimulator.

image the pelvis in the lateral position to identify the ischial tuberosity and ischial spine (Fig. 24-5).

#### *Identification of the Pudendal Nerve*

Palpate the ischial tuberosity posteriorly, and anesthetize the skin 1 cm medial to the tuberosity with 1% lidocaine. Advance a 5.5-inch foramen needle through the skin toward the ischial spine. Stimulate the proximal end of the foramen needle with the standard clip-on stimulating cord (Fig. 24-6). Begin stimulation at 1 Hz, and slowly increase the power from 1 mA to 10 mA while

**Figure 24-4** Electromyographic electrode at the external anal sphincter.

**Figure 24-5** Lateral radiograph of the sacral and pudendal quadripolar leads.

**Figure 24-6** Stimulation of the foramen needle near the ischial spine.

**Figure 24-7** Compound muscle action potential, consistent with pudendal nerve stimulation.

**Figure 24-8** A quadripolar lead is advanced through the lead introducer.

examining the anal sphincter and monitoring the electromyographic tracing. The typical motor response is contraction of the external anal sphincter. This should be confirmed as pudendal stimulation by seeing a classic compound muscle action potential (CMAP) consistent with pudendal stimulation (Fig. 24-7). Assess the patient's sensory response. A typical response is comfortable pulsating in the vagina, scrotum, perineum, or rectum. The nerve of the obturator internus sits close to Alcock's canal; be certain there is no leg rotation noted during the acute testing. If leg movement is seen, reposition the needle until only the pudendal stimulation is identified.

#### *Placement of the Quadripolar Tined Lead*

After the pudendal nerve is identified, advance the directional guidewire, and remove the foramen needle. Make a small skin nick alongside the wire. Advance the lead introducer over the directional guidewire toward the ischial spine using fluoroscopy. The proximal metal trocar of the lead introducer can be stimulated with the standard stimulation cord. Reconfirm pudendal stimulation, advance the quadripolar lead through the lead introducer, and test each electrode in the standard fashion (Fig. 24-8). The ideal placement is identification of pudendal stimulation on all four electrodes. Deploy the tines by removing the lead introducer.

#### *Externalizing the Percutaneous Extension Lead*

The current quadripolar lead is too short to reach the upper buttock where a future IPG will be placed. The lead is tunneled

to a 1-cm, midbuttock incision and connected to the temporary percutaneous extension lead. This lead is tunneled out the contralateral side and externalized. A redundant lead is placed in a subcutaneous pocket underneath the skin, and the incision is closed.

### Stage I Test

Patients are discharged with the standard Medtronic stimulation box, and stimulation is set to a comfortable sensation for the patient. Voiding diaries are kept for 7 to 14 days, and if a 50% or greater improvement occurs, the lead is connected to an IPG. If no improvement occurs, the lead is explanted.

### Implantation of the Implantable Pulse Generator or Removal of the Lead

If the subject does not respond to the stimulation, the midbuttock incision is opened, and the tined lead is removed by gentle traction. If an IPG is to be placed, a standard site is chosen on the upper buttock, and a subcutaneous pocket is created. A 25-cm extension lead is attached to the IPG and tunneled to the midbuttock incision. The tined lead is freed from this incision, and the percutaneous extension lead is removed. The distal end of the 25-cm IPG extension is connected to the proximal end of the tined lead in the standard fashion. The lead and its connector are placed in the subcutaneous pocket of the midbuttock.

### Outcomes of Pudendal Stimulation Using a Tined Quadripolar Lead

A direct comparison of the efficacy of pudendal and sacral nerve stimulation has been completed. This was a randomized, single-blinded, single-center trial in which each subject had a sacral lead and a pudendal lead placed as part of an approved protocol. Subjects were randomized to begin stimulation on the sacral or pudendal electrode. In a blinded fashion, each lead was tested for 7 days. Voiding diaries and questionnaires were completed. Subjects rated their percent improvement on each lead and chose the one to be implanted to a permanent generator based on response. Analysis of the data demonstrated the time to place the sacral lead was 25.85 minutes compared with 23.71 minutes for the pudendal lead ( $P = .57$ ). Twenty-four (80%) of 30 of subjects responded and had an IPG implanted, with 19 (79.2%) of 24 choosing pudendal stimulation and 5 (20.8%) of 24 choosing sacral stimulation. The order in which the lead was stimulated had no impact on the final lead implanted. Pudendal nerve stimulation produced significantly higher rates of improvement of symptoms than sacral nerve stimulation: 51% versus 37%, respectively ( $P = .02$ ). On a 7-point scale from markedly worse to markedly better, pudendal nerve stimulation was superior to sacral nerve stimulation for pelvic pain ( $P = .024$ ), urgency ( $P = .005$ ), frequency ( $P = .007$ ), and bowel function ( $P = .049$ ). This preliminary study demonstrated that pudendal nerve stimulation is feasible, safe, and effective using a tined quadripolar lead.<sup>12</sup>

### Pudendal Nerve Stimulation Using the Bion Microstimulator

The Bion neurostimulator is placed at Alcock's canal in a minimally invasive fashion through a small incision in the perineum. Its stimulation parameters can be adjusted using a physician programmer, and patients have their own remote control for adjustment of the level of stimulation. The battery is recharged

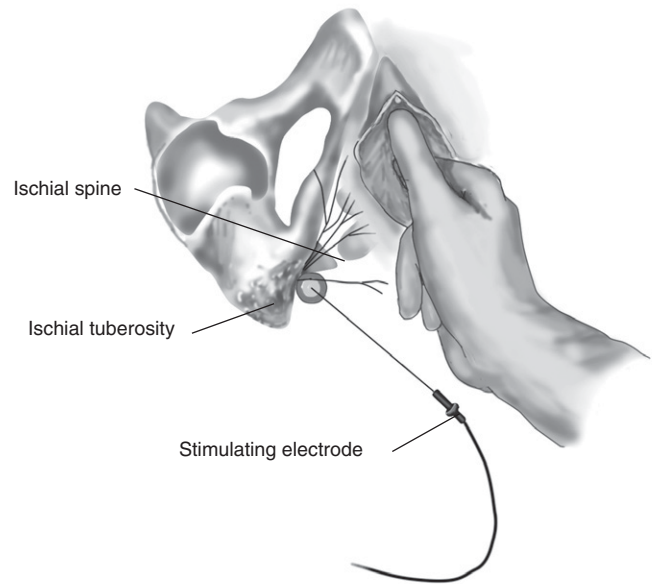

Figure 24-9 Percutaneous screening test.

by sitting on a charging pad daily for 20 to 60 minutes, and the battery life is 15 to 20 years.

### Percutaneous Screening Test

Before implantation of a permanent Bion, a percutaneous test is performed in the office. The patient is placed in the lithotomy position at a 45-degree angle, and the vagina and perineum are prepared and draped in the normal, sterile fashion. Surface electromyographic electrodes are placed at the anal sphincter. A computerized cystometrogram is performed at a fill rate of 25 mL/min while measuring the volume at first sensation, first urge, maximum cystometric capacity, and first unstable contraction. Next, the ischial tuberosity is palpated and marked with a marking pen. The ischial spine is palpated through the vagina or rectum (i.e., site of Alcock's canal). The skin is anesthetized approximately 1.5 cm medial to the ischial tuberosity. With a finger in the vagina or rectum palpating the ischial spine, a stimulating needle is advanced through the perineum toward the ischial spine while applying electrical stimulation (Fig. 24-9). CMAPs are measured. Muscle contractions are assessed by direct vision and palpation. A good response is contraction of the bulbocavernosus muscle and external anal sphincter. A poor response includes contraction of the obturator internus, leg adductors, or lower extremity muscles. The sensory response is determined, and a pulsating or tingling in the vaginal, vulvar, or anal regions is optimal. Poor responses include leg or foot twitching or pain. After needle placement is confirmed, the pudendal nerve is stimulated for 15 minutes at a pulse frequency of 20 Hz, pulse width of 200  $\mu$ s, 50% duty cycle, and pulse amplitude up to 10.0 mA. The bladder is emptied with a catheter, and the urodynamic catheter is replaced. The cystometrogram is repeated while stimulation continues. A 50% increase in the volume of first sensation, first urge, cystometric capacity, or at unstable bladder contraction constitutes a positive test result supporting implantation of the permanent Bion device.

### Implantation of the Bion

Preoperative, broad-spectrum antibiotics are administered. The patient is brought to the operating room, lightly sedated, and

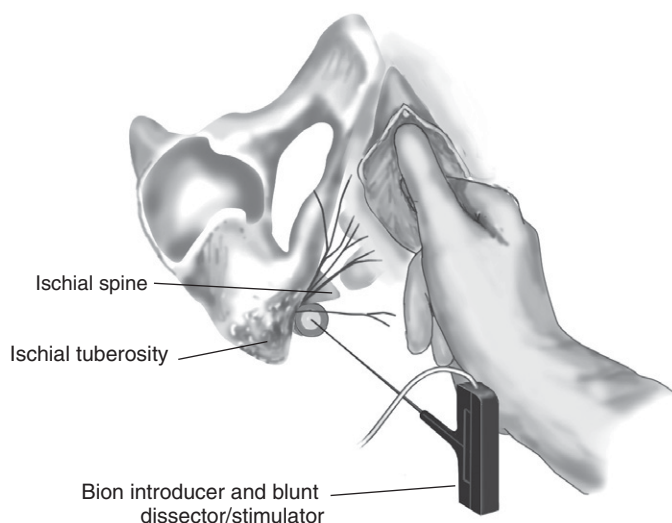

**Figure 24-10** Implantation tools. (Courtesy of Advanced Bionics, Valencia, CA)

placed in the lithotomy position. The perineal area is prepared and draped in the normal, sterile fashion. Surface electromyographic electrodes are placed on the outside of the anal sphincter and connected to an electrodiagnostic monitor. The medial aspect of the ischial tuberosity is marked, the skin is infiltrated with 1% lidocaine approximately 1.5 cm medial to the tuberosity, and a 2- to 3-mm incision is made. The Bion implantation tools include a blunt dissector or stimulator, introducer, Bion holder, and placement device (Fig. 24-10). With a finger palpating the ischial spine through the vagina or rectum, the blunt dissector and introducer are inserted together toward the target (Fig. 24-11). Fluoroscopy in the lateral position can help direct the Bion toward the ischial spine. Clinical and electrophysiologic responses facilitate placement as described previously. After the pudendal nerve is confirmed, the blunt dissector is removed, leaving the introducer in place. The Bion in its holder is advanced through the introducer, and the placement tool is advanced through the Bion holder and locked in place by rotating clockwise until it “clicks” into place. The Bion is turned on and activated with a frequency of 20-Hz, pulse width of 200  $\mu$ s, continuous duty cycle, and amplitude 5 to 10 mA. Sensory, motor, and electrodiagnostic responses are assessed. After the location is optimized, the Bion is delivered by retracting the Bion holder. Retraction is performed by turning the thumbscrew clockwise until it can be turned no further. This deposits the Bion at the site of stimulation. The Bion is deactivated, the introducer is removed, and a Steri-Strip is placed over the skin incision site.

### Postoperative Follow-up

One week after implantation, the patient returns to the office for programming of the Bion and for education regarding the system components. The clinician’s programmer communicates with the Bion and allows the stimulator to be activated and adjusted.

**Figure 24-11** Implantation of Bion microstimulator.

Possible adjustments include frequency, pulse width, burst mode, and stimulation limits. The programmer monitors battery life, records the time the device was activated, and gives a history of recharging events. The patients have their own home kit consisting of a remote control, base station or charger, and chair pad used to charge the Bion. The Bion should last 15 to 20 years and can be recharged even if the battery is allowed to completely deplete. The benefit of the Bion is its small size and the minimally invasive approach to implantation. Results of clinical trials will determine its future in treating voiding dysfunction.

## CONCLUSIONS

The use of neuromodulation has led to a major advance in our ability to treat patients suffering from voiding dysfunction who have been refractory to standard therapies. In the past, these patients continued to suffer from their disease or underwent irreversible operations such as bladder augmentation or urinary diversion to control their symptoms. Neuromodulation continues to be developed, and the pudendal nerve appears to be a safe and effective area to stimulate. Ongoing studies are assessing the feasibility of placing a tined quadripolar lead or the Bion microstimulator at the pudendal nerve. More patients and longer-term follow-up are needed before this approach is considered standard of care.

# DETRUSOR MYOMECTOMY

Linda Ng and Edward J. McGuire

Bladder augmentation has been used in a spectrum of clinical settings in which bladder dysfunction is refractory to more conservative treatment. Enterocystoplasty and gastrocystoplasty offer a reliable improvement in bladder compliance and capacity, decreased rates of upper urinary tract deterioration, and improved quality of life for patients. However, early and late complications related to incorporation of bowel segments in the urinary tract are many, cumulative, and well known. They include bowel contractions leading to incontinence, bowel obstruction, diarrhea syndromes, spontaneous perforation, abundant mucus production leading to stones, chronic bacteriuria, electrolyte imbalances, and the hematuria and dysuria syndrome (if a gastric segment is used).<sup>1-3</sup> Use of bowel segments may also place the patients at risk for future malignancies.<sup>4,5</sup>

Detrusor myomectomy, also known as bladder autoaugmentation, is a simpler, less morbid alternative to enterocystoplasty. Autoaugmentation, as described by Cartwright and Snow<sup>6-8</sup> in 1989, involves excising a portion of the detrusor muscle, allowing the bladder epithelium and lamina propria to form a large-mouthed bladder diverticulum. As the urothelium bulges through the muscular hiatus, bladder capacity is increased, intravesical storage pressures are reduced, and the volume at which a contraction occurs becomes larger. Because only bladder tissue is used in this technique, the risks associated with gastrointestinal segment incorporation into the urinary tract are obviated.

### PATIENT SELECTION

In patients with bladder dysfunction, the first line of treatment is anticholinergic medications,  $\alpha$ -blocking agents, tricyclic antidepressants, and timed voiding or intermittent catheterization. Surgical intervention is appropriate when patients fail to respond clinically, develop upper tract compromise, or persistent compliance abnormalities. Video urodynamics is performed preoperatively for all patients to evaluate bladder storage and urethral continence function.<sup>9</sup> The cystometric volume at an intravesical pressure of 40 cm H<sub>2</sub>O is recorded. In general, enterocystoplasty remains the better procedure for patients with poorly compliant, extremely small-capacity bladders because bladder capacity is increased to a lesser degree after detrusor myomectomy. However, detrusor myomectomy offers many advantages in certain patients in whom bowel complications would exacerbate comorbid conditions, including those who have had prior abdominal surgery, patients with bowel diseases, those with short gut or malabsorption syndromes, and those with prior episodes of peritonitis associated with ventriculoperitoneal shunts. We feel that myomectomy should be the first line of surgical therapy for idiopathic detrusor instability. Bladder autoaugmentation does not preclude a subsequent enterocystoplasty if it is necessary.

### PATIENT PREPARATION

Patients with neuropathic lower urinary tract dysfunction require intermittent catheterization after myomectomy. Patients with idiopathic, non-neurogenic bladder contractile incontinence do not require intermittent catheterization after myomectomy. Patients with a low-compliance bladder related to radiation therapy or chemotherapy usually require intermittent catheterization after myomectomy.<sup>9,10</sup> Selected patients are informed that a conventional enterocystoplasty can be performed if detrusor myomectomy is not a technical option intraoperatively. This option is discussed in detail before the operative date so that mechanical and antibiotic bowel preparation can be performed before surgery in these selected patients. Preoperative intravenous antibiotics are also administered.

### DETRUSOR MYOMECTOMY TECHNIQUE

The technique employed is modified from the original description by Cartwright and Snow.<sup>6-8</sup> A two-way urethral catheter is placed so that bladder filling and emptying can be readily controlled, and a lower Pfannenstiel incision is made (Fig. 25-1). The rectus muscles are then separated in the midline, the prevesical space is entered (Fig. 25-2), and the dissection is continued until the bladder wall proper is cleared of adventitia (Fig. 25-3). Care is taken to sweep the peritoneum off the bladder dome. The

**Figure 25-1** A two-way catheter is placed to control bladder filling and emptying. A Pfannenstiel incision is then made. (From McGuire E: Pubovaginal slings. In Hurt MG [ed]: *Urogynecologic Surgery*. New York, Raven Press, 1992, pp 97-105.)

**Figure 25-2** The prevesical space is entered after separating the rectus muscles in the midline. (From McGuire E: Pubovaginal slings. In Hurt MG [ed]: Urogynecologic Surgery. New York, Raven Press, 1992, pp 97-105.)

**Figure 25-4** The detrusor muscle layer is then stripped, revealing bulging mucosa (arrow). (From McGuire E: Pubovaginal slings. In Hurt MG [ed]: Urogynecologic Surgery. New York, Raven Press, 1992, pp 97-105.)

**Figure 25-3** The bladder wall proper is cleared of adventitia (arrow). (From McGuire E: Pubovaginal slings. In Hurt MG [ed]: Urogynecologic Surgery. New York, Raven Press, 1992, pp 97-105.)

bladder is then distended, and a no. 15 blade is used to carefully divide the detrusor muscle until the bladder mucosa protrudes from the muscle. A combination of gentle traction and sharp dissection is used to strip the entire detrusor muscle layer covering the dome and anterior wall, denuding the underlying bladder mucosa (Fig. 25-4). During the procedure, changing bladder volumes may help to maximize exposure of the plane of dissection between detrusor and urothelium. If the dissection becomes difficult in a particular area, it is best to move on to an easier adjacent area. Ultimate care is taken to avoid perforation of the bladder mucosa because outcomes are much less satisfactory if this happens. As the procedure progresses, distinct bulging of the mucosal layer should occur. Palpation reveals a loose elastic mucosa surrounded by tense, rather rigid musculature. Autoaugmentation generally involves removing the detrusor from at least

one third of the bladder. A urethral catheter is left to provide gravity drainage for 1 to 2 days.

#### POSTOPERATIVE MANAGEMENT

After detrusor myomectomy, the patient is left with an exposed area of thin mucosa that bulges from the bladder with filling. Some surgeons have advocated protection of the mucosal diverticulum with a layer of peritoneum, omentum, or rectus muscle; however, we feel this is unnecessary. Patients who perform intermittent catheterization return to their preoperative routine, and patients on anticholinergic agents maintain their medical regimen. After the diverticulum created by the myomectomy matures, the interval between intermittent catheterization can be increased. Anticholinergic therapy is tapered after follow-up urodynamics reveals improved compliance. Prophylactic antibiotics are used only until removal of the catheter. Patients are seen for follow-up evaluation approximately 3 weeks after detrusor myomectomy. At this time, wound checks are performed, and a thorough interim history is obtained, including the status of “dryness” between intermittent catheterizations or the voiding history. Patients are not evaluated with video urodynamics until 3 months after surgery. An accurate assessment of myomectomy results is feasible at this time.<sup>11,12</sup>

#### CLINICAL OUTCOME OF DETRUSOR MYOMECTOMY

In the first series of 25 pediatric patients undergoing autoaugmentation in 1989, Snow and Cartwright<sup>6,7</sup> reported an overall good result for 52%, acceptable result for 28%, and poor result for 20%. In most patients, bladder compliance was improved, although bladder capacity changes varied. In one half of their patients, capacity increased by only 0% to 25%. In the other half, capacity increased by 5% to 150%. Fifty-eight percent of incontinent patients became dry, and 63% of patients with preopera-

tive hydronephrosis had improvement in their upper tract status.

Experiences from other institutions have been reported for adult patient populations. Kennelly and associates<sup>10</sup> described a series of five adult patients undergoing autoaugmentation. There was an increase in bladder capacity of 40% to 310%, and detrusor compliance improved in all patients. Total continence was achieved in three of five patients, and all were able to extend the interval between catheterizations. Stohrer and colleagues<sup>11</sup> reported their experience in 29 patients with neurogenic and non-neurogenic voiding dysfunction. Their results were generally positive, with increases in bladder capacity, decreased maximal voiding pressure, and improvements in compliance. Outcome was rated subjectively as excellent for 16 patients, good for 8, and improved for 1. In a later study of 50 patients with neurogenic voiding dysfunction, similar efficacy after bladder autoaugmentation was described.<sup>12</sup>

Leng and coworkers<sup>9</sup> compared operative outcomes of 37 patients undergoing detrusor myomectomy with those of 32 patients who had an enterocystoplasty. For comparison, the cases were categorized into six diagnostic subsets: intractable detrusor instability, interstitial cystitis with low-compliance bladder, myelodysplasia, radiation cystitis, neurogenic bladder dysfunction, and other. Preoperative upper tract deterioration was present in 14 patients. Results were stratified for each of the six diagnostic subsets. In 10 patients with idiopathic, overactive bladder incontinence, 8 demonstrated urodynamic improvement, 1 continued to require intermittent catheterization, and 1 failed and went on to augmentation cystoplasty. In the myelodysplasia subgroup, 5 (45%) of 11 patients who underwent detrusor myomectomy exhibited satisfactory urodynamic improvement. This suggests that enterocystoplasty may be superior in some patients with myelodysplasia. MacNeily and associates<sup>13</sup> reported similar findings for 17 patients with

myelomeningocele undergoing autoaugmentation. Based on their data, they concluded that short-term reports after autoaugmentation do not appear durable in this patient population. Leng and colleagues<sup>9</sup> reported improved urodynamic findings in three of nine patients with radiation cystitis who underwent myomectomy as a primary procedure. The overall success rate of primary detrusor myomectomy was 73%, with most failures proceeding to enterocystoplasty. Costs for surgery and length of hospitalization are much less for myomectomy than enterocystoplasty. A minor complication rate of 3% was seen in the myomectomy group compared with a major complication rate of 22% for patients treated with primary enterocystoplasties.

Further refinement of the autoaugmentation technique may lead to an improvement in its success rate and a reduced length of operative time, length of hospitalization, and rate of complications. Several investigators have proposed laparoscopic autoaugmentation, but long-term follow-up is still limited.<sup>14-16</sup>

## CONCLUSIONS

Since its introduction in 1989, detrusor myomectomy has gained increasing acceptance as a successful method of managing bladder dysfunction. However, patient selection remains key. In particular, patients with idiopathic detrusor instability treated with detrusor myomectomy had equivalent success rates. In other patient subsets, however, it is clear that in regard to increased bladder capacity, myomectomy is still inferior to conventional enterocystoplasty. Overall, myomectomy offers a minimally morbid surgical option for the high-risk surgical candidate who cannot tolerate the rigors of major bowel surgery or its potential complications. The recent trend in laparoscopic bladder augmentation may lead to further success of the technique and improvements in outcome.

# BLADDER AUGMENTATION

Linda Ng and Edward J. McGuire

Bladder augmentation has evolved since the initial report in 1899 by Mikulicz,<sup>1</sup> who first described the use of gastrointestinal tract segments for lower urinary tract reconstruction. In large part, this resulted from the introduction of clean intermittent catheterization,<sup>2</sup> the poor long-term results associated with the ileal conduit,<sup>3</sup> realization about the importance of detubularization,<sup>4</sup> and the importance of the role of bladder storage pressures in determining upper tract function.<sup>5</sup> Augmentation cystoplasty with various intestinal segments has become an accepted reconstructive option for intractable incontinence and poor bladder compliance in many neuropathic and non-neuropathic disorders.<sup>6</sup> Patient factors then guide individual selection of the augmentation method used.

### INDICATIONS

The main indications for bladder augmentation are the presence of upper tract deterioration caused by high detrusor pressures at reduced bladder capacity and incontinence resulting from idiopathic detrusor instability. Compromised bladder capacity may be seen in patients with spina bifida, spinal cord injury, multiple sclerosis, or congenital conditions such as bladder exstrophy and its variants. Less common causes of reduced bladder capacity include chronic, interstitial, or radiation cystitis. Preoperative urodynamic studies should demonstrate a low-capacity, high-pressure bladder that is refractory to optimal medical management and intermittent catheterization.<sup>7</sup> When the native urethra is destroyed or cannot be catheterized, a continent catheterizable or an incontinent stoma to the augmented bladder or native bladder can be used. The options for bladder augmentation are intact gastrointestinal segments, seromuscular gastrointestinal segments, augmentation with tissue-engineered urothelium, autoaugmentation, and ureterocystoplasty. Various pros and cons are associated with each of these methods.

### AUGMENTATION USING GASTROINTESTINAL SEGMENTS

#### Augmentation Technique

Enterocystoplasty with ileum or colon is the most commonly used procedure for vesical augmentation. Patients are admitted overnight (i.e., non-neurogenic cases) or 2 days earlier (i.e., neurogenic cases) for a complete mechanical and antibiotic bowel preparation. Intraoperatively, the ileoplasty is fashioned from 25 to 30 cm of ileum at least 15 cm from the ileocecal valve (Fig. 26-1). The segment of chosen bowel on its mesentery should be tested to ensure that it reaches the deep pelvis easily (Fig. 26-2). Using a hand-sewn or stapled technique, an enteroenterostomy is performed. The closed ileal segment is then detubularized at

the antimesenteric border, beginning and ending approximately 2 cm from the closed ends (Fig. 26-3). The two adjacent borders of detubularized ileum forming what will be the posterior wall of the ileocystoplasty are then sutured with 2-0 Vicryl (Fig. 26-4). At this point, the bladder is distended with saline, and the overlying peritoneum is stripped from the posterior and superior surfaces (Fig. 26-5). A transverse “smile” incision is then made approximately 3 cm above the ureteral orifices, creating an anteriorly based detrusor flap.<sup>6</sup> The small bowel is sutured to the

**Figure 26-1** The ileoplasty is fashioned from 25 to 30 cm of ileum at least 15 cm from the ileocecal valve.

**Figure 26-2** The segment of chosen bowel on its mesentery should be tested to ensure that it reaches the deep pelvis easily.

**Figure 26-3** The closed ileal segment is detubularized at the antimesenteric border.

**Figure 26-5** The bladder is distended with saline, and the overlying peritoneum is stripped from the posterior and superior surfaces.

**Figure 26-4** The two adjacent borders of detubularized ileum forming what will be the posterior wall of the ileocystoplasty are sutured with 2-0 Vicryl.

**Figure 26-6** The small bowel is sutured to the bladder using a running transluminal suture in the posterior wall and a running suture of 0 Vicryl up both sides so that the anterior flap of bladder is placed between the two anterior walls of the reservoir.

bladder using a running transluminal suture in the posterior wall and then using a running suture of 0 Vicryl up both sides so that the anterior flap of bladder is placed between the two anterior walls of the reservoir (Fig. 26-6). In patients who cannot perform catheterization, the more distal portion of the ileal segment is left longer to bring it to the skin as an incontinent stoma, usually in the right iliac fossa. Patients in whom urethra closure is required need ileocecal augmentation using a reinforced ileocecal valve or the appendix as a continent neourethra for catheterization. Alternatively, if availability or mobility of the ileum is limited, left or right colon can be used. For ileocecostoplasty, the right colon and ileum are mobilized and prepared as for an Indiana pouch. As first described by Sinaiko in 1956,<sup>8</sup> gastrocystoplasty is a suitable option for patients with cloacal exstrophy or metabolic acidosis from renal insufficiency.<sup>9</sup> Simultaneous pubovaginal slings can also be performed in patients with intrinsic sphincter deficiency, and urethra closure can be carried out in patients with urethral erosion. Overall, whether ileum, colon, or other

segments are used, the goal is to ensure a low-pressure, high-volume reservoir with a low incidence of postoperative incontinence.<sup>4,10-12</sup>

#### **Complications of Gastrointestinal Bladder Augmentation**

The type of metabolic complications that occurs after an enteric augmentation is directly related to the segment of bowel chosen and the amount of time that the urine spends in contact with the bowel mucosa.<sup>13-15</sup> Because vitamin B<sub>12</sub> is absorbed from the terminal ileum and is responsible for erythrocyte formation,<sup>16</sup> ileocystoplasty can potentially lead to vitamin B<sub>12</sub> deficiency and subsequent development of pernicious anemia. The chosen segment of ileum therefore should be selected from an area at least 15 to 20 cm proximal to the ileocecal valve. The interposition of bowel in the urinary tract can also lead to acid-base

changes. Hyperchloremic metabolic acidosis can develop with the use of ileum or colon, and hypochloremic metabolic alkalosis can develop if stomach is used.<sup>17</sup> Patients in chronic alkalotic states would therefore do better with an intestinal cystoplasty, and patients with chronic renal insufficiency or metabolic acidosis should be considered for gastrocystoplasty or composite grafts using stomach. Patients considered for gastrocystoplasty should be advised that up to one third of patients, especially those with a sensate bladder (up to 50%), may experience hematuria and dysuria syndrome.<sup>18-20</sup> This has led to recommendations that this procedure not be performed in patients with intact perineal sensation or in incontinent patients because the acidic urine may lead to excoriation of skin.

Studies have shown that alterations in the intestinal epithelium occur in response to urine contact with bowel mucosa. This leads to inflammatory infiltration of the submucosa, producing progressive fibrosis, goblet cell hyperplasia and subsequent loss, reduction or loss of microvilli, and loss of cellular orientation of the bowel epithelium.<sup>21</sup> Alterations in the enteric epithelium may be associated with long-term complications of bladder augmentation: increased risk of stone formation, progressive loss of compliance, and increased risk of spontaneous perforation and neoplasia.<sup>21</sup> Goblet cell hyperplasia leads to enhanced production of mucus. Mucus, permanent sutures, and staples have been identified as potential nidi for stone formation, especially coupled with stagnant urine. Routine bladder irrigation to evacuate mucus and to ensure complete bladder emptying can reduce these risks.<sup>22</sup> The progressive loss of compliance and the increased risk of spontaneous perforation have also been linked to progressive fibrosis of the enteric submucosa.<sup>21</sup> The reported incidence of spontaneous perforation is highest (9.3%) for ileocystoplasty patients, followed by 4.3% for ileocecal cystoplasty, 4.2% for sigmoid cystoplasty, and 2.9% for gastrocystoplasty.<sup>23</sup> Another infrequent complication is chronic postoperative diarrhea. The risk is highest for neuropathic patients in whom the ileocecal valve was used in the augmentation.

Several case reports of adenocarcinoma in patients with bladder augmentations exist.<sup>24,25</sup> Filmer and Spencer<sup>25</sup> reported tumor development in 14 patients with bladder augmentations. Nine of these patients had an ileocystoplasty, two had a cecocystoplasty, and three had a colcystoplasty.<sup>25</sup> The malignancies develop at or near the enterourothelial junction. It has therefore suggested that augmentation patients undergo periodic endoscopic surveillance after 5 to 10 years.

### SEROMUSCULAR ENTEROPLASTY

Seromuscular enterocystoplasty or de-epithelialized colcystoplasty has been proposed to decrease the complications associated with cystoplasty using intact gastrointestinal segments.<sup>26</sup> It is hypothesized that removal of the functional enteric epithelium can resolve the risk of metabolic complications and stone formation by allowing re-epithelialization with urothelium. Mucus production and metabolic disturbances were virtually eliminated in one follow-up study on seromuscular colcystoplasty patients.<sup>27</sup> However, regeneration of functional mucosal epithelium or extensive denudation of the submucosa often led to subsequent fibrosis and contracture of the bladder augment.<sup>28-30</sup> The mechanical or chemical means to remove the functional enteric epithelium are also fairly impractical, limiting the widespread use of these techniques.

