Complex VVFs include those associated with prior irradiation or malignancy, recurrent fistulas, fistulas of large size (>3 cm), fistulas involving the bladder neck and trigone, and those associated with poor tissue quality or difficult closure. In these cases, the standard transvaginal repair must be modified. Many techniques of tissue interposition have been described. These provide an additional layer of closure and enhance the quality of the reconstructive repair.

#### Radiation-Induced Fistulas

Radiation-induced VVFs require special consideration. The site of fistula formation is typically in the trigone region; it is in a relatively fixed position and radiation effects are more likely. Between 1% and 5% of patients treated for cervical or uterine carcinoma develop radiation-induced fistulas. The fistulas most commonly manifest in a delayed fashion, sometimes 15 to 20 years later.<sup>15</sup> Fistulas associated with prior irradiation should always be biopsied to rule out recurrence of the primary malignancy.

Radiation-induced fistulas result from obliterative endarteritis in the irradiated field.<sup>24</sup> The injury compromises healing. The surrounding tissues are also affected by the endarteritis, complicating an already difficult repair. Video urodynamics and cystoscopy are mandatory before surgery. They allow assessment of bladder capacity and compliance. With adequate capacity and compliance, transvaginal repair is performed with modifications, including tissue interposition and prolonged postoperative catheter drainage. If the bladder has poor compliance and small capacity, augmentation cystoplasty is required, and an abdominal approach is taken. Careful inspection of the bowel is necessary to ensure use of a nonirradiated segment for the augmentation.

#### Martius Graft

The Martius graft (i.e., fibrofatty labial flap) was first described in 1928.<sup>3</sup> This technique is commonly used in pelvic and perineal reconstructive surgery, and it has great utility in treating VVF, rectovaginal fistula, and urethrovaginal fistula and in urethral reconstruction. It has high reported success rates in complex fistula repair<sup>25</sup> and is a convenient source of interposition in transvaginal repair. We use a Martius flap in cases of trigonal or urethral fistula. For fistula located high in the vaginal vault (after hysterectomy), the peritoneum is our preferred source of tissue interposition in these cases.

The Martius graft is a long band of adipose tissue from the labia majora. It has excellent strength and vascularity. The blood supply is threefold. Branches of the external pudendal artery supply the graft superiorly and anteriorly. Obturator branches enter the graft at its lateral border. The inferior labial artery and vein supply the graft inferiorly. The graft may be mobilized superiorly or inferiorly, depending on the desired location of transfer.

The first two layers of the fistula are closed as described earlier. The vaginal flaps are left intact, and the labial retraction suture is removed. A vertical incision is then made over the labia majora, and the subcutaneous tissues are dissected laterally to the lateral border of the dissection, the labiocrural fold. The flap is then dissected posteriorly to the Colles fascia and medially to the labia minora and bulbocavernosus muscle. The main vascular supply is at the base, and the entire thickness of the fat pad is carefully encircled by a Penrose drain. The superior and anterior segment of the graft is clamped, transected, and suture ligated. The remaining dissection is completed, freeing the flap, except at its base (Fig. 81-6A). A tunnel is then made between the perivaginal tissues and vaginal wall. The graft is then passed from the labial area to the vaginal area (through the tunnel) with the aid of a hemostat (see Fig. 81-6B). The Martius graft is placed over the fistula site and secured with interrupted, absorbable suture in a tension-free fashion. The vaginal flap is advanced and closed as previously described, providing a fourth layer of closure. A light pressure dressing may be applied, and ice packs are routinely applied. Eilber and colleagues<sup>26</sup> reported a 97% cure rate with transvaginal repair using Martius graft interposition in 34 patients with complex fistulas.

We have performed an in situ technique for the creation of a Martius flap, avoiding a labial incision. After the creation of the vaginal flaps in the distal vagina, we dissect a tunnel under the vaginal wall in the direction of the fibrofatty tissue in the labia. The medial and lateral segments of the Martius flaps are isolated using a Penrose drain, the upper segment of the Martius flap is dissected free, and the flap is mobilized and transferred to cover the fistula closure.

#### Peritoneal Flap

We use a peritoneal flap in the repair of high fistulas located at the vaginal vault, which are seen most commonly after hysterectomy. Extending a Martius graft to this location may be difficult and inadvertently result in vaginal shortening. A peritoneal flap is an easily available, well-vascularized tissue that can be harvested without the morbidity of a second incision.

The fistula repair begins as described in the first three steps of the transvaginal technique. The fistula is circumscribed, and vaginal flaps are prepared. A catheter in the fistula can help in dissection of the flap. Sharp dissection is used to expose the peritoneum and preperitoneal fat. The fistulous tract is then closed in two layers, as previously described. The preperitoneal fat and peritoneum are advanced to cover the fistula repair and secured to the perivesical fascia with tension-free, interrupted sutures. The vaginal flap is then advanced and closed. Raz and coworkers<sup>27</sup> reported a 91% success rate in their initial experience using a peritoneal flap in 11 patients with VVFs. Eilber and associates<sup>26</sup> reported a 96% cure rate using a peritoneal flap in 83 patients who underwent complex fistula repair. This approach has high success rates, minimal morbidity, and outcomes similar to those of a Martius graft but without a second incision.

#### Omental Interposition

Omental interposition is primarily used in the abdominal approach for fistula repair, although it can be accessed transvaginally in women who have had previous procedures. This technique results in an omental graft that can be placed between the bladder and vagina for an additional layer of protection.

**Figure 81-6** A, Mobilization of a Martius flap based on an inferior pedicle. B, Transfer of a Martius flap to cover a fistula repair (B, from Raz S: Atlas of Transvaginal Surgery. Philadelphia, WB Saunders, 1992.)

### *Rotational Full-Thickness Labial Flap*

In selected complex cases with loss of the vaginal wall, insufficient vaginal epithelium may preclude primary vaginal closure. A full-thickness labial flap can be rotated to substitute for the missing vaginal wall. The advantage of this flap is that combines the use of the fibrofatty tissue of the Martius with a well-vascularized skin flap to cover the deficient or absent vaginal wall. The fistula is closed as previously described, and the vascularized flap is rotated to provide full-thickness skin coverage.

After closure of the fistula, a U-shaped incision is made over the labia, including the lateral labial skin and underlying tissue. The apex of the flap is created at the level of the posterior fourchette and the base at the upper segment of the labia majora. The flap is dissected from the fascia overlying the pubic bone and then rotated to cover the repair. After closure of the fistula, the fatty tissue covers the fistula closure, and the skin of the labia is sutured to the edge of the vaginal flaps. Interrupted, absorbable sutures are used to secure the edges in place.<sup>28</sup> Small series have reported excellent results. Carr and Webster<sup>29</sup> reported excellent outcomes for four patients. Postoperative complications include sensory deficit at the harvest site, poor cosmetic result, wound infection, and flap sloughing.

### *Gluteal Skin Flap*

Gluteal skin flaps are used predominantly in patients with radiation-induced fistulas or severe vaginal wall atrophy with no other viable skin source. In cases of severe radiation-induced fistula, the vaginal canal is very narrow, and access to the fistulous tract can be extremely difficult. Before the repair, a lateral episiotomy, starting at the posterior fourchette (5- or 7-o'clock) is performed and extended toward the vaginal cuff. The first two layers of the fistula are closed, and the vaginal flaps are raised as previously described. The edges of the vaginal wall incision are dissected laterally to widen the vaginal canal and make room for the flap interposition. From the end of the episiotomy incision, the incision is continued in an inverted-U-shaped fashion toward the gluteal area. The skin is then undermined, and the flap is rotated and advanced into the vaginal canal to cover the fistula. The flap contains skin and fatty tissue and is broad based. The flap is secured with interrupted, absorbable sutures, and the vaginal flaps are secured to the skin flap edges.<sup>30</sup> Complications include wound infection, sloughing of the flap, and injury to the anal sphincter.<sup>31</sup> Meticulous surgical technique is mandatory to avoid the sphincter injury.

### *Myocutaneous Gracilis Flap*

The gracilis muscle–based myocutaneous flap is frequently described in association with repair of radiation-induced VVFs in patients with vaginal atrophy or absence. The gracilis muscle is a long, slender muscle that extends from the inferior pubic symphysis to the medial condyle of the femur. It is an accessory muscle (used for thigh adduction and knee flexion), and it can be sacrificed with no loss in function. It sits between the adductor magnus medially and the adductor longus laterally. The blood supply is derived from the medial femoral circumflex artery, a branch of the deep femoral artery.

The flap is harvested with a tennis racquet incision on the medial aspect of the thigh over the gracilis muscle. It begins around 10 cm below the pubic tubercle and extends 20 cm toward the knee. The skin and underlying muscle are mobilized, and care is taken to preserve the vascular supply. The gracilis is transected at its distal insertion. A tunnel is then created underneath the medial aspect of the thigh and labia, and the flap is transferred to the vaginal area, providing additional coverage of the fistula tract and reconstruction of the vaginal canal. This can result in considerable cosmetic scarring, but there is no functional defect.

### INTRAOPERATIVE COMPLICATIONS

Bleeding and ureteral injury represent the two major intraoperative complications. Hemostasis is critical throughout the dissection and can be controlled with fine, absorbable sutures. Electrocautery should be avoided to preserve the vascularity of the tissues and promote healing. Lack of excellent hemostasis can lead to hematoma formation and possible disruption of the fistula repair.

Ureteral catheterization is recommended for fistulas close to the trigone because of the higher risk of iatrogenic ureteral injury. Fistulas located elsewhere do not usually require this maneuver. If there is any concern about ureteral violation, cystoscopy is performed after intravenous indigo carmine is administered. Ureteral catheterization can be done if any question remains about ureteral patency.

### POSTOPERATIVE MANAGEMENT

The vagina is packed with an antibiotic-impregnated gauze, which is left in place for several hours. Surgery is mostly performed on an outpatient basis. The suprapubic and Foley catheters (joined to a Y connector) are left to dependent drainage, typically for 3 weeks. Anticholinergics are given to minimize bladder spasm and increase the patient's comfort. An oral cephalosporin or quinolone is continued until the catheters are removed. Patients are instructed to resume normal activity except for strenuous exercise. Sexual intercourse is prohibited for 12 weeks. The urethral catheter is removed 3 weeks after surgery, and a suprapubic cystogram is performed. If the cystogram

demonstrates no extravasation, the suprapubic catheter is removed.

### OUTCOMES

Many factors must be considered when assessing patient outcomes. Morbidity, patient satisfaction, and cure rate are critical factors in determining the best approach and the likelihood of success. There have been no prospective, randomized studies comparing vaginal and abdominal approaches in VVF repair. Many series have shown success rates of 90% to 100% with both approaches.<sup>15,32-34</sup> The best approach remains the one with which the surgeon has the most expertise and comfort, giving the patient the best chance at cure with the first repair.

### POSTOPERATIVE COMPLICATIONS

#### Early Complications

Vaginal bleeding, bladder spasms, and vaginal infection must be treated aggressively and immediately to prevent fistula recurrence. Secondary vaginal bleeding is treated with repacking and bed rest. Prophylactic anticholinergics should minimize bladder spasms. Belladonna and opium suppositories (e.g., B & O Supprettes) can be used if required. Perioperative antibiotics are continued in the postoperative period to prevent vaginal infections.

#### Delayed Complications

The most important delayed complication is fistula recurrence. Others include vaginal shortening, vaginal stenosis, and unrecognized ureteral injury. Tension-free, multilayered closure with tissue interposition (as needed) results in a greater than 95% success rate. If the fistula recurs, a second vaginal repair may be performed with a Martius graft or peritoneal flap. A minimum waiting period of 3 months after the previous repair allows for resolution of postoperative inflammation. Avoiding excessive resection of the vaginal wall minimizes the odds of significant shortening and stenosis. Secondary vaginoplasty is required in selected cases. Unrecognized ureteral injury manifests more commonly as an obstruction process than a leak. An antegrade approach with percutaneous nephrostomy is preferred to a retrograde procedure because of the possible disruption of the repair by a transurethral approach.

### CONCLUSIONS

VVF remains a significant source of morbidity after gynecologic and pelvic surgery. Transvaginal VVF repair is an outpatient procedure associated with minimal morbidity, short convalescence times, and high cure rates. It is our preferred method of repair unless concomitant abdominal surgery is required.

# ABDOMINAL APPROACH FOR THE TREATMENT OF VESICOVAGINAL FISTULA

*Mariangela Mancini and Walter Artibani*

An abdominal approach can be used to repair a vesicovaginal fistula (VVF). A VVF, an abnormal communication between the bladder and the vagina, is located outside the abdomen. The peritoneum reflects over the bladder dome anteriorly and the lower third of the uterus posteriorly (Fig. 82-1). The lamina of connective tissue interposed between the bladder and the vagina, whose destruction is associated with the formation of the VVF (Fig. 82-2), is found well outside the abdominal cavity. From an anatomic perspective, it appears to be more intuitive and, indeed, to reach a VVF through the vaginal route instead of through the abdomen, specific technique for VVF repair originally was mastered by the vaginal approach. Nevertheless, the abdominal approach for treatment of the VVF has its own indications and can offer specific advantages over the vaginal route. The history of the development of this surgical technique can help us understand the part that the abdominal approach plays in VVF surgery.

## HISTORY

The first surgeons who tried to correct a VVF did so through the vaginal approach. In 1663, Hendrik van Roonhuysse recommended transvaginal repair with the patient in the lithotomy position. Stiff swan quills were passed to the edges of the wound, and the bladder and surrounding tissues were widely mobilized. Van Roonhuysse's book was published in 1676.<sup>1</sup>

The first two successful cases treated with this technique were reported by Johann Fatio in 1675.<sup>2</sup> Despite these preliminary and isolated successful experiences, the presence of a VVF was commonly considered an incurable situation in the years that followed. An important innovation was introduced by Antoine Jobert the Lamballe in 1834, when he performed his first operation of transvaginal closure of a VVF by resection of the margins and coverage of the loss of substance with a cutaneous autograft obtained from the labia or the internal face of the thigh.<sup>3</sup> The first operation was unsuccessful because of necrosis of the graft, but the patient was successfully cured on the second attempt with the same technique. Further developing the technique, Jobert pioneered later a method of tissue mobilization that widely detached the bladder from the vagina, which he called vesicovaginal autoplasty (*autoplastie vesico-vaginale par glissement*). He used this approach to avoid traction on the margins before suturing the edges of the fistula, and thereby obtained several successes in difficult VVF cases.<sup>4</sup>

In 1839, George Hayward<sup>5</sup> reported the first cure of a VVF in the United States. He underscored the importance of accurate dissection of the vagina from the bladder before closing the fistula with stitches and pioneered the flap-splitting technique.<sup>5</sup> In 1852, James Marion Sims<sup>6</sup> published his first report of successful primary repair of a VVF, which was again performed transvaginally. This interesting paper has been recently republished in the medical literature.<sup>6</sup> The correct surgical technique, the use of a

**Figure 82-1** Sagittal section of the female lower abdomen and pelvis. The peritoneum (*bold line*) lines the floor of the abdominal cavity, leaving the vagina and posterior face of the bladder below it.

**Figure 82-2** Female pelvic organs with their subperitoneal sheaths. The connective pillow layer interposed between the vagina and the bladder and urethra is indicated by *cross-hatching*. Damage to this tissue is associated with the formation of a vesicovaginal fistula.

new speculum designed by him, the search for the optimal patient position for exploration of the vagina, and an understanding of the importance of postoperative bladder drainage led to a high success rate for VVF treatment through the vaginal route and to international popularity for Sims.

This brief historical review shows that the basic principles stated by Sims and his predecessors for correct fistula treatment are still valid and that few modifications have been made by the surgeons who followed.<sup>7</sup> However, in 1868, Thomas Addis Emmet, who succeeded Sims as chief surgeon of the Woman's Hospital in New York, described some cases in which extensive scarring of the vagina and proximal location of the fistula compromised optimal access during transvaginal repair, indicating the need for higher access in these situations.<sup>8,9</sup> Some years later, the abdominal approach for the treatment of VVF was introduced. The suprapubic transperitoneal-transvesical route was first described by Friedrich Trendelenburg in 1881,<sup>10</sup> and in 1893, Von Dittel introduced the approach extraperitoneal suprapubic for access to the VVF route.<sup>11</sup> In 1902, Howard Kelly recommended a transperitoneal approach in the treatment of VVFs formed after hysterectomy that were too high in the bladder to be safely reached transvaginally.<sup>12</sup> In 1914, Legueu<sup>13</sup> described in more detail the transperitoneal-transvesical approach.<sup>13</sup> To improve the chance of success in the most difficult cases, the omental graft technique was introduced by Hildebrandt in 1929 and further developed by Bastiaanse in the attempt to cure the challenging cases of postirradiation fistulas.<sup>14</sup>

In 1951, O'Connor and Sokol<sup>15</sup> described the complete range of possible procedures for successful treatment of VVFs, from conservative measures to vaginal or suprapubic closure to urinary diversion.<sup>15</sup> They emphasized the importance of careful selection of patients for each procedure. In some patients who had endured repeated previous failures, the fistulous opening was too high and too far from the bladder floor and the vagina too scarred to allow a vaginal approach. In these cases, a suprapubic procedure, preferably extraperitoneal, was described with bisection of the bladder down to the fistula opening and wide mobilization of the bladder from the vagina. A transperitoneal approach was selected when exposure was difficult because of previous operations, a history of cancer, or when the omentum needed to be used. With proper application of this technique, many successes were reported by O'Connor<sup>16,17</sup> in the following years. However, the suprapubic approach was not used by O'Connor<sup>17</sup> in 35% of his cases, for which a less invasive procedure was chosen.

This information underscores the importance of case selection. With the many possibilities available, VVF often can be treated successfully by tailoring the approach to the patient's condition. It took almost 300 years of surgical research and extended practice with VVF patients, including enormous suffering and great rewards, to achieve this important goal. The history of the approaches to treatment demonstrates that flexibility is the key to successful management of this challenging pathologic condition.

## ABDOMINAL APPROACH

### Indications

An abdominal approach for the treatment of a VVF can be chosen for several reasons. Theoretically, the abdominal approach should be used when a less invasive approach is not feasible, but practically, this can have different meanings in different settings. At

least four factors enter into the decision: the kind of fistula, the patient, the situation in which treatment takes place, and the surgeon. Fistulas are not all the same, and treatment must be individualized. Case selection is important.<sup>18,19</sup> The abdominal approach was developed to treat fistulas that were too high or too far from the bladder floor to be reached transvaginally. Moreover, in some cases, especially after several previous attempts, the vagina can be severely scarred and cannot be used for access to the fistula. Application of this concept depends on the surgeon's experience. Surgeons who have extensive experience with transvaginal surgery perform most repairs in this way, finding treatment of most fistulas amenable to the transvaginal approach.<sup>20,21</sup> Even the most complex fistulas can be repaired with the use of a peritoneal flap.<sup>22</sup>

There have been no abdominal repairs in the Addis Ababa Fistula Hospital in the past 4 years, during which about 4500 patients have been repaired transvaginally. However, one case of a high cervicovaginal fistula was operated on in another hospital. The patient had previously undergone a cesarean section, and in this particular case it was necessary to switch from the vaginal to the abdominal route because the fistula could not be reached safely from the vagina (A Browning, personal communication, 2005). Similarly, in patients who have been treated more than once with less invasive procedures without success, an attempt through a different route may be a reasonable choice. Some patients may express a preference for the abdominal route to increase the likelihood of cure. Some patients may need adjunctive procedures, such as ureteral reimplantation, bladder augmentation, or omental grafting, which need to be performed through the abdominal route.

The treatment setting also can influence operative decisions. In some tropical countries, for example, general anesthesia is not commonly available, which makes widespread use of the abdominal approach almost impossible.<sup>23,24</sup> In this situation, the technical level of hospitals encourages the use of less invasive procedures that can be performed safely under spinal anesthesia.<sup>25,26</sup> The surgeons' preferences are based on general surgical experience, familiarity with the procedure, and personal opinions about the case. Box 82-1 summarizes the indications for the abdominal approach that are consistently reported.

### Timing

The best time to intervene and repair a fistula is unknown. Initially, treatment delay was advocated by some surgeons,<sup>16,27,28</sup> but later data indicate that immediate treatment is beneficial.<sup>26</sup> Treatment decisions are complicated by the fact that fistulas can be completely different pathologic entities, from the small, clear-cut opening produced during pelvic surgery, which is suitable for

### Box 82-1 Indications for the Abdominal Approach

- Fistula too high in the bladder to be reached
- Inaccessible vagina
- Patient's preference
- Previously failed multiple attempts or failed less invasive attempt
- Necessity of other concurrent transabdominal procedures
- Hospital setting
- Surgeon's preference

immediate repair,<sup>29</sup> to the large, necrotic loss of substance, which results from hours of ischemic injury to the bladder during obstructed labor.<sup>30</sup> Timing should be tailored to the specific situation.<sup>31,32</sup>

It seems reasonable that a fistula should be treated as soon after diagnosis as possible, with timing modified according to the individual case. In the developed world, there often is no reason to postpone treatment.<sup>29,31,33-35</sup> Exceptions include the presence of infection or significant edema or a massive hematoma at the site of the fistula, which should be resolved before surgery. Taking care of coexistent problems usually requires not more than a few weeks, during which regular cystoscopic evaluation may be advisable.<sup>36</sup>

The possibility of spontaneous closure should be considered, especially for small, clean, postoperative fistulas, because spontaneous closure has been described in several cases after a trial of observation for 3 to 4 weeks.<sup>26,37-39</sup> After a conservative trial is started, we avoid using an indwelling catheter during the period, to minimize local infection and edema.

Large fistulas, fistulas recurring after previous attempts at repair, multiple fistulas, or those associated with other conditions that require surgical treatment are not prone to spontaneous closure, and there is no reason to consider a conservative approach. These cases are more often treated with the abdominal approach. Box 82-2 addresses the suggested timing of VVF management.