### AUGMENTATION WITH UROTHELIUM

Two other options offered in the search for the ideal material to be used for bladder augmentation include tissue-engineered urothelium and autologous urothelium.<sup>21</sup> The methods used for development of tissue-engineered urothelium involve harvesting uroepithelial cells from the neuropathic or poorly compliant bladder, expanding these cells in culture, and seeding them on an absorbable nonreactive spherical template.<sup>31-33</sup> Concerns exist about whether the physiologic function of tissue-engineered urothelium will be affected by harvesting from hyperreflexic or poorly compliant bladders. Abnormal uroepithelium characteristics such as altered bladder permeability and elevated levels of reactive oxygen species have been associated with cells from neuropathic bladder.<sup>34,35</sup>

Autoaugmentation or detrusor myomectomy is a simpler, less morbid alternative to enterocystoplasty. Autoaugmentation, as described by Cartwright and Snow in 1989,<sup>36,37</sup> involves excising a portion of the detrusor muscle, allowing the bladder epithelium and lamina propria to form a large-mouthed bladder diverticulum. As the urothelium bulges through the muscular hiatus, bladder capacity is increased, intravesical storage pressures are reduced, and the volume at which a contraction occurs becomes larger. Because only bladder tissue is used in this technique, the risks associated with gastrointestinal segment incorporation into the urinary tract are obviated. However, in certain subgroups of neurogenic patients with contracted, poorly compliant bladders, enterocystoplasty remains superior.<sup>38</sup>

### URETEROCYSTOPLASTY

The concept of ureterocystoplasty was inspired by patients with the VURD complex: posterior urethral valves, unilateral vesico-ureteral reflux, and renal dysplasia of the refluxing renal unit.<sup>21</sup> The refluxing ureter or ureters provided material for bladder augmentation, which was lined by urothelium and free of the complications associated with use of gastrointestinal segments. Unfortunately, the long-term results of ureterocystoplasty have not been favorable. In a multi-institutional study, 64 patients who had undergone ureterocystoplasty at five institutions were evaluated.<sup>39</sup> Only 17% (12 of 69) of patients had a compliant and continent bladder after ureterocystoplasty; 42% (29 of 69) of patients underwent repeat augmentation using a gastrointestinal segment, with reoperation pending in 26% of the patients.<sup>39</sup>

Current investigations are focused on native urothelial expansion. Using animal models with surgically reduced bladder capacity, isolated urothelial segments are expanded enough to perform bladder augmentation.<sup>40,41</sup> Although promising, no long-term results are available.

### LONG-TERM RESULTS OF AUGMENTATION CYSTOPLASTY

Several studies have described the long-term results and complications of augmentation cystoplasty in various groups of patients. In a review of metabolic consequences and long-term complications of enterocystoplasty in children, the investigators show that the use of gastrointestinal segments in the urinary tract is not a perfect solution.<sup>42</sup> They describe short gut syndrome,

vitamin B<sub>12</sub> deficiency, steatorrhea, bone and growth impairment, infection, calculi, spontaneous perforations, and the development of latent tumors. Although the rates and severity of these complications after enterocystoplasty may vary, the study authors state that they may have a profound impact on patients' quality of life.<sup>42</sup>

Blaivas and colleagues<sup>43</sup> published a retrospective study evaluating long-term outcomes for 76 patients undergoing augmentation enterocystoplasty (with or without an abdominal stoma) or continent urinary diversion because of benign disease. Preoperative diagnoses included neurogenic bladder in 41 patients, refractory detrusor overactivity in 9, interstitial cystitis in 7, end-stage bladder disease in 7, radiation cystitis in 3, exstrophy in 3, postoperative urethral obstruction in 3, and low bladder compliance in 3. Sixty-nine percent of the patients considered themselves cured, 20% improved, and 11% failed (all 7 patients with interstitial cystitis failed). Mean bladder capacity increased from 166 to 572 mL, and mean maximal detrusor pressure decreased from 53 to 14 cm H<sub>2</sub>O. Long-term complications included stomal stenosis or incontinence in 42% (11 of 26) of patients with stomas; de novo bladder and renal stones in 3% and 1%, respectively; and recurrent bladder stones in 6%. Five patients experienced persistent diarrhea, and 7% of patients had small-bowel obstruction, with surgical exploration required in 6%.<sup>43</sup>

In another study of long-term results and complications using augmentation ileocystoplasty in reconstructive urology, Flood and coworkers<sup>6</sup> reviewed 122 augmentation cystoplasties performed over an 8-year period. The primary urodynamic diagnosis was reduced compliance in 77% of the patients and detrusor hyperreflexia or instability in the remainder of the patients. Preoperative diagnoses included spinal cord injury in 27%, myelodysplasia in 22%, interstitial cystitis in 17%, idiopathic detrusor instability in 11%, radiation cystitis in 7%, Hinman-Allen syndrome in 4%, and miscellaneous causes in 9%. Sixteen patients had a simultaneous fascial sling for urethral incompetence. Mean bladder capacity increased from 108 mL (range, 15 to 500 mL) to 438 mL (range, 200 to 1200 mL). Marked improvement or stability of upper tract function was documented in 99 patients (96%). During the follow-up period, 16% underwent revision of their augmentation; 21% developed bladder stones (30% had recurrent stones); 13% developed urinary incontinence, with one half requiring further treatment; and 11% developed pyelonephritis. Five patients also developed small-bowel obstruction, and in five patients, spontaneous perforation occurred. Overall, the investigators concluded that augmentation cystoplasty has a pivotal role in the treatment of a broad range of lower and upper tract problems, with careful patient selection and close follow-up being the key to successful surgery.<sup>6</sup>

# PATHOPHYSIOLOGY OF STRESS INCONTINENCE

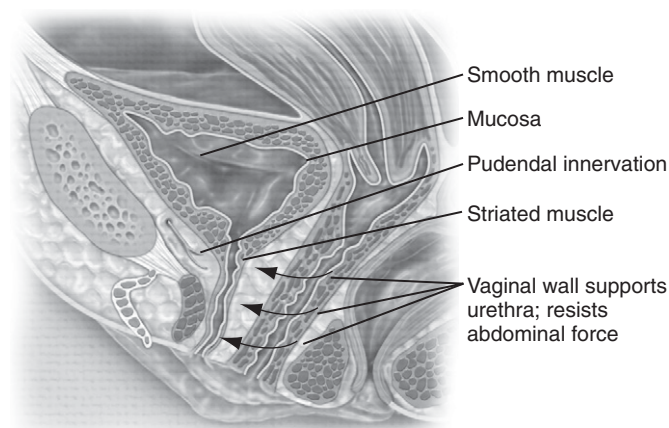

*Christopher R. Chapple and Francesca Manassero*

The lower urinary tract provides continence by storing urine at low pressure until it is socially convenient and appropriate to void. This function is mediated by the presence of an expansible, low-pressure organ, the bladder, and a sphincter-controlled outlet mechanism. The outlet mechanism prevents urinary incontinence during an increase abdominal pressure by means of the sphincter and a complex pelvic support mechanism. Understanding the pathophysiology of stress incontinence at an anatomic level can help to identify specific anatomic defects and direct individualized treatment of patients suffering from incontinence.

### THE STRESS CONTINENCE CONTROL SYSTEM

The urethral closure pressure must be greater than the bladder pressure at rest and during increases in abdominal pressure to maintain continence. The anatomic components necessary to meet this goal are a well-vascularized urethral mucosa and submucosa, a well-organized and functioning intrinsic urethral smooth muscle, a properly functioning striated sphincter with intact pudendal innervation (i.e., rhabdosphincter), and a stable, supportive hammock of surrounding muscular and fascial tissues (Fig. 27-1).

Intrinsic urethral function is the product of coaptation and compression along the length of the urethra, from the bladder

**Figure 27-1** Factors that are essential for urogenital diaphragm support and function include pudendal innervation of the urethra, the mucosa and smooth muscle of the urethra, the striated muscle sphincter, and vaginal wall support. (Adapted from Abrams P, Cardozo L, Khoury S, Wein A: *Incontinence*, 2nd ed. Plymouth, Health Publication, 2002, p 224.)

neck to the proximal and mid-urethra.<sup>1</sup> A robust anatomic support mechanism buttresses a competent bladder neck and functioning urethral mechanics and facilitates appropriate compression and pressure transmission during increases in abdominal pressure affecting the bladder outlet. These functional interactions are complex and remain the subject of ongoing research in terms of understanding mechanisms and developing measures of outlet function. Surgery directed at the bladder outlet continence mechanism at the level of bladder neck or mid-urethra aims to counteract the loss of urethral support by creating a new zone that offers support and acts as a back plate to absorb the transmitted pressure and safeguard the sphincteric configuration.

### Urethral Sphincteric Mechanisms

The glandular secretions of the inner mucosa increase the surface tension, promoting its plasticity and increasing its ability to coapt.<sup>2</sup> The abundant middle spongy vascular tissue of the submucosa forms a watertight seal and provides up to 30% of the total closure pressure<sup>3-5</sup>; this vascular cushion, like the other tissues of the urethra, is under the influence of estrogens.<sup>6-8</sup> Estrogenic deficiency in postmenopausal women results in atrophy of this layer, reduces the hermetic seal of the urethra mucosal, and may contribute to the multifactorial cause of stress incontinence. Although there is some consensus among clinicians about the value of estrogen therapy for treating the symptoms of atrophic vaginitis in postmenopausal stress urinary incontinence, there is no evidence to support the use of exogenous estrogen replacement therapy in treating stress incontinence.<sup>9</sup>

The role of smooth muscle in the maintenance of female continence is still uncertain. The U-shaped loop of the detrusor smooth muscle surrounds the proximal urethra and favors its closure by creating a constant tone. Detrusor fibers at the bladder neck are longitudinally oriented, and they extend from the bladder neck to the subcutaneous adipose tissue that surrounds the urethral meatus. The inner longitudinal smooth muscle layer is surrounded by a circular layer that lies inside the outer layer of striated muscle. The smooth muscle layers are present throughout the upper four fifths of the urethra, and their circular disposition suggests that contraction has a role in constricting the lumen. The longitudinal smooth muscle does not seem to have a passive role during the filling; rather, it has been proposed that it acts by shortening and opening the lumen to initiate micturition.<sup>10</sup>

The striated urogenital sphincter consists of two parts, the rhabdosphincter and the compressor urethra and the urethro-vaginal sphincter distally.<sup>11</sup> The proximal one third of the urethra is surrounded by a sleeve of circular striated muscle that is continuous with a longer ascending cone, which extends to the

vaginal introitus. The rhabdosphincter is composed mainly of type 1 fibers, composed of slow-twitch tissue capable of maintaining constant tonic contractions of the urethral lumen.<sup>12</sup> From manometric and electrophysiologic evaluations, this produces the greatest level of resting pressure and electromyography activity.

This part of the urethra is intrapelvic, immediately posterior to the pubic bone. In the past, it was suggested that when the urethra descended and lost this intra-abdominal position, intra-abdominal forces could no longer constrict it during straining, resulting in stress incontinence. This concept, the *pressure transmission theory*, which was introduced by Enhörning in 1961,<sup>13</sup> evolved into the *hammock theory* of DeLancey<sup>14</sup> (1994), which proposes that the vagina posteriorly offers a back plate against which the urethra is compressed during increases in intra-abdominal pressure. During a sudden increase in intra-abdominal pressure, such as during coughing, a reflex contraction of the pubococcygeus muscle occurs. The vaginal hammock is stretched and stiffened, making it easier for the urethral sphincter to close in a slitwise fashion against this firm back plate. The result and increase in intraurethral pressure, which is thought to be lost in patients suffering from stress incontinence, can be recreated by surgical procedures that stabilize or elevate the sub-urethral vaginal wall.<sup>15-18</sup>

If these postulates are correct, an appropriate contributory factor to female continence is provided by the bladder neck's passive elastic tension, which is important in maintaining urethral closure.<sup>19,20</sup> In the mid-urethra at rest, closure is mostly maintained by the intrinsic striated muscle of the rhabdosphincter; however, the extrinsic striated muscles of pubococcygeus and compressor urethrae may play a significant role in ensuring urethral closure during increases in intra-abdominal pressure. The plasticity of the urethra or its ability to work as a watertight seal is also important in maintaining continence. Approximately one third of the resting urethral pressure is offered by smooth muscle effects, one third by striated muscle effects, and one third by the vascular contribution.<sup>21</sup>

### Urethral Support Systems

The urethral support mechanism comprises all the structures extrinsic to the urethra that offer a supportive back plate on which the proximal urethra and mid-urethra lie (Fig. 27-2). The anatomic support is derived more from the fascial structures than from the musculature itself. The pubourethral ligament attaches the mid-urethra to the inferior side of the pubic symphysis and prevents downward movement during its rotational descent.<sup>22</sup> It works in conjunction with the pubourethralis muscle, a subdivision of the levator ani muscle that forms a sling around the proximal urethra. Together they form the mid-urethral complex. It has been postulated that elongation of the posterior pubourethral ligaments may be a significant contributory factor to the loss of urethral support seen in stress incontinence. Major fascial support to the urethra also is provided by the urethropelvic ligament, which attaches the urethra to the tendinous arc.<sup>23</sup>

The vesicopelvic fascia or pubocervical fascia, extending between the bladder and the vagina, suspends and attaches the vagina and cervix to the pelvic side wall, to each arcus tendineus fascia pelvis, thereby offering posterior support to the bladder and bladder neck. It has two surfaces: the perivesical fascia on the vaginal side and the endopelvic fascia on the abdominal side. Its upper zone supports the bladder above the cervix, the middle

**Figure 27-2** Principles of maintenance of continence. During a sudden increase in intra-abdominal pressure, such as during coughing, a reflex contraction of the pubococcygeus muscle occurs. This stretches and stiffens the vaginal hammock, which makes it easier for the urethral sphincter to close in a slitwise fashion. A role for the pubourethral ligamentous support also has been advocated.

zone supports the trigone, and the lower zone supports the bladder neck. Laxity of the fascia in each of the zones results in uterine prolapse, cystocele, and urethrocele, respectively.<sup>24</sup>

The two arcus tendineus fascia pelvis are tensile structures located bilaterally on either side of the urethra and vagina. They act like the ropes of a suspension bridge and provide the necessary support needed to hang the urethra on the anterior vaginal wall. They originate as fibrous bands from the pubic bone and broaden out as aponeurotic structures moving dorsally to insert into the ischial spine. The cardinal ligaments and the more medially placed uterosacral ligaments support the uterus and cervix; their relaxation results in uterine prolapse.

The pelvic floor musculature, represented by the levator ani muscles, carries the weight of the pelvic contents and prevents the abdominal pressure from stretching the ligamentous support structures. The levator ani includes the puborectalis muscle, which surrounds the rectum, connecting the pubic bones anteriorly in a U-shaped configuration; the pubococcygeus muscle, which crosses from the pubis to the coccyx; and the iliococcygeus muscle. The iliococcygeus arises laterally from the arcus tendineus levator ani and forms a horizontal sheet that spans the posterior opening of the pelvis, providing a shelf on which the pelvic organs lie. The urethra and vagina pass through an aperture in the levator musculature, the urogenital hiatus. The constant muscle tone,<sup>25</sup> maintained by predominantly type I (slow-twitch) striated muscle fibers, compresses the vagina and urethra anteriorly toward the pubic bone and keeps the hiatus closed.<sup>26</sup>

The pudendal nerve provides somatic innervation to the striated muscle of levator ani and to the striated muscle within the external anal and urethral sphincters. The intrapelvic somatic fibers travel along the anterior vaginal wall from the sacral segments S2 through S4 to provide a somatic nerve supply to the pelvic floor.<sup>27</sup> Neuromuscular injuries have been proposed as an important factor in predisposing to pelvic floor dysfunction. Childbirth and age are considered the two major factors predisposing to pelvic floor denervation.<sup>28</sup> Other factors include pelvic surgery (i.e., rectal and vaginal surgery with extensive pelvic dissection), radiotherapy, and congenital neurologic conditions such as spina bifida and muscular dystrophy.

Support and suspension of the pelvic organs depends on a healthy innervated pelvic floor striated muscle, intact robust con-

**Figure 27-3** In this representation of the pelvic floor support mechanism, water represents the pelvic floor musculature, the guy ropes are the ligaments, and the ship is the pelvic organs (A). If the pelvic muscles are weakened, undue force is applied to the ligaments (B), which weaken and may be damaged (C).

nective tissue, and their attachments to the bony frame of the pelvis. A useful analogy is that described by Peggy Norton, who suggested visualizing the relationships of these factors by considering a ship lying moored in dry dock. The ligaments are represented by the mooring ropes and the pelvic floor musculature by the water on which the ship sits. If the dry dock is emptied, then the influence of the supporting water disappears, leaving all of the tension applied to the mooring robes, which will inevitably weaken and fracture (Fig. 27-3).

The levator ani contains type I fibers that provide resting tone and type II (fast-twitch) fibers that maintain the urethral closure under stress and prevent stretching of the pelvic ligaments. Berglas and Rubin showed that in the nulliparous patients, the lower one third of the vagina is oriented more vertically and the upper two thirds deviate horizontally, thereby maintaining the vaginal axis in an almost horizontal position.<sup>29</sup> This configuration is maintained by the posterior attachments of the cervix with the cardinal and uterosacral ligaments and by the anterior

position of the urogenital hiatus. During stressful maneuvers, such as coughing or straining, the levator hiatus shortens anteriorly by the contraction of the pubococcygeus muscles. In the case of genital prolapse, when the levator ani support is lost, the vaginal axis becomes more vertical, the urogenital hiatus broadens, and fascial supports are strained.

#### EFFECT OF PREGNANCY AND CHILDBIRTH ON THE PELVIC FLOOR

An important pathophysiologic factor is the contribution of pregnancy and childbirth to the development of urinary incontinence in women.<sup>30,31</sup> Epidemiologic studies have reported a prevalence of stress incontinence ranging from 23% to 67 % during pregnancy and 6% to 29% after childbirth. The fear of pelvic floor trauma has been used to justify an increase in the number of indiscriminate and often unnecessary cesarean deliveries.<sup>32</sup>

Our knowledge of pathophysiologic impacts of pregnancy and delivery on lower urinary tract function and the development of urinary incontinence remain scanty and often are somewhat confused.<sup>33</sup> Future works needs to investigate the relative contribution provided by the individual components of pregnancy and delivery. The findings could significantly alter our understanding and treatment of stress incontinence.

It is a widely held view that stress incontinence is principally the consequence of delivery trauma to the pelvic floor. However, many studies have demonstrated that about 40% of nulliparous women experience occasional stress incontinence, which is a significant problem in 5% of them.<sup>34,35</sup> The problem regularly worsens during the first pregnancy, and for the women developing stress incontinence in middle life, pregnancy rather than delivery seems to unmask the problem and worsen it.<sup>36</sup> If incontinence emerges for the first time during pregnancy, it tends to resolve after the puerperium, but it may return in future pregnancies, progressively worsening and becoming a significant problem often many years after the pregnancies.

The prevalence of persistent, clinically important stress incontinence is significantly higher with greater multiparity than in nulliparous women, and it can be related to the number of pregnancies.<sup>37</sup> Women who develop stress incontinence during pregnancy are more likely to experience incontinence later in their life. A study by Viktrup and colleagues<sup>38</sup> of 278 women showed that 30% of them had stress urinary incontinence 5 years after delivery. In the group without stress urinary incontinence during pregnancy or after delivery, the incidence 5 years after delivery was only 19%. In the group developing stress urinary incontinence during the first pregnancy or puerperium with resolution of symptoms within 3 months after delivery, 42% of women had complained of recurrent incontinence 5 years later. In the latter group in which the symptoms of stress urinary incontinence did not resolve 3 months after delivery, the symptoms were still present in 92% 5 years later.<sup>38</sup>

Vaginal delivery has been recognized as being potentially traumatic to the pelvic floor. The first delivery may initiate injury to the continence mechanism as a consequence of direct damage to the pelvic floor muscles or nerves, or both, during the passage of the fetus. The perineal branch of the pudendal nerve courses in Alcock's canal, lateral and anterior to the vagina, making it vulnerable to damage during childbirth.<sup>39</sup> Additional deterioration of the urethral musculature and denervation can occur with aging, producing clinical disability many years after the initial trauma.<sup>40</sup>

The fetal head may dilate and overstretch the vaginal wall or avulse the cardinal and uterosacral ligaments, injuring connective support tissues. Moreover, the presenting part of the fetus during labor may constrict the pelvic structures, resulting in an ischemic injury. Compression of the fetal head against the subpubic urethra or paravaginal attachments may directly injure the urinary tract during labor and delivery. There are many mechanisms by which vaginal delivery can increase the risk of developing stress incontinence.<sup>41</sup>

The contribution of vaginal birth to producing denervation has been clarified by Allen's electromyographic studies, which were performed before and after vaginal birth. Allen and colleagues<sup>42</sup> found that most women have signs of neurologic damage after vaginal birth (but not after cesarean section), as confirmed by an increased motor unit potential, and increasing amounts of damage correlated well with greater evidence of stress urinary incontinence.

Vaginal delivery causes partial denervation of the pelvic floor in most primiparous women, but there is electromyographic evidence of reinnervation after vaginal delivery in 80% of them. The nerve damage is more likely in women with a long, active second stage of labor and heavy babies.

The impaired muscle strength in the days after vaginal deliveries returns to normal within 2 months in most women. In a few of them, severe muscular weakness is associated with urinary and fecal incontinence, a prelude to future problems depending on permanent pelvic floor damage.

Multiparity, a long second stage of labor (>30 minutes), the use of the forceps, high birth weight (>4 kg), and a third-degree perineal tear are important risk factors for pudendal nerve damage.<sup>43</sup> After spontaneous and instrumental deliveries, 21% and 34% of women complained of stress urinary incontinence and 5.5% and 4% reported fecal incontinence, respectively. Only 22% of patients incontinent during pregnancy continued to complain about it after delivery.<sup>44</sup>

Episiotomy, one of the few surgical procedures that does not require the patient's informed consent, is widely performed during delivery despite its doubtful usefulness. It is becoming increasingly accepted that an episiotomy may be more harmful than useful. Supporters of routine episiotomy maintain that it avoids uncontrolled lacerations and extended relaxation of the pelvic floor; the contrary view is that there is no evidence that first- or second-degree perineal tears cause long-term consequences and that episiotomies do not seem to protect against third- and fourth-degree tears, which are associated with unpleasant sequelae. Midline episiotomies cause significantly higher rates of third- and fourth-degree perineal tears than mediolateral episiotomies; they are not helpful in protecting the pelvic floor during delivery and can heavily prejudice anal continence.<sup>45,46</sup> Despite this, midline episiotomy is still widely used, probably because it is believed to improve healing and reduce postpartum pain.

Restrictive episiotomy guidelines have many potential advantages, such as less suturing, more minor complications, and less posterior perineal trauma, but they do not result in any difference in pain therapy and the incidence of severe trauma, and they are associated with an increase risk of anterior perineal trauma.<sup>47,48</sup> The consequences of episiotomy are independent of maternal age, duration of second stage of labor, possible complications, the use of forceps or vacuum extraction during delivery, and baby birth weight.

Regional anesthesia may be used to relieve labor pain, but its correlation with pelvic floor damage remains controversial. Epidural anesthesia, relaxing the pelvic floor, provides a greater control of passage of the fetal head and subsequently reduces perineal lacerations, but a prolonged second stage of labor can enhance the incidence of pudendal nerve damage. Analysis of the relationship between regional anesthesia and pelvic floor injury suggested that the rate of significant damage was higher with epidural anesthesia because of the increase in episiotomies and instrumental deliveries.<sup>49</sup>

In many women with stress incontinence, pelvic floor muscle exercise has been effective in improving it,<sup>50</sup> with no additional benefit accruing from biofeedback.<sup>51</sup> The theoretical basis for physical therapy is that facilitation and strengthening of muscles may improve periurethral muscular efficiency and that training of pelvic floor muscles can improve structural support of the pelvic organs. Morkved and Bo,<sup>52</sup> after a prospective, matched, controlled study evaluating the long-term effect of an immediate

postpartum pelvic floor training course, concluded that it is helpful in the prevention and treatment of urinary incontinence and that improvement is still present 1 year after delivery. Miller and coworkers,<sup>53</sup> after studying the characteristics of women “responders” compared with “nonresponders” to pelvic floor electrical stimulation, affirmed that a minimum of 14 weeks was needed to see the first objective improvements (i.e., at least 50% reduction in leakage episodes).

Pelvic floor exercises are not effective in all women. Patient motivation is essential for long-term success, but the quality of the pelvic floor muscles and their innervation are also important. If the muscle is normally innervated and is sufficiently attached to the endopelvic fascia, by contracting her pelvic muscles before and during the stress, a woman is able to reduce the leakage, and the pelvic floor exercises are likely to be an effective therapy. If the pelvic floor muscle is denervated as a result of significant neural damage, it may not be possible to rehabilitate the muscle adequately to make pelvic muscle exercises an effective strategy. If the muscle is totally disconnected from the fascial tissues, any possible contraction may not be effective in supporting the urethra or maintaining its position under strain.<sup>54,55</sup>

### ROLE OF CONNECTIVE TISSUE

The bladder is a complex, distensible organ comprising of an inner urothelium and suburothelial layer, an important smooth muscle component (i.e., detrusor muscle) with neurologically controlled tissue, and an outer serosal layer. Connective tissue, composed of collagen, elastin, smooth muscle, fibroblasts, and blood vessels, is present in all of these layers. It has been suggested that collagen has the primary function of tension transfer in most tissues, and it is reasonable to suppose that it plays an equivalent role in the bladder. Types I and III collagen can be found in the detrusor layer, and type IV collagen is in the basement membrane under the urothelial layer and surrounding individual smooth muscle cells. Although the connective tissue is passive in that it does not require energy to function, it plays a unique structural role in providing the bladder wall tissues with resilience and tensile strength. These physical properties are related to the quantity and types of collagen present and its arrangement. Changes in collagen type and content may affect bladder compliance. Collagen is the main constituent of endopelvic fascia, and abnormalities in the quantity, type, and quality of collagen have been observed in women with stress incontinence and in those with genitourinary prolapse.<sup>56-58</sup>

Regulation of collagen synthesis depends on intrinsic factors within individual cell types and on extrinsic factors such as cytokines, growth factors, and mechanical forces. Because progressive alteration of the connective tissue of the bladder or in the pelvis may result in structural weakness, it is important to investigate and define the factors that contribute to abnormal pathophysiology.

It was suggested by Petros and Ulmsten<sup>59</sup> in 1990 in their *integral theory* that stress and urge incontinence may have a common cause, with the anatomic defects related to a primary abnormality of connective tissue failure. With laxity, the anterior vaginal can be a primary etiologic factor, and this may result in the activation of stretch receptors in the bladder neck and proximal urethra, which triggers an inappropriate micturition reflex. These events may produce detrusor overactivity and cause the filling symptoms of the overactive bladder, including urgency,

frequency, nocturia, and urgency incontinence. The deficient anterior vaginal wall does not efficiently transmit the closure pressure that would otherwise be generated by proper functioning of the pubourethral ligaments, the vaginal hammock, and the pubococcygeus muscles.

We need to identify the cells responsible for the synthesis of the proteins that contribute to defective connective tissue and to describe the mechanisms by which these cells acquire the altered synthetic phenotype. In some individuals, the changes in connective tissue, which can be associated with the pathogenesis of incontinence, may be related to age or the hormonal milieu.

With increasing age, the ratio of connective tissue to muscle is reduced, and although the formation of collagen cross-links stabilizes the collagen molecules, this also prevents remodeling and flexibility. The hormonal changes during pregnancy can result in abnormal remodeling of collagen, which may be another important factor in the development of incontinence. In every case, the exact cellular mechanisms by which hormones, cytokines, or other peptide factors influence the mechanical properties of connective tissue remain unclear.

Connective tissue plays an important role in the overall physiologic function of the lower urinary tract and pelvic floor. The age-related weakening of connective tissues can influence tissue and organ function, and it is likely that the increased focus on connective tissue changes will in the future provide a better understanding of the pathophysiology and lead to more effective management of stress urinary incontinence and vaginal prolapse.

### EFFECT OF URETHRAL POSITION AND FUNCTION ON STRESS URINARY INCONTINENCE

#### Urethral Hypermobility

The cause of urethral hypermobility (i.e., increased mobility) is thought to be a loss of normal extrinsic support of the urethra because of weakness of the endopelvic fascia and pelvic floor muscles. During stress, the bladder neck and the proximal urethra descend, and there is an incomplete distribution of abdominal pressure to the urethra (i.e., pressure-transmission deficit). The bladder pressure exceeds urethral pressure, and urine leaks. Urethral hypermobility can result from abnormalities of vaginal and pelvic anatomy. It is usually initiated by childbirth, and it is worsened by aging and alterations in hormone levels. Stretching, tearing, and avulsion of the levator muscles result in the urogenital hiatus becoming longer and wider. This change results in chronic anterior displacement of the pelvic organs, with loss of any organ support at rest and especially during straining. Stretching or tearing of the cardinal and uterosacral ligaments may result in anterior displacement of the uterus at rest or during straining, and the resultant stretching of the vaginal wall continues this displacement and causes the loss of the normal superior vaginal sulcus and vaginal folds. The consequence of these forces is a rotational descent of the proximal urethra away from its retro-pubic position and the eventual development of stress urinary incontinence.

On lateral cystourethrograms, the main anatomic change is loss of the posterior urethrovaginal angle, with the urethra and trigone falling into the same plane.<sup>60-62</sup> Radiographic studies cannot distinguish between lateral or central defects in vaginal wall support because they appear in the same sagittal plane. It is

necessary when examining the patient to determine which defect is present and to what extent. Because the proximal urethra rotates out of the focal plane of ultrasonographic probes or magnetic resonance imaging (MRI), coronal images of vaginal relaxation cannot provide adequate anatomic information during leakage.

Despite extensive data about anatomic defects, it is difficult to correlate the influence of these defects, the vaginal position, and the urethral closure mechanism. Not all women with stress incontinence had vaginal prolapse, and prolapse repairs do not always cure the stress incontinence. Conversely, women who redevelop stress incontinence after an apparently successful operation do not always have a recurrence of prolapse.<sup>63</sup> Vaginal support is important for maintaining urinary continence, but intrinsic sphincter deficiency also must be considered.

### Intrinsic Sphincter Deficiency

In 1988, Olsson and Blaivas<sup>64</sup> suggested a new classification of stress incontinence, in which for the first time appeared the concept of intrinsic urethral weakness as a cause for incontinence without a vaginal support defect. They called this type III incontinence to differentiate it from types I and II, both of which were associated with movement. This category is often described by the term *intrinsic sphincter deficiency* (ISD),<sup>65</sup> which emphasizes the importance of the intrinsic components of the sphincter acting under the influence of pudendal innervation and comprises the urethral striated and smooth muscle, mucosa, and submucosal layers.

When ISD was proposed as a new type of stress incontinence without vaginal mobility, the diagnostic trend was to evaluate the cause of stress incontinence as a dichotomy caused by hypermobility or ISD. The typical ISD patient was described as having a low urethral closure pressure, a stovepipe (pipe stem) appearance on cystoscopy, and an open or funneled urethra at rest or during minimal effort on radiographic images. Typical causes included ischemia after pelvic or vaginal surgery, multiple previous operations, denervation in neurogenic patients, or radiation damage. These examples of ISD now represent extreme forms and the most severe cases.

Another important aspect is urethral denervation after childbirth and its association with urinary and fecal incontinence.<sup>66,67</sup> Crushing or traction injuries to the pudendal nerve during labor and delivery are a primary cause of sphincteric incompetence. A causal relationship between pudendal nerve injury and stress incontinence has been established in animal studies.<sup>68-70</sup> Because the pudendal nerve innervates the external urethral sphincter, pudendal nerve injury causes denervation and dysfunction of the urethra, resulting in decreased urethral resistance, which is especially evident during stressful physical activities. Stress incontinence is often associated with a decrease in the electrophysiologic function of the pudendal nerve,<sup>71</sup> the striated urethral sphincter,<sup>72</sup> and the pelvic floor muscles.<sup>73,74</sup>

### Hypermobility and Intrinsic Sphincter Deficiency: From Dichotomy to Continuum

In the past few years, there has been a gradual change from a dichotomous classification of stress incontinence as hypermobility or ISD. ISD alone is rare, and urethral hypermobility may occur commonly without significant ISD, but usually there is a combination of both. This evolution in our understanding followed development of the concept of Valsalva leak point pressure

(VLPP), introduced by McGuire in 1995,<sup>75,76</sup> and the analysis of long-term results of incontinence surgery. During studies of urethral bulking with collagen, researchers documented that continence improvements were not related to changes in urethral closure pressure, but instead corresponded to the level of abdominal pressure required to produce leakage in the absence of intrinsic detrusor contraction. Despite lacking a specific anatomic or theoretical basis and standardization of recording methods or a consensus on how to deal with an associated prolapse, a low VLPP (<60 cm H<sub>2</sub>O has been suggested) has been widely considered to be an indicator of ISD, although there is considerable variability in the literature about the extent of correlation between VLPP and outcome. Urethral pressure profilometry has been extensively studied in this context, and a similar lack of correlation with predictive value and outcome appears to exist. For example, a low-pressure urethra may not leak, whereas the high-pressure urethra may, and several studies have failed to show any correlation between the postoperative urethral pressure profile and outcome.<sup>77</sup>

Long-term results of stress incontinence surgery have revealed a higher failure rate for the classic procedures other than slings that seem to ensure the best long-term protection against incontinence recurrence because they offer direct suburethral support.<sup>78</sup> Slings have become the operation of choice for incontinence caused by ISD.

Some degree of ISD may exist in many patients for whom hypermobility is believed to be the only cause of stress incontinence.<sup>79</sup> This understanding clarifies the increasing use of suburethral sling surgery to treat stress incontinence, whereas this procedure formerly was suggested principally for patients with recurrent stress incontinence or severe ISD.<sup>80</sup>

It is necessary to have a unifying hypothesis that can combine all of these observations about hypermobility, ISD, and pudendal denervation. The concept of a continuum of pathologic states offers a model for conducting research and providing treatment for these conditions.

### ROLE OF IMAGING AND ULTRASONOGRAPHY

Radiographic studies have given a significant boost to the study of the physiopathology of stress incontinence since the introduction of simple static and dynamic lateral cystograms. MRI and real-time ultrasonography, simultaneously showing what happens during the leakage in terms of movement of the pelvis and the urethra, have suggested spatial and causal relationships between the proximal urethra and vaginal wall movement.

Dynamic fast-scan MRI has been used to visualize all compartments of the female pelvis at rest and under stress.<sup>81</sup> The pubococcygeal line that extends from the inferior border of the pubic symphysis to the last joint of the coccyx represents the level of the pelvic floor and is the reference marker.<sup>82</sup> MRI studies are more qualitative than quantitative, and they give more details about the soft tissues than previous radiographic studies. However, access to dynamic MRI worldwide is confined to a few centers, and MRI remains limited in its ability to delineate precise details of urethral movement. At this time, ultrasonography is still superior for visualizing mobility of the urethra and the vagina.

Suprapubic, translabial, and transperineal sonographic approaches have been used to quantify stress incontinence. With the improving resolution of sonographic probes, the transperineal approach has reached the same diagnostic level as the tran-

rectal approach. In studies with a transrectal probe, funneling of the bladder neck is the typical sonographic sign seen during leakage.

The observed urethral movement and funneling are compatible with the rotational descent described previously. Ultrasonography studies provide more detail than radiographs. Increasing abdominal pressure forces the anterior vaginal wall out of the urogenital hiatus, and the urethra follows it. The anterior portion of the urethra can be slowed and eventually arrested in its movement while the posterior portion continues to rotate out of the pelvis with the vaginal wall.<sup>83,84</sup> This difference in movement seems to result in shearing apart of the walls of the two adjacent structures, resulting in apparent funneling. Suspension procedures at the bladder neck or the mid-urethra may prevent this exaggerated posterior urethral motion. If they can be placed accurately in an intramural position, injection procedures, which depend on urethral coaptation, should have a higher success rate in a patient in whom the shear force associated with anatomic motion is limited.<sup>85</sup>

These anatomic observations, combined with progressive awareness about the role of pudendal innervation in continent and incontinent patients, help to define the relationship between urethral closure and vaginal movement. When intra-abdominal pressure increases, the proximal urethra is subjected to two types of forces that combine to open it. The first is a *shearing force* produced by the asymmetric descent of the anterior and posterior urethral walls below the pubis under stress and the effect of vaginal mobility on urethral closure, which is opposed by counterforces of vaginal support. The second is an *expulsive force*, which is mediated by the transmission of intra-abdominal forces to the bladder and countered by the intrinsic urethral musculature, which depends primarily on intrinsic closure pressure produced by the pudendally innervated rhabdosphincter combined with vaginal support. If these shear and expulsive forces occur simultaneously as intra-abdominal pressure increases and there is a defect in either component, the urethra will reach a point beyond which urethral closure and continence cannot be sustained.

## CONCLUSIONS

Two factors govern the predisposition to develop stress urinary incontinence and prolapse. First, after the evolutionary changes in pelvic floor anatomy resulting from the changes to orthograde

posture, the pelvic floor had to adapt from its mainly muscular utility (i.e., moving the tail) in four-legged animals to a supportive function in humans. This transition generated a decrease in muscle mass and an increase in connective tissue. Second, the human reproductive process consists of a relatively large fetus with a large bony cranium that must pass through the pelvic floor during the processes of labor and delivery.

The complex causes of stress urinary incontinence and pelvic organ prolapse and the long period over which these problems and their complications develop strongly support the need for prospective studies of the natural history of these processes in the future. An integrated approach to anatomy, radiology, and physiology is essential to a better understanding of the pathophysiology.

The current classification of stress incontinence attempts to incorporate the spectrum of hypermobility and urethral dysfunction. Satisfactory urethral continence depends on many factors (e.g., resting tone, active contraction, external compression, pressure transmission, integrity of configuration), and the focal point appears to be the mid-urethra. Many patients with stress incontinence have some degree of urethral hypermobility and ISD. Some of these patients have primary sphincteric problems, whereas others have an adequately functioning sphincter but significant hypermobility, and the diagnosis for most patients lies between these two extremes.

Repeated episodes of vaginal traction can stretch, tear, or weaken urethral muscles and contribute to a chronically weakened urethra characterized by a low VLPP or low urethral closure pressures, which is suggested to be typical of ISD. However, there is no adequate classification of ISD because most of the measures have limited sensitivity by virtue of their inability to separate the different components of urethral function. Electrophysiologic studies, MRI and, sonography can be used to quantify the morphologic and functional decline in striated sphincter tone, but analysis of the precise etiologic factors is difficult because the pathophysiologic dysfunction develops over many years. Successful operations can restore urethral position but probably do not reverse urethral function, and there are still many questions about whether this is ever possible. In the future, prospective studies taking account of nature and nurture may allow identification of patients who are genetically predetermined to develop these conditions. This information can facilitate the investigation of early, timely interventions to prevent further deterioration of support tissues and urethral closure mechanisms.

# PELVIC FLOOR REHABILITATION IN THE MANAGEMENT OF URINARY STRESS INCONTINENCE

*Alain P. Bourcier*

Stress urinary incontinence (SUI) is the complaint of involuntary leakage on effort, exertion, sneezing, or coughing.<sup>1</sup> It results from specific damage to the muscles, fascial structures, and nerves of the pelvic floor.<sup>2</sup> Commonly accepted etiologic factors include perinatal damage, pregnancy, hereditary predisposition, strenuous physical activity, chronic cough, obesity, and aging.<sup>3,4</sup> Many women have difficulty participating in physical exercises and social activities because of urinary leakage. SUI is not a condition that improves over time without treatment,<sup>5,6</sup> and it is remarkable that so few women seek professional care or advice for their symptoms.

The pelvic floor has an important function in relation to lower urinary tract function. The levator ani complex provides anatomic support to the bladder outlet. Parts of the levator collectively play an important role in maintaining the position of the pelvic viscera. Contraction of the attachments of the levator ani to the vagina and external sphincter is responsible for the anterior movement of these viscera toward to the pubis symphysis.<sup>7,8</sup> Urethral support is an important factor in SUI in women, because support in symptomatic women may be inadequate. According to De Lancey and Delmas,<sup>8</sup> the connections of the vagina and urethra to the levator ani muscles and arcus tendineus fasciae pelvis determine the structural stability of the urethra. If the connective tissue fails, the urethral supports cannot stay in their normal alignment, and SUI often occurs. Conversely, if the muscles are damaged, their action in supporting the urethra may be lost. Genuine SUI is defined as an involuntary loss of urine caused by an increase in intra-abdominal pressure that overcomes the resistance of the bladder outlet in the absence of a true bladder contraction. The decrease in bladder outlet or urethral resistance may result from poor anatomic support of the bladder neck (i.e., urethral hypermobility), loss of urethral function (i.e., intrinsic sphincter deficiency), or low urethral closure pressure, alone or in combination with other factors.<sup>9</sup> The anatomic support of the bladder outlet, which is critical to maintaining continence, is provided by constant levator tone in normal females.<sup>10,11</sup>

Physiotherapy for SUI is a widely accepted mode of conservative treatment that involves pelvic floor muscle exercises (PFMEs), with or without biofeedback, electrical stimulation, and weighted vaginal cones and balls. The purpose of pelvic floor re-education is to increase the strength and functional activity of the pelvic floor muscles, which may reduce the problem of SUI.<sup>12</sup> Because conservative therapy seems to have no side effects, it should be the first choice for treating SUI.<sup>13</sup>

### PELVIC FLOOR MUSCLE EXERCISES

The main function of the pelvic floor muscles is to provide postural support to the pelvic organs. Consequently, type I (slow-twitch) fibers are predominant. In healthy muscle, these fibers have high endurance and low contraction speed, and they are resistant to fatigue. However, to respond to sudden changes in intra-abdominal pressure, the pelvic floor muscles also contain type II (fast-twitch) fibers that contract strongly and quickly to provide short bursts of activity.

According to Gilpin and associates,<sup>10</sup> within the pelvic floor, the distribution of fiber types is approximately 70% slow-twitch fibers and 30% fast-twitch fibers. These investigators also described a decrease in type II fibers in the periurethral and perianal area in women with symptoms of genitourinary prolapse or urinary stress incontinence. This finding suggests that changes in pelvic floor muscle function are associated with prolapse and incontinence.

During periods of increased intra-abdominal pressure, the pelvic floor muscles are believed to act as a type of platform or hammock, as described by DeLancey.<sup>14</sup> The hammock of muscles under the urethra allows the increased intra-abdominal pressure to compress the urethra against this resistance, preventing urine leakage. Recognizing the role of the endopelvic fascia, Petros and Ulmsten<sup>15</sup> proposed the integral hypothesis based on the view that the pelvic floor is a single functional unit. If a part of the structure (e.g., the pubourethral ligament) is weakened, the hammock loses some of its original function and cannot perform efficiently. The integral theory also suggests that obstruction of the urethra is caused by sphincter activity and compression of the urethra as a result of contraction of the pelvic floor muscles.

Dougherty<sup>16</sup> postulated that the effects of pelvic floor muscle training (PFMT) on the symptoms of stress incontinence are the result of muscle hypertrophy. Muscle hypertrophy accounts for most gains achieved by skeletal muscle; however, Dougherty also suggests that neuromuscular coordination is at least as important as hypertrophy for the successful treatment of stress incontinence. In 1998, Miller and colleagues<sup>17</sup> described a study of older women (mean age, 68 years) who had symptoms of mild to moderate stress incontinence. The intervention group was taught the technique of intentionally contracting the pelvic floor muscles before and during a cough, a method called *the knack*. Within a week, the results showed a significant reduction in urine loss when the women used the knack compared with coughing without precontraction of the pelvic floor.

PFME therapy has proved effective for all three forms of incontinence,<sup>18</sup> and PFMEs are recommended as the first choice of treatment for women with these types of urinary incontinence after remediable conditions have been excluded. In prior studies, up to 70% of patients were cured or improved after therapy,<sup>13</sup> but success rates declined during follow-up as adherence to the program deteriorated.<sup>19-21</sup> An intervention aimed at promoting long-term adherence to PFME therapy seems warranted. Various investigators have pointed out that patient education in physiotherapy, especially the part of encouraging adherence behavior, lacks a systematic behavioral approach.<sup>22</sup> A literature search was conducted to evaluate approaches designed to improve adherence to PFME therapy. In four studies, the PFME program included adherence-promoting strategies: audiocassette tapes to guide exercising at home, telephone calls as reminders, and follow-up visits to provide feedback and reinforcement. One study found that after 6 weeks of training at home, adherence was significantly better in the group that had used an exercise tape, compared with the group without the<sup>23</sup> tape. Surprisingly, in the other three studies, adherence behavior itself was not measured<sup>24</sup> or not related to the adherence-promoting strategies,<sup>25</sup> and the efficacy of these strategies therefore remains unclear.

PFME therapy for stress incontinence focused on the integration of the automatic and subconscious use of the pelvic floor muscles during the daily posture and movement pattern and on the integration of PFMEs in daily life. For urge and mixed incontinence, the therapy focused first on bladder training in which a normal voiding frequency of approximately seven voidings per day is trained. Second, the therapy included the same program as for stress incontinence with the addition of learning to prevent leakage when feeling an urge by contracting the pelvic floor muscles. The therapy included teaching the woman about the anatomy and function of the bladder, the pelvic floor muscles, the continence mechanism, toilet behavior, and the importance of adherence to the advice.

Adherence to PFME therapy was operationalized according to the following behavioral advice:

1. Perform PFMEs regularly. Do 10 slow-twitch contractions (10 to 30 seconds) and 10 fast-twitch contractions (2 to 3 seconds), five times each day, with each contraction followed by relaxation. Increase repetitions in each session to the point of fatigue, and incorporate different starting positions and functional activities into the exercise program. Check contractions with self-palpation.
2. Perform correct toileting and drinking behavior. Sit straight on the toilet and relax the pelvic floor muscles during voiding. Drink 1500 to 2000 mL of water each day. Women with deviant voiding frequency should train the bladder by timing their voidings during the day until a normal frequency of seven voidings per day is reached.
3. Use the knack technique to prevent incontinent wet episodes by contracting the pelvic floor muscles when feeling a sudden urge to void or when coughing, sneezing, or laughing.
4. Automatically and subconsciously use the pelvic floor muscles, especially during moments of abdominal pressure, in the daily posture and movement pattern to prevent leakage.

Most women seem to have learned to adapt their adherence behavior to their symptoms. A similar adaptation pattern was found in the study of Burns and colleagues,<sup>24</sup> who argued that

women with mild symptoms may not perceive their incontinence as a problem warranting sustained effort, whereas women with many daily losses recognize it as an ongoing problem and make a persistent effort as a positive response occurs. This structure, coupled with an enthusiastic physiotherapist, seems most important for realizing long-term effects and optimal adherence behavior of organized training.

## PELVIC FLOOR MUSCLE TRAINING PROGRAMS

Kegel<sup>26</sup> recommended performing as many as 300 to 400 pelvic floor muscle contractions daily but gave little information about the intensity of each contraction. As described by Bø,<sup>27</sup> the two main principles of strength training for skeletal muscles are overload and specificity. Specificity is particularly important in relation to the pelvic floor muscles because approximately 30% of women have difficulty performing a correct contraction on the first attempt. The pelvic floor is surrounded by many larger groups of muscles, such as the quadriceps and glutei. Women often incorrectly contract these muscle groups when attempting to contract the pelvic floor muscles.

Another common mistake is to produce a Valsalva, or bearing-down, maneuver. Bø<sup>27</sup> also describes the importance of instructor-conducted exercises in establishing the correct action of the pelvic floor muscle and maintaining motivation to continue with the exercise program.

In addition to the muscle group being exercised, specificity concerns the type of training used in relation to the dysfunction and symptoms. For example, in a case of urinary stress incontinence, the function required of the pelvic floor muscles is to assist the urethral closure pressure provided by the urethral sphincter, the resting tone of the levator ani, and mucosal coaptation. This requires a quick, maximum voluntary contraction of the pelvic floor muscles; in this case, the training program must emphasize type II fibers. During contraction of the pelvic floor muscles, motor units are recruited in order of increasing size, with type I fibers recruited at low intensity and type II fibers recruited only at high intensity. The training program therefore must include high-intensity exercises. Type II fibers fatigue rapidly because of the rapid depletion and slow replacement of adenosine triphosphate. For this reason, the exercise program should allow relaxation between contractions. The contribution of type I fibers should not be overlooked; they are responsible for maintaining the postural position of the pelvic floor, from which type II fibers can then function effectively.<sup>28</sup>

Traditionally, PFMEs are practiced in isolation, without activity of the abdominal or hip muscles. However, Sapsford and colleagues<sup>29</sup> describe how this practice has been challenged by a number of physicians, who noticed activity in the rectus abdominis in association with pelvic floor muscle contraction and palpable coactivation of the abdominal muscles during functional activities, such as raising the head and shoulders. Sapsford and colleagues<sup>29</sup> showed that the rectus abdominis, obliquus internus abdominis, obliquus externus abdominis, and transversus abdominis are coactivated with maximal contraction of the pelvic floor muscles. Sapsford and colleagues<sup>29</sup> also showed that the reverse occurs; pubococcygeal electromyographic activity increased in response to isometric contractions of the abdominal muscles. These investigators suggested that this activity could be used for therapeutic effect by encouraging submaximal deep abdominal isometric contractions to enhance pubococcygeal

training. The study also considered the effect of altering the position of the lumbar spine during exercise and concluded that a neutral or extended position is preferable.

The functional evaluation of pelvic floor musculature is rife with technologic and cultural challenges. Compared with muscles outside of the pelvis, quantitative and reproducible evaluation of the levator ani kinesiologic function is difficult. The levator ani muscles are attached to the bony surfaces of the pelvis, which hinders the measurement of an isometric contraction in a reproducible manner. These data demonstrate that pelvic floor muscle strength increases with exercise training, which is consistent with previous studies that have determined quantitative increases in perineometry,<sup>17</sup> digital pelvic muscle strength scores,<sup>30,31</sup> and gross vaginal electromyographic activity<sup>24,31</sup> with PFMT. The variations in quantitative alterations reported in these studies no doubt reflects variations in training regimens and recording techniques.

Maximal contractions of skeletal muscle increase strength by a combination of an increase in the efficiency of motor unit activation and hypertrophy of type I (slow-twitch) and type II (fast-twitch) muscle fibers,<sup>32</sup> which lead to an increase in muscle volume. The pelvic floor musculature is uncommon in that it is the only group of voluntary muscles except for the respiratory diaphragm in which type I fibers predominate.<sup>10</sup> The mechanism of efficacy of PFMT is unknown, but it is logical that hypertrophy of the striated levator ani<sup>33</sup> with concomitant increases in kinesiologic function should improve continence by increasing bladder outlet resistance during physical stress and during moments of urgency and inappropriate detrusor activity. Studies of muscles outside of the pelvis in elderly women have demonstrated that strength training preferentially increases the diameter of type I fibers with no alteration in the ratio of fiber types within the muscle. In addition to the absolute strength of a pelvic floor muscle contraction, it is possible that the timing of the contraction can affect leakage during physical stress<sup>17</sup> or urge.

Response to PFMT may in part depend on alterations in neurophysiologic performance of the neuromuscular unit. Studies of muscles outside the pelvis demonstrate that training increases the efficiency of neural activation,<sup>34</sup> and in middle-aged and elderly subjects, increases in muscle strength seem to depend more on increased motor unit activation than on muscle fiber hypertrophy.<sup>35</sup> This type of electromyographic testing has not been used to evaluate pelvic floor muscle response to training. Given that pelvic floor musculature has a high proportion of type I (slow-twitch) muscle fibers, it is likely that improvements in resting pelvic floor muscle tone are important in improving continence during daily activities.

### Clinical Studies of Pelvic Floor Muscle Training Programs

Several randomized, controlled trials have demonstrated PFMT to be effective in the treatment of SUI. In experimental studies such as randomized, controlled trials, the investigators seek to change the dependent variable (e.g., urinary leakage) by manipulation of an independent variable (e.g., PFMT) to establish a cause-and-effect relationship.

Few researchers have analyzed the results comparing strength increase or maximal strength with improvement in urinary incontinence after training, and the results of the few published studies are contradictory. Dougherty and colleagues,<sup>36</sup> Hahn and coworkers,<sup>37</sup> and Boyington and associates<sup>38</sup> did not find any correlation between a change in pelvic floor muscle strength and

urine loss. However, modifying their analysis, Boyington and colleagues<sup>38</sup> found an association between a decrease in urine loss variables and increases in pelvic floor muscle pressure curve variables.

Conflicting results have been shown in case-control studies measuring pelvic floor muscle strength in continent and incontinent women. Some researchers have shown a significantly higher degree of pelvic floor muscle strength in continent women.<sup>39-41</sup> In other studies, no differences have been demonstrated.<sup>36,42</sup> The conflicting results may reflect small sample sizes, use of unreliable and insensitive outcome measures, and use of unreliable and insensitive methods to measure pelvic floor muscle strength.

We<sup>43</sup> demonstrated that intensive PFME combined with weekly group training was significantly more effective than the same exercises conducted at home. Because all women participating in this study had learned to contract the pelvic floor muscle correctly and had had the same monthly individual follow-up with measurement of pelvic floor muscle strength, development of muscle strength could be analyzed by combining results from responders and nonresponders from both groups. Another justification for analyzing all participants together is that the study is not looking for treatment effect but instead seeks the relationship between pelvic floor muscle strength and other outcomes.

There is no consensus about which outcome measure to choose for assessing cure or how to classify a responder to treatment for incontinence. However, combinations of subjective report and laboratory measurement of the condition have been recommended.<sup>44,45</sup>

In the few published studies in this area,<sup>46</sup> different methods have been used to evaluate pelvic floor muscle function and showed that urine loss decreased as pelvic floor muscle function increased. Boyington and colleagues,<sup>38</sup> measuring vaginal squeeze pressure, did not find a correlation between an increase in muscle strength and improvement in leakage.

To achieve reduction of urinary leakage by PFMT, the training has to be of sufficient intensity, frequency, and duration to cause a significant change in muscle function.<sup>47</sup> The intensity of the contraction is the most important factor in developing muscle strength.<sup>32</sup> To improve the neural adaptation (i.e., recruitment of efficient motor units and frequency of excitation) and hypertrophy, the training period should be at least 5 months.<sup>48</sup> Lack of or insufficient improvement in muscle strength after PFME may explain why some researchers have failed to find significant differences between methods<sup>49,50</sup> or correlation between the independent and dependent variables.<sup>37</sup>

Several studies have demonstrated that more than 30% of incontinent women are unable to contract the pelvic floor muscle correctly.<sup>30,51</sup> Bump and coworkers<sup>51</sup> showed that only 49% of the women able to contract the pelvic floor muscle performed a contraction effective enough to increase urethral pressure.

This may explain why some researchers have failed to find a correlation between increased vaginal pressure and reduction of leakage. Measurement of voluntary contraction in a supine position may not be a valid assessment of automatic co-contraction during an increase in abdominal pressure in an upright position. One study<sup>52</sup> investigated the effect of two approaches to PFMT in stress incontinent women ( $N = 128$ ). It is common practice for women to receive instruction in strength training combined with advice to voluntarily contract the pelvic floor muscles to prevent leakage with increases in intra-abdominal pressure (e.g., cough). The use of a voluntary contraction before an increase

intra-abdominal pressure, called the knack, and is based on motor relearning principles.

Randomization to an intervention group by opening sequentially numbered, sealed opaque envelopes took place after clinical history taking, physical examination, baseline measures, and an explanation of the normal anatomy, physiology, and function of the bladder and pelvic floor muscles. Women then received instruction based on motor relearning principles alone or a combination of strengthening and motor relearning. Women trained at home for 20 weeks, with four physiotherapy clinic visits and three phone calls to progress the program and maintain motivation. There were no statistically significant differences in the primary measures of outcome between the strength training plus motor relearning or motor relearning program groups.

The confidence intervals for the difference in leakage episodes and cough test do not rule out clinically important differences. Despite an attempt to design a study of adequate power, a larger trial is needed to address the question of important differences between these two approaches to PFMT. One study<sup>53</sup> was undertaken to determine the degree to which complete loss of the pubococcygeal muscle affected women's ability to volitionally augment their urethral closure pressures by using a volitional pelvic floor muscle contraction (i.e., Kegel effort). The sample consisted of a subset of women who volunteered as healthy controls in a larger study approved by an institutional review board. They were free of urinary leakage or prolapse and had a negative stress test result. Multiplanar, proton-density magnetic resonance images of the pelvis were obtained in all women. A trained observer evaluated each scan to determine pubococcygeal muscle status. Women were selected for analysis if they demonstrated an intact pubococcygeus muscle ( $n = 28$ ; mean age, 54 years) or absent pubococcygeal muscle ( $n = 17$ ; mean age, 59 years). Women with parietal defects (e.g., one side only) were excluded. Women were then asked to perform two or three Kegel efforts while the transducer was held at the point of maximal urethral closure pressure. The investigators concluded that women with an absent pubococcygeal muscle are only one half as likely to be able to increase their urethral closure pressure more than 5 cm H<sub>2</sub>O and generate 43% less pressure with pelvic muscle contraction compared with women with normal women muscle training.

## BIOFEEDBACK THERAPY

As described in the Chapter 19, biofeedback can be defined as the use of monitoring equipment to measure internal physiologic events or various body conditions of which the person is usually unaware. The basic approach is to provide individuals with information about the physiologic activities in their bodies, including their brains. These include sensors (i.e., electromyographic and pressure sensors) for detecting and measuring the activity of anal or urinary sphincters and pelvic floor muscles. Techniques have been also developed to measure activity of urinary stress incontinence. One aim of physical therapy has always been to assist patients by improving physiologic self-regulation within their natural environment.

### Pelvic Floor Muscle Biofeedback

Several approaches have been used for measuring pelvic floor muscle activity to provide biofeedback, including urethral, vaginal, or anal feedback using manometry or electromyography.

An important technical issue is the quality of the signal source used for feedback. As early as the 1940s, Kegel<sup>28,54</sup> developed and used the perineometer, an instrument that consisted of an intravaginal balloon attached to an external pressure gauge, which registered the pressure exerted by the pubococcygeus muscles. It was the first biofeedback device for PFMT. This method uses manometry (pressure) biofeedback by means of an intravaginal or intrarectal device. An advantage of pressure manometry is that as the patient contracts her pelvic floor muscles, the device produces a resistive pressure that may give additional feedback to the patient. After the vaginal manometry method, electromyography emerged for recording pelvic floor muscle activity. Different signal sources have been used, but electromyographic activity has evolved as the preferred signal source for many types of biofeedback therapy.<sup>55</sup>

Electromyographic activity of pelvic floor muscle contractions has become a common signal source for the treatment of urinary incontinence.<sup>56</sup> Vaginal electromyographic activity is recorded by means of surface electrodes in the vaginal introitus or a vaginal probe with electrodes embedded. The vaginal probe is easy to insert and remove, and it is usually comfortable.

Biofeedback of the urethral or anal sphincter or pelvic floor muscles is used in the management of urinary incontinence and voiding difficulties. The external anal sphincter and the external urethral sphincter have similar innervation through branches of the pudendal nerves. Although there are conflicts in the literature about the issue of correspondence between the anal and urethral sphincters, several studies indicate that these muscles act in concert,<sup>57</sup> and data indicate that training and controlling the anal sphincter results in urinary sphincter activity that corresponds in magnitude.<sup>58</sup> Anal sphincter activity can be measured by pressure balloons located by the external anal sphincter (for manometry) or by surface electrodes placed around the anus at the 10-o'clock and 2-o'clock positions.

Electromyographic activity can be measured by electrodes embedded in a rectal probe. The electromyographic instruments are designed to detect the weak electrical signals generated during muscle contraction. Surface electrodes are electrically conductive pathways in contact with the skin (over abdominal muscles) or mucosa (vaginal or anal tissue). Continuous monitoring of the electromyographic signal is important to ensure that there is no undetected signal interference and that electrode placement provides an appropriate signal. Correct placement of surface electrodes is fundamental to detect and measure a signal accurately. The three common signal sources (bladder pressure, anal sphincter pressure, and vaginal electromyographic activity) are significantly altered by increases in intra-abdominal pressure. Simultaneous measurement of abdominal activity should be done with all biofeedback therapy techniques. Intra-abdominal pressure can be measured easily using an internal rectal balloon. Electromyographic activity of the rectus abdominis muscles can be determined by surface electrodes. The abdominal muscle activity is displayed by means of two active electrodes placed 3 cm apart just below the umbilicus. A ground electrode is placed on a convenient bony prominence, such as the iliac crest.<sup>59-61</sup>

Electromyographic biofeedback training is used to increase the activity of weak muscle groups and to promote relaxation of spastic or tense muscles.<sup>62</sup> In the case of urinary stress incontinence, the function required is to assist the urethral closure pressure provided by the urethral sphincter. This requires a quick, maximal voluntary contraction of the pelvic floor muscles, and the training program must emphasize type II fibers. However, the contribution of type I fibers should not be overlooked. They

**Figure 28-1** Pelvic floor muscle training programs. **A**, Voluntary contractions of the pelvic floor muscles, called the digital perineal technique, are performed with the help of the therapist. **B**, Pelvic floor muscles exercises with coactivation of the abdominal muscles. It is assumed that the activity encourages submaximal deep abdominal contractions that enhance pubococcygeal training. **C**, A set of vaginal cones ranging from 20 to 90 g are inserted into the vagina. When the patient stands and walks around, the vaginal cones tend to drop out of the vaginal, triggering a reflex contraction.

are responsible for maintaining the postural position of the pelvic floor, from which type II fibers can function effectively (Fig. 28-1).

### Clinical Practice and Techniques

Using three-channel biofeedback, patients are taught to contract and relax pelvic floor muscles selectively without increasing bladder pressure or intra-abdominal pressure. In our practice,<sup>62-64</sup> my colleagues and I use a microcomputer-based system with a wide range of parameters that allows us to regulate the treatment according to the specific requirements of the patient, especially in daily activities. The system records simultaneous measurements of electromyographic activity of the pelvic floor muscles, rectus abdominis muscles, and other skeletal muscles (e.g., gluteal, adductors).