### Preoperative Preparation

The following guidelines for the preoperative preparation of the patient are based on published data and our personal opinions and experience. Preoperative preparation should not delay surgery, unless there is infection, massive hematoma, or significant edema at the site of the fistula (see Box 82-2). The performance status and nutritional status of some patients may require time for improvement. This situation may be more common in countries with a high incidence of VVF among poor patients. In these cases, preoperative preparation to improve the general condition of the patient is indicated, as emphasized in several reports.<sup>14,23,30,40</sup> Box 82-3 summarizes the issues concerning preoperative preparation of VVF patients.

#### Box 82-2 Timing Sequence

- Diagnosis
- Cystoscopic evaluation
- Quick conservative trial (when appropriate)
- Surgery
- Postpone surgery for infection, hematoma, or significant edema

#### Box 82-3 Preoperative Preparation

- Improvement of patient's performance status (when necessary)
- Antibiotic prophylaxis
- Antibiotic treatment (when indicated)
- Cortisone treatment (not supported by evidence)
- Local estrogens (useful)

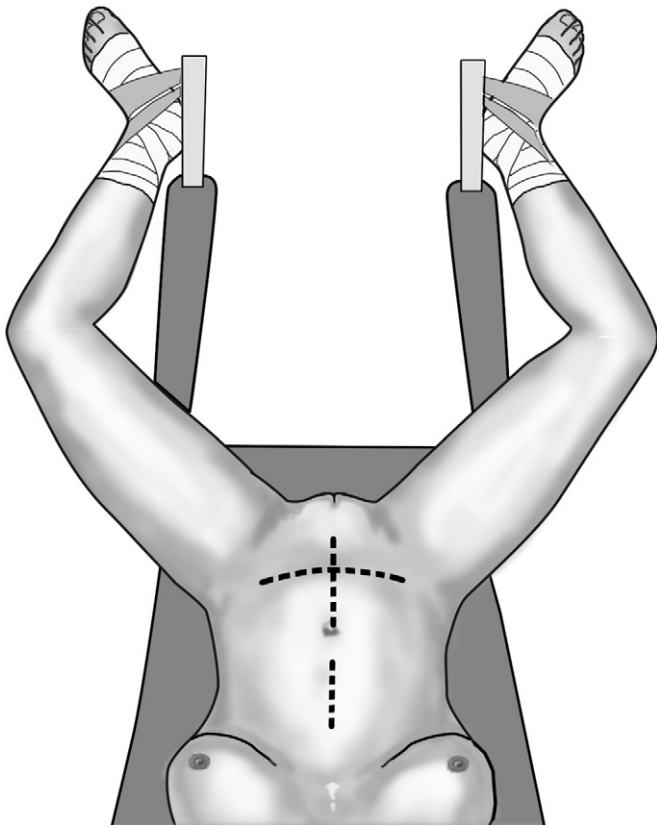

As soon as the patient is ready for surgery the issue of antibiotic prophylaxis must be considered. A randomized control trial, which reported the results for 79 VVF in 1998, showed that antibiotic prophylaxis (500 mg of ampicillin IV) at the start of the operation did not produce benefit in terms of success rates, but it seemed to reduce postoperative urinary infections and the need for long-term antibiotic therapy.<sup>41</sup> Consistent with this first experience, in a large series from Nigeria Waaldjik, reported a success rate of 98% for 1716 cases of VVF without the use of antibiotic prophylaxis.<sup>26</sup> Postoperative wound infection was not never seen, and antibiotic use does not seem to be mandatory according to these data. However, when economic restraints are not severe, antibiotic prophylaxis may be considered and continued postoperatively when necessary or in cases involving surgical manipulation of the intestines.

Another consideration is the use of cortisone. Collins and associates<sup>42</sup> reported the use of oral corticosteroids (100 mg, three times daily for 10 to 12 days preoperatively) in the treatment of fistulas to reduce edema and fibrosis. Cortisone use is not widely accepted before surgery for VVF because it may compromise healing. It is difficult on the basis of the available data to justify the use of steroids before fistula repair.

Local application of estrogen creams has been advocated as a preoperative measure.<sup>17,43,44</sup> Estrogens can improve the cellular proliferation rate and blood supply of the vaginal wall, which contains estrogen receptors in the epithelial layer. Estrogen receptors are also found in the connective tissue of the female pelvis between the bladder and the vagina. This tissue undergoes atrophy with hypoestrogenism. It therefore seems wise to recommend the local use of preoperative estrogen creams, particularly in postmenopausal or post-hysterectomy patients. Even in premenopausal women, the use of estrogen creams has helped in healing postcesarian VVFs soon after delivery.<sup>45</sup> Consistently, the use of tamoxifen, an anti-estrogen drug, has been associated with poor local healing after gynecologic surgery.<sup>46</sup> However, the epithelium that lines the fistulous tract itself contains estrogen and progesterone receptors in vesicouterine fistulas.<sup>47</sup> Estrogen stimulation in this case could antagonize spontaneous closure of the fistula by maintaining the lining epithelium. Jozwik and Jozwik<sup>48</sup> reported spontaneous closure of vesicouterine fistulas with hormonal suppression by induction of amenorrhea, supporting the role of estrogens in the maintenance of this kind of fistula. There are few data on the histology of VVFs. It is not known whether estrogen receptors are present in the epithelium lining VVFs. A case of persistent VVF associated with endometriosis has been reported,<sup>49</sup> but endometriotic tissue was not found on histologic analysis of the fistula's epithelium. In a few cases, estrogens may maintain the fistula's epithelium, but this seems more common in vesicouterine fistulas and has never been demonstrated in VVFs.

### Surgical Technique

The patient is positioned supine on the operating table with the hips abducted and mildly flexed. An appropriate degree of head-down tilt is advisable. The abdomen and perineum are prepared for the operation. Even when the operative approach is through the abdomen, sterile access to the perineum should be provided for catheterization, preoperative cystoscopy (if required), access to the vagina for finger or tampon aid during separation of the vagina from the bladder, or in case a combined perineal-abdominal approach becomes necessary.

**Figure 82-3** Patient position and incision lines for the abdominal approach to treating vesicovaginal fistula. Cutaneous incisions can be on the midline or horizontal (i.e., Pfannenstiel incision). The rectal fascia incision should be performed vertically on the midline in both cases. A Pfannenstiel incision can be combined with a short epigastric incision in case omental mobilization is required. The infra-umbilical median incision can be extended upward.

A catheter is placed in the bladder. The surgical instruments are those used during classic pelvic surgery. Autostatic retractors are useful. Laparotomy can be performed by a lower midline incision or by a Pfannenstiel incision, especially when a previous operation used this route (Fig. 82-3). When needed, both incisions can be extended to the upper abdomen to obtain access for omental preparation. The median incision is extended upward, and the Pfannenstiel incision can be integrated with an extra-short epigastric median incision. Sometimes, reaccessing a previous Pfannenstiel incision may not guarantee proper exposure of the pelvis. In this case, the suprapubic cross incision or a suprapubic V-shaped incision, as described by Turner-Warwick and Chapple<sup>50,51</sup> and Turner-Warwick and coworkers<sup>52</sup> can be a suitable choice. This is particularly valid when the patient previously had surgery by the Pfannenstiel route. An additional midline incision would leave this patient with a double-cross-like scar and a long-lasting memory of the VVF. The suprapubic cross incision allows reopening of the skin through the previous incision, but after dissecting the subcutaneous tissue away from the rectal fascia, it must be transected vertically on the midline up to the umbilicus, not along the previous horizontal fascial incision. The V-shaped incision is a variant, in which after a Pfannenstiel skin incision, the rectus sheath is opened upward and laterally toward the anterior superior iliac spine; distally, the fascial inci-

**Figure 82-4** View of the internal surface of the bladder after an anterior cystostomy during the anterior transvesical approach. Suspension sutures retract the bladder walls for exposure. The ureters have been catheterized. The fistula opening is shown just behind them. The bladder wall is excised around the fistula in a racquet fashion (dashed line).

sion is truncated with a 4-cm horizontal tract at the level of the pubic symphysis.

After the incision is completed, the procedure can take place through the anterior transvesical approach or the classic O'Connor technique by means of the extraperitoneal or intraperitoneal route. The former is described first.

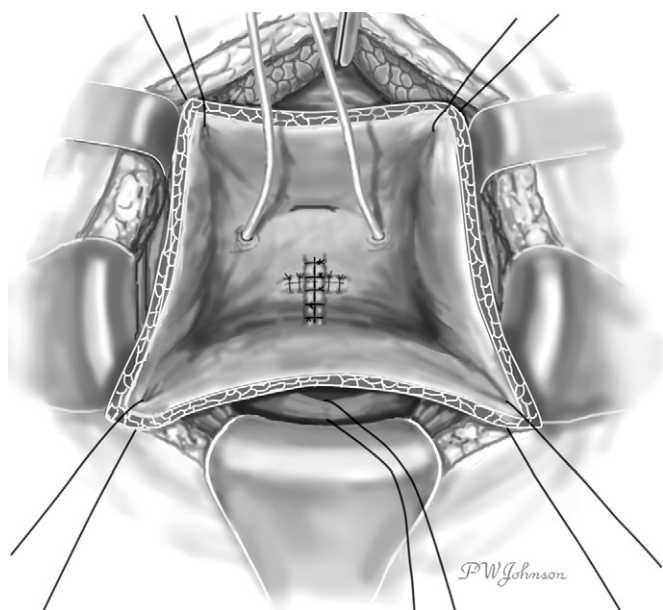

#### **Anterior Transvesical Approach**

After the fascia is open, the Retzius space is entered. Dissection of the Retzius space allows preparation of the preperitoneal surface of the bladder, separating it from the surrounding structures. A self-retaining retractor can be placed at this point to keep the abdominal wall stabilized laterally. A vertical anterior cystostomy is performed, which allows visualization of the internal surface of the bladder with the fistula and the ureteral openings. If fistula and ureteral openings are close, ureteral catheters can be passed in the ureters at this point. A delicate retractor or suspension sutures can be used to separate the bladder walls (Fig. 82-4).

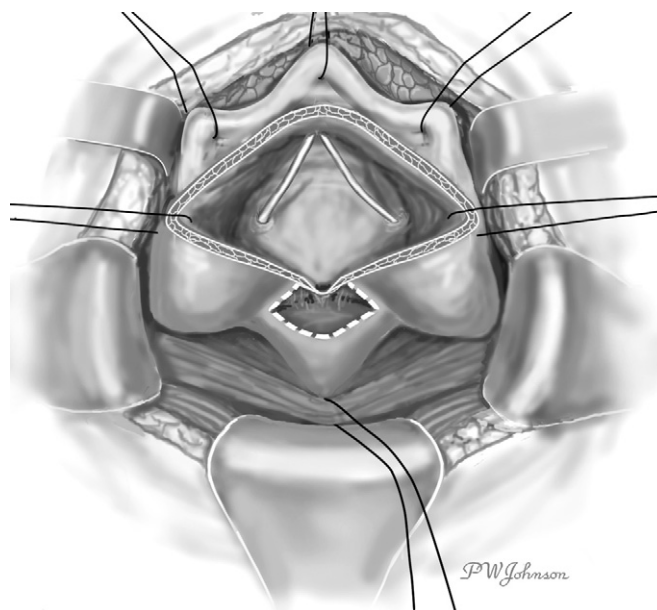

The operation proceeds with a racquet-shaped excision of the bladder wall around the fistula opening in the bladder and of the fistulous tract until clean, well-vascularized margins are obtained (Fig. 82-5). Some methods can help to gain traction on the fistula and facilitate its dissection, including use of a Foley catheter with an inflated balloon<sup>44</sup> and specially designed devices passed through the fistula<sup>53,54</sup> from the bladder opening to the vaginal opening. Dissection of the bladder from the vagina around the fistula is carried out to obtain free lateral margins, which can be then sutured without traction. Meticulous hemostasis is recommended during these maneuvers, with care taken to avoid ischemic damage to the tissue, which may compromise the repair.

At this stage, sutures are placed, starting deeply from the vaginal site. Interrupted, absorbable, 2-0 or 3-0 sutures are

**Figure 82-5** The vagina is sutured, and then the bladder is sutured. The sutures can be placed in directions perpendicular to each other, but the best strategy is to suture the vagina and the bladder according to the lines that allow the least tension on the margins.

**Figure 82-6** The posterior cystostomy is extended downward to include the fistula opening during the O'Connor procedure. Excision of the bladder wall is continued posteriorly widely around the fistula, which is totally excised on the vaginal side to obtain healthy free edges (*dashed line*).

recommended. One layer is enough at the vaginal site. For fistulas located at the bladder neck, it may be feasible to close the vaginal end of the fistula from the vagina, using a combined abdominoperineal approach.<sup>55</sup> The bladder end of the fistula is then closed with a double layer (muscular layer and mucosal layer) of interrupted or continuous sutures (see Fig. 82-5). Absorbable sutures should be used. The ureteral catheters are removed, and the anterior cystostomy can be closed in a similar double-layered fashion. A drain is left in the Retzius space, along with a suprapubic cystostomy or a transurethral catheter, or both. The catheter's balloon is not inflated or inflated with only 4 to 5 mL to avoid balloon compression on the suture lines.

The key points of the technique are wide excision of the fistulous tract until well-vascularized margins are achieved; generous dissection to ensure no tension on sutures; perfect hemostasis; a three-layered suture that includes the vagina, detrusor, and bladder mucosa; and a watertight suture of the bladder.

#### **O'Connor Technique**

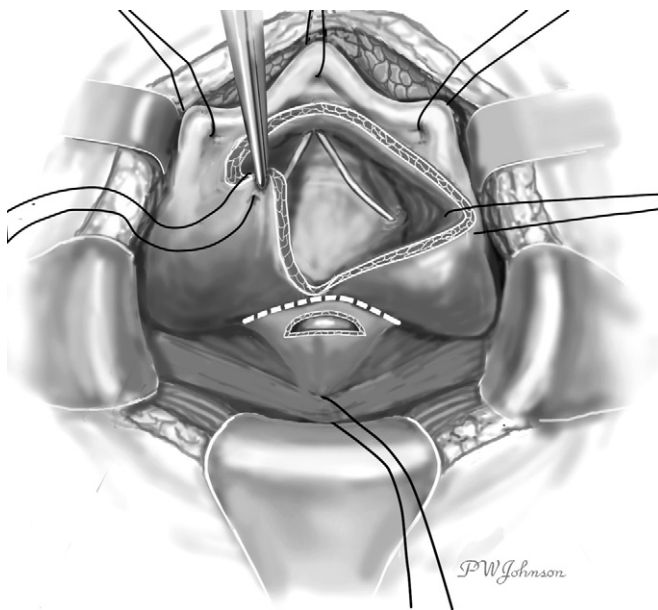

The O'Connor technique is based on complete bisection of the bladder and wide separation of it from the vagina. In its original description, it was performed extraperitoneally, but intraperitoneal access sometimes is required.<sup>15,16</sup>

The bladder is exposed extraperitoneally with as much dissection as necessary to free its posterior wall. The peritoneum can be opened when the extraperitoneal posterior exposure of the bladder is insufficient, when additional procedures or omental interposition is required, or when the patient has undergone previous operations for carcinoma.<sup>17</sup>

After the peritoneum has been opened at the midline, the abdominal cavity can be explored. The bowel is evaluated in case an augmentation cystoplasty has been planned, and the omentum is inspected and measured to verify its ability to reach the pelvis. Adhesions can be separated, and the bladder dome and the Douglas space are reached and prepared. In the extraperitoneal

and intraperitoneal approaches, the bladder is fully mobilized before incising it. A generous vertical cystostomy is performed on the posterior surface of the bladder, from the dome down to the site of the fistula, which is included in the distal part of the incision. To facilitate later closure of the cystostomy, the posterior incision of the bladder can be curved laterally so that the two edges will approximate more comfortably at the end of the operation. The bladder is practically bisected on the posterior wall with this long incision, which reaches the fistula opening. Suspension sutures can be placed along the separated bladder halves to keep them separate and guide the surgeon later during closure.

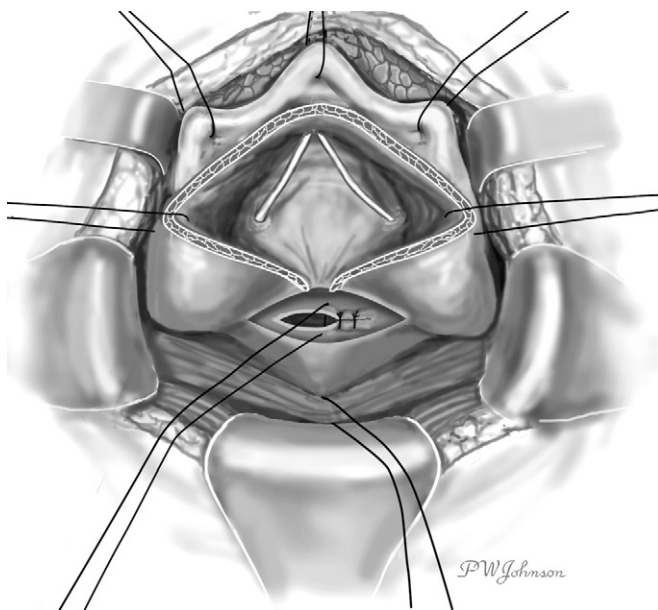

The interior surface of the bladder is inspected, and the ureters can be catheterized. The bladder wall around the fistula is sectioned circularly, and the fistula is excised to obtain free, healthy margins (Fig. 82-6). All necrotic and nonviable tissue is excised; a wide, lateral dissection of the bladder from the vagina is obtained; and the bladder is moved upward and anteriorly, with careful hemostasis to prevent postoperative ischemia (Fig. 82-7). The suturing begins at this point. Transverse vaginal closure is achieved with a single or double layer (double layer in the O'Connor's description of the procedure<sup>15</sup>) of absorbable continuous or interrupted sutures (Fig. 82-8). Longitudinal bladder closure is then achieved with a double layer of absorbable interrupted or continuous sutures. The bladder closure starts from the distal apex of the cystostomy and walks upward (Fig. 82-9). Interposition tissue such as peritoneum or fat can be placed over the top of the vaginal suture to reinforce it. Unlike the original description, the vaginal site of the fistula is not always closed, because some surgeons think that closure can prevent drainage of hematomas from the widely dissected intervesicovaginal space.<sup>56</sup> A drain is left in the retropubic space before closing the abdomen, along with a cystostomy or a transurethral catheter, or both.

**Figure 82-7** The dissection plane lies between the bladder anteriorly and the vagina posteriorly during the O'Conor procedure (*dashed line*). This plane is carefully developed after the fistulectomy has been performed to obtain full separation of the bladder from the vagina.

**Figure 82-9** The last step of the procedure is closure of the bladder wall. This can be performed in one or two layers, starting from the distal end of the posterior cystotomy. The initial curved line of the bladder incision facilitates closure of the bladder wall without tension.

**Figure 82-8** Closure of the vagina with interrupted sutures. The wide mobilization performed earlier allows closure without tension on the margins.

### Interposition Grafts

Interposition grafts are used in VVF surgery because experience indicates that this tissue promotes the success of the procedure, especially in cases of multiple failures and necrotic and poorly vascularized tissues, as in postirradiation fistulas.<sup>57,58</sup> Another indication for interposition grafts is when the loss of substance after fistulectomy is too wide to guarantee a tension-free suture

line or when proximity between the fistula and the ureteral meatus does allow primary closure of the bladder without ureteral reimplantation. Interposition grafts can be used during any abdominal surgical procedure, and they vary in terms of location, vascularization, and type of tissue used.