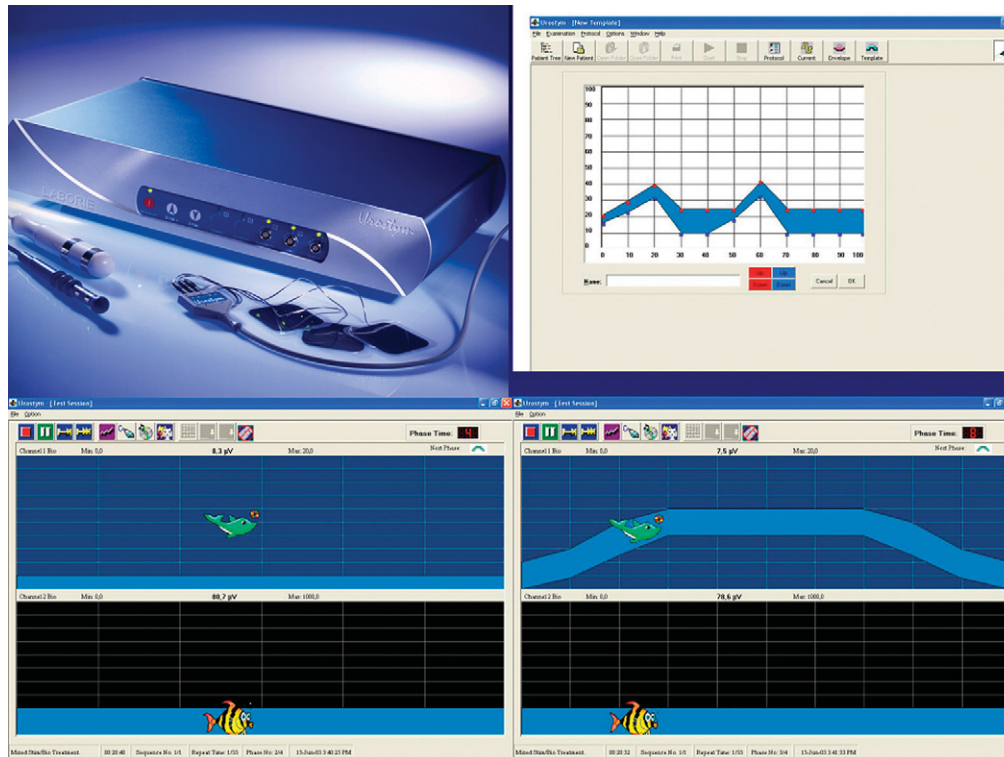

In clinical practice, I use pelvic floor therapy systems, which include products for home-based and office-based treatments and provide the most comprehensive and advanced platforms for treatment of pelvic floor dysfunction. The available equipment typically ensures effective treatment outcomes for most patients. The most important features are adjustable color and screen configuration, session graphs with summaries of data, audio and visual goal setting, annotated markers, templates, and animation (see Fig. 19-5 and 19-6 in Chapter 19). Using such equipment, it is possible to provide more enjoyable exercise programs (i.e., various levels of difficulty) and to conduct statistical analyses (Fig. 28-2).

### Muscle Strengthening

The pelvic floor muscles hold the pelvic organs like a hammock, providing support and stabilization. Normally, when the woman is erect, the levator ani muscles, together with the respective fasciae, contribute to the support of the vaginal canal, urethra, and rectum. In patients with pelvic relaxation, this normal muscular support is lost. The levator ani hiatus is wider, and the levator plate is weakened and relaxed. When the pubococcygeal portions of the levator ani sling contract, they shorten lengthwise, gaining thickness and lessening the pelvic floor aperture transversely, thereby reducing the anteroposterior diameter considerably.<sup>65</sup> A tonic contraction of the levator ani maintains a high position of the vesical neck and may compensate for an increase in intra-abdominal pressure. The levator ani support<sup>66</sup> is provided predominantly by slow-twitch fibers, which are responsible for maintaining static muscle tone. During stressful events, phasic fast-twitch fibers provide a rapid forceful contraction.<sup>67,68</sup> When muscles have weakened, there is little perception of the contraction because the intensity of the proprioceptive feedback to the brain is relative to the amplitude of the muscle contraction. Muscle strength can be improved through a program of PFMEs.

In planning a PFME program, it is important to follow some basic guidelines. Patients should be selected according to grades of the pelvic floor muscles. A trained therapist should be present to give proper instruction about the level of contraction, and the exercise program should be tailored to the individual. Body positions should be modified after several sessions, and types of

**Figure 28-2** A stationary device with a wide range of parameters is used to provide electrical stimulation and biofeedback therapy (*top*). Using this equipment, it is possible to provide more enjoyable exercise programs, such as the dolphin game (*bottom*). (Courtesy of Laborie Medical Technologies, Montreal, Canada.)

contraction should be alternated. During exercise sessions, it is important to recruit fast-twitch fibers by fast contractions to develop strength and recruit slow-twitch fibers by slow contractions to increase endurance.<sup>67</sup> Regular strength training increases the number of activated motor units, frequency of excitation, and muscle volume. To induce hypertrophy, both fast- and slow-twitch fibers should be contracted. To achieve these objectives, a successful PFMT program must include rapid forceful contractions, sustained maximal voluntary contractions, and fast contractions superimposed on the end of each prolonged contraction.

Effective strength training relies on specificity (i.e., co-contraction of other groups of muscles such as the glutei and hip adductors should be minimized) and overload (i.e., increasing length and duration of contractions and reduction of rest periods). The only anatomic relationship between the levator ani and the other pelvic floor muscles is provided by the obturator internus. The pubococcygeal segment of the levator ani originates in the tendinous arch, a thickening of the obturator fascia; the iliococcygeus begins at a membranous insertion to the inner surface of the obturator internus at the tendinous arch of the levator ani.<sup>68</sup> This anatomic consideration of the voluntary or reflex contraction of the levator ani and obturator internus is important in setting up the protocol of a PFMT program. This endopelvic connection to the tendinous arch may assist the levator ani in support because it limits the descent of the pelvic organs during increased intra-abdominal pressure. In patients with weakening and stretching of the levator ani, even in those with partial denervation, some muscular components such as the obturator internus may be recruited in the early stages of PFMEs.

If there is a major weakness of the pelvic floor muscles, contraction of the gluteus maximus can produce an overflow of activity into the levator ani. Different exercises may be proposed to such a patient. The *flick contraction* exercise is performed by contracting and relaxing the levator ani as tightly as possible for 1 second. An average of 3 sets of 12 contractions during the session is recommended.

The *hold contraction* exercise is performed by lifting and pulling up the levator ani and holding the contraction for at least 6 seconds. As control improves, the time of this sustained contraction can be extended to 10 or 12 seconds. Patients are instructed to contract their muscles with 3 sets of 8 slow maximal contractions sustained for 6 to 8 seconds each.<sup>27,43</sup> Effective strength training relies on overload (i.e., increasing resistance to, frequency, or duration of muscle contraction). The *intensive contraction* exercise involves the recruitment of levator ani muscles with other groups of muscles in different positions, controlling the levator ani in increments to the point of maximal tension.

The treatment sessions are essentially training sessions that aim to increase the strength and endurance of the pelvic floor muscles. Because biofeedback requires effort, the sessions should not overtax the patient. In general, the initial sessions are shorter than subsequent sessions, and if the patient's performance begins to deteriorate, the session should be interrupted because muscle fatigue leads to muscle compensation. It is thought that PFMT and PFME is most useful if conducted in a variety of positions, including sitting and standing, rather than restricted to the traditional supine positions. Training periods of at least 20 weeks have been recommended, but it is important to assess patients

individually to determine the degree of pelvic floor muscle weakness to prevent adverse effects caused by muscle fatigue.

### Reflex Contraction

In normal situations, with increased intra-abdominal pressure, the rectum, uterus, and upper vagina are pushed downward and backward. The levator plate tenses and rises because of a reflex muscular contraction. Sudden increases in intra-abdominal pressure are transmitted to the urethra.

Sudden changes in abdominal pressure elicit a reflex contraction of the levator ani muscles. It has been suggested that a strong, fast, well-timed, voluntary pelvic floor muscle contraction<sup>70</sup> can clamp the urethra, preventing urethral descent and leakage during an abrupt intra-abdominal pressure change.<sup>71</sup> It has been claimed that the downward pressure from the abdominal viscera has to be offset by the strength of the urogenital diaphragm and that the forward pressure of the pelvic floor increases the tendency to visceral protrusion. This active element, resulting from a striated muscle effect, allows improved pressure transmission, but it also promotes greater efficiency of the pelvic floor reflex by active means. In pelvic floor disorders, female patients may lose this reflex muscle contraction, and one of the goals of biofeedback therapy is to enable patients to relearn this reflex.<sup>62,72</sup>

The teaching process aims to demonstrate how the levator ani muscles must be contracted before and during increased intra-abdominal pressure, particularly with strenuous effort during

heavy physical activity. During the learning process of the reflex contraction (Fig. 28-3), called the *stress strategy* or the *perineal blockage before stress technique*, the levator ani must be contracted before any rise of intra-abdominal pressure.<sup>62,73</sup> At the end of this process, women must be conscious of a constant contraction of the levator ani and can use the technique of perineal blockage before physical stress. This skill of using pelvic floor muscle contraction to prevent stress leakage has also been called the *knack*.<sup>17,74</sup> In the treatment of SUI, De Lancey<sup>75</sup> posits that a quick, strong pelvic floor muscle contraction can clamp the urethra, increasing urethral pressure and preventing leakage during an abrupt or sustained increase in intra-abdominal pressure. DeLancey<sup>76</sup> also suggests that an effective contraction of the pelvic floor muscle may press the urethra against the pubic symphysis, creating a mechanical pressure rise. The *reflex contraction* is a feed-forward loop because it may precede the bladder pressure rise by 200 to 250 ms.<sup>70</sup>

### Use of New Skills in Daily Activities

Urinary stress incontinence and pelvic organ prolapse are primarily related to erect posture. We may assume that erect posture and a constant increase in intra-abdominal pressure alter female urethrovesical function. In the vertical position, the urethra leaves the bladder at the point of maximal combined intra-abdominal pressure and gravity force. We can assume a certain relationship between pelvic floor support and intra-abdominal pressure. A pelvic floor muscle reflex occurs with a sudden

**Figure 28-3** Recordings of the levator ani muscles (top) and the transversus abdominis muscles (bottom) during the perineal blockage before stress technique or the knack. During the learning process of the reflex contraction, the levator ani must be contracted before any increase of intra-abdominal pressure.

increase in intra-abdominal pressure. On the basis of this concept, my colleagues and I developed the applied biofeedback technique, referring to electromyographic pattern of the levator ani combined with synergistic and antagonistic muscle activity in a standing position.

The evolution of women's professional and business activities and stressful environments represent high-risk factors for pelvic floor relaxation. The intra-abdominal pressure in the standing position is two or three times greater than that in the supine position. Without a treatment protocol implemented in a standing position, especially with movement, neuromuscular re-education is pointless. This method is based on the relationship between pelvic floor muscle control and rise in intra-abdominal pressure.

It consists of pelvic floor muscle contraction during the abrupt increase of the intra-abdominal pressure that occurs during standing and exercising.<sup>62,72,77</sup> In our practice,<sup>62,78,79</sup> my colleagues and I use office equipment that allows patients to assume different positions as they learn to use the pelvic floor muscles to prevent incontinence. The trainer helps patients change their reactions by establishing targets and assisting them in developing new habits and modifying their physical activities. The simulation of daily activities is an important stage in which selected "home stress" or a physical task is used to access the patient's ability to perform a real-life activity (Figs. 28-4 and 28-5). The patient usually should start with easy tasks and progressively make the activities more difficult and more functional. It is optimal for patients to be standing when they perform these exercises.

Successful recovery of the ability to perform daily activities without incontinence is most likely when the pelvic floor muscle strength is combined with a refined control of the functional activity. For this purpose, we use equipment,<sup>62,72</sup> including a video monitor connected to a computerized unit, that monitors the electromyographic activity of muscle groups. The patient is

**Figure 28-4** To monitor the use of new skills in daily activities, we use infrared telemetry, including a video monitor that allows the patient freedom of movement and activities while she uses the knack technique. All these programs are conducted in the standing position, and the patient is fully clothed. A light tampon vaginal probe and surface abdominal electrodes are used during the session. (Courtesy of YSY Medical, Nimes, France.)

**Figure 28-5** Applied biofeedback during physical activities. A short vaginal sensor and electrode wire set for accessory muscles are used for the exercise program. The patient lifts a heavy item while performing the perineal blockage or knack technique.

asked to perform various tasks that are similar to domestic activities, such as carrying a baby basket or lifting items from the floor. The perineal blockage technique is useful in providing feedback for the active woman during exercise.<sup>62,77,79</sup> In some cases, as soon as the pelvic floor contraction is effective, we request perineal contraction with synergic muscles (i.e., external hip rotators, gluteal muscles, and adductor muscles) and later with antagonist muscles (i.e., rectus abdominis). If the patient has some difficulty in performing these exercises, we suggest that she practice in different positions, such as lying and sitting.

For sportswomen,<sup>62,64,72,78</sup> my colleagues and I recommend using a treadmill and recently a new device with a mechanized oscillating platform (Huber, Spine Force, LPGS Systems) (Fig. 28-6), which represents the opportunity to combine speed and endurance. The underlying concept is that the circumstances and precipitants of incontinence must be taken into account during treatment sessions to provoke a reflex pelvic floor muscle contraction in response to stress. Accuracy of speed (2.5 to 6 mph) and slope (5% to 12%) is assumed for a precisely controlled workout. The introduction of the treadmill or other sports equipment into our program for sportswomen is one way to allow the patient to perform real physical activities in a medical environment.<sup>62,72,78</sup>

### Clinical Results

Many studies have demonstrated that treatment with biofeedback reduces incontinence. The data show that the treatments are safe and effective, and they yield high levels of patient satisfaction. PFMT is commonly implemented using simple verbal feedback given to the patient during palpation of the pelvic floor muscle by the therapist or biofeedback involving vaginal or anal electromyographic probes or pressure sensors. Several trials compared PFMT with biofeedback versus PFMT alone.<sup>79-83</sup> Most of the studies investigated the effect of biofeedback for women with stress incontinence with or without detrusor instability, comparing biofeedback-assisted PFMT with pelvic floor training alone.

**Figure 28-6** Applied biofeedback with a treadmill. The patient jogs for 15 minutes, and parameters are selected according to the type of exercise, strength, and endurance.

Burgio and colleagues<sup>80</sup> treated 24 stress incontinent women, who were between the ages of 29 and 64 years, for 6 weeks. One group received simultaneous bladder, sphincter, and abdominal pressure feedback, and the control group received verbal feedback based on vaginal palpation. All patients in both groups received comprehensive training in 100 trials across four training sessions. Cures or improvement (i.e., at least 50% reduction of incontinence) resulted for 92% of the biofeedback group and 55% of the control patients. The biofeedback group averaged 75.9% reduction in the frequency of incontinence, which was significantly greater than the mean of 51% shown by the verbal feedback group. The investigators concluded that although many patients can succeed without biofeedback, it improves the patient's ability to learn appropriate pelvic floor muscle contractions and increases the likelihood of successful outcome.

Berghmans and colleagues<sup>81</sup> suggested that the group that had biofeedback improved more quickly than the group that used only PFMT at 6 weeks, although there were no significant differences at 12 weeks. This finding has not been confirmed by any other study.<sup>81</sup>

In a controlled clinical trial, Wilson and colleagues<sup>82</sup> compared four groups: PFMT at home, hospital-based PFMT with

biofeedback, PFMT with interferential therapy, and PFMT with faradism. They reported greater symptomatic improvement in the group using hospital-based PFMT with biofeedback compared with PFMT at home. In a study by Morkved and colleagues,<sup>83</sup> 94 women with urodynamic stress incontinence were randomized to 6 months of PFMT with a physical therapist, with or without biofeedback at home. Training with home biofeedback resulted in higher rates of objective cure, but the difference between groups was not statistically significant.<sup>83</sup> The researchers found that the value of home biofeedback may be that it motivates many women, and they thought it should be an option in clinical practice.

Using biofeedback, pelvic floor dysfunction, including incontinence, can be brought under conscious awareness, including the contraction and relaxation of skeletal. Although surgery is usually necessary for women who suffer from severe SUI, biofeedback also can be useful for these patients because they can become actively involved in their own treatment and achieve better control of the perineal area.

## ELECTRICAL STIMULATION

### Basic Principles and Mechanism of Action

Electrical currents are applied therapeutically to stimulate muscle contraction, usually through activation of nerves that supply muscles. Electrical stimulation is an effective treatment for stress incontinence. This technique uses natural pathways and the micturition reflexes, and its efficacy relies on a preserved reflex arc, with complete or partial integrity of the pelvic floor muscle innervation.<sup>84</sup> Based on animal experiments, direct stimulation of afferent or efferent fibers appears to be the most important mechanism to enhance the reflex response. The mechanism of electrical stimulation for stress is urethral closure by contraction of the pelvic floor muscle fibers. Urethral closure occurs by direct stimulation. Closure of the urethra by electrical stimulation of the pudendal nerve is caused mainly by direct stimulation of the pudendal nerve efferent, which supplies the striated paraurethral and pelvic floor muscles and is supported by activation of hypogastric efferents to the smooth paraurethral muscles.<sup>85,86</sup>

Electrical stimulation is commonly used in the treatment of urinary incontinence and pelvic floor dysfunction to improve the function of the urethral sphincteric mechanism, levator ani muscles, and external anal sphincter. These muscles have fast- and slow-twitch fibers. The slow-twitch fibers may be important in developing sustained tone to occlude the urethra, whereas the fast-twitch fibers may be involved in pelvic reflex contraction.

Electrical stimulation may increase the bulk of the levator ani muscles and the proportion of fast-twitch fibers, thereby influencing the ability of muscles to respond to a sudden increase in intra-abdominal pressure. The stimulus may increase the number and strength of slow-twitch fibers, improving resting urethral closure. Threshold intensity varies inversely with fiber diameter. Any pulse configuration can provide nerve activation, and many stimulation waveforms have been used to cause neural excitation.<sup>87,88</sup> These configurations include biphasic capacitively coupled pulses, monophasic square pulses, biphasic square pulses, and monophasic capacitively coupled spike pulses. Short square-wave pulses (200 to 1000 ms) are the most effective. To minimize electrochemical reactions at the electrode-mucosa interface, biphasic or alternating pulses are recommended.<sup>89</sup>

The size and position of the electrodes are of utmost importance to the response. Small electrodes and high charge densities are necessary to avoid tissue damage, which presumably depends on the generation of heat and formation of toxic products through electrochemical reactions. Heat production correlates with the amount of energy delivered and the electrochemical reactions to the electrical charge transferred by each pulse. The use of a low frequency further reduces energy consumption. Bidirectional pulses can reduce electrochemical reactions, and intermittent stimulation helps to avoid harmful effects by decreasing total energy.<sup>90</sup>

The effects of electrical stimulation on urethral closure are optimal with stimulation parameters between 35 and 50 Hz. The sacral afferent nerves, particularly the autonomic nerves of the pelvic organs, are poorly myelinated (A $\delta$ ) or unmyelinated (C) fibers, which conduct current at a slow rate of 5 to 20 Hz. Low frequencies (1 to 5 Hz) generate twitch contractions, allowing little sustained tension to develop in the muscle. Slow-twitch muscle fibers have a natural firing rate of 10 to 20 Hz, whereas fast-twitch fibers fire at 30 to 60 Hz. Current frequencies of greater than 40 Hz may cause undue fatigue and should be avoided. In a healthy muscle at frequencies of approximately 30 Hz, muscle contractions usually become fused or tetanized, so that a smooth contraction is apparent. Current frequencies of 10 to 40 Hz that last approximately 250 to 500 ms activate fast and slow motor neurons. At high frequencies, the muscle weakens rapidly because of neuromuscular transmission; at lower frequencies, less fatigue occurs. Chronic stimulation may increase the relative number of slow-twitch fibers, probably by helping to transform fast-twitch fibers to slow units, which can sustain the contraction longer. Stimulation recruits muscle fibers in a less predictable order than that of a voluntary contraction (i.e., type II fibers may be recruited before type I).<sup>91</sup> Long-term electrical stimulation<sup>92,93</sup> induces almost complete transformation of fast-twitch to slow-twitch fibers that have a high-energy capacity. Frequencies of 10 to 60 Hz induce such transformation, which occurs after almost 30 days of electrical stimulation. Most patients have some relapse after 30 days, possibly as a result of the reverse process associated with immobilization or inactivity. During the on time, the stimulation delivers a train of individual pulses of prescribed amplitude, duration, and frequency.

The length of the off time defines the recuperative period for the stimulated muscles.<sup>94</sup> The length of the off time defines the recuperation period for stimulation. The ratio of stimulation time to rest time is called the *duty cycle*. A typical duty cycle is approximately 1 : 2.

The patient's diagnosis and degree of muscle weakness should be considered when identifying a suitable duty cycle for initiation of the electrical stimulation program.<sup>94</sup> In case of weakness or neurologic impairment, a ratio of 1 : 3 may be appropriate.<sup>95</sup> As muscle strength or endurance improves, the ratio of on-to-off time may be decreased. Most commercially available devices allow adjustment of the time that the stimulus takes to reach peak intensity and return to zero intensity. To reduce the problem of discomfort, the amplitude of the stimulus (i.e., intensity) is progressively delivered, allowing the patient to become accustomed to the stimulation as it increases from no perceptible levels to sensory and then to motor thresholds. Most electrical stimulators introduced in the past decade provide constant voltage or constant current that maintains the same current waveform, regardless of changes in impedance. Great individual variations in the

stimulus can be tolerated without incurring unpleasant sensations. This difference is related to impedance.

Significant evidence shows denervation of the pelvic floor in women with pelvic floor dysfunction, mainly as a result of vaginal childbirth or other pelvic trauma, surgery, or aging. Pudendal nerve latency is prolonged by vaginal delivery<sup>96,97</sup> and vaginal surgery for prolapse.<sup>98</sup>

Patients with urinary incontinence or pelvic organ prolapse have longer pudendal nerve latency periods than continent control subjects.<sup>99</sup> Histologic evidence of denervation was seen in biopsy specimens taken from the pubococcygeus at surgery for genital prolapse or stress incontinence.<sup>98</sup>

To improve urethral closure, innervation of the pelvic floor must exist. No effect can be expected in patients with complete lower motor neuron lesions. If the muscles are completely denervated, physiotherapy is unlikely to be effective. However, any surviving muscle fibers will be hypertrophied. After denervation injury, such as occurs after pelvic surgery or vaginal childbirth, electrical stimulation may be used to recondition muscle and facilitate sprouting of surviving motor axons. These abnormalities are potentially reversible or at least treatable, because the nerve supply is not completely disrupted.<sup>91</sup> Because electricity has been used to stimulate denervated muscle for many years, electrical stimulation could be used to produce reinnervation or electrical reorganization of the pelvic floor. Although the reason for stimulating denervated muscle appears logical, findings on the efficacy of such treatment are contradictory.

There is no unanimity of opinion about the ultimate degeneration of denervated muscle fibers. When discussing the therapeutic technique, particular attention must be paid to the following requirements:

- The duration of the impulse should be as short as possible but long enough to elicit a contraction.
- The rest period between successive stimuli should be at least four to five times longer than the duration of the stimulus.
- The increase should be as steep as possible to avoid stimulation of intact axons.
- The intensity of the stimulus must be sufficient to achieve a moderately strong contraction, but it should avoid causing the patient unnecessary discomfort.<sup>84</sup>

Stimulation to enhance motor control, whether it is called a facilitation technique or a muscle re-education program, provides a tremendous amount of sensory information to the central nervous system through a variety of sensory modalities and afferent pathways for automatic and conscious processing. Electrical stimulation may improve reinnervation after partial denervation by enhancing sprouting of surviving motor axons.

In summary, therapeutic stimulation is recommended for women with urinary incontinence and pelvic floor dysfunction<sup>84</sup> who underwent unsuccessful PFMT as a first-line treatment. Pelvic floor electrical stimulation offers a nonsurgical approach for treating urinary incontinence. The stimulation increases the urethral resistance by strengthening the pelvic floor muscles. Electrical stimulation must be performed in conjunction with a pelvic floor training program (for stress incontinence) and biofeedback.

### Extracorporeal Electromagnetic Stimulation

Pulsed electromagnetic fields, rather than continuous fields, are most commonly used for the stimulation of human tissue. These

fields are generated by high-voltage electric currents applied to a surface stimulation coil. At the tissue level, electrical eddy currents are induced by a flow of ions establishing differences in voltage between two spatial points. If the voltage gradient is strong and the change of field is rapid, membrane depolarization occurs, establishing an action potential along adjacent peripheral nerve tissue.<sup>100</sup> In the pelvis, stimulation of the lumbosacral roots initiates this sequence of events, leading to nerve depolarization, stimulation of the motor end plates, and ultimately, pelvic floor muscle contraction.<sup>101</sup> In contrast to electrical stimulation, which directly stimulates the nerve,<sup>102</sup> magnetic stimulation is a vehicle that secondarily generates ion flow and eddy currents to which nerve tissue is particularly sensitive.

Conventional stimulators deliver pulses lasting less than 100  $\mu$ s at frequencies of 20 to 50 Hz. The depth of magnetic field penetration, or focal length, is proportional to the diameter of the stimulating coil. The spatial distribution of the maximum magnetic field reflects the size and shape of the stimulating coil, usually a hollow-centered doughnut, in contrast to the bull's-eye field that is created by electrical stimulation.<sup>102,103</sup> Magnetic pulses can facilitate the stimulation of autonomic and somatic nerve pathways in the pelvic floor without the use of electrodes.<sup>104</sup>

For therapeutic application, it was first reported that high-frequency or continuous magnetic stimulation of S3, delivering up to 20 pulses/sec, produced clinically useful stimulation of the pelvic floor musculature, increased pressure in the anal canal,<sup>105</sup> and generated contraction of the external sphincter. Extracorporeal electromagnetic stimulation does not require any probes, skin preparation, or physical or electrical contact with the skin surface.<sup>102,103</sup>

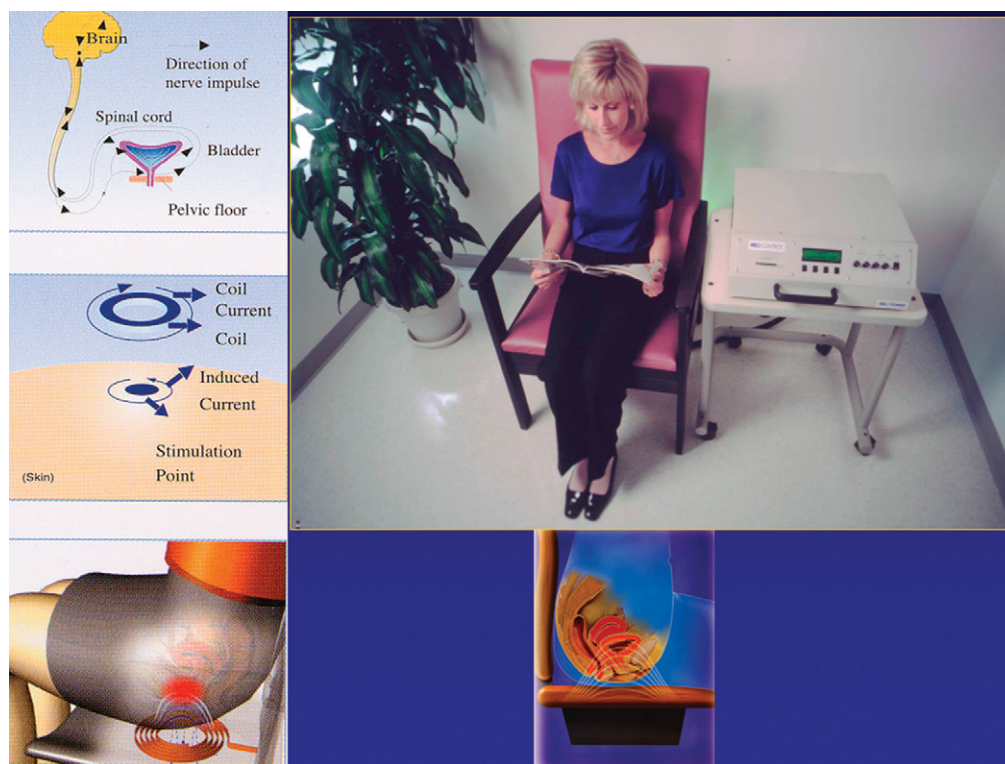

The patient sits fully clothed on a chair that contains an electromagnet controlled by an external power source (Fig. 28-7). Optimal coil position can be mapped by visual confirmation of toe flexion or abduction of the legs and the sensation of anal contractions. In clinical practice, treatment is typically performed for 6 to 10 weeks, with two sessions weekly. Each session lasts 24 minutes, with 10 minutes at 20 Hz and 10 minutes at 50 Hz and with 4 minutes of rest.

Extracorporeal electromagnetic stimulation provides a useful alternative for patients who do not respond to drug therapy, are poor surgical candidates, or lack the agility to manage electrical stimulation devices.<sup>102,103</sup> Electrical stimulation is indicated for patients who are not strongly motivated to perform pelvic floor exercises, for those with weak pelvic floor muscle activity, and for those with contraindications to surgery (e.g., genuine stress incontinence) or medication (e.g., urinary incontinence).

Electrical stimulation is an effective mode of therapy for urinary incontinence and pelvic floor dysfunction. As the use of electrotherapy grows because of advances in technology, it is necessary for health care professionals to carefully analyze innovative applications and demand a demonstration of the efficacy of this therapy.

### Clinical Results of Electrical Stimulation

The interpretation of data may be limited because patients often are not classified urodynamically. Sand and colleagues<sup>106</sup> conducted the only placebo-controlled study of electrical stimulation. It showed the unquestionable superiority of the treatment arm. Fifty-two women with genuine stress incontinence were

**Figure 28-7** Principle of extracorporeal electromagnetic stimulation. The patient sits fully clothed on a chair that contains an electromagnetic controlled by an external power source. The magnetic field activates all of the branches of the pudendal nerves, inducing repetitive contractions of the pelvic floor musculature. (Courtesy of Neotonus Inc., Marietta, GA.)

enrolled (35 in the treatment group; 17 in the placebo group). The treatment group underwent 12 weeks of stimulation twice daily, and current was delivered through a single vaginal electrode. The parameters used were 50 Hz with a pulse width of 0.3 ms. Intensity varied from 0 mA to 100 mA, and the duty cycle was 5 seconds on and 10 seconds off. The placebo group received sham electrical stimulation with output limited to 1 mA. The number of episodes of incontinence decreased significantly in the treatment group, as measured by daily ( $P = .04$ ) and weekly ( $P = .009$ ) leakage and by the pad test.

Subjective assessment of frequency of urine loss showed significant improvement in the treatment group. Luber and Wolde-Tsadik<sup>107</sup> performed a prospective, randomized, controlled study to evaluate the effect of electrical stimulation on urinary incontinence. They used a sample of 54 patients who had genuine stress incontinence. Patients in the treatment group ( $n = 20$ ) underwent treatment for 15 minutes twice daily for 12 weeks with vaginal electrode stimulation at a frequency of 50 Hz and pulse duration of 2 ms. The placebo group ( $n = 24$ ) underwent sham electrical stimulation with no current in the patient circuit. Subjective cure and improvement rates at 3 months were 25% and 29.2% in the treatment and sham treatment groups, respectively. Rates of objective cure (i.e., negative stress test results on urodynamic studies) were 15% of treatment group and 12% of control group. Subjective cure was improvement in 25% in the treatment group.

Clinic-based electrical stimulation may be useful for women unable to produce a voluntary contraction. However, clinic-based treatment requires that women attend on a regular basis and uses clinic resources and the therapist's time. It has been suggested that home-based electrical stimulation would provide a more cost-effective option.

An interesting study<sup>108</sup> set out to investigate how effective this approach might be in clinical practice. One hundred seventy women, who were diagnosed as having urodynamically proven genuine SUI, were recruited to the study over a 3-year period, and 20 were randomized to have treatment deferred and then went on to receive active stimulation. Having given informed consent, they were randomized to one of four treatment groups: closely supervised conventional pelvic floor exercises, the same exercise program with the use of a portable stimulator, the exercise program and use of an identical but electrically disabled dummy stimulator, or no initial treatment (i.e., control group). Treatment was carried out over a 14-week period and was closely supervised by an experienced research physiotherapist. The control group had no treatment for a 14-week period before entering the active stimulation group. The deferred group showed no statistically significant improvement compared with the other treatment groups.

Symptom scores and quality-of-life scores improved significantly in all treatment groups, but not in the control group. No statistically significant differences between treatment groups were detected. Compliance was assessed as *excellent* if the PFMEs and use of the stimulator were performed daily, *good* if more than three times per week, *poor* if less often than this, and *unrecorded* if not recorded or withdrawn from the study. Compliance with PFMEs was generally good, with three fourths of the women in all groups performing exercises more than three times weekly. Compliance with use of the stimulators was poor, with less than one half of the stimulator groups using the devices regularly. Reasons given for poor compliance with the stimulators included lack of time, lack of privacy, and discomfort caused by the stimu-

lator. The researchers concluded that in a group of women with urodynamically proven genuine SUI, PFMEs under the supervision of an experienced physiotherapist led to significant improvements in pad-test urine loss, symptom scores, and quality-of-life scores. The addition of home electrical stimulation did not improve the results of therapy. Clinic-based electrical stimulation, under supervision, may enhance the results of physiotherapy, but the use of home stimulators is of little benefit and merely increases the cost and complexity of treatment.

Another study reported the women's preferences for treatment of urodynamic stress incontinence by physiotherapy or surgery.<sup>113</sup> A package was developed for women with urodynamic stress incontinence that had three sequenced sections: a questionnaire eliciting the patient's current knowledge of available treatments, including the origins of the knowledge; three one-page information sheets describing pelvic floor treatment (PFT) by women's health physiotherapists, the tension-free vaginal tape (TVT), and open colposuspension as options for treatment, including success rates and complications; and a questionnaire eliciting hand-written responses about the patient's preferred treatment, the reasons for her choice, and whether she wished to ask questions.

The package was developed by three urogynecologists, two physiotherapists, and a professor of medical sociology. The patients were informed that regardless of their preferences, the final decision about treatment modality would be made jointly between themselves and a doctor after the questionnaire was completed. Based on an estimation that 70% of women choose pelvic floor treatment over surgery and an estimated prevalence of 240 cases of urodynamic stress incontinence per year in the three units, a sample size of 138 was determined. After reading the information sheets, 44 (66%) women chose PFT as their preferred management, followed by the TVT (24%) and colposuspension (9%), with nonsignificant differences among the three units. Nine percent of women attempted to avoid making a choice, requiring encouragement and guidance by the doctor administering the questionnaire. Of the 44 women who chose PFT, 67% cited lack of invasiveness and low risk as the main reasons. Ten percent wanted to avoid a possible cesarean section in the event of a subsequent pregnancy. Of those who chose the TVT, the predominant reasons were failed home pelvic floor exercises (25%), the minimal invasiveness of the TVT (23%), and the early discharge and recovery associated with this procedure (29%) compared with colposuspension. Of those who chose colposuspension, the most common reason (50%) was that it sounded more permanent than the TVT.

Forty-two percent of women said that their physicians did not discuss treatment options. Patients who stated that their physicians discussed only physiotherapy ( $N = 20$ ) chose this treatment in 80% of cases. In contrast, those whose physicians discussed only surgery ( $N = 6$ ) chose PFT in only 17% of cases. Similarly, of seven patients who indicated they knew of friends who were happy with their surgical treatment, six chose a surgical option. Among 19 women whose physicians did not discuss treatment and who did not hear about friends' choices, 74% chose PFT, which was not significantly different to the overall PFT. There were 38 (58%) who wanted to ask a question. The most common question was "What does the doctor think is best for me?" (23%). The investigators concluded that making a decision based purely on factual information is difficult for many women. However, when given standardized, unbiased information, 33% of women bypassed PFT and chose surgery, citing failed home pelvic floor

training, minimal invasiveness, and fast recovery as the predominant reasons for TVT and the long-lasting effect for colposuspension. Two thirds of women chose PFT, citing low risk as the main reason. These are informed choices based on standardized information sheets, and they may suggest that women choosing surgical options have a speedier course to surgery. Whether in an era of informed choice women choosing surgery should be permitted to bypass PFT is beyond the scope of this study, but it is a matter for debate. The influences on women's preferences are unclear, but it may be that women whose physicians or friends emphasize one treatment are likely to come to urogynecology units with predetermined preferences and are likely to choose that option.

### INTRAVAGINAL RESISTANCE DEVICES AND ANTI-INCONTINENCE DEVICES

Many devices—mainly air- or water-inflated balloons or perineometers—operate on the same principle. After the device is inserted into the vagina, the patient is asked to contract the pelvic floor muscles. The device then is pulled out of the vagina with a pulley system that applies gradually increasing force.

Vaginal cones were developed by Plevnik in 1985<sup>114</sup> as a new method to allow patients to train the pelvic floor musculature on a daily basis at home, without the need for a physiotherapist. This simple concept uses a set of cones ranging from 20 to 100 g that are inserted into the vagina. When the patient stands and walks around, the cones tend to slip out of the vaginal ring, giving a sensation of falling out that results in a pelvic floor muscle contraction. After the patient can hold the 20-g cone in the vagina for 20 minutes on two separate occasions, the next heaviest cone is used.

This pelvic floor muscle contraction is carried out through reflex activation of the sensory afferent fibers of the pudendal and pelvic nerves. The activation occurs when vaginal wall mechanical tension receptors are activated and stimulate the pelvic floor muscles by pudendal nerve efferents mediated through an S2-S4 sacral cord reflex. This technique has the advantage of forcing the patient to contract only the pelvic floor muscles and not other groups of muscles, such as the abdominal or gluteal muscles, which are often contracted simultaneously during voluntary pelvic floor exercises. A single trial compared PFMT in combination with cones with PFMT alone and found significant improvement in both groups, with almost identical cure rates (84.5% and 85.5%).<sup>115</sup> PFMT alone seems to be as effective as PFMT combined with biofeedback, intravaginal resistance devices, or electrical stimulation. Many physiotherapists use these other techniques as adjunct treatments for genuine SUI or mixed incontinence.<sup>116</sup>

Devices that are used to manage urinary stress incontinence work by the following mechanisms:

- External urinary collection
- Intravaginal support of the bladder neck
- Blockage of urinary leakage by occlusion at the external meatus or with an intraurethral insert

Indications for anti-incontinence devices include the following:

- Initial or long-term management of urinary incontinence
- As an adjunct to conservative therapy, such as PFMT

- To postpone or avoid surgery
- After other forms of therapy have failed

These devices may allow women to resume a normal level of activity or to participate in sports without the need for surgery. Various degrees of manual dexterity are required, depending on the type of device used. External collecting devices are cumbersome and do not have documented efficacy. Intravaginal devices are familiar to most women because they are similar to sanitary tampons. They are easy to use and can be worn for longer periods without being removed to allow micturition. These features make them practical for everyday use, and they reduce the cost of treatment. Intraurethral devices may be difficult to insert and can cause urethral irritation, urinary tract infection, hematuria, and migration to the bladder. They must be removed to allow voiding, making them expensive for daily use. Various external occlusive devices are available, some of which can be reapplied after voiding and reused for up to 1 week. However, long-term efficacy and safety data have not been reported.

### POSTOPERATIVE RECOMMENDATIONS

Changing a person's behavior, environment, or lifestyle can mitigate or reduce symptoms (i.e., urine leakage or incontinence, urgency, frequency, and nocturia), even after anti-incontinence surgery. The main reason for these postoperative recommendations is that most of the causes that lead to urinary stress incontinence remain the same after surgery. Patients can be divided into two categories: those who still have the same lifestyle (group 1) and those who present with high-risk factors for pelvic floor dysfunction (group 2). Group 1 patients present with different conditions, such as smoking, bad dietary habits, obesity, or constipation. Group 2 patients include active women who wish to practice high-impact sports after surgery. Repetitive bouncing can increase abdominal pressure and transmit the impact to the bladder. Because urinary stress incontinence occurs during physical exertion, this condition represents a major problem for women participating in fitness programs or sports activities and is probably a cause of relapse after surgery. Other patients who are at risk after surgery work in a standing position and are obliged to lift heavy loads during the day. This movement may place these women at risk for urine loss due to increased intra-abdominal pressure and an increased gravity load.

Interventions include lifestyle changes (e.g., cessation of smoking, weight reduction, elimination of dietary bladder irritants, adequate fluid intake, bowel regulation, moderation of physical activities, and exercises), toileting programs (e.g., habit training, prompted voiding), and bladder retraining through PFMEs. From our current knowledge about the effect of PFMT, specific training programs should be recommended as the first treatment choice. The perineal blockage technique or the Knack appears to be an adjunctive modality for pelvic floor rehabilitation and can be proposed for active women. The impact of carefully instructed pelvic floor exercises on sports-related incontinence does not have the same beneficial effect as on the normal female population.

### CONCLUSIONS

PFMEs and visits to a physiotherapist seem to help to preserve the results of surgery for several years and prevent a relapse of

SUI. Many physicians<sup>13</sup> think that conservative therapy should be the first choice for treatment of SUI.

Electrical stimulation should be used for women not able to contract their pelvic floor muscles. Electrical stimulation applied once each week is not enough when a patient is unable to identify her pelvic floor muscles or if the purpose is to activate motor units and increase pelvic floor muscle function in cases of SUI. Electromyographic biofeedback is very important at the beginning of therapy and in the follow-up period, and it is highly reproducible and reliable in the assessment of pelvic floor muscle activity.<sup>118</sup> It makes it easier for the therapist to teach isolated pelvic floor muscle contraction, facilitates goal setting, and helps the patient to maintain good motivation. It also can detect differences in strength between the right and left pelvic floor muscles.<sup>12</sup> Several methods have been used to stimulate the striated muscles of the pelvic floor, including the levator ani, external urethral sphincter, and external anal sphincter. Correction of

continence with electrical stimulation has been achieved with various techniques, with results showing an increased urethral closure.

Many studies demonstrate that PFMEs, biofeedback, and weighted vaginal cones and balls are an effective combination for treatment of female SUI, even in the long term. Electrical stimulation should be used for women who are not able to identify their pelvic floor muscles or if support is needed to back up home exercises. For optimal results, appropriate instruction for using pelvic floor muscles correctly in a standing position, motivation, and follow-up are essential. There is a need for long-term studies to identify optimal therapy modes and common management strategies for female SUI. The conventional first-line treatment for urinary stress incontinence is conservative. However, in an era of informed choice, some women have shown a preference for surgery. Treatment preferences are influenced by their physicians' information, hearsay, and social factors.

# SELECTING THE BEST SURGICAL OPTION FOR THE TREATMENT OF STRESS URINARY INCONTINENCE

*Michael Edward Albo*

The number of surgical procedures available to treat stress incontinence continues to grow, complicating the process of choosing which procedure should be performed on which patient. The surgeon and patient expect that the procedure chosen will be the one that provides the highest degree of efficacy with the least amount of morbidity. Do certain patients have better outcomes or less morbidity with one surgical treatment or another, and is their evidence to support the decision?

The American Urological Association's guidelines for the surgical treatment of stress urinary incontinence, published in 1997 by Leach and colleagues,<sup>1</sup> were developed from meta-analyses of the incontinence literature through 1996. The report made recommendations for the surgical treatment of stress urinary incontinence (SUI) in an index patient, defined as a woman with uncomplicated SUI who is undergoing her first incontinence surgery and who has no concomitant morbidities. The guidelines state that for short-term efficacy, any of the four classes of procedures evaluated were acceptable but found that the Burch colposuspension and pubovaginal sling had better long-term outcomes.<sup>1</sup> These guidelines predate the arrival of the mid-urethral sling, the development of alternative allogenic and xenograft sling materials, and the use of laparoscopy in the treatment of incontinence, and they are in the process of being updated.

The guidelines may not be relevant for patients who have any of several complicating factors, including women who have undergone multiple incontinence procedures or who have mixed urinary incontinence symptoms, concomitant prolapse, or a host of other medical comorbidities that may affect the efficacy and safety of a given procedure. To achieve the goal of maximal efficacy with minimal morbidity in nonindex women, we must look beyond the guidelines to other criterion. This chapter looks at a number of nonindex patients and reviews the literature supporting the use of one procedure or another for the treatment of stress incontinence. It discusses the reasons for choosing a procedure for certain patients, even when the evidence is not available. It also presents an algorithm for matching procedures with patients.

### CHOOSING AN INCONTINENCE PROCEDURE

Several factors influence the choice of a surgical procedure that is most appropriate for a given patient. These factors include the pathophysiology of the incontinence (e.g., sphincter dysfunction or anatomic incontinence), the presence of mixed urinary

incontinence symptoms, a history of incontinence surgery, or the need for concomitant prolapse surgery. Specific medical comorbidities, such as such as the patient's age, obesity, estrogen status, preexisting voiding dysfunction, history of pelvic irradiation or neurologic disease, may also play a role in the decision. Clinicians have preferences for one procedure over another based on their training and clinical experience. Patients also have certain values or opinions that can factor into which procedure they are willing to undergo. Some patients are risk averse and seek the operation with the longest track record. Others are willing to forgo long-term data for a newer procedure that offers less short-term morbidity.

Evidence based-medicine is founded on the premise that therapeutic decisions for medical and surgical conditions use five levels of scientific evidence.<sup>2,3</sup> Level 1 evidence is derived from meta-analyses of randomized, clinical trials or a single, good-quality randomized, clinical trial. Level 2 evidence is derived from meta-analyses of prospective cohort studies. Level 3 evidence is gained from good-quality case-control studies, level 4 evidence comes from high-quality case series, and level 5 evidence is derived from expert opinion. Although the ideal is to look for the highest level of evidence, this may not exist for some decisions. When Leach and coworkers<sup>1</sup> performed their meta-analysis in 1996, they remarked on the paucity of level 1 evidence in the incontinence literature. Downs and Black's review<sup>4</sup> of the incontinence literature also highlighted this problem. Since these reviews, there have been efforts to improve the quality of studies in the incontinence field. A number of randomized, clinical trials have assessed outcomes for various procedures performed for the treatment of SUI.<sup>5,6</sup>

Unfortunately, it remains difficult to find adequately powered randomized, clinical trials or cohort studies assessing the differences between two procedures in any of the subgroups of incontinence patients who are thought to be at a higher risk for failure or complications. Most data are from analyses of subgroups within larger series. These are usually retrospective analyses or studies that were not designed to look at those subpopulations, and consequently, they are underpowered to identify significant differences. When we try to compare the results from different studies, we are hindered by the lack of standardized definitions and outcomes measures. Recommendations in the literature for how to treat a given high-risk patient population are based on level 4 and 5 evidence consisting of case-control series and expert opinion. The subsequent discussion looks at the evidence in the literature regarding how these factors may influence the choice of procedure performed.

### INTRINSIC URETHRAL DYSFUNCTION

Historically, the presence of intrinsic urethral dysfunction (ISD) has been a critical factor in deciding which procedure to perform for the treatment of SUI. The party line has been that patients with ISD should be identified and treated differently from patients without ISD. This was based on a number of studies suggesting that patients with ISD did not do as well with standard bladder neck suspensions as they did with sling procedures. This concept has become at best controversial and at worst irrelevant in the past few years for a number of reasons. First, there is a lack of agreement on the definition of ISD. It has been defined in a variety of ways, including maximal urethral closure pressure (MUCP) less than 20 cm H<sub>2</sub>O, Valsalva leak point pressure (VLPP) less than 60 cm H<sub>2</sub>O, or an open bladder neck identified on cystourethrography. Attempts to show correlations between these definitions have been unsuccessful, preventing comparison of studies that used different definitions.<sup>7,8</sup> Second, the measurement tools used to diagnose ISD have been plagued by poor standardization and poor correlation with physiologic parameters. Third, even when similar definitions are used, there are conflicting results with regard to whether and how ISD relates to outcomes of stress incontinence therapy. Weber<sup>9,10</sup> critically assessed MUCP and VLPP as diagnostic tests and found that both fall short with regard to standardization, reproducibility, and predictive value for outcomes. Nevertheless, studies reporting on the difference in outcomes between those with or without ISD have had a significant impact on how patients have been treated in over the past 20 to 30 years. It is useful to look at some of this literature to understand how we got from there to where we are today.

Sand and colleagues<sup>11</sup> published a retrospective analysis in 1987 of patients who had undergone Burch colposuspension and found that those who had an MUCP less than 20 cm H<sub>2</sub>O had lower success rates than those with higher MUCPs (82% versus 46%).<sup>11</sup> At the same time, other investigators were reporting good success rates in women with type III incontinence who had undergone pubovaginal sling procedures.<sup>7,12</sup> Subsequent reports documented the long-term success rates of the pubovaginal sling in patients regardless of the presence or absence of ISD defined by VLPP. Chaikin and coworkers<sup>13</sup> reported an overall long-term cure rate of 73% for pubovaginal sling procedures in 251 women with types I, II, or III stress incontinence. Morgan and associates<sup>14</sup> described 247 women who had undergone autologous pubovaginal sling procedures. Continence rates were 91% for type II and 84% for type III incontinence. Hassouna and Ghoniem<sup>15</sup> assessed long-term cure rates with questionnaires in women who had undergone a sling procedure for ISD. They found a 78% cure rate in this population at a mean follow-up of 3 to 4 years. Zaragoza<sup>16</sup> reported 60 consecutive pubovaginal sling procedures in women with type II or type III incontinence and found a 95% continence rate at 2 years. These kind of results, coupled with the belief that there were two distinct types of stress incontinence, led to a widely held view that patients with ISD should undergo pubovaginal sling procedures rather than Burch colposuspension or needle suspension procedures, which should be reserved for women with hypermobility and no ISD.

The data on ISD and its association with outcomes have been less convincing. Culligan and Sand<sup>17</sup> compared the long-term results for modified Burch and pubovaginal sling procedures in women with a low-pressure urethra (MUCP < 20 cm H<sub>2</sub>O). Thirty-six women with urodynamic stress incontinence, a low-pressure urethra, urethral hypermobility, and no significant

pelvic organ prolapse were randomly assigned to undergo a modified Burch procedure ( $n = 19$ ) or sling placement ( $n = 17$ ). The investigators did not demonstrate any difference between the Burch and pubovaginal sling procedures in subjective cure rates at 3 months (90% versus 100% respectively) or at 6 years of follow-up (93% and 84% respectively). Long-term objective cure rates were also similar for the two groups (84.6% versus 100%). The statistical power of this study was compromised by the unexpectedly high success rates of the Burch colposuspension.<sup>17</sup> Maher and colleagues<sup>18</sup> performed a retrospective review on a subgroup of 45 women (21 Burch and 24 pubovaginal sling procedures) with low preoperative MUCPs from a larger trial comparing outcomes between Burch and pubovaginal sling procedures. Subjective outcomes were based on a visual analogue scale, with patients rating an improvement of 8 or higher on a scale of 1 to 10 considered to be cured and with objective outcome based on the presence of stress incontinence verified by urodynamic study (UDS). The groups were similar in age, body mass index (BMI), parity, presence of hypermobility, and history of previous pelvic surgery. There were no statistically significant differences in outcomes, although there was a trend for higher success rates in the Burch colposuspension group compared with the pubovaginal sling in all categories: subjective (90% versus 71%;  $P = .12$ ), patient-determined visual analogue score (76% versus 67%;  $P = .22$ ), and objective success (67% versus 50%;  $P = .26$ ). Complications were higher in the pubovaginal sling group (5% versus 25%;  $P = .06$ ).<sup>18</sup> One criticism of this paper is that the success rates for slings are lower than has been reported in most sling series. The investigators have suggested that it may reflect that urge incontinence was included in the definition of failure, whereas other studies did not include it. This underscores the need for similar outcome measures to compare results of studies.

Several studies have looked at the success rates of tension-free vaginal tape (TVT) procedures in patients with a so-called bad urethra or ISD. None of these studies provides more than level 3 or 4 evidence, and none compares TVT procedures with other procedures. Some of the studies suggest women fare worse if they have ISD, whereas other studies report no difference. Rezapour and colleagues<sup>19</sup> analyzed data from their series of 400 women who had undergone TVT procedures and identified a subgroup of women with MUCPs less than 20 cm H<sub>2</sub>O. This group had a lower cure rate (74%) compared with previously reported cure rates for the general population (85% to 90%). When they performed a multivariate analysis of the bad urethra group, they found the worst cure rates in a subpopulation of women who were older, had an immobile urethra, and had low resting MUCPs.<sup>19</sup> Kulseng-Hanssen<sup>20</sup> demonstrated more severe post-operative incontinence after TVT procedures in women with MUCPs less than 20 cm H<sub>2</sub>O. Paick and coworkers<sup>21</sup> performed a retrospective analysis of their data from 221 patients who had undergone TVT procedures. They divided the patients into two groups: VLLP more than 60 ( $n = 160$ ) and VLPP less than 60 ( $n = 61$ ). At the 6-month follow-up, subjective and objective cure rates were 93% and 82% ( $P = .013$ ).<sup>21</sup>

Several investigators have suggested that urodynamically defined ISD does not correlate with TVT outcomes. Fritel and associates<sup>22</sup> compared patients with MUCPs less than 20 cm H<sub>2</sub>O to those with MUCP more than 20 cm H<sub>2</sub>O who had undergone TVT procedures. They reported objective cure rates of 80% and 85%, respectively. Rodriguez and colleagues<sup>23</sup> analyzed their prospective series of distal polypropylene slings and found no differences in outcomes based on urodynamically defined incontinence.

There is no evidence suggesting that there is a difference in outcomes between the transobturator approach to the mid-urethral sling (TMUS) and the retropubic approach to the mid-urethral sling (RMUS) for patients with ISD. Mellier and associates<sup>24</sup> retrospectively looked at 52 patients with ISD defined by an MUCP less than 30 cm H<sub>2</sub>O who had undergone a TMUS procedure ( $n = 26$ ) or a TVT procedure ( $n = 26$ ). They did not see any difference in outcomes.<sup>24</sup> This study is significantly limited by the nonconcurrency of the procedures and a limited telephone response rate of only 75%.<sup>24</sup>

Urethral injections of various bulking agents have been used to treat ISD, and the data confirm the effectiveness in this group. Herschorn and coworkers<sup>25</sup> reported long-term follow-up with collagen that did not differ significantly when subanalyzed for urethral function. Not many studies have compared the overall effectiveness directly with that of standard incontinence procedures. Success rates for collagen are generally lower than those obtained by most series of anti-incontinence surgery, but these results may improve if a longer-lasting bulking agent is developed. Given the significant differences in efficacy and safety between collagen and pubovaginal sling procedures, an adequately designed study to compare the two on multiple levels would be a welcome addition to the literature. With the advent of minimally invasive slings, a randomized, clinical trial comparing urethral injection with mid-urethral sling would also be helpful. Until this is done, the bulking agents are an option for women who do not want surgery or are not candidates for a surgical procedure.

In summary, although it makes sense that a poorly functioning urethra causes more severe incontinence and may be more difficult to repair, there is little evidence demonstrating that one procedure is superior to another in treating this population. The tools used to assess urethral function have not been subjected to adequate analysis with regard to their ability to represent changes in urethral function and how that change correlates with clinical symptoms. To answer the question this chapter poses, whether ISD is a variable that should direct our choice of procedures, we need to compare specific procedures in a standardly defined group of patients with ISD in a properly designed randomized trial.

### URETHRAL HYPERMOBILITY

The so-called fixed urethra was associated with severe incontinence and poor urethral function even before the urodynamic definitions for ISD were created. Incontinence in the absence of hypermobility was interpreted as an indicator of poor urethral function. There is controversial evidence regarding the relationship between Burch colposuspension outcomes and the presence or absence of hypermobility. However, there is increasing evidence in the TVT literature suggesting that patients with hypermobility have better outcomes after TVT procedures than those with a fixed urethra.<sup>22,26</sup> Fritel found that success of TVT correlated positively with the amount of preoperative hypermobility. Patients were divided into three groups based on hypermobility defined by cystourethrography: more than 60 degrees, 30 to 60 degrees, and less than 30 degrees. Success rates after TVT procedures were 97% for patients with more than 60 degrees of hypermobility, 86% for patients with 30 to 60 degrees of hypermobility, and 70% for those with less than 30 degrees of hypermobility. The lowest success rates were for women with previous surgery

and no urethral hypermobility (68%).<sup>22</sup> There are two theories about this finding. The first is that the mechanism by which TVT cures SUI is urethral kinking during increases in pelvic pressure that occurs due to a downward movement of the urethra against the fixed mesh of the TVT. The second possible explanation is that a fixed urethra needs external compression to increase the resistance. The tension-free sling, by definition, does not place any compression on the urethra. A comparison of mid-urethral sling approaches is needed to investigate whether this is also true of the TMUS procedures.

Transurethral injections were initially indicated only for patients without evidence of hypermobility. Subsequently, a number of studies have shown them to be equally effective in patients with hypermobility.<sup>25</sup>

In summary, although there is no level 1 evidence documenting the superiority of pubovaginal sling or Burch procedures over the mid-urethral sling in patients with immobile urethras, there is level 3 and 4 evidence to suggest that the tension-free mid-urethral sling is less effective in patients with an immobile urethra than it is in patients with evidence of hypermobility.

### RECURRENT STRESS INCONTINENCE

Patients who have had a previous anti-incontinence procedure have lower success rates and higher morbidity with subsequent procedures. The reasons include a higher incidence of ISD, increased age of the patients and scarring in the retropubic space. Other confounding variables include the type of procedure the patient had previously undergone. A study looking into complications of TVT after Burch colposuspension is not necessarily going to provide information on the safety and efficacy on performing a TVT after a failed TVT. Comparison of results is difficult given the various outcome measures used in different studies.

The only level 1 evidence that compares two procedures for this subgroup of patients is from a prospective, randomized study comparing the Burch colposuspension with the Lyodura sling in the management of women with recurrent urinary stress incontinence and in whom the only previous continence procedure was anterior repair.<sup>27</sup> Although the objective success rates for the Burch colposuspension (86%) and the pubovaginal sling (92%) were similar, the incidence of detrusor instability and voiding difficulty was significantly greater after sling procedures (29%) compared with Burch colposuspensions (10%). The meta-analyses by Black and Downs<sup>4</sup> identified no difference in outcomes between the Burch and sling procedures when performed as secondary procedures. However, they acknowledged that the number of studies was limited and that all had low power to detect significant differences.<sup>4</sup> Thakar and associates<sup>28</sup> reported on a prospective, cross-sectional, observational study of 56 women who had undergone a secondary Burch colposuspension for recurrent stress incontinence. At 4 years, the median subjective cure rate was 71%, and the objective cure rate was 80%. They did not compare these patients with a cohort of women who were undergoing a primary Burch colposuspension.<sup>28</sup>

Nilsson and Kuuva<sup>29</sup> performed a retrospective review of their TVT series. They reported equivalent outcomes for patients undergoing TVT as primary or secondary procedures. However, they reported twice as many bladder perforations in the secondary group.<sup>29</sup> Rardin and colleagues<sup>30</sup> performed a retrospective, multicenter study of 245 women who had undergone

TVT procedures; 157 patients had primary procedures, and 88 patients had failed previous surgical treatment. At a mean follow-up of 38 weeks, the cure rates were 87% and 85%, respectively. The bladder perforation rates were similar, although overall complication rates were higher in the secondary procedure group (7.6% versus 4.5%).<sup>30</sup> In 2001, Tamussino and coworkers<sup>31</sup> reviewed the data from the Austrian registry for 2795 patients who had undergone TVT procedures. They reported bladder perforation rates twice as high for patients who had previous surgery (4.4% versus 2%).<sup>31</sup> Haab and colleagues<sup>32</sup> found perforation rates of 30% for patients with a history of incontinence surgery and 2.1% for patients with no such history. Because none of these studies included patients who had undergone primary TVT procedures, it remains unclear whether similar results would be obtained for women undergoing repeat TVT procedures.

Several investigators have tried to control for the confounding variables that can affect outcomes of patients undergoing repeat surgical repairs. In a selected group of patients that excluded patients with low VLPPs and concomitant prolapse repairs, Rezapour<sup>33</sup> reported cure rates of 82% for women with recurrent SUI who underwent TVT.

Transurethral injection therapy and the TMUS procedures have the advantage of avoiding the retropubic space, and therefore may prevent bladder injuries in patients at higher risk for complications due to retropubic scarring from previous procedures. Gorton and associates<sup>34</sup> assessed the long-term outcomes of periurethral collagen injections. The number of previous continence operations did not seem to affect the outcome after bulking agents. The transobturator approach has not been adequately evaluated with regard to long-term incontinence outcomes or complications.

In summary, there is no level 1 evidence suggesting that patients with recurrent stress incontinence should undergo one procedure versus another. Most studies suggest lower efficacy or an increased complication rate in this patient population, but few have controlled for the confounding variables potentially responsible for the worse outcomes. The higher morbidity rate among patients who have had previous surgery, especially with regard to bladder perforation with TVT procedures, is reason to further investigate the TMUS procedures. Ultimately, the patient with a history of previous surgery may be a more complicated patient who requires preoperative evaluation aimed at identifying the reason for the failure and defining the type of incontinence causing the patient's symptoms.

### MIXED INCONTINENCE

The literature suggests that patients who present with mixed incontinence preoperatively can have both resolution or worsening of their urge-type symptoms after surgical procedures for SUI. Persistent urge incontinence is cited as one of the most common reasons for patient dissatisfaction after surgery for SUI. A number of studies have shown that patients expect their urge symptoms to improve (Mallet VTM, for the Urinary Incontinence Treatment Network, personal communication, 2005). Several studies have looked at risk factors for worsening of urge incontinence and urge symptoms. There have been no randomized, clinical trials to assess whether one procedure is better than another for patients with mixed symptoms. The existing data are limited to level 3 and 4 evidence, and comparisons between studies are hindered by the lack of standardized definitions for urgency and urge incontinence symptoms.

To illustrate the point on how definitions can influence outcome data, we can refer to the two reports by Chaikin and colleagues<sup>13</sup> and Chou and coworkers<sup>35</sup> on patients with mixed urinary incontinence. They reported in 1998 that patients with mixed urinary incontinence do worse than patients with pure SUI after a pubovaginal sling procedure.<sup>13</sup> In 2003, the same investigators, using a slightly different definition for mixed urinary incontinence, reported similar outcomes for patients with mixed incontinence compared with those with pure stress incontinence after pubovaginal sling procedures. They evaluated 131 women, 46 of whom had pure stress incontinence and 52 of whom had mixed urinary incontinence identified by symptoms or on UDS. The 12-month follow-up using the Urinary Incontinence Outcome Score (UIOS) (i.e., 24-hour diary, pad test, and questionnaire) demonstrated no difference in rates of cure or improvement (97% versus 93%).<sup>35</sup> Several investigators have demonstrated a difference in cure rates depending on the type of detrusor overactivity identified on preoperative urodynamics. The latest publication was a report by Schrepferman and colleagues.<sup>36</sup> They looked at 70 patients with mixed urinary incontinence identified by UDS who underwent autologous pubovaginal sling procedures and found that patients with low-pressure involuntary detrusor contractions did better than patients with high-pressure involuntary detrusor contractions and those with sensory urgency (91.3% versus 27.8% and 39.3%).<sup>36</sup>

The TVT literature reports 42% to 100% improvement or cure rates for urgency and urge incontinence. The only comparative trials of TVT procedures with other procedures did not show a difference in outcomes for patients with preoperative mixed urinary incontinence.<sup>6,37,38</sup> The Hilton trial, although not powered to look for a difference in this subgroup, reported similar rates of de novo urge incontinence.<sup>6,38</sup> Rezapour and coworkers<sup>39</sup> retrospectively analyzed a subgroup of 80 patients from their overall TVT series who had urodynamic evidence of preoperative overactivity. At the 4-year follow-up, this group had outcomes similar to those for the group as a whole, with 85% considered cured of incontinence (defined as a 24-hour pad test result of less than 10 g, a negative cough stress test result, and more than 90% improvement in quality of life). No studies have been powered to show a difference between the TMUS and RMUS procedures for patients with mid-urethral slings. Even the TMUS case-controlled series do not have sufficient numbers of patients to assess the difference in outcomes between those with pure SUI and those with mixed urinary incontinence.