### Free Bladder Mucosa

A simple procedure using free bladder mucosa can be applied easily during a limited anterior transvesical approach. A patch of bladder mucosa is harvested from the bladder dome in a size proportional to the size of the fistula, and it is then placed between the bladder and vagina, with the mucosal surface directed toward the vagina or the bladder, and it is fixed in place with a few stitches. The bladder wall is then sutured over the graft. The patch is harvested, leaving the underlying detrusor muscle intact. The donor bed fully re-epithelizes after a few weeks.<sup>59</sup> This method has shown good results in avoiding reimplantation of the ureters when they were close to the fistula opening in the vagina, because no attempt is made to separate the vaginal and vesicle layers of the fistula<sup>60</sup> or close the vaginal or bladder site of the tract.<sup>61,62</sup>

### Sliding Bladder Wall

Gil-Vernet<sup>63</sup> described a technique to advance downward a portion of full-thickness bladder wall to close a large loss of substance after fistulectomy. It is a type of vesical autoplasty that has been successful in resolving complex VVFs, especially when the fistula is close to the ureteral meatus. In this procedure, a flap obtained from the posterior bladder wall is moved down to replace the mucosa excised during the fistulectomy. After closing the vaginal site, the bladder wall is bilaterally incised from the fistula opening upward, allowing a flap to be brought down to the bladder neck and sutured to the distal bladder wall in a single layer. In this way, the vaginal suture line can be completely

covered. This technique is easy to perform, and it limits the need to use omentum in cases of large, complex fistulas when the bladder cannot be closed primarily. It has the advantage of replacing bladder with bladder.<sup>64</sup>

#### *Dura Mater*

A graft of solvent-dehydrated human dura mater can be used for interposition during the extraperitoneal approach, even in cases of limited exposure and when the fistula has not been excised. After closure of the vaginal site, the dura mater graft is placed over the suture and fixed with interrupted, absorbable suture. Subsequently, the bladder is closed in two layers.<sup>65</sup> The use of dura mater as a bladder or ureteral wall substitute has been successfully demonstrated.<sup>66</sup>

#### *Abdominal Wall Fat*

When abdominal wall fat is used for interposition, an extraperitoneal approach is undertaken in the usual fashion. The fistula is excised, and the free graft of abdominal wall fat is placed over the vaginal suture line before closing the bladder site. This simple technique can be performed easily in cases of limited exposure.<sup>67</sup>

#### *Rectus Abdominis Muscle Flap*

A rectus abdominis muscle flap can be raised during an extraperitoneal approach; blood for the flap is supplied by the inferior epigastric artery. This muscle has excellent vascularization, and it can be rotated easily and brought down into the pelvis in cases of complex fistulas, especially when the omentum is not available for interposition. A rectus abdominis myofascial flap has been used successfully in one patient with a large postirradiation VVF.<sup>68</sup> In another case of postirradiation VVF, a rectus abdominis myocutaneous flap covered a large loss of substance in the bladder after fistulectomy adjacent to the ureteral meatus, with the skin side of the graft covering the bladder inner wall.<sup>69</sup> Rectus abdominis myocutaneous flaps have been used successfully in a complex cases of irradiated pelvic wounds and pouch-vaginal fistulas, for which several previous transvaginal and transabdominal approaches had failed.<sup>70</sup> Successful use of rectus abdominis muscle flaps has been reported for four other cases of difficult, recurrent VVFs.<sup>71,72</sup>

#### *Gracilis Muscle Flap*

In complex cases when the omentum is not available, the gracilis muscle can be considered for tissue interposition during an abdominal repair. The access is extraperitoneal. The muscle is harvested from the thigh based on the profunda femoris artery, and the flap is transposed between the bladder and the vagina. Two cases of recurrent VVFs were successfully treated with this technique.<sup>73</sup>

#### *Peritoneal Flap*

When using a flap of peritoneum for interposition, access is gained through the transperitoneal route. After incision of the bladder and excision of the fistula, a flap of peritoneum with an appropriate pedicle is raised from the lateral pelvic wall. The vaginal site is closed, and the flap is placed between the bladder and the vagina and fixed with interrupted absorbable sutures. The bladder wall is closed over the flap. Care is taken at the end of the procedure to suture the peritoneal lateral edges from which the flap has been harvested, but this is not always necessary.

This simple technique can be used successfully to repair recurrent or postirradiation fistulas.<sup>74</sup> One possibility when using the

peritoneum is to harvest a flap of the peritoneum that lines the broad ligament. A portion of the anterior surface of the broad ligament can be raised and moved medially to cover the vaginal site of a VVF in case of a large fistula.<sup>75</sup> An epiploic appendix can be used as interposition tissue and be brought behind the bladder when using an intraperitoneal or an extraperitoneal approach; in the latter case, access is gained by cutting a small opening in the peritoneum.<sup>76</sup>

#### *Seromuscular Intestinal Graft*

A patch of seromuscular intestinal graft obtained from a segment of small bowel can be used to repair VVFs. This technique requires intraperitoneal access and interruption of the bowel for harvesting the intestinal segment. The loop obtained is opened along the antimesenteric border, and the mucosal lining is mechanically removed, obtaining a seromuscular graft of small intestine. This patch is then used as interposition tissue between the bladder and the vagina, with the seromuscular face positioned toward the bladder. Complete re-epithelization of the seromuscular face of the graft with transitional epithelium occurs after a few weeks, and a 100% cure rate has been reported for treating complex postirradiation fistulas in four patients.<sup>77</sup>

#### *Omentum*

The omentum has excellent capacity for tissue healing, revascularization, lymphatic drainage, and anti-inflammatory activity. Unlike other tissues such as muscle, the omentum does not undergo atrophy or fibrosis after transposition. A transperitoneal approach always allows access to the omentum. However, this does not necessarily mean that the omentum can be used, because in some cases, it may be retracted or not available for interposition because of previous surgical procedures. Availability of the omentum can be established only after opening of the peritoneum. The omentum reaches directly into the pelvis in only 30% of patients.<sup>78</sup> In 70%, omental mobilization is required.

A complete description of the surgical technique for omental interposition was published by Turner Warwick.<sup>50</sup> The key point is maintenance of the vascularization of the omentum by careful preparation of its vascular pedicle. Vascularization of the omentum is based on the gastroepiploic arteries. The right artery usually is larger. The two arteries form an arch along the greater curvature of the stomach, which needs to be mobilized for elongation of the omentum when this is needed. Because mobilization should be based on the right gastroepiploic artery, the omentum should be released from the greater curvature, starting high on the left and moving down to the right. Variations of this procedure may vary from a limited tract to the entire length of the greater curvature.

The prepared omental apron is displaced in the pelvis and interposed between the bladder and the vagina, where it is secured in place with a few stitches. It is important to protect the passage of the omentum by mobilizing the ascending colon and placing the omentum behind it.<sup>51</sup> Suction drainage of the stomach can protect it from postoperative overdistention that could put the sutures on the small vessels along the greater curvature under tension.

### **Complex Repairs**

Combined grafting with omentum and a gastric segment has been described in a case of postirradiation VVF with large sub-

stance loss. The gastro-omental graft was based on the right gastroepiploic pedicle. The gastric wall was used successfully to replace the posterior bladder wall, and the omentum closed the vaginal defect, which was not sutured.<sup>79</sup> Large postirradiation fistulas may require bladder augmentation during repair. An ileocystoplasty can be successfully performed in these cases; it can be combined with omental interposition, without closure of the vaginal site when this is not possible.<sup>80,81</sup>

Augmentation cystoplasty should be performed when the bladder capacity is small as a consequence of previous failed repairs, because it may prevent the necessity of urinary diversion.<sup>82</sup> However, urinary diversion as a final option in the treatment of VVF can be employed with good functional results. Continent diversions are more acceptable to patients, especially in countries when the local culture does not accept external diversions or the economic and clinical support for the external incontinent stoma is not available.<sup>83</sup> Continent urinary diversions performed with the Mitrofanoff procedure can be a valuable technique to restore continence in the most difficult patients.<sup>84,85</sup> When good anal continence is preserved, an uretero-sigmoidostomy, such as a Mainz II pouch, can be considered.<sup>86,87</sup> A colon pouch can be similarly used for a continent external diversion.<sup>88</sup>

### Laparoscopic Repair

Laparoscopic repair of a VVF fistula is a less invasive strategy than the open abdominal approach. This is especially true when the VVF resulted from a previous laparoscopic procedure. Successful laparoscopic repair of a VVF was first described by Nezhat and colleagues<sup>89</sup> in 1994 in a patient who had been previously treated laparoscopically for an ovarian remnant syndrome. Subsequently, more experience with this technique were published.<sup>90-96</sup>

Preoperative cystoscopy and ureteral catheterization are advisable before laparoscopy. During cystoscopy, a ureteral catheter or a Foley catheter can be passed through the fistula into the vagina and retrieved outside through the introitus. This helps with identification of the fistula during dissection. Leaving the cystoscope in the bladder with the light on can facilitate identification of the fistula during the operation.<sup>96</sup> The patient is placed in the low lithotomy position. For access, one 10-mm infraumbilical incision is made to insert the video laparoscope and the CO<sub>2</sub> laser, and three additional 5- to 10-mm incisions are made in the lower abdomen for the suction-irrigation probe, the grasping forceps, and the bipolar forceps.

The principles of laparoscopic surgery do not differ from those of open surgery. A classic O'Connor technique is reproducible laparoscopically.<sup>95,96</sup> Cystotomy on the posterior bladder wall and careful dissection of the bladder from the vagina are performed under direct vision, with the advantage of magnification provided by the laparoscopic approach. An inflated glove or a wet sponge in the vagina can help to maintain the pneumoperitoneum after the vagina has been opened. The pneumoperitoneum can also help to distend the bladder after the cystotomy has been performed. After excision of the fistula and mobilization of the bladder from the vagina, the vagina and then the bladder are each sutured with one layer of interrupted or continuous absorbable sutures using extracorporeal knotting. Intracorporeal knotting has also been performed,<sup>93</sup> as has double-layered closure of the bladder.<sup>94,96</sup> A flap of parietal peritoneum can be used for interposition.<sup>89</sup> The omentum can be mobilized with staplers and interposed without closure of the vaginal site<sup>91</sup> or after the vagina

has been sutured.<sup>92-96</sup> Patients can be discharged on the first or second postoperative day.

Additional intra-abdominal procedures, such as ureteral reimplantation or nephrectomy, can be performed during the laparoscopic approach.<sup>93,96</sup> Two large series of patients treated laparoscopically have been reported,<sup>95,96</sup> consisting of 6 (plus 2 cases of vesicouterine fistulas) and 15 cases of VVFs. Success rates of 100% and 93% were reported for these series.

### Robotic Repair

A robotic system can be used as an alternative to laparoscopy in VVF repair, especially during the reconstructive period. Robotic surgical systems offer several technical advantages: high magnification, three-dimensional imaging, and a degree of freedom in movement that surpasses the possibilities of the human hand and laparoscopic instruments. Successful repair of VVFs using the Da Vinci robotic system is possible.

The first case managed with this technique was reported in 2005.<sup>97</sup> The patient is placed in the low lithotomy position. Preoperative cystoscopy with ureteral catheterization is performed. The patient is then moved into an extreme Trendelenburg position, and the ports are placed. Port placement does not differ from the technique used in robotic-assisted radical prostatectomy.<sup>98</sup>

In the first part of the operation, exposure of the bladder and cystotomy on the posterior bladder wall are performed, with identification of the fistula and excision of the fistulous tract, using a standard laparoscopic technique. The Da Vinci system is docked for the reconstructive part of the operation. The vaginal layer is closed with a single layer of sutures, and the bladder is then closed in two layers. The patient is discharged on the second postoperative day.

It is probable that robotic repair of VVFs will become more common in the future. The hope is that technologic improvements, such as the Da Vinci robot, can help surgeons successfully manage the more difficult cases with less invasive procedures and faster postoperative recovery while maintaining or improving the standards for proper surgical repair.

### POSTOPERATIVE CARE

The key aspect of postoperative care in VVF surgery is continuous bladder drainage.<sup>6</sup> This can be accomplished by a transurethral or a suprapubic catheter, or both, placed at the end of the operation. Prevention of kinking and obstruction by blood or mucus of the catheter is crucial. The transurethral catheter balloon should not be inflated or inflated with no more than 5 mL to prevent compression on the suture lines, especially if the fistula was at the level of the bladder neck. Suprapubic and transurethral urine drainage can be beneficial in case one catheter stops functioning. Maintenance of a high urine output with adequate fluid intake is a good postoperative measure to keep the patient hydrated and prevent blockage of the catheter.<sup>26,99</sup> Bladder drainage should be maintained for a minimum of 10 days<sup>100</sup> and, more often, for 2 weeks.

The timing of catheter removal varies and must consider the patient's circumstances. More prolonged catheterization is required for extension of the bladder sutures and for poor tissue quality.<sup>101</sup> The transurethral catheter can be removed before or after the suprapubic catheter. The suprapubic catheter should be

**Box 82-4 Postoperative Care**

- Adequate bladder drainage
- High fluid intake
- Intra-abdominal fluid drainage
- Temporary gastric drainage after omentum mobilization
- Avoidance of traction on the sutures: no tampons, no sex for 2 months
- Adjuvant therapy: antibiotics, anticholinergic agents, estrogens

clamped before removal is attempted to check for effective voiding. A voiding cystogram is obtained before removing the last catheter to make sure that there is no leak from the bladder. If incomplete closure is suspected, the catheter can be left in place for 1 or 2 weeks longer. A drain in the paravesical space can be left at the end of the operation to ensure drainage of blood or fluids from the pelvis. An intraperitoneal drain can be placed during transperitoneal procedures or when the omentum has been mobilized. Drains can be removed starting 5 or 6 days after the operation. It may be advisable to leave the paravesical drains longer. Ureteral catheters can usually be removed at the end of the operation, unless the ureters have been reimplanted. After a transperitoneal procedure, especially when the omentum was mobilized, temporary gastric drainage may be advisable, to prevent gastric overdistention. Alternatively, a gastrostomy performed at the time of surgery may be a more comfortable option for the patient.<sup>50,102</sup> A vaginal pack is removed on the first postoperative day.

Bed rest may be advised in cases of large, necrotic fistulas and poor vascularization of surrounding tissues.<sup>24</sup> In other cases, ambulation on the first or second postoperative day is encouraged. Postoperative antibiotic prophylaxis is administered for 10 days or until the drains are removed, but antibiotics are not always mandatory. Oral or local estrogen treatment may be useful in postmenopausal women. Mechanical stress or tension on the suture line should be avoided. The use of vaginal tampons is discouraged for a few weeks, and sexual intercourse is not allowed for 2 months after surgery. Anticholinergic drugs may help to reduce bladder spasms that can put tension on the sutures.<sup>99,103</sup> These drugs should be stopped 24 hours before obtaining the voiding cystogram. Postoperative care issues are summarized in Box 82-4.

**RESULTS**

It is difficult and sometimes impossible to compare published series of VVF repair. In all cases, patient selection is critical, and different series may be not comparable in terms of patients, hospital setting, strategy used, and the type of fistulas involved. Cure rates are not always intended as closure at the first operation.

The relevant clinical characteristics of VVF cases are provided in Box 82-5. They should be taken into account when comparing cases and series. Tables can be found in the medical literature that compare reported series.<sup>104,105</sup> This approach to comparing series is common, but it sometimes is impossible to summarize in a table all the information for a reported experience. For this reason, in the next sections, we provide brief descriptions of some

published experiences and our own experience with the abdominal approach to VVF repairs.

**Review of Reported Series**

El-Imam and colleagues,<sup>106</sup> 2005: Thirty of 50 cases of VVF were selected for the abdominal approach (20 operated vaginally). The fistulas are described as large, recurrent, high fistulas occurring in older women. Causes included obstructed labor and hysterectomy. The success rate for repairs using the abdominal approach was 99%.

Vyas and coworkers,<sup>60</sup> 2005: Twenty-two VVFs were treated. Causes included : obstetric issues in 15 and post-hysterectomy fistula formation in 7. All were operated using the transabdominal extraperitoneal approach (some through a combined abdominoperineal approach) and free bladder mucosa autograft. Five patients had undergone previous repairs; of these, two had recurrences. The success rate was 91%.

Naru and associates,<sup>107</sup> 2004: Fifty-six VVFs were treated. In these cases, 72.4% had obstetric causes, and 26.4% occurred after gynecologic surgery. A transabdominal approach was chosen in 69% of the cases. In one case, a ureterosigmoid diversion was performed. The overall success rate was 83.8% (79.4% at first attempt). In this report, one ureterosigmoid diversion was done, and the patients lost at follow-up were considered as failures.

Alagol and colleagues,<sup>65</sup> 2004: Eleven VVFs were treated. All cases were caused by hysterectomy for benign disease. Two patients had undergone previous repair attempts. The approach was transabdominal extraperitoneal with interposition of a dura mater free graft. The success rate was 100%.

Navarro Sebastian and coworkers,<sup>108</sup> 2003: Eighteen VVFs and two vesicouterine fistulas were treated. Causes included postoperative formation in 83% (13 hysterectomies, 1 cesarean section) and cancer in 17% of patients. Twelve patients were operated transabdominally, nine using an intraperitoneal approach and peritoneal graft (six cases) or omental interposition (three cases), and three operations used an extraperitoneal transvesical approach. The success rate was 88.5%.

Rafique,<sup>109</sup> 2002: Thirty-six VVFs and two 2 vesicouterine fistulas were treated. The cause in all cases was obstetric. Twenty-nine patients were operated using a transabdominal, transvesical approach with bladder bisection. Omentum interposition was used in all cases. Two ureteral reimplantations and two hysterectomies were performed. The success rate was 89.6%.

Kam and associates,<sup>110</sup> 2003: Twenty VVFs were treated. Fourteen VVFs occurred after gynecologic surgery. Four patients were operated using the transvaginal approach, seven using the extraperitoneal transabdominal approach, and eight using an intraperitoneal approach with bladder bisection. In one case, a urinary diversion (i.e., ileal conduit) was performed. Interposition flaps

were used in six cases. The success rate was 85%. Three failures were reoperated using the extraperitoneal approach with complete success.

Wook Bai and colleagues,<sup>111</sup> 2003: Twenty-six VVFs were treated. The fistulas were caused by hysterectomy or delivery. A transabdominal extraperitoneal approach was selected in 11 cases, and a combined abdominoperitoneal approach was used 7. The success rate for the first attempt was 90%, and for the second attempt, 80%.

Benchekrout and coworkers,<sup>112</sup> 2003: In this large report of 1050 cases of urogenital fistulas, 48% were VVFs. Obstetric causes accounted for 93% of the VVFs. The patients were operated preferentially transvaginally, but the abdominal route was preferred when the fistulas were high or posterior, if other procedures or omental interposition were planned, or in case of severe vaginal sclerosis. The success rate was 95%.

Sharifi and associates,<sup>62</sup> 2002: Fourteen VVFs were treated. Thirteen occurred after hysterectomy, and one was caused by obstructed labor. The access was transvesical extraperitoneal, and free bladder mucosa autograft was used. In 12 of 14, there was immediate success, but 2 required prolonged catheterization.

Kochakarn and colleagues,<sup>113</sup> 2000: The surgeons treated 230 VVFs. Known causes included hysterectomy in 195, obstructed labor in 10, and irradiation in 9. Thirty-five patients had undergone previous attempts at repair. The transvesical extraperitoneal approach was performed in 168 cases (73%), including 29 reoperations and 139 first operations. The success rates were 78% (109 of 139) for the first-operation group and 62% (18 of 29) for the reoperation group. Of the 30 failures in the first-operation group, 15 were postirradiation fistulas. The O'Connor technique with bladder bisection was performed in 30 patients (success rate of 93.3%). Twenty patients were operated transvaginally (success rate of 100%). Urinary diversion (i.e., ileal conduit, colon conduit, or bilateral ureterostomies) was performed in 10 patients.

Evans and associates,<sup>58</sup> 2001: Thirty-seven VVFs were treated. Twenty-five resulted from gynecologic surgery. A transperitoneal O'Connor procedure was used. In some cases, interposition flaps were used (with 100% success), and the others were operated without flaps (63% success rate).

Mondet and colleagues,<sup>56</sup> 2001: Thirty VVFs in 28 patients were treated. Causes included gynecologic surgery in 78%, of which 86% occurred after hysterectomy, and cesarean section in 14%. In 30% of the patients, previous procedures had been performed. A transperitoneal-transvesical approach was used. The vaginal site was not closed in 66% of the cases. In 10 cases (83% of the trigonal fistulas), ureteral reimplantation was necessary. The overall success rate was 85%; success rates were 93% for supratrigonal and 75% for trigonal fistulas. Postoperative voiding disorders were documented in 38% of the patients. The failures were treated with urinary diversion in three cases (one transileal noncontinent cutaneous ureterostomy and two ureterosigmoidostomies). In one case, a second transperitoneal operation was undertaken with ureteral reimplantation (not performed in the first procedure), and it was successful.

Flores-Carreras and coworkers,<sup>114</sup> 2001: The surgeons treated 153 VVFs. Fistulas resulted from hysterectomy in 90%, cesarean section in 3.9%, and Burch procedures in 1.9%. Thirty-two (20.9%) patients had been previously operated. In 113 patients (68%), a vaginal approach was chosen, with a success rate of 90% at the first attempt and 100% at the second or third attempt. Thirty-three percent of the patients underwent a transvesical

suprapubic procedure (success rate of 91% at the first attempt). Of three failures, two were reoperated, and the third patient refused reoperation (final success rate of 97%). The transperitoneal approach was used in eight patients, with two failures (75% success rate); one had a successful second operation using the transvesical approach.

Langkilde and associates,<sup>115</sup> 1999: Fifty-five patients VVFs were treated, 49 of whom had operations. Fistulas resulted from pelvic surgery (23 after hysterectomy) in 30 patients, cesarean section in 4, Burch procedures in 2, and radiation treatment in 19. Eight patients had undergone previous attempts. Among the 30 postoperative cases, 23 patients underwent an abdominal procedure (with transperitoneal-transvesical access), and 7 had a vaginal procedure. In four patients, reimplantation of the ureter was necessary. The success rate was 90% at the first attempt and 100% at the second (treatment of failures included two abdominal and one vaginal approach). Among those with postirradiation fistulas, 12 patients underwent urinary diversions (five ureterocutaneous ostomies and seven ileal conduits), 2 had an abdominal procedure, and 5 had a vaginal procedure (with a high failure rate in the postirradiation group: 6 of 7 cases).

Nesrallah and colleagues,<sup>104</sup> 1999: Twenty-nine VVFs were treated. All fistulas were supratrigonal in this group. Fistulas resulted from hysterectomy in 28 patients (25 operations for benign disease, 2 after irradiation plus hysterectomy, and one cesarean section). Nine (34%) of 29 had undergone previous operations. In all cases, the transperitoneal approach was used, and an O'Connor procedure was performed, often with omental interposition. Four ureteral reimplantations were added. The success rate was 100%.

Ostad and coworkers,<sup>61</sup> 1997: Six VVFs were treated. All fistulas resulted from hysterectomies. A transabdominal approach with free bladder mucosa graft was chosen. The success rate was 100%.

Brandt and associates,<sup>59</sup> 1997: Eighty VVFs were treated. Fistulas resulted from gynecologic surgery for benign disease. Three patients had undergone previous attempts at repair. The approach was extraperitoneal with free bladder mucosa autograft. The success rate was 96%, and there were no late failures.

Blaivas and colleagues,<sup>31</sup> 1995: Twenty-four VVFs were treated. Most fistulas resulted from previous surgery (15 from hysterectomy, 2 from anterior colporrhaphy, 2 from urethral diverticulectomy, and 1 from an anti-incontinence procedure). Procedures included 16 vaginal repairs with a Martius flap, 1 with a gracilis flap, and 7 suprapubic transvesical repairs with omentum. In two patients, the procedure was started vaginally and then switched to the abdominal route because of poor exposure. The overall success rate was 96%.