Overall, we continue to lack information on the best form of therapy for the mixed urinary incontinence patient population. There are insufficient data to recommend a specific procedure when performing SUI surgery, and we do not know which patients should have surgery at all. Postoperative urge incontinence remains one of the most significant reasons for persistent incontinence and patient dissatisfaction. It reinforces the concept that the distinction is not one that most patients make, even when they are advised on what to expect from SUI surgery. As clinicians, we must take more time to educate the patients about their expectations and continue to evaluate methods for identifying those at the highest risk for failure.

### VOIDING DYSFUNCTION

Most incontinence procedures can cause some element of obstruction and can lead to urinary retention or dysfunctional voiding.<sup>40,41</sup> These possibilities prompted concern that women

who demonstrate evidence of voiding dysfunction preoperatively may have worsening of their symptoms or end up in urinary retention postoperatively. Investigators have tried to identify specific patient populations at increased risk and whether one procedure may be more likely to cause postoperative voiding problems. Various results are reported in the literature, and they are limited by nonstandardized definitions of voiding dysfunction and different outcome measures for assessing voiding dysfunction. All of the following have been used in creating a definition of voiding dysfunction: patient-reported symptoms, elevated postvoid residual volume, use of a catheter, and any of several UDS parameters, including abnormal flow rate, abnormal flow pattern, high-pressure voiding, absence of detrusor pressure during voiding, electromyographic activity during voiding, and augmentation or substitution of the detrusor pressure with abdominal pressure during voiding. Another significant limitation is the timeframe after surgery during which voiding is assessed or treatment is initiated. Studies vary in defining urinary retention from 2 days to 6 weeks postoperatively.

The American Urological Association guidelines reported a slightly higher risk for obstruction in patients who had undergone sling procedures.<sup>1</sup> Bhatia and Bergman<sup>42</sup> cited a 12-fold increase in urinary retention after Burch procedures for women who had detrusor pressures less than 15 cm H<sub>2</sub>O during voiding. Iglesia and associates<sup>43</sup> retrospectively reviewed their series of 50 women who had undergone pubovaginal sling procedures between 1994 and 1996 and compared women who had preoperative Valsalva-induced voiding with a group of women who had non-Valsalva-induced voiding. They defined patients with Valsalva-induced voiding as those who exhibited a more than 10 cm increase in abdominal pressures during a pressure-flow study. They found a lower objective success rate (46% versus 83%;  $P = .011$ ) and longer duration in postoperative catheterization (median, 23 days versus 14 days;  $P = .049$ ) in the 13 Valsalva-induced voiders compared with the 35 non-Valsalva-induced voiders.<sup>4</sup>

Kobak and colleagues<sup>44</sup> demonstrated higher rates of retention or prolonged time to adequate voiding after bladder neck suspension procedures for patients who had preoperative, urodynamically defined evidence of poor detrusor function or Valsalva augmentation during voiding. Miller and associates<sup>45</sup> performed a retrospective review of 73 patients who had undergone pubovaginal sling procedures between 1998 and 2000 in an attempt to identify preoperative, urodynamically defined factors that could predict postoperative voiding dysfunction. They identified four patients with urinary retention and nine who met their criterion for delayed return to voiding. The only predictor of urinary retention was voiding without a detrusor contraction during pressure-flow studies. The risk factor for delay in return to voiding was the postvoid residual volume.<sup>45</sup> Lo<sup>46</sup> assessed symptoms, uroflow, postvoid residual volume, and pressure-flow study results and found no change in the maximal flow rate, postvoid residual volume, or urethral pressure profile for cured or improved patients after TVT procedures. Sokol and colleagues<sup>47</sup> found no association between preoperative subjective or objective voiding parameters and time to adequate voiding after a TVT procedure. Some investigators have theorized that the TMUS procedures may be less obstructive because the sling's position under the urethra is at a less acute angle. This has yet to be confirmed by any level of evidence.

In summary, although any incontinence procedure is potentially obstructing and there may be subpopulations at increased risk for obstruction or voiding dysfunction postoperatively, there

is no scientific evidence to support one procedure over the other based on preoperative voiding parameters. More work is required to standardize the definition of voiding dysfunction and the tools used to assess the subjective and objective parameters used to define the problem.

### CONCOMITANT SURGICAL PROCEDURES

Incontinence frequently is associated with other pelvic floor dysfunction. The realization that the entire pelvic floor should be assessed when evaluating patients with urinary incontinence has led to significant improvements in treating both disorders. Multiple studies suggest that concomitant surgery does not affect outcomes of patients compared with outcomes for patients not having concomitant surgery. No studies have randomized patients undergoing pelvic floor surgery to one incontinence procedure or another. Cross and coworkers<sup>48</sup> looked at 42 women who underwent pubovaginal sling procedures concomitantly with a grade III and IV cystocele repair. Thirty-six patients returned for a mean follow-up of 12 months, and four required a subsequent procedure for recurrent SUI. In 2003, Lo<sup>46</sup> conducted a literature review and found six publications that provided sufficient detail to assess differences in outcomes for patients undergoing a TVT procedure and concomitant prolapse surgery. Overall, there was little difference in outcomes between the two groups.<sup>46</sup> Meschia and colleagues<sup>49</sup> reported similar cure rates and no increase in morbidity for the patients undergoing a TVT procedure and prolapse repair compared with those undergoing a TVT procedure alone.<sup>49</sup> There is still no agreement on whether the TVT procedure should be performed before or after the prolapse repair is complete or whether it should be done through a separate vaginal incision.

In summary, there is no level 1, 2, or 3 evidence suggesting that one procedure is better than another in women who are undergoing concomitant prolapse repair. Several case-control series suggest it is not a factor in outcomes. This decision more than others is likely to be determined by the clinician's preference. Some clinicians advocate performing a Burch colposuspension in patients who undergo an abdominal prolapse repair because the abdomen is already open. The minimally invasive techniques may lose some of their advantages with regard to length of hospital stay and postoperative discomfort because the prolapse repair usually is the more morbid of the procedures. These recommendations are based solely on physicians' preferences.

### CHARACTERISTICS AFFECTING ANTI-INCONTINENCE SURGERY

#### Age

Increasing age is associated with many of the previously discussed variables that are thought to affect outcomes in stress incontinence surgery. The elderly are known to be at greater risk for morbidity with any surgery. Nevertheless, the choice of procedures for the elderly should be based on the same goals as for the population as a whole: to maximize efficacy and minimize morbidity.

A number of investigators have performed subanalyses of larger series based on patients' ages. Outcomes generally appear to be less favorable and the complications more frequent. Gillon

and Stanton<sup>50</sup> reported similar efficacy but longer hospital stay and higher perioperative morbidity in elderly women who underwent Burch procedures. Karantanis and colleagues<sup>51</sup> looked at a group of elderly women (>65 years) who were matched to a younger cohort for BMI, parity, mode of anesthesia, and whether it was a primary or secondary continence procedure. Exclusion criteria included mixed symptoms and concomitant prolapse surgery. The investigators demonstrated lower satisfaction rates for incontinence outcomes in the elderly group. At a median of 12 months, 15 (45%) older versus 24 (73%) younger women had no urinary symptoms ( $P = .05$ ).<sup>51</sup> Other reports are primarily observational and did not match the patients for other variables. Sevestre and associates<sup>52</sup> reported a 70% cure rate for a group of 76 women after a mean of 2 years. Rezapour and colleagues<sup>19</sup> demonstrated that women older than 70 years with a low MUCP and no hypermobility had a lower success rates with TVT procedures than women not fitting these criteria. Two studies have suggested no difference for outcomes in the elderly. Lo and coworkers<sup>26</sup> performed an observational study of 45 older women who had undergone TVT procedures and reported a 90% cure rate with a low rate of morbidity.<sup>42</sup> Carey and associates<sup>53</sup> compared women older than 80 years with those younger than 80 and found no difference in outcomes for procedures using the cadaveric fascia sling. Herschorn and colleagues<sup>25</sup> reported no difference in outcomes of transurethral collagen injections based on age.

In summary, most case-control series of older women demonstrate lower efficacy and higher morbidity, but there is no evidence that this is specific to the type of procedure performed. Age is associated with a higher incidence of other factors affecting the outcome and morbidity of the treatment, and only when a multivariate analysis is performed are we able to determine definitive correlations. If someone is not a candidate for surgical therapy because of comorbidities, it is irrelevant whether a Burch colposuspension is as effective as a TVT procedure. The deciding factor is which procedure the patient can tolerate given her comorbidities.

### Body Mass Index

Some studies suggest that obese patients have worse outcomes and higher complication rates with traditional surgical procedures for stress incontinence,<sup>54,55</sup> although others have not found obesity to affect outcomes.<sup>56-61</sup> The transobturator procedures are being promoted as less morbid procedures in obese women because the abdomen can be completely avoided. This idea has not been substantiated. Although there is no level 1 evidence comparing procedures in patients with high BMIs, a number of published studies have looked at the safety and efficacy of the mid-urethral sling in this population.

Chung and colleagues<sup>56</sup> retrospectively compared the efficacy and safety of the TVT and laparoscopic Burch procedures in treating genuine SUI in obese patients. They described 91 consecutive cases of TVT alone or TVT combined with other procedures from April 1999 to March 2000 and 51 consecutive cases of the laparoscopic Burch procedures from January 1998 to February 1999. They found no difference in the outcomes based on BMI.<sup>56</sup> Mukherjee and Constantine<sup>59</sup> compared the subjective cure rates for TVT procedures at 6 months in three groups of women: BMI of 30 or more ( $n = 87$ ), BMI of 25 to 29 ( $n = 98$ ), and BMI less than 25 ( $n = 58$ ). They reported similar cure rates for all three groups.<sup>59</sup> Zivkovic and coworkers<sup>61</sup> retrospectively

reviewed the 5-year outcome data from 187 of 291 patients who had undergone various procedures for stress incontinence. Patients were separated into similar groups by BMI: BMI of 30 or more ( $n = 42$ ), BMI of 25 to 29 ( $n = 90$ ), and BMI less than 25 ( $n = 55$ ). They also reported no difference in efficacy among the BMI groups, although they had only 26% power to show a significant difference because of the sample size.<sup>61</sup> Rafii and colleagues<sup>60</sup> reported a series of 187 patients who had undergone TVT procedures and who were separated into the three groups according to BMI: BMI of 30 or more ( $n = 86$ ), BMI of 25 to 29 ( $n = 62$ ), and BMI less than 25 ( $n = 39$ ). No differences were detected in the persistence of stress incontinence or the complication rate. Statistically significant differences were seen in the rate of urge incontinence between first group (3.4%) and the second group (6.4%) and third group (17.9%).<sup>60</sup>

The 2000 review of obesity and stress incontinence therapy by Cummings and Rodning<sup>58</sup> is still relevant. They concluded that "although intuitively and experimentally such procedures are technically more difficult, outcome data reported to date justifies recommending them as the standard of care."<sup>58</sup> In summary, although patients with higher BMIs may have higher overall risks associated with surgery and although the mid-urethral sling procedures may theoretically reduce these risks with less anesthetic and surgical time, there are no data to support selecting a procedure based only on BMI.

### Neurogenic Bladder

The therapeutic approach to the neurogenic patient must be based on an understanding of how her neurologic disease plays a role in the symptoms and the role it may play afterward. These patients have the potential for higher morbidity after surgical treatment of SUI, including voiding dysfunction, urinary retention, or de novo urge incontinence. The implications of a lower success rate or higher morbidity on the patient's quality of life are more profound than in the non-neurogenic patient. Preoperative UDS plays a significant role in this group of patients as a plan is developed. They all are at risk for postoperative urinary retention requiring catheterization to empty the bladder. It is therefore important to assess their ability and willingness to do so. Documentation of urodynamic overactivity may make postoperative management of urge symptoms easier.<sup>62</sup> There is no specific evidence to suggest one procedure over another based solely on the presence of neurologic disease. The potential need for intermittent catheterization may reduce the efficacy with collagen. Use of the artificial urinary sphincter may be considered in this group of patients.

### History of Pelvic Radiation Therapy

Patients who have previously undergone radiation therapy have a number of confounding variables that may affect the outcomes and morbidity of stress incontinence procedures. Irradiated tissue has reduced elasticity and vascularity. The patients are more likely to have an immobile urethra and lower urethral resistance because of atrophy and decrease submucosal vascularity. The use of synthetic material, although not contraindicated, may have a higher rate of complications because of urethral or vaginal wall erosion. The need to add compression to a fixed urethra as describe previously may preclude the use of synthetic material due to the added tension that must be place on the sling. The higher incidence of detrusor overactivity or small-capacity

bladder must be assessed before increasing urethral resistance. There are no studies in the literature specifically looking at this challenging group of patients.

### Plans for a Future Pregnancy

The usual recommendation from most clinicians is that patients should wait until they completed their childbearing years before undergoing a repair procedure for SUI.<sup>63,64</sup> The TVT product label states that the desire to have children is a contraindication to placement of the TVT. If they have undergone a procedure, they may be advised to undergo a cesarean section as the mode of delivery. A survey of European urogynecologists asked clinicians what type of procedure they would do for a woman who expressed interest in having more children.<sup>63</sup> Seventy-eight percent said they would offer treatment if the patient expressed interest, but 91% would offer cesarean section to women who were continent at the time of delivery. Although most would offer the woman a surgical option, many would not perform a TVT procedure, and most would advise cesarean section as the method of delivery. Urethral injection therapy is also an option in this population. There are few published data to guide the clinician in this area. In all cases, the patient needs to be informed about the potential risks.

### HOW AND WHEN TO INCLUDE A NEW PROCEDURE

New procedures are being developed rapidly in this field, but we should remember that there are procedures with documented efficacy and safety that are considered the gold standards in incontinence surgery. Deviation from these established procedures should be based on clearly outlined advantages in achieving better efficacy or less morbidity and demonstrated with high level of evidence. As clinicians, we must remain committed to studying these procedures before widespread use is accepted. When that evidence is lacking but clinical experience suggests a benefit exists for our patients, we must demand that the properly designed studies be performed to assess the procedure or product. We must make sure our patients understand what we know about a new procedure when we counsel them about which procedure is best for them.

The fastest-growing procedure for incontinence is the TMUS. Although it addresses an important concern of many clinicians and educators regarding the RMUS—the potential morbidity associated with passing a trocar blindly into the retropubic space—it has not undergone sufficient evaluation to recommend it for widespread use, even in subpopulations of women with SUI. The RMUS sling has produced a significant body of literature over the past 10 years, with more than 250 articles posted on PubMed. It has been compared with one of the gold standards in incontinence surgery, the Burch colposuspension, in a well-

designed trial treating incontinence surgery and found to be equally as effective.<sup>6</sup> Before the TMUS procedure can be considered interchangeable with the RMUS procedure, which has been in use for 8 years and has hundreds of articles published in the international literature on its safety and efficacy, the TMUS procedures must be subjected to a rigorous comparison. This procedure must continue to undergo evaluation in properly designed trials before it can be accepted as a standard option in our surgical armamentarium for the treatment of SUI.

The following algorithm for choosing an incontinence procedure is based on the information provided in this chapter.

*Retropubic mid-urethral sling:* for the otherwise healthy woman who is bothered by predominant SUI and desires surgical therapy, exhibits hypermobility on examination (i.e., Q-tip resting or straining angle > 30 degrees), has postvoid residual volume of less than 100 mL, with or without the need for concomitant prolapse surgery, regardless of the following urodynamic study parameters: VLPP, detrusor overactivity, or voiding mechanism

*Urethral bulking agent:* for the poor operative candidate

*Transobturator mid-urethral sling* (after discussing paucity of data with patient): for those at high risk for retropubic scarring or with a history of multiple procedures

*Autologous pubovaginal sling or urethral bulking agent:* for those at high risk for erosion, with a history of radiation therapy, with an immobile urethra, or with acute urethral syndrome

*Urinary diversion:* for a woman with a neurogenic bladder or severely incompetent urethra

*Burch colposuspension or mid-urethral sling:* for those undergoing simultaneous abdominal prolapse repair

### CONCLUSIONS

Despite having many options for treating SUI, we still have insufficient evidence to recommend which procedure will have the greatest efficacy and least morbidity to specific patient populations. To make more evidence-based decisions on which procedure to perform in which patients, we must randomize similar groups of patients to undergo different procedures. Until we have the results of those trials, we must continue to rely on case report series and theoretical reasons for our decisions. Ultimately, the most important tool we have as clinicians is the individualized assessment of and conversation with each patient. This approach includes a thorough history and physical examination that evaluates the neurologic and anatomic condition of the pelvic floor and the patient's comorbidities. These data are combined with our understanding of the mechanism by which a given procedure resolves incontinence to guide the choice of procedure.

# OUTCOME MEASURES FOR PELVIC ORGAN PROLAPSE

Lynn Stothers

Developers of outcome measures for pelvic organ prolapse are faced with the difficult task of addressing a wide range of symptoms from the bowel, bladder, and uterus. Historically, instruments were developed that addressed a single organ, but they have progressed to validated tools that include information relating to all three organs. The modern tools should be completed as part of the patient's medical record, along with the physical examination and diagnostic tests. They can be performed before and after medical or surgical treatment. They are an essential part of the clinician's and researcher's tools in partnership with diagnostic tests.

This chapter describes commonly used validated tools developed specifically for women with pelvic organ prolapse and related symptoms. The instruments can be broadly classified as those that quantify and stage prolapse and those that quantify the range of symptoms associated with prolapse. Some scales, such as the Pelvic Organ Prolapse Questionnaire (POP-Q),<sup>1</sup> provide a means of accurately describing the position of the organs relative to one another and the amount of relative descent of each of the organs. Others provide a means of assessing the wide range of urinary tract, bowel, sexual, pain, and quality-of-life symptoms related to prolapse. Some symptom scales are comprehensive measures that try to address all symptoms resulting from bowel, bladder, and uterine prolapse. Others are focused scales that ask detailed questions about a single complex, such as sexual dysfunction.

### QUANTIFYING AND STAGING PROLAPSE

Historically, outcome measures for pelvic organ prolapse were single-organ instruments that required supplementation with diagnostic tests for accuracy and reproducibility. For example, the degrees of a cystocele could be staged using a standing-voiding cystourethrogram. To be accurate over time, these scales required repetition of the diagnostic tests to maintain the accuracy of the staging through the patient's treatment and follow-up. More commonly, staging is done by physical examination alone, without the benefit of diagnostic tests. When physical examination of the patient with prolapse is done, the clinician can only speculate about which organs may be included in the prolapse in the descent of the anterior or posterior vaginal wall or the top of the vault. In this situation, the terms *anterior vaginal wall prolapse* and *posterior vaginal wall prolapse* are more appropriate than the terms *cystocele* or *rectocele*.

Researchers and clinicians recognized the need for a more comprehensive staging system that included all the pelvic organs. Although some of the older scales, such as the traditional four-stage classification system,<sup>2</sup> are still in limited use, the POP-Q is the most widely recognized internationally.<sup>3-6</sup>

### Pelvic Organ Prolapse Questionnaire

The POP-Q provides a descriptive and quantifying system for the relative position of the organs within the pelvis and enables objective staging of pelvic prolapse. The system, adapted from several classifications by Baden and Walker,<sup>7</sup> was developed by the International Continence Society Committee on Standardisation of Terminology, Subcommittee on Pelvic Organ Prolapse and Pelvic Floor Dysfunction, in collaboration with the American Urogynecologic Society and the Society of Gynecologic Surgeons.<sup>1</sup> The POP-Q system arose from the efforts of the committee to develop a terminology standardization document. The original document was drafted in 1993 and refined in 1994. In 1994, it underwent a 1-year review and trial, during which time several minor revisions were made.

Reproducibility studies for the POP-Q were conducted in six centers in the United States and Europe, documenting interobserver and intraobserver reliability and clinical utility of the system in 240 women.<sup>8-12</sup> Interobserver reliability was studied in 48 women with a mean age of  $61 \pm 14$  years, parity of  $3 \pm 2$ , and weight of  $74 \pm 31$  kg. Correlations for each of the nine measurements ( $r = 0.817, 0.895, 0.522, 0.767, 0.746, 0.747, 0.913, 0.514, \text{ and } 0.488$ ) were highly significant ( $P = 0.0008$  to  $<0.0001$ ). Staging and substaging were reported to be highly reproducible ( $\tau_{0.05} = 0.702$  and  $0.652$ , respectively). In 69% of subjects, the stages identified were identical, and in the remainder, they did not vary by more than one stage among observers. Intraobserver reliability was studied in 25 women. Correlations ( $r$ ) for the nine measurements were  $0.780, 0.934, 0.765, 0.759, 0.859, 0.826, 0.812, 0.659, \text{ and } 0.431$ . The position of the subject during measurement was found to affect staging, with upright examinations reflecting greater prolapse. Staging and substaging were reported to be highly reproducible ( $\tau_{0.05} = 0.712$  and  $0.712$ , respectively). In 64% of subjects, the stages identified were identical, and in the remainder, they did not vary by more than one stage. All variation was increased in the upright position.<sup>12</sup> The standardization studies were done in the English language, and the standardization document was formally adopted by the International Continence Society in October 1995.

### The Pelvic Organ Prolapse Questionnaire Descriptive System

The POP-Q descriptive system allows the clinician to quantify precisely a woman's pelvic support without assigning a severity value; to make accurate, site-specific observations of the stability or progression of prolapse over time; and to accurately describe outcome of surgical repair. The system uses six reference points

**Figure 30-1** Six sites used for pelvic organ support quantitation (points Aa, Ba, C, D, Bp, and Ap), genital hiatus (gh), perineal body (pb), and total vaginal length (tv). (From Bump RC, Mattiasson A, Bo K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10-17, 1996.)

anterior wall <b>Aa</b>	anterior wall <b>Ba</b>	cervix or cuff <b>C</b>
genital hiatus <b>gh</b>	perineal body <b>pb</b>	total vaginal length <b>tv</b>
posterior wall <b>Ap</b>	posterior wall <b>Bp</b>	posterior fornix <b>D</b>

**Figure 30-2** Three-by-three grid for recording a quantitative description of pelvic organ support. (From Bump RC, Mattiasson A, Bo K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10-17, 1996.)

(Fig. 30-1) and a 3 × 3 grid (Fig. 30-2) for recording a quantitative description of pelvic organ support.

The POP-Q descriptive system uses the hymen as the best available fixed point of reference that can be consistently and precisely identified. Six points—two on the anterior vaginal wall, two in the superior vagina, and two on the posterior vaginal wall—are located with reference to the plane of the hymen. The anatomic positions of the six points are recorded as centimeters above or proximal to the hymen (negative number) or centimeters below or distal to the hymen (positive number), with the plane of the hymen recorded as 0.

Points Aa and Ba are located on the anterior vaginal wall. Point Aa (range, -3 to 3 cm relative to the hymen) is located in the midline of the anterior vaginal wall 3 cm proximal to the external urethral meatus. This point corresponds to the approximate location of the urethrovesical crease, a landmark that is obliterated in many patients. Point Ba (-3 cm in the absence of prolapse) represents the most distal or dependent position of any part of the upper anterior vaginal wall from the vaginal cuff or anterior vaginal fornix to point Aa. In women with total post-hysterectomy vaginal eversion, point Ba has a positive value equal to the position of the cuff.

Two points on the superior vagina represent the most proximal locations of the lower reproductive tract in a normal position. Point C represents the most distal or dependent edge of the cervix or the leading edge of the vaginal wall cuff (i.e., hysterectomy scar) after total hysterectomy. Point D represents the location of the posterior fornix or pouch of Douglas in a woman who still has a cervix and the level of uterosacral ligament attachment to the proximal posterior cervix. It is helpful in differentiating suspensory failure of the uterosacral–cardinal ligament complex from cervical elongation (symmetric or eccentric), in which the location of point C is significantly more positive than the location of point D. Point D is omitted in the absence of the cervix.

There are two points on the posterior vaginal wall. Point Bp (–4 cm in the absence of prolapse) represents the most distal or dependent position of any part of the upper posterior vaginal wall from the vaginal cuff or posterior vaginal fornix to point Ap. In a woman with total post-hysterectomy vaginal eversion, point Bp has a positive value equal to the position of the cuff. Point Ap (–3 to 3 cm relative to the hymen) is located in the midline of the posterior vaginal wall 3 cm proximal to the hymen.

The numbers in the descriptive system can be recorded in the grid or, more commonly, as a series of numbers (e.g., –2, –2, –6, –7, –3, –3, 10, 3, 2), which represents clinical findings for the six vaginal points relative to the hymen and the total vaginal length (tvL), genital hiatus, and perineal body. The position of the patient during measurement should be documented, because the upright position potentially increases the stage of the descent.

**Pelvic Organ Prolapse Questionnaire Staging System**

The POP-Q system includes a staging method for quantifying prolapse for the purpose of describing and comparing populations, evaluating symptoms related to prolapse, and assessing and comparing the results of treatment options:

*Stage 0:* No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at –3 cm, and point C or D is between –tvL and –tvL-2 cm (i.e., the quantitation value for point C or D is less than or equal to tvL-2 cm). Figure 30-3 demonstrates stage 0.

*Stage I:* The criteria for stage 0 are not met, but the most distal portion of the prolapse is more than 1 cm above the level of the hymen (i.e., its quantitation value is less than –1 cm).

*Stage II:* The most distal portion of the prolapse is less than or equal to 1 cm proximal to or distal to the plane of the hymen (i.e., its quantitation value is more than or equal to –1 cm but less than or equal to 1 cm).

*Stage III:* The most distal portion of the prolapse is more than 1 cm below the plane of the hymen but protrudes no further than 2 cm less than the total vaginal length in centimeters (i.e., its quantitation value is more than 1 cm but less than tvL-2 cm). Figure 30-4A demonstrates stage III Ba, and Figure 30-4B demonstrates stage III Bp prolapse.

*Stage IV:* Essentially, complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least tvL-2 cm (i.e., its quantitation value is more than tvL-2 cm). In most instances, the leading edge of stage IV prolapse is the cervix or vaginal cuff scar. Figure 30-3A demonstrates stage IV C prolapse.

The POP-Q systems provide an excellent means of staging and describing an individual patient’s anatomy. However, they do not provide the whole picture of what is happening to the patient unless considered along with symptom scores and a quality-of-life index.

**OUTCOME MEASURES FOR PROLAPSE-RELATED SYMPTOMS**

Pelvic organ prolapse can involve symptoms from one or more organs, including the uterus or cervix, bowel, and bladder and their supporting anatomic structures. The clinician needs to consider a range of symptoms, from obstructive symptoms to incontinence, sexual dysfunction, and pain, keeping in mind that the alleviation of specific symptoms can be of greater or lesser importance to an individual patient.

Two studies looked at patient-centered and patient-selected goals for pelvic organ prolapse repair.<sup>13,14</sup> The goals of patients in a study by Elkadry and colleagues<sup>13</sup> included improvement or

**Figure 30-3** A, Grid and line diagram of complete eversion of the vagina. The most distal point of the anterior wall (point BA), the vaginal cuff scar (point C), and the most distal point of the posterior wall (point Bp) are all at the same position (8), and points Aa and Ap are maximally distal (both at 3). Because total vaginal length equals maximum protrusion, this is stage IV prolapse. B, Normal support. Points Aa and Ba and points Ap and Bp are all –3 because there is no anterior or posterior wall descent. The lowest point of the cervix is 8 cm above hymen (–8), and the posterior fornix is 2 cm above this (–10). Vaginal length is 10 cm, and the genital hiatus and perineal body measure 2 and 3 cm, respectively. This represents stage 0 support. (From Bump RC, Mattiasson A, Bo K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. Am J Obstet Gynecol 175:10-17, 1996.).

**Figure 30-4** **A**, Grid and line diagram of a predominant anterior support defect. The leading point of prolapse is the upper anterior vaginal wall, point Ba (6). There is significant elongation of the bulging anterior wall. Point Aa is maximally distal (3), and the vaginal cuff scar is 2 cm above the hymen (C = -2). The cuff scar has undergone 4 cm of descent because it would be at -6 (total vaginal length) if it were perfectly supported. In this example, the total vaginal length is not the maximum depth of the vagina with an elongated anterior vaginal wall maximally reduced, but rather the depth of the vagina at the cuff with point C reduced to its normal full extent. This represents stage III Ba prolapse. **B**, Predominant posterior support defect. The leading point of prolapse is the upper posterior vaginal wall, point Bp (5). Point Ap is 2 cm distal to the hymen (2), and the vaginal cuff scar is 6 cm above the hymen (-6). The cuff has undergone only 2 cm of descent because it would be at -8 (total vaginal length) if it were perfectly supported. This represents stage III Bp prolapse. (From Bump RC, Mattiasson A, Bo K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10-17, 1996.)

relief of urinary incontinence (58%), pelvic organ prolapse (53%), general health or lifestyle (50%), activity (44%), urgency or frequency (12%), sexual function (11%), and urinary retention (6%). In a study by Hullfish and coworkers,<sup>14</sup> patients identified additional goals, including improvements in bowel symptoms, activity level, social relationships (including sexual activity), self-image, and physical appearance. Elkadry and colleagues<sup>13</sup> found that objective cure, defined as no urodynamic stress incontinence and stage 0 or 1 prolapse, was not related to patient satisfaction, emphasizing the need to evaluate other outcomes.

Several quality-of-life scales have been developed specifically for pelvic organ prolapse conditions. The scales usually cover a broad range of symptoms, such as activities of daily living; urinary, sexual, and bowel function; and pain. In addition to these comprehensive scales, there are more focused scales for urinary symptoms, sexual function, and pain. Incontinence, a symptom frequently associated with pelvic organ prolapse and often evaluated using the stress, emptying, anatomic, protection, and instability (SEAPI) test domains for the score.<sup>15,16</sup>

### Quality of Life

#### *Urogenital Distress Inventory and Incontinence Impact Questionnaire*

Commonly used, condition-specific, validated quality-of-life measures for pelvic organ prolapse, the Urogenital Distress Inventory (UDI) and the Incontinence Impact Questionnaire (IIQ), were first described by Shumaker and colleagues.<sup>17</sup> The shorter versions, the UDI-6 and the Urge UDI, have also been described.<sup>18,19</sup> FitzGerald and coworkers<sup>20</sup> evaluated the sensitivity of the UDI and IIQ to changes in clinical status after surgery for genuine stress incontinence or pelvic organ prolapse. Of 34 patients surgically treated for pelvic organ prolapse, 31 (90%) were subjectively cured of their prolapse symptoms. Mean IIQ

and UDI scores were lower for patients who were subjectively continent.<sup>20</sup> The UDI and IIQ have been used alone or in combination in several studies of outcome after surgical repair for prolapse.<sup>21-23</sup> The two questionnaires can be obtained by contacting the Women's Health Center of Excellence, Wake Forest University Baptist Medical Center, Winston-Salem, NC ([http://www.wfubmc.edu/women/whcoe\\_iiq\\_udi\\_instrument.htm](http://www.wfubmc.edu/women/whcoe_iiq_udi_instrument.htm)).