Kristensen and Lose,<sup>116</sup> 1994: Eighteen VVFs were treated. All fistulas were caused by hysterectomies. A total of 27 previous attempts had been performed. An O'Connor procedure with a transperitoneal approach was performed in all cases. In four, ureteral reimplantation was necessary, of which one was bilateral. Only 1 of 18 had a recurrence, with successful repair on the second attempt with interposition of omentum.

Arrowsmith,<sup>24</sup> 1994: Ninety-eight VVFs were treated. Fistulas resulted from obstetric causes in 93 patients, surgery in 4, and trauma in 1. Twenty-five cases were treated abdominally with the O'Connor procedure (omentum was used in nine cases), three used a combined abdominoperitoneal approach, and the rest used a vaginal approach. Nineteen percent underwent multiple procedures. The success rate was 96%. Larger fistulas did not fare

worse than smaller fistulas ( $P = .87$ ). However, treatment failure was significantly associated with bladder neck damage ( $P < .015$ ) or severe vaginal scarring ( $P < .005$ ).

Blandy and coworkers,<sup>29</sup> 1991: Twenty-five VVFs were treated. Fistulas resulted from hysterectomy in 24 patients and transvaginal uterine prolapse surgery in 1 patient. A transperitoneal transvesical approach was chosen, with interposition of omentum. The success rate was 100%.

Motiwalla and associates,<sup>117</sup> 1991: Sixty-eight VVFs were treated. Fistulas resulted from hysterectomy in 48 patients, cesarean section in 15, and labor in 5. Fifty-one were supratrigonal fistulas. Four patients had undergone previous repairs. A transperitoneal-transvesical approach was chosen, with omentum grafts in 10 cases, and 58 used an extraperitoneal approach. Two ureteral reimplantations were necessary. The success rate was 95% for the extraperitoneal procedures and 90% for the transperitoneal cases.

Gil-Vernet and colleagues,<sup>63</sup> 1989: Forty-two VVFs were treated. Fistulas resulted from gynecologic operations in 28 patients, obstetric causes in 11, and irradiation in 3. All the patients had undergone previous surgical attempts at repair. An extraperitoneal approach was performed, with the sliding bladder wall technique described previously. The success rate was 100%.

Lee and coworkers,<sup>19</sup> 1988: The surgeons treated 182 VVFs. Fistulas resulted from hysterectomy in 156 patients, obstetric operations in 19, malignancy in 10, and trauma in 6. Ninety-one patients had undergone previous attempts at repair. The approach chosen was abdominal in 37 cases (20%) and transvaginal in 145. The success rate was 98%.

Udeh and associates,<sup>55</sup> 1985: Thirty-one VVFs were treated. All fistulas resulted from obstructed labor. Twenty-one patients had undergone previous attempts at repair. Two underwent elective diversion, and 29 were operated abdominally with an anterior transvesical approach. The success rate was 86%.

## Personal Experience

### Patients

Eighty-four patients with urinary fistulas have been operated using the abdominal approach at the Department of Urology of the University of Padova, Italy, between May 1979 and March 2003, under the chairmanship of Professor Francesco Pagano. Patients' data have been collected and analyzed retrospectively. Sixty-five of 84 patients developed a VVF after hysterectomy for benign or malignant disease; 7 of them had received adjuvant radiation treatment for cancer. Two patients had undergone radiotherapy alone. Four patients developed a VVF after vaginal delivery, one after cesarean section, one after a bladder biopsy, one after bladder diverticulectomy, one after resection of a urethral lesion, one after a vaginoplasty procedure, one after sacral colpopexy, and one after radical cystectomy and orthotopic ileal neobladder. In five cases, the patients' records were incomplete for cause. In one case, a clear reason for the fistula could not be identified. The most common onset symptoms were recorded for 82 of 84 patients: vaginal leakage with a preserved micturition pattern was present in 58 patients and complete urinary incontinence through the vagina in 24.

The patients received a preoperative evaluation, including cystoscopy, endovenous pyelography, retrograde ureterography, voiding cystography, vaginoscopy, and pressure-flow studies (for

seven). Seventy-six (90%) of 84 patients presented with a VVF, 5 with a VVF and associated rectovaginal fistula, 2 with a uretero-VVF, and 1 with an orthotopic neobladder-vaginal fistula. In 56 patients, the fistula was supratrigonal; in 15, it was at the trigonal level; in 5, it was at the bladder neck; and in 3, it was on the lateral bladder wall. In five cases, fistula localization was not described. Before coming to our attention, 21 (25%) patients had received previous unsuccessful treatments in other institutions (with a median delay in this group of 25 weeks from onset of symptoms): 14 had undergone one previous attempt (2 patients had been treated endoscopically with collagen injection or diathermocoagulation of the fistulous tract), 11 had been operated using the vaginal approach, and 7 had been treated using the abdominal approach. One patient had been treated for cervical malignancy and had received an "external diversion" that was not better described. The other seven patients had undergone two previous attempts in another institution, two endoscopically with collagen or Teflon infiltration, two treated transvaginally, and three treated transabdominally.

### Surgical Technique

In 64 of 84 patients, the fistula was corrected using an extraperitoneal transvesical approach, and in 14 of 84, a transperitoneal approach was used; omental interposition was performed in three of these cases. Additional intraperitoneal procedures were performed in 12 cases: augmentation ileocystoplasty in 6 cases and ureteral reimplantation in 6 cases (four bilateral and two monolateral procedures). Urinary diversion was performed as the first procedure in six patients (i.e., one continent ileal reservoir with a Mitrofanoff procedure and five external noncontinent diversions, three with colon, one with ileum, and one ureterocutaneostomy). The bladder catheter was maintained for an average period of 10 days after surgery.

### Outcomes

Excluding the patients treated with urinary diversion (6 of 84), successful closure was obtained in 94% (73) of the 78 other patients in whom abdominal repair was performed. Five patients had fistula recurrences between 0 and 95 weeks; two were successfully reoperated transvaginally, with one using a Martius flap interposition. Two were treated endoscopically with collagen or silicone injection (one failed, requiring after 12 weeks a second successful abdominal repair with ureteral reimplantation and omentum interposition). One had a ureteral-sigmoid-cutaneous diversion.

### Long-Term Follow-Up

Long-term follow-up was possible for 62 of 84 patients. The minimum follow-up in this group was 2 years (average,  $12.5 \pm 8.4$  years). All patients were satisfied with their situation; 61 of 62 patients were dry, and 1 complained about mild urinary incontinence but declined further treatment.

## CONCLUSIONS

The ideal treatment for a VVF is the one that provides rapidly the best result with the least invasive approach. The abdominal approach for treatment of VVF, which is an invasive approach, has several indications, and when properly selected, it can provide the definitive solution to VVFs not treatable with less invasive procedures. New techniques, such as laparoscopy or robotic

surgery, can reduce the invasiveness of the open abdominal approach and make the procedure more acceptable to the patient. Some of the strategies for repair highlighted in this chapter can increase the chances of success. These strategies, which are independent of the approach used, are summarized in Box 82-6. Using these strategies, we think that major improvements can be made in the treatment of this undesirable clinical condition can be made in the near future.

### Box 82-6 Strategies for Success

- Case selection
- Surgical experience, training opportunities
- Choice of less invasive procedures
- Steps taken to minimize chances of failure
- Use of interposition flaps when possible
- Prioritization of postoperative uninterrupted bladder drainage
- Correct analysis of comparable series

# RECTOVAGINAL FISTULA

*Matthew P. Rutman, Larissa V. Rodríguez, Donna Y. Deng, and Shlomo Raz*

A rectovaginal fistula consists of an abnormal, epithelium-lined communication between the rectum and the vagina. It represents an extremely distressing problem for the patient and a surgical challenge for the physician. The reconstructive pelvic surgeon must have a full understanding of rectovaginal fistula to provide the patient with the most appropriate treatment option.

### PATHOPHYSIOLOGY

It is important to consider the underlying cause of the rectovaginal fistula in preparing for a successful repair. The most common cause of rectovaginal fistula remains obstetric trauma,<sup>1,2</sup> usually caused by an unrecognized injury with traumatic vaginal delivery, wound infection, or an inadequate repair of a third- or fourth-degree perineal laceration. Up to 5% of vaginal deliveries result in these lacerations. Most heal when repaired at the time of labor. Prolonged labor and compression can result in ischemic necrosis of the vaginal septum, predisposing the delivering woman to development of a rectovaginal fistula. This is a greater concern in developing nations and likely not a large factor in industrialized countries such as the United States and Canada.

Vaginal, rectal, and pelvic operations, such as rectocele repair, low anterior resection, and hemorrhoidectomy, may lead to rectovaginal fistula as a result of intraoperative injury or postoperative infection. Rectovaginal fistula can result from nonobstetric blunt and penetrating trauma. Inflammatory processes of the bowel, such as diverticulitis, Crohn's disease, and ulcerative colitis, can produce a rectovaginal fistula.

Rectal, cervical, uterine, and vaginal malignancy and radiation therapy are known causes of rectovaginal fistulas. The incidence of rectovaginal fistula after irradiation is 0.3% to 6%.<sup>3,4</sup> The fistula may occur up to 2 years after irradiation because of progressive radiation damage. Any fistula associated with radiation therapy and malignancy must be biopsied to rule out recurrent malignancy before formal repair.

Inflammatory or infectious processes near the rectovaginal septum or cul-de-sac may result in formation of a rectovaginal fistula. Prolonged use of a vaginal pessary can result in a rectovaginal fistula.

The location of rectovaginal fistulas may mandate a particular surgical approach. The fistula may be in the high, middle, or low rectal region. Most fistulas associated with obstetric trauma are classified as low types. Diverticular disease and other intra-abdominal pathologic conditions are associated with higher rectovaginal fistula. The high fistula usually is associated with intra-abdominal conditions such as diverticulitis or abscess formation, and it may require a laparotomy. The low fistula of rectal origin can be repaired transvaginally, avoiding the morbidity of an abdominal approach.

### EVALUATION

The diagnosis is obvious in patients with a large rectovaginal fistula because bowel content is evacuated through the vagina. Patients with a smaller fistula may be completely asymptomatic.

A thorough history and physical examination are mandatory for every patient suspected of having a fistula. The interview should include questions about prior malignancy, radiation therapy, complicated obstetric history, inflammatory bowel disease, and prior anorectal surgery. Physical examination should reveal the size, location, and number of fistulous tracts. The perineal body must be examined to determine the function and tone of the anal sphincter. Bimanual examination allows the physician to palpate the thickness of the perineal body and identify the fistula. Multiple fistulas and perianal fissures may suggest Crohn's disease. If the fistula is not easily identified, vaginal speculum examination should be performed.

If the diagnosis is still in doubt, a dye test can be performed. Methylene blue dye is instilled into the rectum, and a tampon or sponge inserted into the vagina. Staining of the pad confirms the diagnosis and can be helpful in identifying a small fistula. Proctoscopy, colonoscopy, barium examination, and computed tomography should be performed if indicated. Any area of suspicious inflammation, ulceration, or mass should be biopsied to rule out a malignant process or recurrence. Examination under anesthesia can be performed to make the diagnosis if all of the previous measures fail and the physician still suspects a fistula.

Before formal repair, it is necessary to evaluate the patient for fecal incontinence. A review of 52 patients at the University of Minnesota revealed a 48% incidence of coexistent fecal incontinence.<sup>5</sup> Among women who develop rectovaginal fistula after obstetric trauma, the incidence is probably much higher. It is essential to assess the function of the anal sphincter before surgical repair. Endoanal ultrasonography, anal manometry, and pudendal nerve terminal motor latency testing remain valuable tools to aid with the clinical evaluation. Ultrasound can easily identify defects in the internal anal sphincter. Defects in the external anal sphincter are more difficult to identify because of the hyperechoic pattern. Manometry can help quantify the resting and squeezing pressures of the sphincter muscle. Pudendal nerve testing helps identify underlying neuropathy.

### PREOPERATIVE CONSIDERATIONS

Management of rectovaginal fistulas depends on several factors: cause, size, number, and location of the fistulas and the surgeon's preference. Anal sphincter integrity and prior operations

influence the choice of treatment. Regardless of the approach chosen, several principles require consideration before repair.

Antibiotic coverage and topical hormonal replacement help optimize the health of local tissues and decrease any associated infection and inflammation. The health of the surrounding tissues influences the waiting period before surgical repair. Any inflammation or infection should be resolved. Waiting 3 to 6 months in these cases allows resolution and increases the chance of successful repair. In patients with prior failed repair, a longer waiting period may be necessary. In patients with postirradiation rectovaginal fistulas, a much longer waiting period may be required. Patients with complex fistulas (e.g., large size, radiation induced, neoplasm induced, multiple failed repairs) may require a diverting colostomy before formal repair. After diversion, a waiting period of 2 to 3 months before vaginal repair allows local tissue healing. Complete bowel preparation is given before surgery.

Excellent exposure allows good mobilization of tissue flaps. The fistulous tract should be exposed in its entirety and left intact. We tend to not excise the tract. This prevents iatrogenic enlargement of the fistula and allows us to use it in our repair. The rectal opening is closed in multiple, tension-free layers. Interposition of healthy tissue between the rectum and vagina should be used routinely. Common sources include labia fatty tissue (i.e., Martius flap), labial skin and underlying fatty tissue, gluteal skin, gracilis muscular flaps, and omentum. Case reports have described pudendal thigh fasciocutaneous island flaps and gluteal-fold flap repairs to aid in rectovaginal fistula repair.<sup>6,7</sup> Several common techniques of tissue interposition can be found in Chapters 81 and 82. After closure of the fistula, anal sphincter defects should be addressed to restore normal sphincter function.

### SURGICAL REPAIRS

Surgical options can be divided into transvaginal repair, transanal repair, transperineal repair, and abdominal repair. Reconstructive urologists and gynecologists typically use a transvaginal approach, whereas colorectal surgeons prefer a transanal approach. An abdominal approach is often used in treating radiation-induced rectovaginal fistulas. We use a multilayered transvaginal approach, avoiding the morbidity of a laparotomy, in most rectovaginal fistula repairs.

Complete bowel preparation is done, and antibiotics are given preoperatively. The patient is given general or spinal anesthesia and placed in the high lithotomy position. A Foley catheter is placed in the bladder. Use of a surgeon's headlight and a ring retractor help to optimize exposure. A Foley catheter is inserted into the fistulous tract (Fig. 83-1). A circumferential incision is made around the Foley catheter, and the tract is dissected to the rectal wall (Fig. 83-2). A flap of distal vaginal is also prepared. The fistulous tract is then excised, leaving the rectal wall with an indwelling catheter (Fig. 83-3). The rectal wall is closed in two layers using 2-0 absorbable sutures (Fig. 83-4). The levator musculature is included in the closure.

A Martius flap is prepared. A vertical incision is made lateral to the labia, and a fibrofatty flap is developed and isolated, preserving the inferior vascular pedicle (Fig. 83-5). The flap is then tunneled through the vagina and rotated to cover the fistula. Interrupted sutures are used to fix the flap to the rectal wall. The wound is then closed in layers, advancing the vaginal wall distally

Figure 83-1 The fistulous tract is catheterized.

Figure 83-2 The circumferential incision is dissected to the rectal wall.

and ensuring new tissue covers the area of the fistula (Fig. 83-6). Vaginal packing is left for a few hours, and the patient resumes a regular diet. Oral antibiotics are continued for 1 week. For patients who had a prior diverting colostomy, we routinely wait 3 to 6 months before takedown. Physical examination and a radiographic contrast study confirm complete healing of the fistula.

Intraoperative complications are rare. If tissue quality is poor intraoperatively (because of infection or irradiation), the surgery should be aborted and a diverting colostomy performed to allow tissue healing. Postoperative complications include recurrent

**Figure 83-3** Excision of a fistulous tract.

**Figure 83-4** Closure of the rectal wall.

fistula. Recurrent fistula requires a diverting colostomy, if not previously performed, before re-exploration.

A second transvaginal approach includes inversion of the fistula. The patient is placed in the lithotomy position as described earlier. The vaginal mucosa is incised in a circumferential fashion around the fistula and mobilized in all directions. After excising the fistulous tract, a purse-string suture is placed around the opening of the rectovaginal septum, and the suture is secured, inverting the fistula into the rectum. The muscle and vaginal mucosa are then closed, resulting in three layers of repair.<sup>8</sup>

Case reports have reported successful use of cadaveric dermal allograft<sup>9</sup> interposition and porcine dermal graft interposition<sup>10</sup> Dexon mesh has been used to separate the suture lines between

**Figure 83-5** The Martius flap is based on an inferior vascular pedicle.

**Figure 83-6** The vaginal wall flap is advanced to cover the fistula.

the vaginal and rectal walls.<sup>11</sup> These may be viable alternatives to traditional autologous flaps.

Although not commonly used by urologists and gynecologists, colorectal surgeons often advocate a transanal approach. The most common of the approaches uses an advancement flap.<sup>12</sup> The patient is given standard antibiotics and mechanical bowel preparation preoperatively. After general anesthesia is provided, the patient is placed in the prone jackknife position. The vagina and perineum are cleansed in standard sterile fashion. Proctoscopy identifies the fistula and allows irrigation of the lower rectum to clear any residual fecal contents. Rectal retractors help optimize exposure. Injectable Xylocaine with epinephrine is infiltrated into the dissection planes. A trapezoidal flap consisting of mucosa, submucosa, and internal sphincter (i.e., circular muscle) is raised

around the fistula and mobilized 4 to 5 cm cephalad. The flap should easily advance to cover the fistula tract, and any tension should be avoided. Excess flap, including the fistula itself, is excised, and the remaining flap is advanced and sutured with 3-0 absorbable sutures. The vaginal aspect of the fistula is left open for drainage.

Layered closure can be performed transanally.<sup>13</sup> A transverse elliptical incision is made around the fistula through the rectovaginal septum. It is dissected circumferentially for about 3 cm. The fistula tract is excised, and a two-layer closure is performed. The rectal mucosa is then advanced distal to the deeper portion of the repair and reapproximated.

Transperineal approaches can be organized into three categories: fistulotomy, perineoproctotomy, and sphincteroplasty. Fistulotomy converts a fistula into a fourth-degree perineal laceration, resulting in fecal incontinence due to sphincter damage. This procedure is not recommended as a solo primary approach.

Perineoproctotomy with layered closure is a commonly used transperineal technique.<sup>1</sup> It is often used by obstetricians for repair of lower vaginal rectovaginal fistulas. The patient is prepared with standard antibiotics and bowel preparation and placed in the lithotomy position. The fistula is identified, and the bridge of skin, sphincter, and perineal body between the posterior fourchette and fistula are divided. The fistula becomes a fourth-degree perineal laceration. The fistulous tract is excised, and the defect is then closed in standard layered fashion (i.e., vaginal wall, sphincter muscle, and rectal mucosa). The perineal body is reconstructed. Postoperative complications include vaginal stenosis and dyspareunia. Fecal incontinence may result with scarring of the transected anal sphincter.

Sphincteroplasty performed through a transperineal approach allows correction of any underlying sphincter defect.<sup>14</sup> The patient is prepared as previously described and placed under general anesthesia. A Foley catheter is placed, and the patient is placed prone in the jackknife position. A curvilinear incision is made through the perineum. A flap of anoderm distally and mucosa and submucosa proximally is raised. The ends of the sphincter (external and internal) muscles are identified laterally and left intact. Levatoroplasty is often needed at this stage of the surgery if the injury involves the deep external sphincter muscle. The ends of the mobilized sphincter muscles are sutured in an overlapping manner using horizontal mattress sutures. This reconstructs the sphincter mechanism. Tissue is then interposed between the rectum and vagina. The endorectal flap is sutured to the reconstructed sphincter muscle, and the perineal incision is closed. The vaginal mucosa is left open to drain.

Transabdominal procedures to repair rectovaginal fistula are necessary for complex fistulas resulting from irradiation, inflammatory bowel disease, and failed previous repairs. Surrounding tissues are often poorly vascularized, and local repair is a poor option. Abdominal approaches leave the anal sphincter intact and allow easy interposition of well-vascularized tissues.

In patients with a high fistula location and normal surrounding tissues (i.e., no irradiation or inflammatory bowel disease), simple abdominal repair can be performed. A laparotomy is performed, and the rectovaginal septum is mobilized. The diseased segment is divided, and layered closure of the rectal and vaginal defects is performed. Omentum is interposed between the rectum and the vagina.

Most commonly, an abdominal approach is chosen because of poor local tissue quality. These approaches are typically per-

formed after a primary diverting colostomy has been done or concomitantly with fecal diversion. The abdominal approach allows repair of the fistula with concomitant bowel resection. The patient undergoes complete bowel preparation, is given antibiotics, and is placed under general anesthesia. A laparotomy is performed. The splenic flexure, left colon, and sigmoid colon are fully mobilized down to the levator hiatus. The diseased bowel segment is resected. At this point, a coloanal anastomosis is performed by a pull-through<sup>15,16</sup> or sleeve anastomosis.<sup>17</sup>

A non-resectional onlay patch technique was introduced by Bricker and Johnson in 1979 for radiation-induced rectovaginal fistula.<sup>18</sup> The rectosigmoid colon is divided and an end-sigmoid colostomy performed. The distal end is then folded and sutured to the exposed and débrided edges of the fistulous opening in the rectum. At a later stage, after healing is confirmed, the colostomy is taken down and anastomosed to the side of the folded loop of the rectosigmoid. The major downfall of this procedure is that it leaves behind irradiated tissue, and it is rarely used today.