#### *Pelvic Floor Distress Inventory and Pelvic Floor Impact Questionnaire*

The Pelvic Floor Distress Inventory (PFDI) and Pelvic Floor Impact Questionnaire (PFIQ),<sup>24</sup> which incorporate the UDI and IIQ, were developed because of the frequent coexistence and complex interaction of pelvic floor disorders. The PFDI, which assesses symptom distress in women with pelvic floor disorders, has three scales: the UDI, the Colorectal–Anal Distress Inventory, and the Pelvic Organ Prolapse Distress Inventory (Table 30-1). The PFIQ was designed to assess life impact in women with pelvic floor disorders, and it contains the original IIQ and items related to other pelvic floor disorders. The PFDI and PFIQ were shown to be reliable and valid condition-specific, quality-of-life instruments for women with pelvic floor disorders.<sup>24</sup> The instruments are designed for research use and are considered too long to be practical for use in clinical practice (completion time of about 23 minutes in an older population). Short forms have also been validated (Figs. 30-5 and 30-6).

A simpler valid and reliable quality-of-life instrument designed for use in women with pelvic organ prolapse is the Prolapse Quality of Life (P-QOL) questionnaire (Fig. 30-7).<sup>25</sup> In testing the P-QOL questionnaire, 155 symptomatic and 80 asymptomatic women attending gynecology outpatient clinics were asked to complete it. There was a strong correlation between severity according to the P-QOL result and vaginal examination findings

2. Do you usually experience *heaviness or dullness* in the pelvic area? No Yes  
 If yes, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit
3. Do you usually have a bulge or something falling out that you can see or feel in the vaginal area? No Yes  
 If yes, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit
4. Do you usually have to push on the vagina or around the rectum to have or complete a bowel movement? No Yes  
 If yes, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit
5. Do you usually experience a feeling of incomplete bladder emptying? No Yes  
 If yes, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit
6. Do you ever have to push up on a bulge in the vaginal area with your fingers to start or complete urination? No Yes  
 If yes, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit
7. Do you feel you need to strain too hard to have a bowel movement? No Yes  
 If other than never, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit
8. Do you feel you have not completely emptied your bowels at the end of a bowel movement? No Yes  
 If other than never, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit
9. Do you usually lose stool beyond your control if your stool is well formed? No Yes  
 If yes, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit
10. Do you usually lose stool beyond your control if your stool is loose or liquid? No Yes  
 If yes, how much does this bother you?  
1                      2                      3                      4  
 Not at All                      Somewhat                      Moderately                      Quite a bit

11. Do you usually lose gas from the rectum beyond your control? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
12. Do you usually have pain when you pass your stool? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
13. Do you experience a strong sense of urgency and have to rush to the bathroom to have a bowel movement? No Yes  
 If other than never, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
14. Does a part of your bowel ever pass through the rectum and bulge outside during or after a bowel movement? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
15. Do you usually experience frequent urination? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
16. Do you usually experience urine leakage associated with a feeling of urgency, that is a strong sensation of needing to go to the bathroom? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
17. Do you usually experience urine leakage related to coughing, sneezing, or laughing? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
18. Do you usually experience small amounts of urine leakage (that is, drops)? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
19. Do you usually experience difficulty emptying your bladder? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit
20. Do you usually experience *pain* or *discomfort* in the lower abdomen or genital region? No Yes  
 If yes, how much does this bother you?  
1 2 3 4  
 Not at All Somewhat Moderately Quite a bit

**Figure 30-5, cont'd** The Pelvic Floor Distress Inventory–Short Form 20. (Adapted from the Cleveland Clinic Foundation, Gynecology. Available at <http://www.surgery.usc.edu/divisions/Cr/makeanappointment.html/> Accessed July 11, 2005.)

Instructions: Some women find that bladder, bowel, or vaginal symptoms affect their activities, relationships, and feelings. For each question, place an X in the box next to the response that best describes how much your activities, relationships, or feelings have been affected by your bladder, bowel, or vaginal symptoms or conditions over the past 3 months. Please be sure to mark an answer in all 3 columns for each question. Thank you for your cooperation.

How do symptoms or conditions usually affect your:	<i>Bladder or urine</i>	<i>Bowel or rectum</i>	<i>Vagina or pelvis</i>
1. Ability to do household chores (cooking, housecleaning, laundry)?	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit
2. Ability to do physical activities such as walking, swimming, or other exercise?	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit
3. Entertainment activities such as going to a movie or concert?	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit
4. Ability to travel by car or bus for a distance greater than 30 minutes away from home?	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit
5. Participating in social activities outside your home?	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit
6. Emotional health (nervousness, depression, etc.)?	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit
7. Feeling frustrated?	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit	<input type="checkbox"/> Not at all <input type="checkbox"/> Somewhat <input type="checkbox"/> Moderately <input type="checkbox"/> Quite a bit

**Figure 30-6** Pelvic Floor Impact Questionnaire–Short Form 7. (Adapted from the Cleveland Clinic Foundation, Gynecology. Available at <http://www.surgery.usc.edu/divisions/Cr/makeanappointment.html/> Accessed July 11, 2005.)

**Table 30-1** Items in the Scales and Subscales of the Pelvic Floor Distress Inventory and the Pelvic Floor Disorders Impact Questionnaires

Instrument*†	Number of Items	Instrument	Number of Items
<b>Pelvic Floor Distress Inventory</b>	46 total	<b>Pelvic Floor Disorders Impact Questionnaire</b>	93 total
Urogenital Distress Inventory	28 total	Urinary Impact Questionnaire	31
Obstructive/discomfort	12	Pelvic Organ Prolapse Impact Questionnaire	31
Irritative	11	Colorectal Impact Questionnaire	31
Stress	5	For each of the above:	
Pelvic Organ Prolapse Distress Inventory	16 total	Travel	6
General	7	Social	11
Anterior	6	Emotional	7
Posterior	3	Physical activity	6
Colorectal-Anal Distress Inventory	17 total		
Obstructive	3		
Incontinence	4		
Pain/irritation	7		
Rectal prolapse	2		

\*Some items are used in more than one scale.

†Copies of the questionnaires can be obtained by contacting MD Barber, MHS, 9500 Euclid Avenue A81, Cleveland Clinic Foundation, Cleveland, OH 44145.

**Prolapse Quality of Life (P-QOL) Version 4**

Name \_\_\_\_\_ Age \_\_\_\_\_ years Today's date \_\_\_\_\_

A prolapse is a bulge coming down the vagina causing discomfort.

**PLEASE FILL IN THIS QUESTIONNAIRE EVEN IF YOU FEEL YOU DO NOT HAVE A PROLAPSE.**

**Please tick one answer to each question.**

1. How would you describe your health at present? Very good  Good  Fair  Poor  Very poor   
 2. How much do you think your prolapse problem affects your life? None  A little  Moderately  A lot

**Please indicate with a tick mark if you have any of the following symptoms and how much they affect you.**

	Not applicable	None	A little	Moderately	A lot
3. Going to the toilet to pass urine very often.	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
4. Urgency: a strong desire to pass urine	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
5. Urge incontinence: urinary leakage associated with a strong desire to pass urine	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
6. Stress incontinence: urinary leakage associated with coughing	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
7. Feeling a bulge/lump from or in the vagina	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
8. Heaviness or dragging feeling as the day goes on from the vagina or the lower abdomen	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
9. Vaginal bulge interfering with you emptying your bowels	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
10. Discomfort in the vagina which is worse when standing and relieved by lying down	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
11. Poor urinary stream	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
12. Straining to empty your bladder	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
13. Urine dribbles after emptying your bladder	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
14. Bowels do not completely empty after opening	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
15. Constipation: difficulty in emptying	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
16. Straining to open your bowels	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
17. Vaginal bulge which gets in the way of sex	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
18. Lower backache which worsens with vaginal discomfort	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
19. Do you help empty your bowels with your fingers?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
20. How often do you open your bowels?	More than once a day <input type="checkbox"/>	Once a day <input type="checkbox"/>	Once every two days <input type="checkbox"/>	Once every 3 days <input type="checkbox"/>	Once a week or more <input type="checkbox"/>

Below are some daily activities that can be affected by your prolapse problem. How much does your prolapse problem affect you?

**We would like you to answer every question.** Simply tick the square that applies to you

	None	A little	Moderately	A lot	
<b>Role Limitations</b>					
21. To what extent does your prolapse affect your household tasks (e.g., cleaning, shopping, etc.)?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
22. Does your prolapse affect your job or your normal daily activities outside the home?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
<b>Physical and Social Limitations</b>					
23. Does your prolapse affect your physical activities (e.g. going for a walk or run, participating in sports or working out)?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
24. Does your prolapse affect your ability to travel?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
25. Does your prolapse limit your social life?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
26. Does your prolapse limit your ability to see/visit friends?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
	Not applicable	None	A little	Moderately	A lot
<b>Personal Relationships</b>					
27. Does your prolapse affect your relationship with your partner?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
28. Does your prolapse affect your sex life?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
29. Does your prolapse affect your family life?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
	None	A little	Moderately	A lot	
<b>Emotions</b>					
30. Does your prolapse make you feel depressed?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
31. Does your prolapse make you feel anxious or nervous?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
32. Does your prolapse make you feel bad about yourself?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
<b>Sleep energy</b>	Never	Sometimes	Often	All the Time	
Does your prolapse affect your sleep?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
Do you feel worn-out/tired?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
How often do you use tampons/pads/firm knickers to help your prolapse problem?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
How often do you push up the prolapse?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
How often do you have pain or discomfort due to the prolapse?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
Does the prolapse prevent you from standing?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	

**Thank you. Please check that you have answered all the questions.**

**Figure 30-7** Prolapse Quality of Life (P-QOL)–Version 4. (Adapted from Digesu GA, Khullar V, Cardozo L, et al: P-QOL: A validated questionnaire to assess the symptoms and quality of life of women with urogenital prolapse. Int Urogynecol J Pelvic Floor Dysfunct 16:176-181, 2005.)

**Figure 30-8** The 10-cm visual analogue scales are used for measurement of pain and pain relief. (From Huskisson EC: Measurement of pain. *Lancet* 2:1127-1131, 1974.)

( $P < 0.01$ ,  $r > 0.5$ ). Total scores for each P-QOL domain were significantly different between symptomatic and asymptomatic women ( $P < 0.0001$ ). Interrater reliability on all items was good (Cronbach's alpha  $> 0.80$ ). Test-retest reliability showed a highly significant correlation between the total scores for each domain.

Mouritsen and Larsen<sup>26</sup> evaluated patients with pelvic organ prolapse using their own validated questionnaire by relating type and severity of symptoms from the bladder, mechanical, sexual, and bowel domains to bother from the symptoms and to type and grade of prolapse measured. The symptoms from all domains were common and had little relation to the POP-Q value.

### Pain

Pain is a recognized symptom related to pelvic organ prolapse. The nature of an individual patient's pain should be evaluated, including vaginal pressure or heaviness, vaginal or perineal pain, sensation or awareness of tissue protrusion from the vagina, low back pain, abdominal pressure or pain, and observation or palpation of a mass.<sup>1</sup> Many standardized tools are available for the evaluation of pain, but none is specific for pelvic organ prolapse. The visual analogue scale (Fig. 30-8) has been shown to be a reliable tool for measuring pain in urogynecologic research.<sup>27,28</sup>

### Bowel Dysfunction

There are no isolated scales specifically designed to elicit information about bowel dysfunction associated with pelvic organ prolapse. However, there are useful tools included in more comprehensive scales, including the Pelvic Floor Impact Questionnaire—Long Form (PFIQ-L) (Fig. 30-9) and the PFDI Wexner (Fig. 30-10).<sup>24</sup> These scales include questions related to urgency of bowel movements, frequency of bowel incontinence, and behavioral techniques that women adopt to reduce the impact of bowel dysfunction on quality of life.

### Sexual Dysfunction

Pelvic organ prolapse has been strongly associated with sexual complaints in studies of women seeking treatment for pelvic floor disorders. According to a study by Barber and coworkers,<sup>29</sup> pelvic floor symptoms and detrusor instability are more commonly cited as reasons for sexual inactivity than other conditions.

According to Bump and colleagues,<sup>1</sup> some of the sexual function symptoms that should be evaluated include the following areas:

- Is the patient sexually active?
- If she is not sexually active, why?

- Does sexual activity include vaginal coitus?
- What is the frequency of vaginal intercourse?
- Does the patient have pain with coitus?
- Is the patient satisfied with her sexual activity?
- Has there been any change in orgasmic response?
- Is any incontinence experienced during sexual activity?

Several instruments have been designed specifically to address sexual dysfunction related to pelvic organ prolapse, including the long and short versions of the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ).

### Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire

The Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ-31) is the long or research form of a condition-specific, self-administered, valid, and reliable questionnaire designed to evaluate sexual function in patients with incontinence or uterovaginal prolapse. In the original study by Rogers and associates,<sup>30</sup> factor analysis identified three domains—Behavioral/Emotive, Physical, and Partner-Related—for the 31 questions. There was a strong correlation between sexual function scores and scores on the Sexual History Form-12 (SHF-12) for the questionnaire ( $r = -0.74$ ;  $P < 0.001$ ) and for the Behavioral/Emotive and Partner-Related domains ( $r = -0.79$  and  $-0.5$ , respectively;  $P < 0.001$ ). The Physical domain was correlated with scores on the IIQ-7 ( $r = -0.63$ ;  $P < 0.001$ ). The PISQ, along with the IIQ, was used in a study of sexual function after surgery for pelvic organ prolapse and showed a decline in sexual function scores after surgery despite improvement in IIQ scores.<sup>21</sup> The questionnaire can be found in the original journal article.<sup>30</sup>

### Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire

A shorter version of the PISQ-31, the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ-12) (Fig. 30-11),<sup>31</sup> is less time consuming to complete and therefore more appropriate for clinical use. A data subset from 99 of the original 182 women surveyed for the PISQ-31 was used, along with data from an additional 46 patients. All subset regression analyses with  $r$  greater than 0.92 identified 12 items that predicted PISQ-31 scores. Short-form scores correlated well with long-form scores ( $r = 0.75$  to  $0.95$ ). Correlations between the short-form score and other tests such as the IIQ-7, SHF-12, and symptom questionnaires scores were similar to correlations between the long-form score and these same tests. Test-retest reliability using data from 20 patients showed moderate to high reliability. A Spanish version of the PISQ-12 also has been validated.<sup>32</sup>

Instructions: Please answer these questions by putting an X in the appropriate box. If you are unsure about how to answer a question, give the best answer you can.

Q1: In general, would you say your health is:

- 1  Excellent  
 2  Very Good  
 3  Good  
 4  Fair  
 5  Poor

Q2: For each of the items, please indicate how much of the time the issue is a concern of you *due to accidental bowel leakage*. If it is a concern for you for reasons other than accidental bowel leakage then check the box under Not Apply (N/A).

Q2. Due to accident bowel leakage:	Most of the Time	Some of The Time	A little of the Time	None of the Time	N/A
a. I am afraid to go out	1	2	3	4	<input type="checkbox"/>
b. I avoid visiting friends	1	2	3	4	<input type="checkbox"/>
c. I avoid staying overnight away from home	1	2	3	4	<input type="checkbox"/>
d. It is difficult for me to get out and do things like going to a movie or to church	1	2	3	4	<input type="checkbox"/>
e. I cut down on how much I eat before I go out	1	2	3	4	<input type="checkbox"/>
f. Whenever I am away from home, I try to stay near a restroom as much as possible	1	2	3	4	<input type="checkbox"/>
g. It is important to plan my schedule (daily activities) around my bowel pattern	1	2	3	4	<input type="checkbox"/>
h. I avoid traveling	1	2	3	4	<input type="checkbox"/>
i. I worry about not being able to get to the toilet in time	1	2	3	4	<input type="checkbox"/>
j. I feel I have no control over my bowels	1	2	3	4	<input type="checkbox"/>
k. I can't hold my bowel movement long enough to get to the bathroom	1	2	3	4	<input type="checkbox"/>
l. I leak stool without even knowing it	1	2	3	4	<input type="checkbox"/>
m. I try to prevent bowel accidents by staying very near a bathroom	1	2	3	4	<input type="checkbox"/>

Q3: *Due to accidental bowel leakage*, indicate the extent to which you AGREE or DISAGREE with each of the following items. (If it is a concern for you for reasons other than accidental bowel leakage then check the box under Not Apply, N/A).

Q3. Due to accidental bowel leakage:	Strongly Agree	Somewhat Agree	Somewhat Disagree	Strongly Disagree	N/A
a. I feel ashamed	1	2	3	4	<input type="checkbox"/>
b. I can not do many of things I want to do	1	2	3	4	<input type="checkbox"/>
c. I worry about bowel accidents	1	2	3	4	<input type="checkbox"/>
d. I feel depressed	1	2	3	4	<input type="checkbox"/>
e. I worry about others smelling stool on me	1	2	3	4	<input type="checkbox"/>
f. I feel like I am not a healthy person	1	2	3	4	<input type="checkbox"/>
g. I enjoy life less	1	2	3	4	<input type="checkbox"/>
h. I have sex less often than I would like to	1	2	3	4	<input type="checkbox"/>
i. I feel different from other people	1	2	3	4	<input type="checkbox"/>
j. The possibility of bowel accidents is always on my mind	1	2	3	4	<input type="checkbox"/>
k. I am afraid to have sex	1	2	3	4	<input type="checkbox"/>
l. I avoid traveling by plane or train	1	2	3	4	<input type="checkbox"/>
m. I avoid going out to eat	1	2	3	4	<input type="checkbox"/>
n. Whenever I go someplace new, I specifically locate where the bathrooms are	1	2	3	4	<input type="checkbox"/>

Q4: During the past month, have you felt so sad, discouraged, hopeless, or had so many problems that you wondered if anything was worthwhile?

- 1  Extremely so – to the point that i have just about given up  
 2  Very much so  
 3  Quite a bit  
 4  Some – enough to bother me  
 5  A little bit  
 6  Not at all

**Figure 30-9** Pelvic Floor Impact Questionnaire–Long Version, bowel-related items. (Adapted from the University of Southern California Center for Colorectal and Pelvic Floor Disorders. Available at <http://www.surgery.usc.edu/divisions/Cr/makeanappointment.html/> Accessed July 11, 2005.)

Instruction: Please circle the number that describes the status of your fecal incontinence.

Incontinence type	Never	Rarely: <i>less than once a month.</i>	Sometimes: <i>less than once a week but more than once a month.</i>	Usually: <i>less than once a day but more than once a week</i>	Always: <i>once a day or more</i>
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Wears pad	0	1	2	3	4
Lifestyle alterations	0	1	2	3	4

7. Does fear of incontinence (either stool or urine) restrict your sexual activity?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
8. Do you avoid sexual intercourse because of bulging in the vagina (either the bladder, rectum or vagina falling out)?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
9. When you have sex with your partner, do you have negative emotional reactions such as fear, disgust, shame or guilt?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
10. Does your partner have a problem with <i>erections</i> that affects your sexual activity?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
11. Does your partner have a problem with premature ejaculation that affects your sexual activity?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
12. Compared with orgasms you have had in the past, how intense are the orgasms you have had in the past six months?	Much less intense <input type="checkbox"/>	Less intense <input type="checkbox"/>	Same intensity <input type="checkbox"/>	More intense <input type="checkbox"/>	Much more intense <input type="checkbox"/>
Scoring: Scores are calculated by totaling the scores for each question with 0 = never, 4 = always. Reverse scoring is used for items 1, 2, 3, and 4. The short-form questionnaire can be used with up to two missing responses. To handle missing values, the sum is calculated by multiplying the number of items by the mean of the answered items. If there are more than two missing responses, the short form no longer accurately predicts long-form scores. Short-form scores can only be reported as total or on an item basis. Although the short form reflects the content of the three factors in the long form, it is not possible to analyze the data at the factor level. To compare long- and short-form scores, multiply the short-form score by 2.58 (12/31).

## CONCLUSIONS

The most comprehensive clinical picture of a patient with pelvic organ prolapse includes an anatomic assessment using the POP-Q (descriptive and staging) and a comprehensive symptom index. The clinician may choose to supplement these with an in-depth, symptom-specific index to document the patient's perception of

the impact of treatment on her symptoms. The benefit of consistent use of a validated, descriptive, and standardized staging index is accurate, ongoing documentation of the success or failure of treatment for the individual patient, regardless of whether management is medical or surgical. It also serves as the foundation for communication among clinicians and researchers.

# URETHRAL INJECTABLES IN THE MANAGEMENT OF STRESS URINARY INCONTINENCE

*Ehab A. Elzayat and Jacques Corcos*

### HISTORICAL BACKGROUND

Urethral bulking agents have been used for many years to treat intrinsic sphincter deficiency. They are minimally invasive alternatives to operative procedures such as anterior repairs, suspensions, and urethral slings for the management of stress urinary incontinence (SUI). Urethral injection, which can be delivered under local anesthesia as an outpatient procedure, is relatively safe and has few complications. It is an effective treatment for SUI, with complete patient satisfaction comparable to surgery. Urethral injection is cost-effective with less operating time and a shorter hospital stay compared with more invasive surgery.<sup>1,2</sup>

The concept of urethral injectables to increase urethral resistance has been known for 70 years. Murless,<sup>3</sup> in 1938, was the first to report his experience with injection of the sclerosing agent sodium morrhuate into the anterior vaginal wall in 20 patients to induce an inflammatory reaction that compressed the urethra with sclerosis, leading to destruction of the urethral musculature and decreased the compliance of the urethral wall. Quackels,<sup>4</sup> in 1955, injected paraffin wax perineally in two incontinent patients after prostatectomy. Dondren is another sclerosing agent that has been used for urethral injection with some success.<sup>5</sup>

The injection of sclerosing materials such as sodium morrhuate, paraffin, or Dondren causes unacceptable complications, including sloughing of the urethra, urethral stenosis, and pulmonary embolism.<sup>5</sup> Polytetrafluoroethylene (Teflon) was proposed as the first bulking agent by Lopez and colleagues<sup>8</sup> in 1964, and it became popular in the 1970s.<sup>6,7</sup> Since then, several bulking agents have been developed, and new ones are being studied. Nonautologous substances, such as collagen and hyaluronic acid, and autologous substances, such as fat, chondrocytes, and muscle, have been employed clinically or are still under investigation. This chapter reviews the safety and efficacy of available injectable agents for the treatment of female SUI.

### MECHANISM OF ACTION OF BULKING AGENTS

The mechanism of continence in urethral injection therapy is uncertain and controversial. Many factors enable normal continence in females, including contraction of the sphincter muscles, musculofascial support of the bladder neck, and a urethra seal mechanism.<sup>8</sup> The functional urethral seal mechanism is probably a major contributor to continence because of its ability to increase urethral resistance and urethral opening pressure during coughing and straining. Common causes for loss of the urethral seal

mechanism are scarring from previous operations, birth trauma, estrogen deprivation, or pelvic radiotherapy.<sup>9</sup> Submucosal urethral injection of bulking materials augments bladder neck length and urethral mucosa coaptation and improves the closure mechanism of the urethral sphincter in response to increased intra-abdominal pressure.<sup>10</sup> Some investigators suggest an obstructive mechanism for the action of urethral injectables, as witnessed sometimes by a decrease in the maximum flow rate and heightened voiding maximum detrusor pressure after injection.<sup>11,12</sup> Several laboratories have reported elevation of Valsalva leak point pressure (VLPP) as a result of an increase in functional urethral length.<sup>13-15</sup> Others have found that bulking materials improve the ratio of urethral resistance to abdominal pressure by raising the VLPP but not the detrusor leak point pressure or voiding pressure.<sup>16,17</sup> Monga and Stanton<sup>18</sup> postulated that prevention of bladder neck opening during stress is the mechanism of action of collagen injection, not obstruction.

Cephalad elongation of the urethra caused by bulking agent injection at the bladder neck or proximal urethra probably accounts for increased abdominal pressure transmission in the first quarter of the urethra.<sup>18,19</sup> Placement of the injectable material more distally does not increase the functional length of the urethra or prevent bladder neck opening during episodes of stress. It is suggested that the bulking materials should be placed just distal to the urethral-vesical junction and that the position of the injectable is more important than its quantity for a good bulking effect.<sup>19,20</sup>

### INDICATIONS AND CONTRAINDICATIONS

Injectable agents are classically indicated in patients with SUI. Several studies have shown good efficacy for bulking agents, even in the presence of bladder neck mobility. There is a trend to admit some degree of intrinsic sphincter deficiency (ISD) in all cases of SUI. Bulking agent indications then become much broader, and physicians are influenced by other parameters, such as patient preferences, cost, the need for concomitant procedures (e.g., for prolapse), and product availability.<sup>22-25</sup>

An overactive bladder should be treated before undertaking urethral injection. Many physicians believe that untreated bladder instability and low compliance are contraindications to urethral injection; others think that urethral injection can be used to treat the incompetent outlet of an overactive bladder without adverse effects on clinical outcome.<sup>26</sup>

Contraindications to urethral injections are untreated urinary tract infection and hypersensitivity to the injectable materials

**Figure 31-1** Hypersensitive cutaneous reaction after collagen skin testing.

(Fig. 31-1). Extensive scarring of tissue from irradiation or previous surgery or trauma may decrease the retention of injectable material in tissue, leading to a poor outcome.

### INJECTION TECHNIQUE

The goal of injection therapy in SUI patients is restoration of the urethral submucosal “cushion” to improve urethral closure pressure during stress episodes without compromising voiding detrusor pressure. The advantages of injection therapy are its minimal invasiveness and technical simplicity, allowing delivery in an outpatient facility under local anesthesia. Urine culture for all patients should be negative, and if collagen is chosen, a skin test to rule out hypersensitivity to collagen must be performed at least 4 weeks before the treatment (see Fig. 31-1). Perioperative antibiotics (e.g., one dose of extended-release quinolone) are usually recommended. After having emptied her bladder, the patient is installed in the lithotomy position, prepared with antiseptic cleaning solution at the level of the external genitalia and urethral meatus, and then draped as usual.

Three injection methods have been proposed: periurethral, transurethral or intraurethral, and antegrade.<sup>27</sup> Only the transurethral technique is still in use.

#### Periurethral Technique

Injections are usually administered with instillation of transurethral topical anesthetic (i.e., 2% lidocaine jelly) and 3 to 4 mL of 1% lidocaine injected in the periurethral tissues at the 3- and 9-o’clock positions. A 20-gauge needle connected to the syringe of bulking agent is successively inserted slowly at the 3-, 6-, and 9-o’clock positions and advanced into the submucosal tissues (i.e., layer just under the urothelium), approximately 0.5 cm distal to the bladder neck, to raise a urethral bleb. Needle position is controlled by urethroscopy under a 0-degree lens. At each position, the bulking agent should be injected slowly to avoid rupturing the expanding urothelium. The injection is continued until the mucosa appears pale and the lumen is about 30% occluded.<sup>24</sup> To ensure success, visualization of complete coapta-

**Figure 31-2** Coaptation of the urethra after injection of bulking agents at the 3- and 9-o’clock positions.

**Figure 31-3** Perforation of the mucosa during periurethral injection (arrow points to the needle).

tion (i.e., bilateral kissing lobes) of the urethral mucosa at the end of the procedure is recommended (Fig. 31-2). For some physicians, this technique can also be done under ultrasonic guidance.<sup>28</sup> In some cases, positioning of the needle can be difficult, leading to repeated mucosal perforations (Fig. 31-3).

#### Transurethral or Intraurethral Technique

Two transurethral techniques are available: the cystoscopically guided technique and the blind technique. In the first one, needle insertion into the submucosal tissue is achieved under cystoscopic vision with different injection devices. It requires a

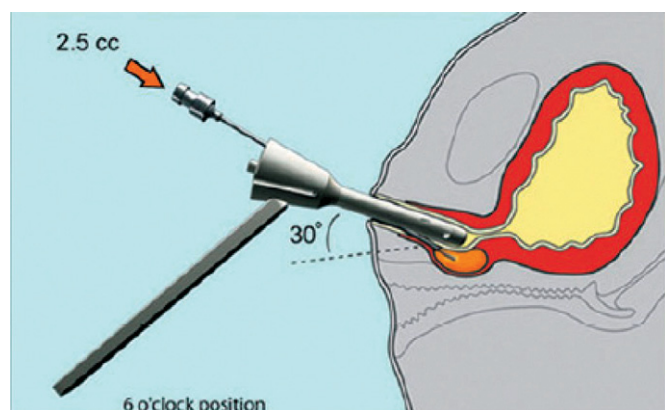

Figure 31-4 Macroplasty injection device.

cystoscope or a urethrocystoscope with an injection needle (needle size depends on the viscosity of the injectable material) and usually a 0- or 12-degree lens.<sup>29</sup> The needle should be inserted into the submucosal space approximately 0.5 to 1.5 cm distal to the bladder neck at the 3-, 6-, and 9-o'clock positions. The bulking agent is injected slowly until it raises a urethral bleb. Because of the high viscosity of some injectable agents, such as Teflon or silicone microparticles, an injection gun may be necessary (Fig. 31-4). After injection, the physician must avoid advancing the cystoscope beyond the injection site to prevent compression and extrusion of the injectable material.

Faerber and associates<sup>30</sup> compared the intraurethral and periurethral routes and demonstrated significant differences in cure (46% versus 33%) and improvement (50% versus 67%) rates in favor of the intraurethral route. However, Schulz and colleagues<sup>31</sup> compared periurethral and intraurethral injection randomly in 40 women and concluded that both routes of injection were equally effective. In Faerber's report, it was evident that the intraurethral route required much less injectable material (4.7% versus 10.1 mL) for better results. The average number of sessions (1.3) was identical with both approaches. These findings explain why most centers now use only the intra-urethral approach.

The blind transurethral technique uses injection devices that do not require cystoscopic guidance. Henalla and coworkers<sup>32</sup> were the first to apply Macroplastique implantation system to improve and simplify the injection technique (see Fig. 31-4). With this device, the success rate was 74.3%, and the rate of acceptability by surgeons was 95%. The implantation device was developed to control accurate placement of the bulking agent at predefined sites and depth in the female urethra without the need for cystoscopic guidance.<sup>33</sup> The device is advanced into the urethra until urinary drainage is established and then withdrawn 1 cm. The injection needle is inserted into the first deployment site, angling the device in the direction of the injection site to ensure penetration of the mucosa.<sup>34</sup> The device enables consistent bolus placement at a predetermined depth and site. Usually, two to three punctures (at the 4-, 8-, and 12-o'clock positions) are needed for material delivery. If injection treatment fails, transvaginal or transurethral ultrasound can be performed to investigate correct Macroplastique placement. A different version of the device has been introduced by Q-Med AB (Uppsala, Sweden) (Fig. 31-5). The Implacer device has been developed for administration of dextranomer/hyaluronic acid (Dx/HA; Zuidex) without the need for cystoscopic guidance. The Implacer uses

Figure 31-5 Implacer device for Zuidex injection.

four syringes (each containing 0.7 mL of Dx/HA) and 23-gauge needles. The device unfolds and fixates the urethral wall to ensure symmetric placement of the injectable agent at four evenly spaced locations around the urethra.