For patients with a fistula resulting from a neoplasm, abdominoperineal resection and vaginectomy are typically required. Patients with severe inflammatory bowel disease may ultimately require proctocolectomy. Patients with terminal malignancies or major medical comorbidities (i.e., unfit for major surgery) and symptomatic rectovaginal fistulas may be best served by a diverting colostomy.

## ALTERNATIVE TREATMENTS

Alternative procedures for rectovaginal fistula have been described in the literature. Fibrin glue has been injected into the fistulous tract, with reported success rates of 74% and 80%.<sup>19,20</sup> In patients with Crohn's disease, several medical regimens have been studied. Sands and colleagues<sup>21,22</sup> reported fistula closure with infliximab infusion in 13 of 29 patients after 14 weeks of follow-up. Similar improvements have been reported with intravenous and oral cyclosporine.<sup>23,24</sup> Metronidazole and 6-mercaptopurine have been used to effectively treat rectovaginal fistula resulting from Crohn's disease.<sup>25</sup>

The Latzko technique used in vesicovaginal fistula repair can also be used to repair a high rectovaginal fistula located at the apex of the vagina. The anterior and posterior vaginal walls are denuded, and an incision is made around the fistula margins. Three layers of closure invert the fistula, close the rectal muscle and fascia, and close the vaginal mucosa.

## RESULTS

The many different approaches to repair of rectovaginal fistula have various success rates and outcome measures. Success should be evaluated according to objective measures and the results of self-reported questionnaires about patient satisfaction. Successful repair of the fistula sounds great, but secondary fecal incontinence or dyspareunia may alter the outcome. The existing literature primarily reports success or failure based on healing of the rectovaginal fistula. Future reports should report on fistula healing, fecal continence, sexual function, and quality of life.

Transvaginal repairs using a layered closure have success rates of 84% to 100%.<sup>2,26-28</sup> Advancement flaps placed by means of a

transanal approach have success rates in the range of 78% to 100%.<sup>29-31</sup> The rates were higher for patients undergoing initial repair.<sup>32</sup> Success rates of 88% to 100% have been reported for perineoproctotomy and layered closure.<sup>1,2,8,33-35</sup> The combination of sphincteroplasty and levatoroplasty has a success rate of 93%.<sup>32</sup> Transabdominal repairs also have high cure rates, in the range of 80% to 100%.<sup>4,17,36</sup>

## CONCLUSIONS

The management of rectovaginal fistulas remains a challenge for the reconstructive pelvic surgeon. The decision-making algorithm must include the size, location, and cause of the fistula. The health of the patient and judgment of the treating physician greatly influence successful repair and a good outcome.

# URETEROVAGINAL FISTULA

David Ginsberg

### DEFINITION AND INCIDENCE

A ureterovaginal fistula is an abnormal communication between the distal ureter and the vagina that results in urinary incontinence. Formation is often preceded by pelvic surgery, with an unrecognized ureteral injury occurring at the time of surgery. Damage to the ureter can lead to ureteral obstruction or leakage of urine at the site of injury. The urine often makes its way out through the vaginal cuff, which ultimately results in the formation of the ureterovaginal fistula.

Ureteral injury has occurred in about 0.5% to 1% of all pelvic surgeries.<sup>1</sup> Total abdominal hysterectomy is the most common procedure leading to injury to the ureter and subsequent ureterovaginal fistula, accounting for 75% of all cases in one study.<sup>2</sup> Enlarged uteri, pelvic adhesions, and significant intraoperative bleeding also appear to increase the risk of ureteral injury at the time of gynecologic surgery.<sup>3</sup> Other operations that may lead to ureterovaginal fistula include anterior colporrhaphy, colorectal surgery, and oophorectomy. Obstetric causes rarely lead to ureterovaginal fistula formation and are primarily attributed to cesarean section (especially after prior cesarean section),<sup>3</sup> although traumatic vaginal delivery has been reported as a cause of ureterovaginal fistula.<sup>4</sup> Other unusual causes of ureterovaginal fistula include vaginal foreign body<sup>5</sup> and residual stone fragments after shockwave lithotripsy.<sup>6</sup> Radiation therapy by itself or in conjunction with surgery can place a patient at risk for ureteral injury and subsequent formation of ureterovaginal fistula.<sup>7</sup> Persistent urinary leakage resulting from an injury to the ureter during any of these procedures places the patient at risk for developing an ureterovaginal fistula. Later series looking at laparoscopic pelvic surgery found a rate of ureteral injury of less than 1% to 2%, with a much lower incidence of injury associated with diagnostic laparoscopy compared with laparoscopic intervention.<sup>8,9</sup>

The injury to the ureter usually occurs in the distal third. Types of injury include ischemia, transection, excision, and ligation. Ischemia is most commonly associated with radical (Wertheim's) hysterectomy, which requires the ureter to be stripped from its fascial encasement in the broad ligament. More commonly, the ureter is injured by a suture, with resultant extravasation leading to fistula formation. The left ureter is much more at risk, and most prior series reveal ureterovaginal fistula formation on the left three to five times more often than on the right side. This increased risk to the left ureter is related to its course, which places it much closer to the cervix than the right ureter. Another common site of injury is at the level of the pelvic brim, where the ureter crosses the iliac vessels. Injury at this site is thought to occur during the manipulation and division of the infundibulopelvic ligament.<sup>3</sup> Patients with pelvic inflammatory disease, prior pelvic surgery, and other conditions that can distort

the normal pelvic anatomy may be at greater risk for ureteral injury and subsequent fistula formation.

### PRESENTATION

In most series, patients with ureterovaginal fistula present 1 to 4 weeks after pelvic surgery with an acute onset of continuous incontinence. Many also void normally despite the continuous leak, because the bladder continues to fill normally through the contralateral ureter, which is usually uninvolved (bilateral ureterovaginal fistulas are rare). The presentation of ureteral injury alone in the absence of fistula formation is often missed because the symptoms are nonspecific. The most common symptoms of ureteral injury include abdominal pain, flank pain, and nausea, all of which can be easily overlooked and confused with postoperative complaints after the initial surgery or masked by postoperative narcotic use. Because symptoms of ureteral injury are nonspecific, a high degree of suspicion should be maintained for any patient with these complaints and prior pelvic surgery. Complaints about urinary incontinence should result in an evaluation to look for problems such as a vesicovaginal or ureterovaginal fistula.

### EVALUATION

Renal ultrasound may be helpful as a screening tool, but the result may be normal if distal obstruction is absent. The most commonly used modality to evaluate for ureteral injury is intravenous urography (IVU). It can identify a ureteral injury in most cases, and it enables evaluation of renal function and potential obstruction on the affected side (Fig. 84-1). IVU may not identify a ureterovaginal fistula in every patient. Lask and colleagues<sup>10</sup> evaluated iatrogenic ureteral injuries in 44 patients, 10 of whom had a ureterovaginal fistula. The fistula was identified in only 3 of 10 patients undergoing IVU.<sup>10</sup> These findings highlight the importance of retrograde pyelography, which may be required to identify the fistula in some patients.<sup>11</sup> This is especially true if the IVU result is abnormal but does not reveal ureterovaginal fistula and the patient complains of urinary incontinence after recent pelvic surgery.

Any obstruction at the level of the injury should be identified because an untreated distal blockage makes spontaneous healing of the fistula extremely unlikely. If conservative attempts at therapy are to be attempted, such as placement of a ureteral stent as discussed in the next section, the retrograde pyelogram can be done simultaneously. Computed tomography should be considered for patients who are systemically ill to evaluate for possible

**Figure 84-1** Intravenous urography (IVU), with coned down view of the pelvis. The patient underwent total abdominal hysterectomy 2 weeks earlier and now complains of flank pain and urinary incontinence. IVU demonstrates fullness of the distal ureter and an injury that has resulted in a ureteral leak and subsequent ureterovaginal fistula.

urinoma or abscess formation, which should be percutaneously drained.

In addition to radiographic evaluation, the double-dye test can be used. This was initially described using intravenous indigo carmine,<sup>12</sup> but it has been modified to eliminate the need for intravenous access to perform the test. With the modified test, a patient is given Pyridium orally until the urine turns orange. A tampon is placed vaginally, and the bladder is emptied with a catheter. Through that catheter, the bladder is filled with a mixture of 300 mL of normal saline and 5 mL of methylene blue dye. After 5 minutes, the bladder is emptied, and the tampon is removed and inspected. An orange stain at the top of the tampon indicates a ureterovaginal fistula, a blue stain in the middle of the tampon indicates a vesicovaginal fistula, and a blue stain at the distal tip of the vagina indicates leakage of urine through the urethra.<sup>13</sup>

## ENDOSCOPIC THERAPY

A variety of minimally invasive therapies have been described for the management of ureterovaginal, and they have a wide range of results. The least invasive option is observation. This has been reported with periodic success in the past and was primarily used before the use of fluoroscopy and modern endoscopic equipment made ureteral stent placement commonplace.<sup>11,14,15</sup> Clinical and radiographic features that are likely to predict a successful outcome with nonsurgical management of a ureterovaginal fistula include minimal to moderate obstruction on the affected side, a mild degree of periureteral extravasation, upper tract improvement on subsequent follow-up studies, adequate control of urinary tract infection, and the use of absorbable suture material at the time of the initial procedure that caused the injury to the ureter.<sup>14</sup> The risk of expectant management is stricture formation, which may require regular dilations or, if not followed carefully, can lead to chronic obstruction, loss of kidney function, and the need for subsequent nephrectomy.<sup>16</sup>

Physicians had some success with a nephrostomy tube alone when a stent could not be passed by the area of ureteral occlusion. Nephrostomy tube placement protects the upper tracts if the patient is obstructed and has successfully led to ureterovaginal fistula resolution in a small number of patients.<sup>10,11</sup> This should be the first option if the patient is too ill to undergo anesthesia and an attempt at retrograde stent placement. This technique protects the renal unit while the patients improves and can therefore allow stent placement at a later date through an antegrade approach.<sup>10</sup>

The increased likelihood of fistula resolution with stent placement (and not nephrostomy drainage alone) was elucidated by Dowling and coworkers.<sup>17</sup> In this series, all six of the ureterovaginal fistulas that had a stent placed successfully (antegrade or retrograde) required no further therapy; all three patients managed with nephrostomy alone failed the primary mode of therapy and subsequently required surgical intervention.<sup>17</sup> Further evidence that nephrostomy drainage alone is insufficient was reported by Schmeller and associates<sup>18</sup> in a review of 11 patients with ureterovaginal fistula. With this mode of management, six patients had a persistent fistula, and two had issues of ureteral stricture.<sup>18</sup> It is unlikely that nephrostomy tube drainage alone will lead to spontaneous resolution of a ureterovaginal fistula if the ureter is obstructed distally.

The goal of all minimally invasive therapy should be placement of a stent across the fistula and site of injury. This protects the kidney from potential damage from distal obstruction and can lead to spontaneous healing of the fistula. Some studies have reported resolution of up to 100% of ureterovaginal fistulas if the stent was left in place for an appropriate length of time.<sup>19,20</sup> If the stent is successful, it is important to remember that these patients are at risk for ureteral stricture in the future, and they should be followed in the early period after stent removal with regular renal ultrasound examinations. This approach allows appropriate evaluation for the presence of de novo hydronephrosis, which can indicate stricture formation. With current endourologic techniques, it is likely that a stricture could be managed with endoscopic techniques alone, avoiding the need for open intervention.<sup>19</sup>

The primary difficulty with most of these patients is stent placement. The injury that led to ureterovaginal fistula formation is often obstructing and does not allow easy, retrograde passage of a ureteral stent. An antegrade approach can allow for stent

passage when this cannot be done in a retrograde fashion.<sup>21</sup> Chang and colleagues<sup>20</sup> report successful resolution of ureteral fistula with an antegrade stent approach in 10 of 12 patients and recommend a stent diameter of 8 to 12 Fr to minimize the risk of subsequent ureteral stricture formation. If the stent cannot be passed by a retrograde or antegrade approach, a combined approach can be performed. Ureteroscopic assistance may be invaluable<sup>22</sup> and can be used in a “cut to the light” approach if the ureteral lumen is completely occluded.<sup>23</sup> This can be done with ureteroscopes proximal and distal to the level of the occlusion. If access to the kidney has yet to be obtained, this can be done with the patient in the prone split-leg position.<sup>23</sup> However, if access to the kidney has already been obtained and a percutaneous nephrostomy tube is in place, this can be done with the patient in a modified flank position to allow for simultaneous retrograde and antegrade approaches. Stents have been placed with passage of a wire from above through the strictured proximal segment and then retrieval from below with a ureteroscope; this technique requires only one ureteroscope and one surgeon, compared with cutting to the light, which is a two-surgeon procedure.<sup>24</sup> Fluoroscopy should be used, and after continuity is reestablished, the strictured segment should be incised proximal and distal to the lesion. All of these techniques were successful with strictures less than 2 cm long, and they should be performed by surgeons comfortable with the various endoscopic techniques that may be required.

### SURGICAL THERAPY

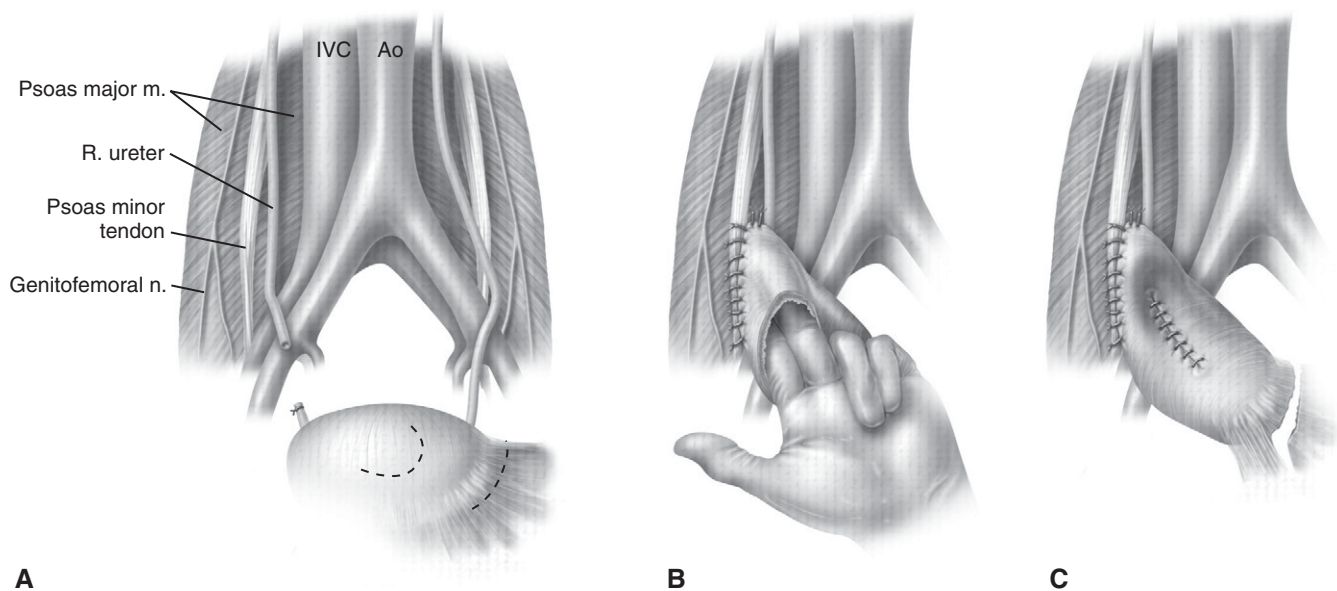

Open surgical intervention is indicated for patients who cannot be stented or in those who have failed attempts at minimally invasive therapy. How to define a failure of conservative therapy has not been addressed in the literature. It is hard to imagine a

ureterovaginal fistula spontaneously healing if leakage continues after a stent is in good position, and most fistulas that heal with drainage alone do so within 4 to 8 weeks after stent placement.<sup>19</sup> After it is clear that open surgery will be required, there is no reason to wait. Patients are bothered by the constant urinary leakage that occurs with this fistula, and evidence supports the success of early surgical intervention.<sup>7,25,26</sup> Surgical options include ureteroureterostomy, ureteroneocystostomy (often with a psoas hitch ureteral reimplant or Boari flap), ileal ureter, transureteroureterostomy, and nephrectomy.

Surgical tenets that have been recommended in the past when repairing a ureterovaginal fistula include the sacrifice of all abnormal ureter, no attempt to stay extraperitoneal, reestablishment of continuity between the ureter and bladder, and adequate postoperative drainage.<sup>25</sup> Excision of the affected segment of ureter and ureteroureterostomy is rarely indicated. The injury tends to be in the distal portion of the ureter, which does not lend itself to primary reanastomosis, and if done, it often results in postoperative ureteral stricture.

The most commonly performed intervention for the treatment of the ureterovaginal fistula is a ureteroneocystostomy. This allows for the injured distal area to be bypassed, obviating the need for to localize and dissect the injured portion of the ureter.

The method of ureteroneocystostomy depends on the level of ureteral injury or fistula, the level at which healthy ureter is found distally, and the degree of bladder mobility. Most patients can be managed with a psoas hitch ureteral reimplant (Fig. 84-2). This allows a tension-free anastomosis in most patients, with the psoas hitch also decreasing any risk of ureteral kinking caused by excessive bladder mobility. Goodwin and Scardino<sup>7</sup> had a success rate of 100% for the 16 patients in their series treated with ureteroneocystostomy. Bleland<sup>25</sup> found that reimplantation of the ureter with an anti-refluxing technique is preferable; however, a

**Figure 84-2** Diagram of psoas hitch ureteral reimplantation. **A**, The lateral attachments to the bladder on the side contralateral to the reimplantation side are taken down to allow for sufficient bladder mobility. A wide-based anterior bladder wall flap is made with a curvilinear incision. **B**, The bladder wall is mobilized superiorly. The posterosuperior bladder wall is secured to the psoas tendon with interrupted sutures. **C**, The ureter is reimplanted, and the bladder incision is closed. (Modified from Payne CK, Raz S: Ureterovaginal and related fistulae. In McAninch JW [ed]: *Traumatic and Reconstructive Urology*. Philadelphia, WB Saunders, 1996.)

ureteroneocystostomy without tunneling is unnecessary and is equally successful in regard to fistula resolution.<sup>27,28</sup> More important than an anti-refluxing anastomosis is a tension-free connection between the bladder and the ureter. Extra bladder mobility can be achieved with a psoas hitch by taking down the lateral attachments to the bladder on the side contralateral to the hitch.

If a psoas hitch is unable to reach the ureter without tension, another option is a Boari flap. One indication for using this primarily is the finding of a pelvic abscess at the time of reconstruction. The Boari flap allows the surgeon to perform the ureteroneocystostomy away from the infected field of the abscess.<sup>11</sup> More complex procedures such as transureteroureterostomy, renal autotransplantation and ileal ureter interposition are available, but they are rarely needed for this patient population.

Nephrectomy is a last resort and is rarely needed for these patients, as shown in the evolution of literature. Lee and Symonds<sup>29</sup> reported a nephrectomy rate of 48% in their review, with most nephrectomies performed before 1958. This rate

decreased to 5% as reported by Goodwin and Scardino in 1980,<sup>7</sup> and in current series, the rate is essentially zero among patients able to maintain appropriate follow-up.<sup>10,19</sup>

## CONCLUSIONS

Ureterovaginal fistula is a rare complication of pelvic surgery. It is most commonly seen after total abdominal and radical hysterectomy. Because symptoms of ureteral injury can be vague in the initial postoperative period, the physician should remain alert to the possibility, especially in patients with new-onset incontinence 1 to 2 weeks after pelvic surgery. The diagnosis can be made radiographically with IVU or retrograde pyelography or through the use of the double-dye test. Initial therapy with stent placement allows healing of the fistula in a high percentage of patients. If this is not possible, definitive therapy can be achieved with ureteroneocystostomy, usually in conjunction with a psoas hitch, with a high rate of success.

# URETHRAL DIVERTICULA

*Eric S. Rovner*

Diverticula of the female urethra present some of the most challenging diagnostic and reconstructive problems in female urology. These cases can be simultaneously fascinating and frustrating. Urethral diverticula have a bewildering variety of clinical manifestations, ranging from completely asymptomatic, incidentally noticed lesions identified on physical examination or radiographs to very debilitating, painful vaginal masses associated with incontinence, stones, or tumors. Anatomic variations between patients and in the location, size and complexity of these lesions ensure that each case is unique (Fig. 85-1).

Although described as early as the 19th century,<sup>1</sup> the modern era of diagnosing and treating female urethral diverticula began in 1956 with the advent of positive-pressure urethrography introduced by Davis and Cian.<sup>2</sup> Over the next several years, there was a dramatic increase in number of cases of urethral diverticula reported in the literature. Davis and Telinde's<sup>3</sup> series of 121 cases published in 1958 approximately doubled the number of cases reported during the previous 60 years. Development of adjuvant imaging techniques such as ultrasound and magnetic resonance imaging (MRI) during the past 3 decades has contributed greatly to understanding of urethral diverticula. With the expanding use of these imaging modalities, the diagnosis and evaluation of this condition continues to evolve. After the diagnosis is confirmed, definitive therapy often consists of operative excision and reconstruction. Successful surgical excision and reconstruction requires a detailed knowledge of the relevant operative anatomy, adherence to basic surgical tenets, and an ability to be creative and sometimes even improvisational in the operating room.

### ANATOMY OF THE FEMALE URETHRA

The normal female urethra is a musculofascial tube approximately 3 to 4 cm long. It extends from the bladder neck to the external urethral meatus, and it is suspended from the pelvic side wall and pelvic fascia (i.e., tendinous arc of the obturator muscle) by a sheet of connective tissue called the urethropelvic ligament. The urethropelvic ligament is composed of two layers of fused pelvic fascia that extend toward the pelvic side wall bilaterally (Fig. 85-2). This structure can be considered to have an abdominal side (i.e., endopelvic fascia) and a vaginal side (i.e., periurethral fascia). Within and between these two leaves of fascia lies the urethra.