#### Antegrade Technique

The antegrade technique has been described mainly for incontinence in men after prostatectomy. It is performed through a suprapubic cystostomy and under cystoscopic control. The bulking agent is injected submucosally around the bladder neck until coaptation occurs. The technique can be performed under intravenous sedation, general anesthesia, or spinal anesthesia. It is indicated for patients with a scarred, noncompliant urethra.

#### POSTOPERATIVE CARE

Patients are usually discharged to their homes after satisfactory voiding. If urinary retention occurs, a small-caliber catheter (14 Fr or smaller) is inserted to empty the bladder. In rare cases of persistent retention, intermittent catheterization with a small-caliber catheter is required until normal micturition resumes.<sup>24</sup> Mechanical pressure to the perineum (e.g., hard seat covers, hard stools, intravaginal sexual intercourse) should be avoided for 2 weeks. If a second injection is necessary, it should be performed after a few weeks to allow healing of the previous implant.<sup>28</sup>

#### ASSESSMENT OF CLINICAL OUTCOMES

No validated, reproducible, well-accepted instruments have existed for the assessment of outcomes of treatment of urinary incontinence.<sup>35</sup> There is no standard definition of success in studies of anti-incontinence procedures, making it difficult to objectively compare results. Assessment of cure depends on subjective or objective measurements, which are not correlated. In most reported studies, *cure* is defined as the patient being dry by the end of the follow-up period. *Improvement* is defined as rare or minimal leakage and patient satisfaction with the result of the injection.<sup>36</sup>

**Table 31-1 Results of Polytetrafluoroethylene Injections**

Study	No. of Patients	Follow-up (mo)	Mean No. of Injections	Mean Injection Volume (mL)	Results
Politano, <sup>43</sup> 1982	51	6 (6-16)	1.8	10-15	71% (51% dry, 20% improved)
Lim et al, <sup>48</sup> 1983	28	12	1	11-12	54% (33% improved, 21.4% dry)
Schulman et al, <sup>49</sup> 1983	56	3 (3-24)	1.5	9	86% (16% improved, 70% cured)
Deane et al, <sup>50</sup> 1985	28	13 (3-24)	NS	10	29% improved, 32% dry
Osther and Rohl, <sup>51</sup> 1987	36	3	NS	12	50% good or moderate results
Lockhart et al, <sup>44</sup> 1988	20	NS	1.9	7	50% dry, 35% improved
Vesey et al, <sup>52</sup> 1988	36	9 (3-36)	1-2	7-14	67% (56% dry, 11% improved)
Kiilholma and Makinen, <sup>53</sup> 1991	22	60	NS	7.3	18% (dry or improved)
Beckingham et al, <sup>45</sup> 1992	26	36	1-3	9	27% improved, 7% dry
Lopes et al, <sup>54</sup> 1993	74	31	1.3	19	19% improved, 54.3% dry
Harrison et al, <sup>46</sup> 1993	36	5.1 yr	1-3	7	33% (11% dry, 22% improved)
Herschorn and Glazer, <sup>47</sup> 2000	46	12	2	2.5	30.4% dry, 41.3% improved

NS, not stated.

Initial patient assessment should include a symptom evaluation, patient satisfaction score, quality-of-life questionnaire, leakage gravity index (e.g., pad test, visual scale), physical examination, and urodynamic measurement. Follow-up should monitor the same parameters plus the length of time since the last injection, number of injections performed, volume per injection, and cure criteria (e.g., physical examination, pad usage, pad-weighting tests, urodynamics).<sup>37</sup>

There is a large consensus in favor of a redefinition of outcomes for incontinence treatment. Clinicians and researchers are developing new measures that take into consideration the patient's goals and expectations. We strongly believe that these new paradigms will in the near future replace classic assessments.

## INJECTABLE MATERIALS

Ideal bulking agents should be biocompatible, biodegradable, nonmigratory (bulking > 80  $\mu\text{m}$ ), nonerosive, noncarcinogenic, nonimmunogenic, permanently bulking, and easily injected.<sup>25</sup> Unfortunately, none of the available bulking agents entirely meets these requirements.

### Polytetrafluoroethylene

Polytetrafluoroethylene (PTFE; Teflon, Polytef) was described as a bulking agent by Lopez and colleagues in 1964,<sup>8</sup> and it was popularized by Berg<sup>6</sup> and Politano<sup>7</sup> in 1970. It is a paste consisting of colloidal PTFE micropolymeric, various-sized particles (up to 300  $\mu\text{m}$ , with most being < 50  $\mu\text{m}$ ).<sup>8</sup> It is an inert, stable material with a high molecular weight and high viscosity, and it is nonallergenic.

Teflon has several disadvantages that limit its acceptability and prevent it from being approved by the U.S. Food and Drug Administration (FDA) for periurethral injection in the United States. It is difficult to inject because of its density, requiring very high pressure through a large-bore needle. Because of the small size of the particles, PTFE (90% < 40  $\mu\text{m}$  in diameter) can be phagocytosed, resulting in distant migration to the brain, lungs, and lymph nodes.<sup>38,39</sup> Among other major inconveniences, PTFE is not biodegradable, and it carries a risk of granuloma formation

at the injection site and at some sites of distant migration.<sup>40</sup> PTFE produces an inflammatory reaction that may lead to urethral fibrosis, periurethral abscess, and urethral diverticulum.<sup>41</sup> The carcinogenic potential of PTFE injection has been suggested but not proved and never reported clinically.<sup>42</sup>

Politano and coworkers<sup>43</sup> first used Teflon for incontinence in men after prostatectomy and later for stress incontinence in women. Their short-term results were promising, with cure and improvement rates of 57% to 85%. However, long-term data have ranged from 18% to 76%.<sup>44-46</sup> The reasons for failure of Teflon injection include the high pressure needed for injection, leading to tissue extrusion, absorption, and migration of Teflon particles, and the inflammatory reactions affecting urethral function.<sup>37</sup> Failures in this series were associated with prior incontinence operations and bladder instability. To minimize the risk of migration, Herschorn and Glazer<sup>47</sup> evaluated the injection of low-volume Teflon, with a success rate of 71.7% (Table 31-1).

### Glutaraldehyde Cross-Linked Collagen

Bovine glutaraldehyde cross-linked collagen (Contigen) is the most widely studied bulking agent. It is a well-established injectable material that gained FDA approval in 1993.<sup>24</sup> Periurethral injection of glutaraldehyde cross-linked collagen was first reported by Shortliffe and associates in 1989.<sup>55</sup> Contigen, a highly purified suspension of bovine collagen in normal saline, contains more than 95% type I collagen and less than 5% type III collagen cross-linked with glutaraldehyde. This cross-linking makes collagen more stable and durable, hindering its breakdown by fibroblast-secreted collagenase and enhancing its invasion by fibroblasts and blood vessels with deposition of host collagen, promoting long-term efficacy of the implant.<sup>56</sup> The decreased antigenicity of this mixed collagen is obtained by hydrolysis of the antigenic parts of the molecules, the amino-terminal and carboxyl-terminal segments. Cross-linking also reduces hypersensitivity.

Collagen injection is an easy procedure. It can be delivered periurethrally or transurethrally through a small needle (22 gauge) under local anesthesia. Each syringe contains approximately 2.5 mL of collagen, and some patients may need repeated injections (e.g., two to five injections). If the collagen is placed

too deeply, it will be quickly reabsorbed. However, the position and volume of injected collagen are not predictive of clinical outcome, as determined by a magnetic resonance study.<sup>57,58</sup> The advantages of collagen injection include its durable efficacy and safety, with no proven risk of granuloma formation or migration.<sup>59</sup> Considering its price, cost-effectiveness is a concern. Berman and Kreder<sup>60</sup> reported that sling cystourethropexy is more cost-effective than collagen injection in women with type III incontinence. The collagen injection is allergenic in up to 5% of patients, requiring skin tests to rule out hypersensitivity 1 month before injection.<sup>61</sup> There also is some concern regarding the potential for disease transmission from bovine products.<sup>34</sup>

Early results have disclosed subjective cure and improvement rates up to 95% and objective cure rates of 61% to 91%.<sup>36</sup> Herschorn and colleagues<sup>62</sup> reported an early experience with intra-urethral injection of collagen in 31 women, with a mean follow-up of 6 months. The combined cure and improvement rate was 90.3%. Longer-term results of cure and improvement rates vary from 57% to 94% (Table 31-2). In a North American multicenter study, 148 women underwent collagen injection for ISD, with an overall success rate of 78% (45% cured, 33% improved) at 2 years of follow-up.<sup>63</sup> Monga and coworkers<sup>67</sup> achieved a success rate of 86% at 3 months, 77% at 12 months, and 68% at 24 months after urethral injection of collagen in 60 women with SUI. Swami and associates<sup>74</sup> treated 111 patients with periurethral collagen injection for a success rate of 85% at 6 months and 65% at 3 years after injection. There was no difference in maximum urethral closure pressure before and after collagen injection and no predictive factors of success. Some physicians have reported that patients who underwent prior anti-incontinence surgery may have better results than those without previous surgery.<sup>63,65</sup> These findings may be explained by periurethral tissue support and limited mobility by scarring.<sup>63,65</sup> Others have observed no correlation between the degree of urinary incontinence preoperatively and the success rate.<sup>70</sup> Some investigators have obtained higher percentages of injection failure in patients with preoperative detrusor instability.<sup>70,73</sup> The use of collagen in cases of urethral hypermobility has produced results comparable to those without hypermobility.<sup>16,67,69,70,72</sup> Steele and colleagues<sup>82</sup> reported a higher success rate for collagen injection in patients with hypermobility than in those without hypermobility.

Long-term studies have demonstrated continuing success, with a cure rate of 25% to 45% and an improvement rate between 25% and 50%. Corcos and Fournier<sup>78</sup> reported the 4-year follow-up results for 40 women who underwent collagen injection. The cure rate was 30%, and the improvement rate was 40%. One third of these patients required a top-up injection 18 to 24 months after the initial treatment. Gorton and coworkers<sup>79</sup> published their long-term results of collagen injection in 46 women with ISD, showing an overall success rate of 35%.

The morbidity associated with collagen injection is minimal and self-limited. The most common complication is transient urinary retention, urinary tract infection, and transient hematuria. In 337 collagen injection cases, Stothers and associates<sup>83</sup> documented a complication rate of 20%, including de novo urinary urgency in 12.6% of patients. In many patients, the symptoms were irreversible (21% did not respond to anticholinergics) and included hematuria (5%) and urinary retention (1.9%). Delayed reaction at the skin test site occurred in 0.9% (3) of patients and was associated with arthralgia in two cases. Others identified urinary retention (8%), urinary tract infection (4%), hematuria (2%), and urinary urgency in less than 1%.<sup>84</sup>

Rare complications after collagen injection included sterile abscess at the injection site.<sup>85,86</sup> Pulmonary embolism, urethral prolapse, and osteitis pubis have been encountered after urethral collagen injection.<sup>86-88</sup>

### Autologous Fat

Autologous fat was first used in plastic surgery to augment soft tissue defects. Periurethral fat injection was introduced in 1989 by Gonzales and colleagues<sup>89,90</sup> to treat ISD. Fat was harvested from lower abdominal subcutaneous tissue by liposuction using a trocar or aspiration syringe under local or general anesthesia. Between 15 and 20 mL of fat was mixed with Ringer's solution or insulin before periurethral or transurethral injection. The advantage of autologous fat is that it is readily available, biocompatible, and inexpensive. Its disadvantages are fat resorption and replacement by fibrous tissues, which necessitate repeated injections. Horl and coworkers<sup>91</sup> employed magnetic resonance imaging to demonstrate a 55% volume loss at 6 months after fat injection but no further volume decline at 9 and 12 months of follow-up. Approximately 50% to 90% of transferred adipose grafts do not survive.<sup>92</sup> Graft survival depends on minimal handling, low suction pressure during liposuction, and large-bore needles for reinjection to minimize injury.<sup>93</sup>

Periurethral fat injection has a reported success rate that is lower than with other injectables (Table 31-3). Palma and associates<sup>97</sup> obtained a success rate of 76% (64% dry and 12% improved) with repeated injections of fat, compared with 69% (31% dry and 38% improved) with a single injection. Haab and associates<sup>76</sup> compared the outcome of fat and collagen injection in 67 women with ISD and achieved cure rates of 13% and 24% for the fat and collagen groups, respectively. Lee and colleagues<sup>99</sup> published the results of a randomized, double-blind, controlled study of fat and saline injection (as a control) and reported success rates of 22% and 20.7% for the fat and saline groups, respectively. They concluded that periurethral fat injection does not appear to be more effective than placebo for treating stress incontinence.

The complications of fat injection include urinary tract infection, urinary retention, hematuria, pain, and hematomas at the site of liposuction. Complications such as urethral pseudolipoma and death due to fat embolism have also been reported.<sup>99-101</sup> These data should exclude fat injection for the treatment of SUI.<sup>37</sup>

### Silicone Microimplants

Silicone microimplants (e.g., Macroplastique) are soft, flexible, solid-textured, irregularly shaped implants of heat-vulcanized polydimethylsiloxane (i.e., silicone rubber) suspended in a carrier gel (i.e., polyvinylpyrrolidone). The silicone particles are encapsulated in fibrin, and the nonsilicone carrier gel is absorbed by the reticuloendothelial system and excreted in the urine. The injected particles are organized within 6 to 8 weeks into firm nodules with infiltrated collagen and surrounded by a fibrous sheath that is well developed at 9 months.<sup>102</sup>

Silicone particles are inert, inducing very little local inflammatory reaction. The material is biocompatible, nonbiodegradable, nongenotoxic, noncarcinogenic, and nonteratogenic. The mean particle size ranges from 100 to 300  $\mu\text{m}$  in diameter, limiting the risk of migration, which usually occurs with particles less than 70  $\mu\text{m}$ .<sup>103</sup> Macroplastique can be injected transurethrally or periurethrally under cystoscopic vision or transurethrally with a

**Figure 13-6** Ratchet gun and flexible needle for Macroplastique injection.

special injection system (see Fig. 31-5). The material is viscous, and the needle must be prelubricated with 1 to 2 mL of carrier gel before the vial (2.5 mL) of silicone paste is discharged by means of a high-pressure ratchet gun (Fig. 31-6).

Silicone elastomers have been used since the early 1990s as bulking agents for treating SUI, but they are still not approved for application in the United States. The reported cure rate with silicone ISD varies between 14% and 66.7%. Improvement rates range from 46% to 80%. When ISD is associated with urethral hypermobility, the cure and improvement rates are between 0% and 21.4% and between 0% and 58.9%, respectively.<sup>104</sup>

Sheriff and colleagues<sup>105</sup> reported a success rate of 90% at 1 month after injection, with a time-dependent decrease to 48% at 2 years postoperatively. Other long-term results usually show a lower cure rate and are summarized in Table 31-4.

Reported complications after silicone injection are minimal and self-limited, such as hematuria, dysuria, urinary tract infection (0.9%), and urinary retention (6.8%).<sup>108</sup> There is still concern about small particle migration and granuloma formation, with possible risks of autoimmune reactions associated with silicone injection.<sup>103</sup>

### Dextranomer/Hyaluronic Acid Copolymer

Dextranomers are well-known polysaccharides that have been used for topical wound cleaning. HA has been applied in eye surgery and for joint injection.<sup>116</sup> Dx/HA is a copolymer (Zuidex) in a gel of nonanimal, stabilized HA. A high-molecular-weight polysaccharide, HA works as a carrier gel and is resorbed within 2 weeks after injection. Zuidex is a highly viscous solution, non-immunogenic and biocompatible, with no risk of allergy or granuloma formation. Dx microspheres, the bulking agent, are 80 to 200  $\mu$ m in diameter and do not fragment, eliminating the risk of distance migration.<sup>117</sup> Dx/HA is biodegraded very slowly by hydrolysis, and it remains at the injected site for up to 4 years. Stenberg and coworkers<sup>118</sup> established that the volume of subcutaneously injected Dx/HA implants decreased by 23% over 12 months in rats. Because the implant consists of 50% microspheres and 50% HA, volume reduction soon after injection should be expected. However, endogenous tissue augmentation is caused by ingrowths of collagen and fibroblasts between the microspheres. Dx/HA has been shown to be well tolerated for endoscopic injection in vesicoureteric reflux (VUR) in children, with efficacy persisting for at least 5 years.<sup>119</sup> It has been approved by the FDA in the United States for VUR and approved in Europe and Canada for the treatment of VUR and SUI.<sup>120</sup>

Initial studies of Dx/HA injection in patients with stress incontinence are promising. Stenberg and associates<sup>121</sup> attained an initial success rate of 85% (cured or improved) for 20 patients with stress incontinence. Long-term follow-up (up to 6.7 years) of their cohort revealed that 57% were still cured or improved without any adverse effects (Table 31-5).<sup>122</sup> Van Kerrebroek and colleagues<sup>123</sup> reported a success rate of 71% among 42 women 1 year after Dx/HA injection. The few adverse effects encountered included a sterile abscess ( $n = 1$ ), urinary tract infection ( $n = 5$ ), hematuria ( $n = 4$ ), urethral disorder ( $n = 3$ ), and decreased urinary flow ( $n = 3$ ). A case of granuloma after Dx/HA injection has been documented.<sup>126</sup> Injection therapy does appear to preclude future surgical interventions, because it does not cause any major tissue changes.<sup>127</sup>

### Carbon-Coated Zirconium Beads

Durasphere is a mixture of nonabsorbable, carbon-coated zirconium beads in a water-based carrier gel with  $\beta$ -glucan (i.e., 97%

NS, not stated.

**Table 31-5 Reported Results of Dextranomer/Hyaluronic Acid Injections**

Study	No. of Patients	Follow-up (mo)	No. of Injections	Volume of Injections (mL)	Results
Stenberg et al, <sup>121</sup> 1999	20	3-6	2-4	5.5	85% cure or improvement
Stenberg et al, <sup>122</sup> 2003	20	78	1.6	6.4	57% success, with recurrence in 25%
van Kerrebroeck et al, <sup>120</sup> 2004	42	12	NS	2.8-4	71% subjective improvement at 3 mo, 61% at 12 mo
van Kerrebroek et al, <sup>123</sup> 2004	42	12	NS	2.8-4	75% objective success (24% cured, 51% improved)
Haab et al, <sup>124</sup> 2004	139	6	2.1	NS	67% success rate at 6 mo
van Kerrebroek et al, <sup>125</sup> 2004	20	24		2.8-4	70-90% initial success rate, and 60% at 2 yr

water and 3% glucan). It is safe and has been exploited for many years in heart valve replacements.<sup>37</sup> There is no risk of allergy or distant particle migration because particle size ranges between 250 and 300  $\mu\text{m}$  in diameter. Durasphere is the latest bulking agent approved by the FDA (Table 31-6).

Lightner and coworkers<sup>128</sup> undertook a multicenter, randomized, double-blind study comparing Durasphere ( $n = 178$ ) and collagen ( $n = 177$ ) for the treatment of ISD. At 1 year of follow-up, the success rates were 80.3% and 67.1% for Durasphere and collagen, respectively. The mean number of injections was similar (Durasphere = 1.55, collagen = 1.69), but the injected volume was significantly different (Durasphere = 4.83 mL, collagen = 6.23 mL;  $P < .001$ ). Pannek and associates<sup>129</sup> treated 13 women and 7 men with Durasphere injection and achieved limited success (33% at 1 year after injection). There was distant particle migration in two patients despite the large-size of the Durasphere particles. Chrouser and colleagues<sup>131</sup> studied

Durasphere and collagen for the treatment of 43 women with SUI. The initial success rate (63%) was similar in both groups. Longer follow-up (12, 24, and 36 months) showed that Durasphere remained effective in 35%, 33%, and 21% of patients, whereas the collagen efficacy rates were only 33%, 19%, and 9%, respectively. For Chrouser and coworkers<sup>131</sup> the lack of durability of both agents was thought to result from physiologic changes of the bladder neck and urethra with time, altered tissue compliance in response to injection, or poor long-term performance of the agent.

The complication rate with Durasphere is higher than with collagen. Urinary urgency is seen in 24% and 16.9% of patients, respectively. However, resolution of urgency symptoms is greater in the Durasphere group than in the collagen group. Urinary retention is also greater with Durasphere (11.9% versus 3.4%),<sup>128</sup> but it rarely persists to a point at which endoscopic evacuation of Durasphere at the injection site is necessary.<sup>132</sup>

**Table 31-6** Reported Results of Durasphere Injection

Study	No. of Patients	Follow-up (mo)	No. of Injections	Volume of Injections (mL)	Results
Lightner et al, <sup>128</sup> 2001	178	11	1.6	4.8	80.3% overall success

Madjar et al, <sup>130</sup> 2003	46	9.4	1.5	2-3	65.2% (13% cured, 34.7 improved)
Chrouser et al, <sup>131</sup> 2004	56	37	1.6	NS	63% initial success, 33% at 1 yr, 21% at 3 yr

ISD, intrinsic sphincter deficiency; NS, not stated.

**Figure 31-7** Implanted microballoons (arrows).

### Microballoon Implantation

Implantable microballoons (UroVIV) are elastomeric silicone capsules with an inflatable volume ranging from 0.2 to 0.9 mL, and they are filled with a poly-*N*-vinyl pyrrolidinone–based, high-water-content, cross-linked hydrogel (Fig. 31-7). In an aqueous environment, the hydrogel remains a gel due to interaction with the hydrophobic domains. The capsule device primarily consists of a membrane and check valve to prevent escape of the solution injected at the time of implantation.<sup>133</sup> A self-detachable, implantable balloon system developed by Atala and coworkers<sup>134</sup> was initially used for the treatment of VUR in children. It was found to be safe, injectable material that was biocompatible and without the risk of migration or local inflammation. It was detectable on plain radiography and ultrasound.

The balloon is injected periurethrally under cystoscopic control. The inflated balloon is approximately 8.5 × 21 mm, and it is usually placed at the 3- and 9-o'clock positions; if necessary, another balloon can be implanted at the 6-o'clock position.<sup>135</sup> Compared with previously described bulking agents, we consider this technique to be complicated, requiring significant training. The injection system is somewhat cumbersome; newer systems with adjustable balloons are being developed.<sup>37</sup>

Pycha and associates<sup>135</sup> treated 19 female SUI patients (6 type I, 4 type II, 9 type III) with microballoon implants (mean, 4.2 balloons), with a 42% cure rate and 36.8% improvement after a mean follow-up of 14.4 months. The procedure failed in all patients with type II SUI, and four patients incurred significant detrusor overactivity. The investigators stated that type III SUI is the ideal indication for microballoon implantation. Mazouni and colleagues<sup>135</sup> recorded an overall success rate of 65% for 59 women 6 months after microballoon injection. Two patients developed urinary retention, balloon migration through the urethral wall occurred in three cases, and three others experienced balloon loss.

### Calcium Hydroxylapatite

Calcium hydroxylapatite (CaHA) is a normal constituent of bone and is therefore nonimmunogenic and nontoxic. The bulking substance is a synthetic particle of CaHA with a spherical mean diameter of 100 μm (75 to 125 μm) in an aqueous gel composed of sodium carboxymethylcellulose. Preclinical studies in animal models have confirmed long-term safety and biocompatibility, with minimal inflammation.<sup>137</sup> This material has had previous medical applications in dental restoration and orthopedics.<sup>138</sup> It is radiopaque and can be easily detected by ultrasound, which can aid in its implantation and localization.

The injections are delivered by a 3-ml syringe through a 7-Fr Cook transurethral injection catheter and a 21-gauge needle attached to a ratchet gun. The initial injections are targeted at the 4- and 8-o'clock positions at the bladder neck, and then delivered as needed to provide visual coaptation. Mayer and coworkers<sup>138</sup> described 10 women with ISD who were treated by CaHA injection; the mean volume was 3.9 mL. The average number of injection sites at each treatment was 3.82 (range, 2 to 6 sites). Subjective improvement in pad use 1 year after injection was rated as excellent (no pads) in three patients, good (many fewer pads) in four patients, fair (fewer pads) in two patients, and poor (no change) in one patient. VLPP increased from 39 to 46 cm H<sub>2</sub>O at 12 months, with two patients dry on testing. There were no complications except for a higher incidence of transient urinary retention in five patients.

### Ethylene Vinyl Alcohol Copolymer

Ethylene vinyl alcohol copolymer (Uryx) is a biocompatible polymer composed of a random mixture of ethylene (hydrophobic) and vinyl alcohol (hydrophilic). It is dissolved in an 8% concentration of anhydrous dimethyl sulfoxide (DMSO). When this mixture comes into contact with aqueous media, DMSO

rapidly diffuses away, causing in situ precipitation and solidification of the polymer, with the formation of a spongelike plug that can seal cavities.<sup>139</sup> It has been employed successfully for the embolization of tumors and vascular malformations by selective arterial occlusion in a rabbit model and for brain arteriovenous malformations in clinical cases.<sup>140</sup>

Dmochowski and associates<sup>141</sup> reported the first use of Uryx in women with SUI in a multicenter, randomized, controlled study that compared it with collagen. Two hundred thirty-six women with genuine SUI were randomized and then treated prospectively with Uryx or collagen. The mean total volume injected was 4.6 mL for Uryx and 7.1 mL for collagen. At 1 year, pad tests showed that 68% of Uryx patients were dry, compared with 44% of collagen patients. Significant improvement of incontinence quality-of-life scores at 1 year was achieved in 32% with Uryx and in 20% with collagen. The most common complications of both treatment arms were delayed voiding, dysuria, and frequency. The investigators concluded that the success rate with Uryx was higher compared with collagen and with less injected volume.

### Dermal Collagen Implants

Cross-linked collagen fibers can be extracted from intact cadaveric dermal skin specimens. The harvested dermis is separated from the epidermis, pulverized mechanically, and dispersed in solution. The intact fibers are suspended in a buffered phosphate solution at neutral pH.<sup>37,142</sup>

The bulking agent of autologous collagen is recognized as self by the body and therefore should not elicit an immune response. The injected collagen is thought to undergo a breakdown process similar to that occurring in normal scar formation. Natural cross-linking increases implant durability and resists biodegradation by collagenase.<sup>143</sup> Griffiths and Shakespeare<sup>144</sup> undertook a 3-year study of the histologic appearance of glutaraldehyde-treated human fibrous dermal collagen allografts. There was no immune or inflammatory response, and no fibrous capsule was seen. The implants were colonized by host fibroblasts and blood vessels, and collagen resorption was observed.<sup>144</sup>

Permacol is a sterile, tough but flexible, acellular, cross-linked porcine dermal collagen with constituent elastin fibers. It has an acellular architectural organization very close to human tissue and works by supporting fibroblast infiltration and revascularization, so that it gradually becomes permanently incorporated. The disadvantage of this material includes its limited availability and higher viscosity, requiring a large-bore needle. Dermal collagen has been successfully deployed in many ear, nose, and throat procedures, in plastic surgery, in ophthalmology, and in orthopedic and cardiothoracic surgery.<sup>145</sup>

Bano and colleagues<sup>146</sup> studied Macroplastique and porcine dermal collagen (Permacol) in the treatment of 50 women with SUI. At 6 weeks, 64% of Permacol patients were improved (60% were dry) on quantified pad losses compared with 54% of Macroplastique patients (41.6% were dry). These results persisted up to 6 months.

### Autologous Chondrocytes

Tissue engineering is an attractive and promising field for treatment approaches to a variety of challenging urologic conditions. Atala and associates<sup>147</sup> are innovators in the application of tissue engineering in urology. In 1994, they reported VUR in a porcine

model. Injected chondrocytes can survive in vivo and synthesize new cartilaginous structures according to a template after they are seeded onto preformed biodegradable polymers.<sup>148</sup> The material consists of autologous chondrocytes in a calcium alginate (i.e., natural polysaccharide) gel injected endoscopically through a 22-gauge needle. Chondrocytes isolated from biopsy specimens (approximately 6 × 6 mm) of the external pinna of the patient's ear are expanded in tissue culture media in vitro for 6 weeks and combined with sodium alginate before transfer into five 3-mL syringes for injection.<sup>149</sup> The gel serves as a substrate for injectable delivery and then undergoes hydrolytic biodegradation over time. The newly formed chondrocytes secrete a natural matrix that maintains the volume of the original injection over time and results in new cartilage formation, which is stable, nonantigenic, and nonmigrating.<sup>148</sup>

Autologous chondrocytes have been injected with success and low risk for the treatment of VUR in children.<sup>150</sup> Bent and associates<sup>149</sup> reported 32 patients treated with autologous ear chondrocytes for ISD; 16 patients (50%) were cured, and 10 (31.3%) improved at 12 months. The investigators concluded that endoscopic treatment of ISD with autologous chondrocytes is safe, effective, and durable.

### Autologous Myoblasts

Cultured myoblasts can be delivered to the bladder wall (i.e., cellular myoplasty) and urethral sphincter to regenerate, forming new myofibers that build up and improve the urinary sphincter and detrusor contractility.<sup>151</sup> Myoblasts, the mononucleate precursor cells of skeletal muscle, can differentiate to form multinucleated muscle fibers capable of muscle contraction. They fuse to form postmitotic myotubes, which express bioactive protein in a stable fashion for a prolonged period, representing a potentially advantageous method of gene therapy.<sup>152</sup> Age-dependent reduction in the number of striated muscle cells may cause SUI in elderly women and men.<sup>153</sup> Myoblast injection directly into the urethral sphincter to reconstruct the muscle and augment the sphincter may become a possible option in the treatment of ISD. Injected myoblasts may produce strengthened sphincter contractility by fusing with existing muscle fibers.

Strasser and colleagues<sup>154</sup> performed the first clinical trial of myoblast injection in seven women with SUI. Before injection, skeletal muscle biopsies were taken from the left arm to obtain cultures of autologous myoblasts and fibroblasts. One year after the injection, five of these women remained symptom free. Three-dimensional ultrasound revealed that the thickness of the urethra and rhabdosphincter had increased significantly compared with baseline. Autologous therapy is an exciting field with promising preliminary results for the treatment of SUI.

### CONCLUSIONS

Injection therapy for the management of SUI and urethral hypermobility is an attractive alternative to surgery. It is a minimally invasive and easy procedure that can be performed on an outpatient basis. If injectables are well accepted for the frail elderly after the failure of other procedures, and when surgery is contraindicated, their role as the primary treatment of SUI is debatable. Cost-effectiveness must be addressed before promoting a new treatment for SUI, but cost-effectiveness studies are rare or employ questionable methodologies.

Many injectable materials have been shown to be effective with few complications. However, the ideal bulking agent is still to be discovered. It must be biocompatible, biodegradable, non-migratory, nonallergenic, durable, easy to inject, and cost-effective. All available injectables have a potential for migration, shrinking, or being displaced, requiring multiple injections to achieve or maintain a good result.

Collagen has been the most extensively studied injectable, and it is still the most commonly used. It is reabsorbed with time and

warrants preoperative skin testing to check for hypersensitivity. Autologous fat is also reabsorbed, but it has the potential for lethal complications. Durasphere, Zuidex, CaHa, microballoons, and ethylene vinyl alcohol copolymer injections have had initial success in the treatment of SUI, but further long-term and comparative studies of other modalities are required for ensuring safety, efficacy, and cost-effectiveness. Tissue engineering and autologous therapy are promising fields but are in their early developmental phases.