The urethral lumen is lined by an epithelial layer that is a transitional cell type proximally and a nonkeratinized stratified squamous cell type distally. The urethra can be considered to be a rich, vascular, spongy cylinder surrounded by an envelope of consisting of smooth and skeletal muscle and fibroelastic tissue.<sup>4</sup> Within the thick, vascular lamina propria-submucosal layer are the periurethral glands (Fig. 85-3). These tubuloalveolar glands exist over the entire length of the urethra posterolaterally, but

they are most prominent over the distal two thirds, with most glands draining into the distal one third of the urethra. Skene's glands are the largest and most distal of these glands. These glands drain outside the urethral lumen, lateral to the urethral meatus. Most acquired female urethral diverticula originate from pathologic processes involving the periurethral glands.

The urethra has several muscular layers: an internal longitudinal smooth muscle layer, an outer circular smooth muscle layer, and a skeletal muscle layer. The skeletal muscle component spans much of the length of the urethra but is more prominent in the middle third. It has a U-shaped configuration and is deficient dorsally. Ventral to the urethra but separated from it by the periurethral fascia lies the anterior vaginal wall.

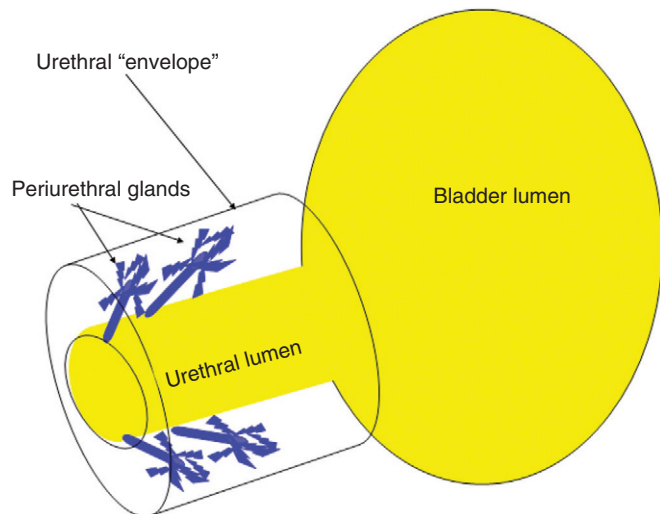

Arterial inflow to the urethra derives from two sources. The proximal urethra has a similar blood supply as the adjacent bladder, whereas the distal urethra derives its blood supply from

**Figure 85-1** The postvoid film after voiding cystourethrography demonstrates a collection of contrast below the bladder that suggests a urethral diverticulum.

**Figure 85-2** Representative anatomy of the mid-urethra in a coronal plane.

**Figure 85-3** Periurethral glands are located within the submucosa of the urethra deep to the muscular envelope. They drain distally but arborize proximally.

the terminal branches of the inferior vesical artery through the vaginal artery, which runs along the superior lateral aspect of the vagina. Lymphatic drainage of the female urethra is to the sacral lymph nodes, internal iliac nodes, and inguinal lymph nodes. Innervation to the female urethra is from the pudendal nerve (S2 to S4), and afferents from the urethra travel by means of the pelvic splanchnic nerves.

## URETHRAL DIVERTICULA

### Pathophysiology and Etiology

As conceptualized by Raz and colleagues,<sup>4</sup> a urethral diverticulum represents an epithelialized cavity dissecting within the confines of the fascia of the urethral pelvic ligament. This defect is often an isolated cystlike appendage with a single, discreet connection to the urethral lumen, called the neck or ostia (Fig. 85-4). However, complicated anatomic patterns may exist, and in certain cases, the urethral diverticula may extend partially (i.e., saddlebag urethral diverticula) around the urethra, anterior to the urethra,<sup>5</sup> or circumferentially about the urethra (Fig. 85-5).<sup>6</sup>

**Figure 85-4** Diagram of a urethral diverticulum. The urethral diverticulum forms within and between the layers of the urethral pelvic ligament.

**Figure 85-5** Different morphologies of urethral diverticula may exist.

The exact origin of urethral diverticula is unknown. A major debate in the earlier part of the 20th century focused on whether urethral diverticula were congenital or acquired lesions.<sup>7-9</sup> Although this condition exists in children, it may represent a different clinical entity from adult female urethral diverticula. Scattered reports of congenital urethral diverticula in female infants have been described.<sup>10</sup> Marshall<sup>11</sup> reported five cases of urethral diverticula in young females, and three diverticula underwent spontaneous regression. Congenital anterior urethral diverticulum is a well-described entity in boys,<sup>12-14</sup> but this is considered to be a different clinical entity from urethral diverticula in the female. Congenital Skene's glands cysts have been reported<sup>15,16</sup> but are considered to be rare. Diverticula in the pediatric population have been attributed to a number of congenital anomalies, including an ectopic ureter draining into a Gartner's duct cyst and a form fruste of urethral duplication.<sup>17-19</sup> Most urethral diverticula are likely to be acquired and are diagnosed in female adults. In two large series of urethral diverticula, there were no patients reported who were younger than 10 years old,<sup>20,21</sup> arguing against a congenital origin for these lesions. Although it is possible that there exists a congenital defect in patients that results in or represents a precursor to urethral diver-

tacula that becomes symptomatic only later in life, it remains unproven.

There are many theories regarding the formation of acquired urethral diverticula. For many years, acquired urethral diverticula were thought to be most likely caused by trauma from vaginal childbirth.<sup>22</sup> It was postulated that mechanical trauma during vaginal delivery resulted in herniation of the urethral mucosa through the muscular layers of the urethra, with the subsequent development of a urethral diverticula. However, 20% to 30% of patients in some urethral diverticula series are nulliparous,<sup>23,24</sup> which may significantly discount parity as a risk factor. Trauma with forceps delivery, however, has been reported to cause urethral diverticula,<sup>25</sup> as has the endoscopic injection of collagen.<sup>26</sup>

The periurethral glands are the probable site of origin of acquired urethral diverticula.<sup>4</sup> Huffman's<sup>27</sup> anatomic work with wax models of the female urethra were critical to the early theories regarding the pathophysiology of urethral diverticula and the involvement of the periurethral glands. By reviewing 10- $\mu$ m transverse sections, he refuted earlier anatomic descriptions of the glandular anatomy of the female. He characterized the periurethral glands as located primarily dorsolateral to the urethra, arborizing proximally along the urethra and draining into ducts located in the distal one third of the urethra (see Fig. 85-3). He found that periductal and interductal inflammation was common. In support of these observations and an infectious (acquired) cause of urethral diverticula, in more than 90% of urethral diverticula cases, the ostium is located posterolaterally in the middle or distal urethra, which corresponds to the location of the periurethral glands.<sup>28,29</sup>

Although there are probably other factors that facilitate the initiation, formation, or propagation of urethral diverticula, infection of the periurethral glands seems to be the etiologic factor in most cases. Peters and Vaughn<sup>30</sup> found a strong association between concurrent or previous infection with *Neisseria gonorrhoea* and urethral diverticula. However, the initial infection and especially subsequent reinfections may be caused by a variety of organisms, including *E. coli*, other coliform bacteria, and vaginal flora.

Urethral diverticula have been historically attributed to recurrent infection of the periurethral glands with obstruction, suburethral abscess formation, and subsequent rupture of these infected glands into the urethral lumen. Continual filling and pooling of urine in the resultant cavity may result in stasis, recurrent infection, and eventual epithelialization of the cavity, forming a permanent urethral diverticulum. This concept was first popularized by Routh<sup>31</sup> more than a century ago, and it has become the most widely accepted theory regarding the formation of female urethral diverticula. Reinfection, inflammation, and recurrent obstruction of the neck of the cavity are theorized to result in patients' symptoms and in enlargement of the diverticulum. This proposed pathophysiology appears to adequately explain the anatomic location and configuration of most urethral diverticula and is supported by the work of Huffman.<sup>27</sup> However, Daneshgari and colleagues<sup>32</sup> have reported noncommunicating urethral diverticula diagnosed by MRI. Whether this lesion represents a forme fruste of urethral diverticula or simply an obstructed urethral diverticula ostium is unclear.

Raz and colleagues<sup>4</sup> formulated a modern hypothesis regarding the pathogenesis of urethral diverticula through extensive clinical experience with this entity, including the diagnosis, imaging, and surgical repair of urethral diverticula. These inves-

tigators propose that acquired urethral diverticula result from infection and obstruction of the periurethral glands. These glands are normally found in the submucosal layer of the spongy tissue of the distal two thirds of the urethra. Repeated infection and abscess formation in these obstructed glands eventually result in enlargement and expansion. Initially, the expanding mass displaces the spongy tissue of the urethral wall and then enlarges to disrupt the muscular envelope of the urethra. This results in herniation into the periurethral fascia. The enlarging cavity can then expand and dissect within the leaves of the periurethral fascia and urethropelvic ligament. This expansion occurs most commonly ventrally, resulting in the classic anterior vaginal wall mass palpated on physical examination in some patients with urethral diverticula. However, the lesions may also expand laterally or even dorsally about the urethra. Eventually, the abscess cavity ruptures into the urethral lumen, resulting in the communication between the urethral diverticula and the urethral lumen. An appreciation of the anatomy and pathophysiology of urethral diverticula is important in understanding the surgical approach to the excision and reconstruction of these lesions.

### Prevalence

Moore<sup>33</sup> stated that urethral diverticula as an entity is "found in direct proportion to the avidity with which it is sought." Although no longer considered a rare lesion, fewer than 100 cases of urethral diverticula were reported in the literature before 1950. With the development of sophisticated imaging techniques, including positive-pressure urethrography in the 1950s, the diagnosis of urethral diverticula became increasingly common.

The true prevalence of female urethral diverticula is unknown, but it is reported to occur in up to 1% to 6% of adult females in some series. Determining the true prevalence of urethral diverticula would require appropriate screening and imaging of a large number of symptomatic and asymptomatic adult female subjects in a primary care setting, which has not been done. Bruning<sup>34</sup> found urethral diverticula in 3 of 500 female autopsy specimens. In 1967, Andersen reported the results of positive-pressure urethrography on 300 women with cervical cancer but without lower urinary tract symptoms and found urethral diverticula in 3%.<sup>35</sup> Aldridge<sup>36</sup> reported a prevalence of urethral diverticula in 1.4% of women presenting with incontinence and related symptoms. Stewart<sup>37</sup> found urethral diverticula in 16 of 40 highly symptomatic females investigated with positive-pressure urethrography. Endorectal coil MRI was performed on 140 consecutive female patients with lower urinary tract symptoms, and the incidence of urethral diverticula was approximately 10%.<sup>38</sup> However, this represented a series of symptomatic females at a tertiary referral center, which probably did not reflect the general population.

Some series have suggested a definite racial predilection, with blacks being as much as six times as likely to develop urethral diverticula as their white counterparts.<sup>20</sup> The reasons for this racial distribution is not well understood. It has not been confirmed in some modern case series, and it may reflect referral bias at the urban academic centers in the original reported series.<sup>39</sup>

### Diverticular Anatomy

Most commonly, urethral diverticula represent an epithelialized cavity with a single connection to the urethral lumen. The size of

**Figure 85-6** T2-weighted magnetic resonance images demonstrate a large urethral diverticulum extending to the trigone of the bladder in the sagittal (A), axial (B), and coronal planes (C).

the lesion may vary from only a few millimeters to several centimeters. The size may vary over time because of inflammation and intermittent obstruction of the ostia with subsequent drainage into the urethral lumen.

The epithelium of urethral diverticula may be columnar, cuboidal, stratified squamous, or transitional. In some cases, the epithelium is absent, and the wall of the urethral diverticula consists of only fibrous tissue. These lesions are found within the periurethral fascia bordered by the anterior vaginal wall ventrally. Urethral diverticula are most often located in the sagittal plane, and they are centered at the level of the middle third of the urethra, with the luminal connection or ostia located posterolaterally. They may extend distally along the vaginal wall almost to

the urethral meatus or proximally up to and beyond the bladder neck, underneath the trigone of the bladder (Fig. 85-6). A bewildering array of configurations can be identified on imaging and at surgical exploration (Table 85-1). In the axial plane, the urethral diverticula cavity may extend laterally along the urethral wall, and in some cases, they may extend around to the dorsal side of the urethra or wrap circumferentially around the entire urethra. Urethral diverticula may be bilobed (i.e., dumbbell shaped), extending across the midline in a so-called saddlebag configuration (see Fig. 85-5). Multiple loculations are not uncommon, and at least 10% of patients have multiple urethral diverticula at presentation. Various degrees of sphincteric compromise may exist because of the location of diverticulum relative to the

### Box 85-1 Signs and Symptoms of Urethral Diverticula

#### Symptoms

Vaginal or pelvic mass  
 Pelvic pain  
 Urethral pain  
 Dysuria  
 Urinary frequency  
 Postvoid dribbling  
 Dyspareunia  
 Urinary urgency  
 Incontinence  
 Urinary hesitancy  
 Vaginal or urethral discharge  
 Double voiding  
 Sense of incomplete emptying

#### Signs

Recurrent urinary tract infections  
 Hematuria  
 Vaginal or perineal tenderness  
 Urinary retention  
 Vaginal mass  
 Urethral discharge with stripping of anterior vaginal wall

proximal and distal urinary sphincter mechanisms. This is a consideration for surgical repair.

### Presentation

Most patients with urethral diverticula present between the third and seventh decade of life.<sup>7,23,33,40,41</sup> The presenting symptoms and signs of patients with urethral diverticula are protean (Box 85-1). The classic presentation of urethral diverticula has been described historically as the *three Ds*: dysuria, dyspareunia, and dribbling (postvoid). However, individually or collectively, these symptoms are neither sensitive nor specific for urethral diverticula. Although presentation is highly variable, the most common symptoms are irritative (e.g., frequency, urgency) lower urinary tract symptoms, pain, and infection.<sup>20,21,30,42</sup> Dyspareunia is reported by 12% to 24% of patients.<sup>20,21</sup> Approximately 5% to 32% of patients complain about postvoid dribbling.<sup>20,23</sup> Recur-

rent cystitis or urinary tract infection is a frequent presentation in one third of patients,<sup>20,23</sup> likely due to urinary stasis in the urethral diverticula. Multiple bouts of recurrent cystitis should alert the clinician to the possibility of a urethral diverticulum. Other complaints include pain, a vaginal mass, hematuria, vaginal discharge, obstructive symptoms or urinary retention, and stress or urge incontinence. Up to 20% of patients diagnosed with urethral diverticula may be completely asymptomatic. Patients may present with complaints of a tender or nontender anterior vaginal wall mass, which on gentle compression may reveal retained urine or purulent discharge through the urethral meatus. Although spontaneous rupture of these lesions is rare, urethro-vaginal fistula may result under these circumstances.<sup>43</sup>

The size of the urethral diverticula does not correlate with symptoms. In some cases, very large urethral diverticula may result in minimal symptoms, and some urethral diverticula that are not palpable may result in considerable patient discomfort and distress. Symptoms may wax and wane and even resolve for long periods. The reasons for these exacerbations and remissions are poorly defined but may be related to periodic and repeated episodes of infection and inflammation.

Because many of the symptoms associated with urethral diverticula are nonspecific, patients may be misdiagnosed and treated for years for a number of unrelated conditions before the diagnosis of urethral diverticula is made. This may include therapies for interstitial cystitis, recurrent cystitis, vulvodynia, endometriosis, vulvovestibulitis, and other conditions. In one series of 46 consecutive women eventually diagnosed with urethral diverticula, the mean interval from onset of symptoms to diagnosis was 5.2 years.<sup>44</sup> In this series, women consulted with an average of nine physicians before the definitive diagnosis was made, despite the fact that 52% of women had a palpable mass on examination. This underscores the importance of a baseline level of suspicion and a thorough pelvic examination in female patients complaining of lower urinary tract symptoms or other symptoms that may be associated with urethral diverticula.

### Evaluation and Diagnosis

The diagnosis and complete evaluation of urethral diverticula can be made with a combination of a thorough history; physical examination; appropriate urine studies, including urine culture and analysis; endoscopic examination of the bladder and urethra; and selected radiologic imaging. A urodynamic study may also be used in selected cases.

**Figure 85-7** Large anterior vaginal wall mass. The urethral catheter is seen superiorly and a weighted vaginal speculum is seen inferiorly. Scott retractor hooks are seen exposing the anterior vaginal wall in this operating room photo.

### Physical Examination

During physical examination the anterior vaginal wall should be carefully palpated for masses and tenderness. The location, size, and consistency of suspected urethral diverticula should be recorded. Most urethral diverticula are located ventrally over the middle and proximal portions of the urethra, corresponding to the area of the anterior vaginal wall 1 to 3 cm inside the introitus (Fig. 85-7). However, urethral diverticula also may be located anterior to the urethra or extend partially or completely around the urethral lumen. These particular configurations may have significant implications when undertaking surgical excision and reconstruction. Urethral diverticula may extend proximally toward the bladder neck. The urethral diverticula may produce distortion of the bladder outlet and trigone of the bladder on cystoscopy or on radiographic imaging, and special care should be taken during surgical excision and reconstruction because of concerns about intraoperative bladder and ureteral injury and the potential for development of postoperative voiding dysfunction and urinary incontinence. More distal vaginal masses or perimeatal masses may represent other lesions, including abnormalities of Skene's glands. The differentiation between these lesions sometimes cannot be made on the basis of a physical examination alone and may require additional radiologic imaging. A particularly hard anterior vaginal wall mass may indicate a calculus or cancer within the urethral diverticula, and it mandates further investigation. During physical examination, the urethra may be gently stripped or milked distally in an attempt to express purulent material or urine from within the urethral diverticula cavity. Although often described for the evaluation of urethral diverticula, this maneuver is not successful in producing the diagnostic discharge through the urethral meatus in most patients.<sup>39</sup>

The vaginal walls are assessed for atrophy, rugation, and elasticity. Poorly estrogenized, atrophic tissues are important to identify if surgical treatment is being considered. These tissues are often surgically mobilized and may be used for flaps during excision and reconstruction. The distal vagina and vaginal introitus are also assessed for capacity. These factors may influence surgical planning because a narrow introitus can make surgical exposure difficult and may mandate an episiotomy. During the physical examination, a provocative maneuver to elicit stress

incontinence should be performed, and the presence or absence of vaginal prolapse should be assessed.

### Urine Studies

Urinalysis and urine culture should be performed. The most common organism isolated in patients with urethral diverticula is *Escherichia coli*. However, other gram-negative enteric flora and *Neisseria gonorrhoea*, *Streptococcus*, and *Staphylococcus* are often present.<sup>3,45</sup> A sterile urine culture does not exclude infection because these patients are often on antibiotic therapy at presentation. For patients with irritative symptoms or when a malignancy is suspected, urine cytology can be performed.

### Cystourethroscopy

Cystourethroscopy is performed in an attempt to visualize the urethral diverticular ostia and to rule out other causes of the patient's lower urinary tract symptoms. A specially designed female cystoscope can be helpful in evaluating the female urethra. The short beak maintains the discharge of the irrigation solution immediately adjacent to the lens, which aids in distention of the relatively short (compared with the male) urethra, permitting improved visualization. It may also be advantageous to compress the bladder neck while simultaneously applying pressure to the diverticular sac with an assistant's finger. Luminal discharge of purulent material can often be seen with this maneuver or with simple digital compression of the urethral diverticula during urethroscopy. The urethral diverticular ostium is most often located posterolaterally at the level of the mid-urethra, but it can be very difficult to identify in some patients. The success rate in identifying a diverticular ostium on cystourethroscopy is highly variable and is reported to be between 15% and 89%.<sup>20,23,39</sup> Patients with urethral diverticula are often highly symptomatic, and endoscopic examination can be difficult to initiate or complete. A positive examination result may help in surgical planning, but the failure to locate an ostium on cystourethroscopy should not influence the decision to proceed with further investigations or surgical repair.

### Urodynamics

For patients with urethral diverticula and urinary incontinence or significant voiding dysfunction, a urodynamic study can be helpful.<sup>46-48</sup> Urodynamics may document the presence or absence of stress urinary incontinence before repair. Approximately 50% of women with urethral diverticula are found to have stress urinary incontinence on urodynamic evaluation.<sup>23,49</sup> A video urodynamic study combines a voiding cystourethrogram and a urodynamic study, consolidating the diagnostic evaluation and decreasing the number of required urethral catheterizations during the patient's clinical workup. For patients undergoing surgery for urethral diverticula with coexistent, symptomatic stress urinary incontinence demonstrated on physical examination or by urodynamic study or for those found to have an open bladder neck on preoperative evaluation, concomitant anti-incontinence surgery can be offered. Many investigators have described successful concomitant repair of urethral diverticula and stress incontinence in the same operative setting.<sup>23,49-51</sup> Alternatively, on urodynamic evaluation, a small number of patients may have evidence of bladder outlet obstruction due to the obstructive or mass effects of the urethral diverticula on the urethra. Stress urinary incontinence may coexist with obstruction,<sup>52</sup> but both conditions can be treated successfully with a carefully planned and executed operation. Urethral pressure pro-

filometry has also been used by some physicians to assess or diagnose patients with urethral diverticula by noticing a biphasic pattern at the level of the lesion during the study.<sup>47,48,53</sup>

### Imaging

Critically important to the success of surgical treatment of female urethral diverticula is high-quality preoperative imaging. Along with its utility as a diagnostic entity, radiologic imaging should provide an accurate reflection of the anatomy of the urethral diverticulum, including its relationship to the proximal urethra and bladder neck.

Several imaging techniques have been applied to the study of female urethral diverticula, and no single study can be considered the gold standard for this purpose. Each technique has relative advantages and disadvantages, and the ultimate choice of diagnostic study in many centers depends on several factors, including local availability, cost, and the experience and expertise of the radiologist. Available techniques for the evaluation of urethral diverticula include double-balloon positive-pressure urethrography (PPU), voiding cystourethrography (VCUG), intravenous urography (IVU), ultrasonography, and magnetic resonance imaging (MRI) with or without an endoluminal coil (eMRI).

#### *Positive-Pressure Urethrography, Voiding Cystourethrography, and Intravenous Urography*

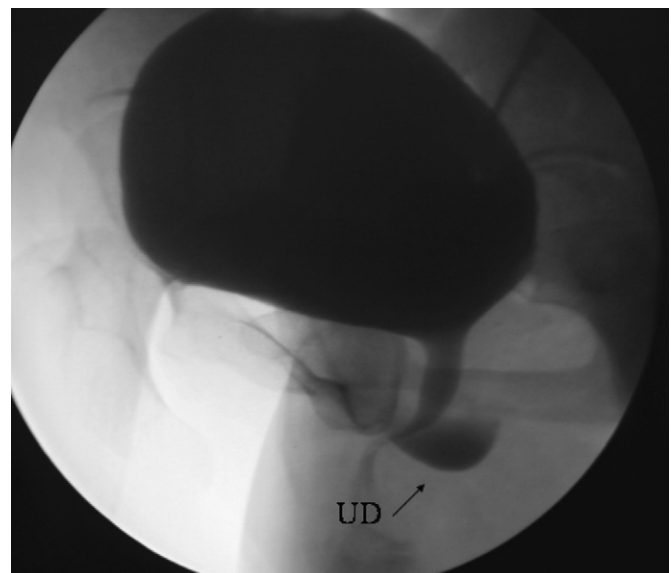

Classically, double-balloon PPU had been considered to be the best study for the diagnosis and assessment of female urethral diverticula.<sup>2,21,23,54</sup> With this technique, a highly specialized catheter with two balloons separated by several centimeters is inserted into the female urethra (Fig. 85-8). This catheter contains a channel within the catheter that exits through a side hole between the two balloons. One balloon is positioned adjacent to the external urethral meatus, and the other balloon is situated at the bladder neck. Both balloons are inflated, sealing the urethral lumen. Contrast is then infused through the channel under slight pressure, distending the urethral lumen between the two balloons and forcing contrast into the urethral diverticula, thereby opacifying the cavity. This highly specialized study provides outstanding images of the urethra and urethral diverticula, and unlike

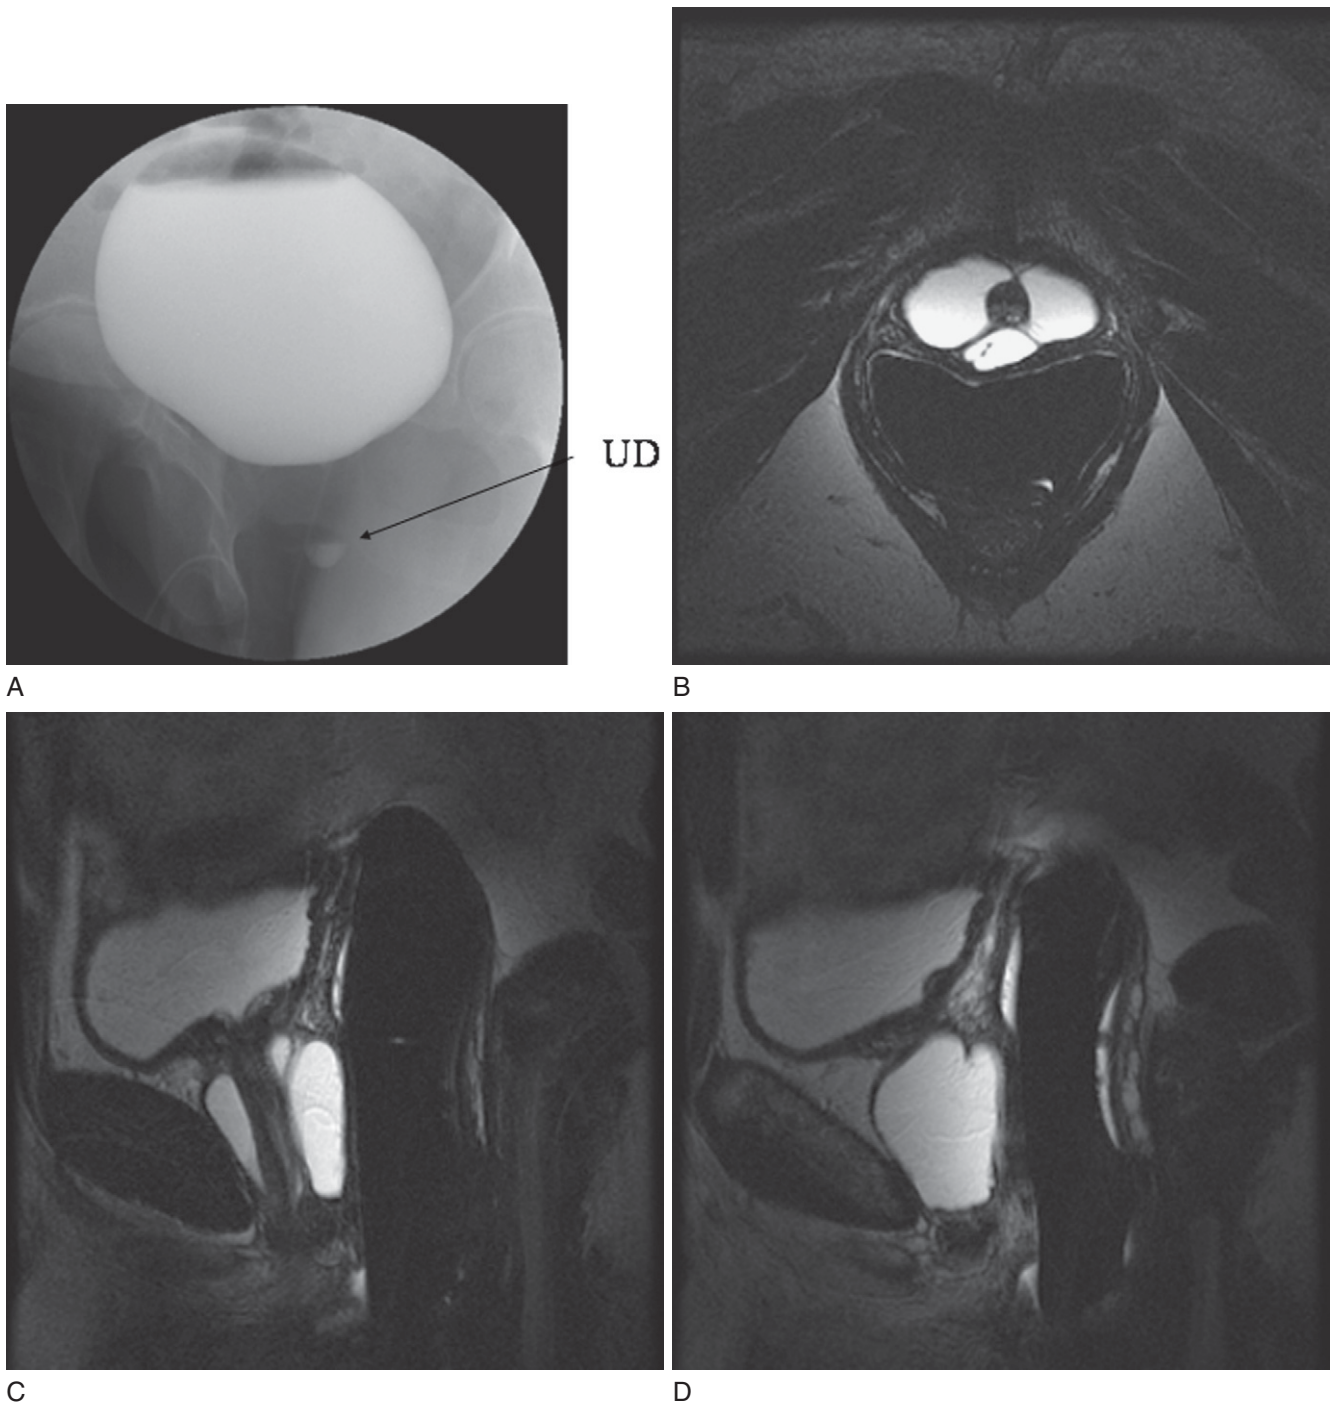

**Figure 85-8** Diagram of a double-balloon catheter. Balloons are inflated at the bladder neck and external urethral meatus. Contrast is then infused through an additional port, and it exits through a side hole between the balloons, distending the urethral lumen under pressure and filling the urethral lumen and diverticulum (UD).

VCUG, it does not depend on the patient successfully voiding during the study. However, PPU is not widely performed clinically. It is a complicated study requiring a very specific type of modified urethral catheter and expertise in the performance and interpretation of the study by the radiologist. It is invasive, requiring catheterization of the urethra, and in the setting of acute inflammation commonly seen with female urethral diverticula, it can cause considerable patient discomfort and distress. Noncommunicating urethral diverticula<sup>32</sup> and loculations within existing urethral diverticula cannot be visualized with PPU because the contrast does not enter and fill these areas in the absence of a connection to the urethral lumen.

As an alternative to PPU, VCUG may provide excellent imaging of urethral diverticula (Fig. 85-9). It is widely available and is a familiar diagnostic technique to most radiologists. Sensitivity for urethral diverticula with this technique varies from 44% to 95%.<sup>23,55</sup> After a scout film, the bladder is filled through a urethral catheter. The catheter is removed at bladder capacity, and images of the bladder and bladder neck are obtained. Ideally, voiding images are obtained in the anteroposterior, lateral, and oblique projections. A postvoid film is obtained. Although VCUG is probably the most widely used study for the diagnosis and evaluation of patients with known or suspected urethral diverticula, it has several limitations. VCUG is invasive, requiring catheterization of the urethra for bladder filling. This can result in considerable patient discomfort and may risk translocating bacteria from an infected urethral diverticulum into the bladder during catheterization, resulting in bacterial cystitis. This is also a risk of PPU. Successful imaging of the urethral diverticulum occurs only during the voiding phase of the VCUG with subsequent filling of the urethra. Occasionally, only the postvoid film demonstrates the urethral diverticulum.<sup>56-58</sup> Not uncommonly, patients are somewhat inhibited or otherwise unable to void during VCUG for a variety of reasons, including pain from the initial urethral catheterization. Unfortunately, in the absence of contrast entering the urethra, opacification of the diverticulum does not occur. An inability to generate an adequate flow rate

**Figure 85-9** A voiding cystourethrogram demonstrates a urethral diverticulum (UD).

**Figure 85-10** Voiding cystourethrography (VCUG) and magnetic resonance imaging (MRI) demonstrated a large, circumferential urethral diverticulum (UD). VCUG (A) shows poor opacification of the proximal urethra with suboptimal distention of the urethral diverticulum due to a poor voiding effort. Endoluminal MRI demonstrates the full extent and complexity of the lesion on the T2-weighted axial (B), midline sagittal (C), and parasagittal (D) images.

during the VCUG results in suboptimal filling of the urethral diverticulum and an underestimation of its size and complexity (Fig. 85-10). Some urethral diverticula may not opacify after a technically successful VCUG because of acute inflammation of the ostium or neck of the diverticulum or because the diverticulum does not otherwise communicate with the urethral lumen. These noncommunicating urethral diverticula exist within the

urethropelvic ligament and can be successfully imaged with cross-sectioning techniques such as MRI.<sup>32</sup>

Three studies have compared VCUG with PPU and concluded that PPU is a more sensitive test for urethral diverticula than VCUG.<sup>55,59,60</sup> In one study of 32 patients, VCUG failed to demonstrate the urethral diverticula in 69% of patients, whereas PPU failed to demonstrate the lesion in only 6%.<sup>55</sup>

**Figure 85-11** Surface coil, T2-weighted magnetic resonance imaging demonstrates a urethral diverticulum in the sagittal (A) and axial (B) planes.

IVU may be considered in patients in whom it is necessary to delineate the upper urinary tract or to rule out an ectopic ureterocele.<sup>61</sup> The postvoid film of the urogram can be helpful for the diagnosis of urethral diverticula in some patients.<sup>56,57</sup>

### Ultrasound

Ultrasound has been advocated for the preoperative assessment of urethral diverticula.<sup>62-71</sup> Abdominal, transvaginal, translabial, and transurethral techniques have been described. Transvaginal imaging often provides information regarding the size and location of urethral diverticula. On ultrasonographic imaging, the urethral diverticulum appears as an anechoic or hypoechoic area with enhanced through transmission. Ultrasound is relatively noninvasive and does not expose the patient to radiation. Another significant advantage of ultrasound is that successful imaging of urethral diverticula does not require voiding. However, ultrasound may not produce detailed, high-resolution images that demonstrate precise surgical anatomy. This study can be somewhat operator dependent. Transurethral ultrasound techniques are evolving and may provide an incremental improvement in resolution. Similar to PPU and VCUG, the transurethral techniques are invasive because the ultrasound probe is placed per urethra and can cause patient discomfort and bacterial seeding of the lower urinary tract.

### Magnetic Resonance Imaging

As an alternative to the radiologic investigations described previously, MRI permits relatively noninvasive, high-resolution, multiplanar imaging of urethral diverticula. Urethral diverticula appear as areas of decreased signal intensity on T1-weighted images compared with the surrounding soft tissues, and they have high signal intensity on T2-weighted images (see Fig. 85-10). Additional advantages of MRI compared with PPU and VCUG are that successful imaging of urethral diverticula is wholly independent of voiding and free from ionizing radiation. Surface-coil (Fig. 85-11)<sup>72,73</sup> and endoluminal techniques<sup>38,60,74,75</sup> have been described. Endoluminal imaging (eMRI) places the magnetic coil into a body cavity adjacent to the area of interest. This location produces an improved signal-to-noise ratio and high-resolution imaging of these areas.<sup>74,75</sup> For the evaluation of urethral diverticula, the coil is placed intravaginally or intrarectally (Fig. 85-12). Surface-coil MRI and eMRI appear to be superior to VCUG and PPU in the evaluation of urethral diverticula,<sup>74,76,77</sup> but the technology is expensive and not widely available. The few contraindications to MRI for urethral diverticula include metallic foreign body fragments, claustrophobia, and an inability to tolerate the endoluminal probe.

**Figure 85-12** Sagittal and axial, T2-weighted endoluminal magnetic resonance images show the relevant anatomy of a patient with a urethral diverticulum (UD).

**Figure 85-13** Large anterior vaginal wall leiomyoma.

#### Differential Diagnosis of Urethral Diverticula: Periurethral Masses Other Than Urethral Diverticula

Periurethral masses other than urethral diverticula comprise a wide spectrum of conditions that must be differentiated from each other and urethral diverticula. It may be possible to make a definitive diagnosis based on the history and physical examination alone; in other cases, judicious use of radiographic and cystoscopic studies is necessary to exclude urethral diverticula.

#### Vaginal Leiomyoma

Vaginal leiomyoma is a benign, mesenchymal tumor of the vaginal wall that arises from smooth muscle elements. It commonly manifests as a smooth, round mass on the anterior vaginal wall (Fig. 85-13). It is an uncommon lesion; approximately 300 cases have been reported in the literature.<sup>78</sup> In a series of 79 patients with periurethral masses, 4 (5%) were found to have leiomyoma.<sup>79</sup> These benign tumors were apparent on physical examination as freely mobile, nontender masses on the anterior vaginal wall. They may be misdiagnosed as urethral diverticula.<sup>80</sup> Symptoms, if they exist, are usually related to the size of the lesion

**Figure 85-14** Skene's gland cyst in a 19-year-old woman. Notice the large periurethral mass with displacement of the urethral meatus.

and include a mass effect, obstruction, pain, and dyspareunia. They commonly present in the fourth to fifth decade. Like uterine leiomyomas, these lesions are usually estrogen dependent and have been demonstrated to regress during menopause.<sup>81</sup> Excision or enucleation<sup>78</sup> using a vaginal approach is often curative and is recommended to confirm the diagnosis, exclude malignant histology, and alleviate symptoms.

#### Skene's Gland Abnormalities

Skene's gland cysts and abscesses are similar lesions that are differentiated based on clinical findings (Fig. 85-14). Both lesions manifest as small, cystic masses just lateral or inferolateral to the urethral meatus. They may be lined with transitional or stratified

squamous epithelium. Abscesses may be extremely tender and inflamed, and in some cases, purulent fluid can be expressed from the ductular orifice. Unlike urethral diverticula, these lesions do not communicate with the urethral lumen. Skene's gland cysts may be seen in neonatal girls and young to middle-aged female patients.<sup>16</sup> Symptoms may include dysuria, dyspareunia, obstruction, and pain. Differentiation from urethral diverticula can often be made on the basis of the physical examination, because these lesions are located relatively distally on the urethra, often distorting the urethral meatus, compared with urethral diverticula, which most commonly occur over the middle and proximal urethra. Various treatments for Skene's glands abnormalities have been described, including aspiration, marsupialization, incision and drainage and simple excision.

Adenocarcinoma arising in Skene's glands has been reported. Because of homology of these glands with the prostate, these patients may demonstrate elevated prostate-specific antigen (PSA) levels, which normalize with treatment.<sup>82</sup>

### *Gartner's Duct Cysts*

Gartner's duct cysts represent mesonephric remnants and are found on the anterolateral vaginal wall from the cervix to the introitus. Because they are mesonephric remnants, they may drain ectopic ureters from poorly functioning or nonfunctioning upper-pole moieties in duplicated systems. They have been reported with single-system ectopia, although this is much less common in female patients.<sup>83,84</sup> It is not clear what proportion of patients with Gartner's duct cysts have ipsilateral renal abnormalities, but upper tract evaluation is recommended. In contrast, approximately 6% of subjects with unilateral renal agenesis have a Gartner's duct cyst.<sup>85</sup> Up to 50% of patients with Gartner's duct cysts and renal dysplasia may also have ipsilateral müllerian duct obstruction.<sup>86</sup>

Treatment depends on symptoms and association with ectopic ureters. If the lesions are asymptomatic and are associated with a nonfunctioning renal moiety, they can be observed. Aspiration and sclerotherapy have been successful.<sup>87</sup> Simple excision or marsupialization has been recommended for symptomatic lesions. If the cyst is associated with a functioning renal moiety, treatment must be individualized.

### *Vaginal Wall Cysts*

Vaginal wall cysts usually manifest as small, asymptomatic masses on the anterior vaginal wall.<sup>88</sup> They may arise from multiple cell types: mesonephric (Gartner's duct cysts), paramesonephric (müllerian), endometriotic, urothelial, or epidermoid (inclusion cyst) tissues. A specific diagnosis cannot be reliably made until the specimen is removed and examined by a pathologist. The histologic subtype is usually of little consequence, although epidermoid cysts are usually associated with previous trauma or vaginal surgery. Pradhan and Tobon<sup>89</sup> described the pathologic characteristics of 43 vaginal cysts removed from 41 women over a 10-year period. The derivation of the cyst was müllerian in 44%, epidermoid in 23%, and mesonephric in 11%. The others were Bartholin gland, endometriotic, and indeterminate types. As with other periurethral masses, they must be differentiated from urethral diverticula. Treatment is usually by simple excision in symptomatic patients.

### *Urethral Mucosal Prolapse*

Urethral prolapse manifests as a circumferential herniation or eversion of the urethral mucosa at the urethral meatus. The pro-

lapsed mucosa commonly appears as a beefy red, doughnut-shaped lesion that completely surrounds the urethral meatus. It may be asymptomatic or manifest with bleeding, spotting, pain, or urinary symptoms. It is commonly seen in two populations: postmenopausal women and prepubertal girls. Although thought to be more common in young African American girls, later series do not confirm this predilection.<sup>90,91</sup> In children, it is often causally related to a Valsalva maneuver or constipation. Eversion of the mucosa may occur because of a pathologically loose attachment between smooth muscle layers of the urethra.<sup>92</sup> The cause is much less clear for postmenopausal women, although it has been epidemiologically linked to estrogen deficiency.

Treatment may be medical or surgical. Medical treatment involves topical creams (e.g., estrogen, anti-inflammatory ointment) and sitz baths. Various surgical techniques have been described, including cauterization, ligation around a Foley catheter, and complete circumferential excision. Circumferential excision with suture reapproximation of the remaining urethral mucosa to the vaginal wall can be performed with few complications. Rudin and colleagues<sup>91</sup> reported outcomes for 58 girls with urethral prolapse. Medical treatment was initially successful in 20 patients, among whom there were five recurrences. The remaining 38 patients failed initial conservative management and underwent surgical excision, with four complications, including urethral stenosis in two. Jerkins and coworkers<sup>93</sup> found superior results in surgically treated patients compared with medical management or catheter ligation.

### *Urethral Caruncle*

Urethral caruncle is an inflammatory lesion of the distal urethra that is most commonly diagnosed in postmenopausal women. It usually appears as a reddish, exophytic mass at the urethral meatus that is covered with mucosa. These lesions are often asymptomatic and identified incidentally on gynecological examination. When irritated, they may cause underwear spotting or become painful. Less commonly, they may cause voiding symptoms. They are etiologically related to mucosal prolapse. Chronic irritation contributes to hemorrhage, necrosis, and inflammatory growth of the tissue, which corresponds to the histology of excised lesions. If the lesion is atypical in appearance or behavior, excision may be warranted to exclude other entities. Intestinal metaplasia, tuberculosis, melanoma, and lymphoma have been reported to coexist with or mimic urethral caruncles.<sup>94-98</sup>

There is a paucity of literature regarding optimal treatment of urethral caruncle. Most urologists recommend initial conservative management with topical estrogen or anti-inflammatory creams and sitz baths. Large or refractory lesions may be managed with simple excision. The tip of the lesions should be grasped and traction employed to fully expose the base of the caruncle. The lesion can then easily be excised. If a large defect remains, the mucosa may be reapproximated with absorbable suture. In most instances, the urethral mucosa heals around a Foley catheter, which may be left in place for several days.

### **Classification of Urethral Diverticula**

Although not widely adopted, a classification system for urethral diverticula has been proposed by Leach and associates.<sup>99</sup> This staging system for urethral diverticula, called the L/N/S/C3 classification system, is similar to that used for cancer staging and is based on several characteristics of urethral diverticula, including location, number, size, anatomic configuration, site of commu-

nication to the urethral lumen, and continence status of the patient. This system attempts to standardize description of urethral diverticula, but it has not been prospectively applied or validated by other investigators. Another proposed classification scheme uses the location of the urethral diverticula as the primary determinant of surgical approach, with distal lesions undergoing marsupialization and more proximal lesions undergoing excision and reconstruction.<sup>40</sup>

A classification system proposed by Leng and McGuire<sup>100</sup> divides urethral diverticula into two categories based on the presence or absence of a preserved periurethral fascial layer. In some patients with urethral diverticula who have undergone prior vaginal or urethral surgery, the periurethral fascial layer may be deficient, resulting in a pseudodiverticulum. These investigators suggest that the recognition of this anatomic configuration has important implications for surgical reconstruction. Patients may require additional reconstruction or interposition of a tissue flap or graft to buttress the repair and prevent recurrence or postoperative urethrovaginal fistula formation.

## SURGICAL REPAIR OF FEMALE URETHRAL DIVERTICULA

### Indications for Repair

Although often highly symptomatic, not all urethral diverticula mandate surgical excision. Some patients may be asymptomatic at presentation, and the lesion is incidentally diagnosed on imaging for another condition or incidentally identified on routine physical examination. Other patients may be unwilling or medically unable to undergo surgical removal. Very little is known regarding the natural history of untreated urethral diverticula. Whether these lesions will progress in size, symptoms, or complexity with time is unknown. For these reasons and because of the lack of symptoms in selected cases, some patients may not desire surgical therapy. However, there are many reports in the literature of carcinomas arising in urethral diverticula,<sup>101-110</sup> and it is possible that certain carcinomas arising in urethral diverticula are asymptomatic and may not be prospectively identified on radiologic imaging. Counseling and ongoing monitoring is necessary for patients who elect primary nonoperative management.

Symptomatic patients, including those with dysuria, refractory and bothersome postvoid dribbling, recurrent urinary tract infections, dyspareunia, and pelvic pain in whom the symptoms can be attributed to the urethral diverticula, may be offered surgical excision. Those with urethral diverticula and symptomatic stress urinary incontinence can be considered for a concomitant anti-incontinence procedure at the time of urethral diverticular excision (discussed later).

### Techniques for Repair

#### Alternative Techniques

A variety of surgical interventions for urethral diverticula have been reported since 1805, when Hey<sup>1</sup> described transvaginal incision of the urethral diverticula and packing of the resulting cavity with lint. Approaches have included transurethral<sup>20</sup> and open<sup>111,112</sup> marsupialization, endoscopic unroofing,<sup>113,114</sup> fulguration,<sup>115</sup> incision and obliteration with oxidized cellulose<sup>116</sup> or polytetrafluoroethylene,<sup>117</sup> coagulation,<sup>117</sup> and excision with

## Box 85-2 Principles of Transvaginal Urethral Diverticulectomy

- Mobilization of a well-vascularized anterior vaginal wall flap (or flaps)
- Preservation of the periurethral fascia
- Identification and excision of the neck of the urethral diverticulum or ostia
- Removal entire urethral diverticulum wall or sac (mucosa)
- Watertight urethral closure
- Multilayered, non-overlapping closure with absorbable suture
- Closure of dead space
- Preservation or creation of continence

reconstruction. Most commonly, complete excision and reconstruction are performed as described subsequently. However, for distal lesions, a transvaginal marsupialization as described by Spence and Duckett<sup>111,118</sup> and Roehrborn<sup>112</sup> may reduce operative time, blood loss, and recurrence rate. During this procedure, care must be taken to avoid aggressively extending the incision proximally, which could result in vaginal voiding or potentially damage the proximal and distal sphincteric mechanism, resulting in stress urinary incontinence. This approach is probably applicable only to urethral diverticula in selected cases involving the distal one third of the urethra. It is not commonly performed.

#### Excision and Reconstruction

Excision and reconstruction is probably the most common surgical approach to urethral diverticula in the modern era. The principles of the urethral diverticulectomy operation have been well described (Box 85-2). There are a few issues about which some surgeons may disagree, including the type of vaginal incision (inverted U versus inverted T), whether it is necessary to remove the entire mucosalized portion of the lesion, and the optimal type of postoperative catheter drainage (urethra only versus urethra and suprapubic). These are, however, minor points, and they are addressed subsequently.

Complex urethral reconstructive techniques for the repair urethral diverticula have been described. Fall<sup>119</sup> described the use of a bipediced vaginal wall flap for urethral reconstruction in patients with urethral diverticula and urethrovaginal fistula. Laterally based vaginal flaps have also been used as an initial approach to urethral diverticula.<sup>120,121</sup> Complex anatomic configurations may exist, and many novel approaches have been described for complicated, anteriorly located or circumferential lesions.<sup>5,6,122</sup> The technique described here is similar to that described by Leach and Raz<sup>42</sup> and based on earlier work by Benjamin and colleagues<sup>123</sup> and Busch and Carter.<sup>124</sup>

#### Preoperative Preparation

Prophylactic antibiotics can be used for a period preoperatively to ensure sterile urine at the time of surgery. Patients can also be encouraged to strip the anterior vaginal wall after voiding, thereby consistently emptying the urethral diverticulum and preventing urinary stasis and recurrent urinary tract infections. This may not be possible in those with noncommunicating urethral diverticula or in those who have significant pain related to the urethral

diverticula. Application of topical estrogen creams for several weeks before surgery may be beneficial in some patients with postmenopausal atrophic vaginitis in improving the overall quality of the tissues with respect to dissection and mobilization. Preoperative parenteral antibiotics are often administered, especially for those with recurrent or persistent urinary tract infections.

Patients with symptomatic stress urinary incontinence can be offered simultaneous anti-incontinence surgery. Preoperative video urodynamics may be helpful in evaluating the anatomy of the urethral diverticula, assessing the competence of the bladder neck, and confirming the diagnosis of stress urinary incontinence. In patients with stress urinary incontinence and urethral diverticula, Ganabathi and coworkers<sup>23</sup> and Lockhart and associates<sup>125</sup> have described excellent results with concomitant needle bladder neck suspension in these complex cases. Pubovaginal fascial slings have been used in patients with urethral diverticula and stress urinary incontinence with satisfactory outcomes.<sup>44,50,51</sup>

Further complicating these cases may be associated symptoms such as pain, dyspareunia, voiding dysfunction, urinary tract infections, and urinary incontinence. These associated symptoms often are improved or eliminated with surgical repair. The importance of appropriate preoperative patient counseling regarding surgery and postoperative expectations of cure cannot be overemphasized.

### Procedure

The patient is placed in the lithotomy position with all pressure points well padded. The use of padded adjustable stirrups for the lower extremities greatly enhances operative access to the female perineum. A standard vaginal antiseptic preparation is applied. A weighted vaginal speculum and Scott retractor with hooks aid in exposure. A posterolateral episiotomy may be beneficial in some patients for additional exposure, although the mid-urethral (and therefore somewhat distal in the vaginal canal) location of most urethral diverticula usually precludes the need for this type of adjunctive procedure. A Foley catheter is placed through the urethra, and a suprapubic tube may be used for additional unobstructed postoperative urinary drainage. Often, a small-caliber urethral catheter is used during the case, and the placement of a suprapubic tube during the procedure ensures adequate postoperative urinary drainage. If desired, a suprapubic tube is placed at the start of the procedure using the Lowsley retractor or percutaneously under direct transurethral cystoscopic visual guidance. Placement of the suprapubic tube at the end of the case is not advisable because it requires traversing the fresh urethral suture line, which risks disruption of the repair.

An inverted U is marked out along the anterior vaginal wall, with the base of the U at the level of the distal urethra and the limbs extending to the bladder neck or beyond (Fig. 85-15). Care is taken to ensure that the limbs of the U are progressively wider proximally (toward the bladder neck) to ensure adequate vascularity at the distal lateral margins of the anterior vaginal wall flap. Unlike the inverted-T-shaped incision, the inverted-U-shaped incision provides excellent exposure laterally at the level of the midvagina, and it can be extended proximally as needed for lesions that extend beyond the bladder neck. Injectable saline can be infused along the lines of the incision to facilitate dissection. An anterior vaginal wall flap is created by careful dissection in the potential space between the vaginal wall and the periurethral fascia. The use of sufficient countertraction during this portion

**Figure 85-15** An inverted-U-shaped incision (*dashed line*) on the anterior vaginal wall. Retraction is aided by the use of Allis clamps and a ring retractor with hooks.

of the procedure is important in maintaining the proper plane of dissection. Care is taken to preserve the periurethral fascia and to avoid inadvertent entry into the urethral diverticula.

A distinct layer of periurethral fascia is usually interposed between the vaginal wall and the urethral diverticula. Preservation and later reconstruction of this layer is important to prevent recurrence, close dead space, and avoid urethrovaginal fistula formation postoperatively. Pseudo-diverticula have been described where this layer of tissue is considerably attenuated or even absent.<sup>100</sup> In these patients, an interpositional flap or graft such as a pubovaginal sling may be used for reconstruction.

The periurethral fascia is incised transversely (Fig. 85-16). Proximal and distal layers of periurethral fascia are carefully developed avoiding entrance into the urethral diverticula. The urethral diverticula is then grasped and dissected back to its origin on the urethra within the leaves of the periurethral fascia (Fig. 85-17). In many cases, it is necessary to open the urethral diverticulum to facilitate dissection from the surrounding tissues. The ostium or connection to the urethra is identified, and the walls of the urethral diverticulum are completely removed. Every effort should be made to remove the entire mucosalized surface of the urethral diverticulum to prevent recurrence.<sup>23,65</sup> This may involve removing small, adherent or inflamed portions of the urethral wall, especially in the ostial area (Fig. 85-18). All abnormal tissue in the area of the ostium should be removed if possible to ensure that no mucosal elements of the urethral diverticular wall remain, which can result in postoperative urine leakage and

**Figure 85-16** After reflection of the anterior vaginal wall, a transverse incision (*dashed line*) is made in the periurethral fascia.

**Figure 85-17** The periurethral fascia is incised and dissected from the underlying urethral diverticulum.

recurrence. Elaborate methods of identifying the full extent of the urethral diverticular cavity have been described, including catheterization of the urethral diverticulum with urinary<sup>33,126</sup> and Fogarty<sup>127</sup> catheters, packing the urethral diverticulum with gauze,<sup>128</sup> infusing and staining the urethral diverticulum with methylene blue,<sup>8</sup> and the use of silicone<sup>129</sup> or cryoprecipitate<sup>130</sup> to create a solid mass and ease dissection. However, these measures are mostly of historical interest and are usually unnecessary in modern urethral diverticular surgery.<sup>23,39</sup>

The Foley catheter is usually seen after complete excision of a urethral diverticulum (Fig. 85-19). The urethra can be reconstructed over as small as a 12-Fr Foley catheter without long-term risk of urethral stricture,<sup>4</sup> and it should be closed in a watertight fashion with absorbable suture (Fig. 85-20). The closure should be tension free. Uncommonly, a urethral diverticulum may extend circumferentially around the urethra and require segmental resection of the involved portion of the urethra and complex reconstruction.<sup>6,131</sup>

The periurethral fascial flaps are reapproximated with absorbable suture in a perpendicular orientation to the urethral closure line to minimize overlap and the risk of postoperative urethrovaginal fistula formation (Fig. 85-21). Care is taken to secure the periurethral fascial flaps to close all dead space.

If desired, a fibrofatty labial (Martius) flap can be harvested at this point and placed over the periurethral fascia as an additional layer of closure.<sup>64</sup> Indications for such a flap are not universally agreed on. However, in patients with poor-quality tissues

or attenuated periurethral fascia or in whom significant inflammation is encountered intraoperatively, a well-vascularized adjuvant flap (e.g., Martius flap) may reduce the risk of wound breakdown and subsequent complications such as urethrovaginal fistula.

The anterior vaginal wall flap is then repositioned and reapproximated with absorbable suture (Fig. 85-22). This completes a three-layer closure (four layers if a Martius flap is used). An antibiotic-impregnated vaginal pack is placed.

#### Postoperative Care

Antibiotics are continued for 24 hours postoperatively. The vaginal packing is removed and the patient discharged home with closed urinary drainage. Antispasmodics are used liberally to reduce bladder spasms. Pericatheter VCUG is obtained at 14 to 21 days postoperatively. If there is no extravasation, the catheters are removed. If extravasation is seen, repeat pericatheter VCUG is performed weekly until resolution is documented. In most cases, extravasation resolves in several weeks with this type of conservative management.<sup>132</sup>

#### Complications

Careful adherence to the principles of transvaginal urethral diverticulectomy should minimize postoperative complications. Nevertheless, complications may arise (Box 85-3). One small series suggested that large diverticula (>4 cm) or those associated with a lateral or horseshoe configuration may be associated with

**Figure 85-18** The urethral diverticulum sac is freed from the periurethral fascia.

**Figure 85-20** The urethra is closed with absorbable suture.

**Figure 85-19** The urethral catheter is seen after complete excision of the urethral diverticulum sac.

### Box 85-3 Complications of Transvaginal Urethral Diverticulectomy

Urinary incontinence (1.7-16.1)*
Urethrovaginal fistula (0.9-8.3)
Urethral stricture (0-5.2)
Recurrent urethral diverticulum (1-25)
Recurrent urinary tract infection (0-31.3)
Other
Hypospadias or distal urethral necrosis
Bladder or ureteral injury
Vaginal scarring or narrowing (e.g., dyspareunia)

\*The range of reported incidence (%) is given within parentheses.  
Adapted from Dmochowski R: Surgery for vesicovaginal fistula, urethrovaginal fistula, and urethral diverticulum. In Walsh PC, Retik AB, Vaughan ED Jr, Wein AJ (eds): Campbell's Urology, 8th ed. Philadelphia, WB Saunders, 2002, p 1214.

a greater likelihood of postoperative complications.<sup>133</sup> Common complications include recurrent urinary tract infections, urinary incontinence, and recurrent urethral diverticula.

Urethrovaginal fistula is a devastating complication of urethral diverticulectomy and deserves special mention. A fistula located beyond the sphincteric mechanism should not be associated with symptoms other than perhaps a split urinary stream and or vaginal voiding. As such, an asymptomatic distal urethrovaginal fistula may not require repair, although some patients may request repair. Conversely, a proximal fistula located at the

**Figure 85-21** The periurethral fascia is closed with care to obliterate any dead space.

**Figure 85-22** The anterior vaginal wall flap is advanced over the periurethral suture line and secured with running, interlocking absorbable suture.

bladder neck or at the mid-urethra in patients with an incompetent bladder neck will likely result in considerable symptomatic urinary leakage. These patients should undergo repair with the use of an adjuvant tissue flap such as a Martius flap to provide a well-vascularized additional tissue layer. The timing of the repair relative to the initial procedure is controversial. Meticulous attention to surgical technique, good hemostasis, avoidance of infection, preservation of the periurethral fascia (Fig. 85-23), a well-vascularized anterior vaginal wall flap, and multilayered closure with nonoverlapping suture lines should minimize the potential for postoperative urethrovaginal fistula formation.

#### Persistence of Symptoms after Urethral Diverticulectomy

Some patients have persistence or recurrence of their preoperative symptoms postoperatively. The finding of a urethral diverticulum after a presumably successful urethral diverticulectomy may occur as a result of a new medical problem (e.g., urinary tract infection), a new urethral diverticulum, or recurrence of the original lesion. A urethral diverticulum may recur because of incomplete removal of the urethral diverticulum, inadequate closure of the urethra or residual dead space, or other technical factors. Lee<sup>134</sup> identified a recurrent urethral diverticulum in 8 of 85 patients at follow-up of between 2 and 15 years from resection of the initial urethral diverticulum.<sup>134</sup> Repeat urethral diverticulectomy can be challenging due to altered anatomy, scarring, and the difficulty in identifying the proper anatomic planes.

**Figure 85-23** Diagrams demonstrate the importance of preserving and reconstructing the periurethral fascia. **A**, Defect in the periurethral fascia after removal of the epithelial lining of the urethral diverticulum. **B**, Closure of the urethra and periurethral fascia.

### Urethral Diverticula and Associated Conditions

Malignant and benign tumors may be found in urethral diverticula. Both are rare, and fewer than 100 cases of carcinoma within urethral diverticula have been reported in the English language literature.<sup>106</sup> The most common malignant pathology in urethral diverticula is adenocarcinoma, followed by transitional cell and squamous cell carcinomas.<sup>106</sup> This contrasts with primary urethral carcinoma, in which the primary histologic type is squamous cell carcinoma. Some investigators have suggested that urethral diverticulum is associated with the development of urethral adenocarcinoma in women.<sup>135</sup> If this is true, nonexcisional therapy of urethral diverticula, such as marsupialization or endoscopic incision, should always be combined with a biopsy to rule out malignancy.<sup>136</sup> There is no consensus on proper treatment in these cases, and recurrence rates are high with local treatment alone.<sup>106</sup> The incidental finding of malignancy can be particularly troubling when found intraoperatively or on the postoperative pathology report. It has not been conclusively demonstrated that any particular preoperative imaging modality such as ultrasound or MRI can reliably and prospectively diagnose a small malignancy arising in a urethral diverticula. When considering curative therapy, it is unclear whether extensive surgery, including cystourethrectomy with or without adjuvant external beam radiotherapy, is superior to local excision followed by radiotherapy.<sup>104</sup>

Many benign lesions, including nephrogenic adenoma and endometriosis, have been described within urethral diverticula.<sup>137-140</sup> Pathologically, nephrogenic adenoma can be difficult to differentiate from adenocarcinoma.

Calculi within urethral diverticula may be diagnosed in 4% to 10% of cases,<sup>44,141,142</sup> and they are most likely caused by urinary stasis or infection. This may be suspected by physical examination findings or found incidentally on imaging evaluation. The presence of a stone does not significantly alter the evaluation or surgical approach, and it can be considered an incidental finding (Fig. 85-24).

Urethral diverticula have manifested during pregnancy. Moran<sup>143</sup> reported four cases of urethral diverticula diagnosed during pregnancy. Conservative treatment included antibiotics and aspiration or incision and drainage. Two women delivered vaginally, and the other two delivered by cesarean section for unrelated reasons. In one patient, drainage was performed during labor to facilitate delivery. Three of the four women had definitive repair performed after delivery. It is not known whether pregnancy is associated with formation of urethral diverticula, although patients may be more likely to become symptomatic during this period. Usually, conservative management with antibiotics may be desirable until after delivery to avoid precipitating premature labor, although successful surgical treatment during pregnancy has been reported.<sup>144</sup>

# URINARY TRACT INFECTIONS IN WOMEN

Amanda M. Macejko and Anthony J. Schaeffer

## EPIDEMIOLOGY

Urinary tract infections (UTIs) are the most common bacterial infections and account for a substantial number of office and emergency room visits as well as hospital admissions each year. Additionally, UTI is the most common cause of nosocomial infection.<sup>1</sup> The morbidity of UTIs varies widely, from self-limited to life-threatening conditions. The focus of this chapter is on UTI in women, who make up a significant proportion of UTI sufferers. The annual incidence among women is 12.1%. Peak incidence in women occurs between the ages of 20 to 24 years.<sup>2</sup> Health care costs attributed to UTIs are substantial. The estimated overall costs of UTI among ambulatory women in the United States exceeds \$1 billion annually.<sup>3</sup>

## Pathogenesis

The interaction between bacterial virulence and host defense factors can ultimately result in UTI. More virulent bacteria are necessary to infect healthy hosts with a normal urinary tract, whereas less virulent bacteria may easily infect compromised hosts.

Laboratory studies of uropathogenic strains of *Escherichia coli* (UPEC) have helped to obtain a better understanding of the pathogenesis of UTIs. The initial step is bacterial adherence to the urothelium. Type 1 pili are filamentous adhesive organelles encoded by almost all UPEC, and they are significant virulence factors associated with UTIs. FimH is an adhesin molecule at the tip of type 1 pili that specifically binds to the luminal surface of the bladder.<sup>4</sup> Bacterial colonization then precipitates a host inflammatory response, which includes neutrophil influx followed by apoptosis and exfoliation of the bladder's epithelial cells in an effort to rid the bladder of bacteria. Despite the host's response, however, high titers of UPEC persist in the bladder for several days.<sup>5</sup>

How are the bacteria able to elude the host defenses? Recent research has shown that UPEC avoids clearance by invading and replicating within the epithelial cells. They form "bacterial factories" that are refuges in which bacteria may persist and form biofilms. Bacteria within a biofilm are resistant not only to host defenses but also to typical courses of antimicrobials.<sup>5</sup> These bacteria may subsequently reemerge and cause recurrent acute infections.<sup>6</sup> Historically, the vagina and intestine have been accepted as UPEC reservoirs; however, this new paradigm demonstrates that the bladder itself may be a reservoir for UPEC.

## Host Factors

Host factors include genetic, anatomic, functional, and behavioral factors that affect the host's susceptibility to uropathogens and its ability to overcome them (Table 86-1).

### Vaginal Colonization

In order for a UTI to occur, the infecting organism must first obtain access to the urinary tract. In the 1960s, Stamey hypothesized that bacteria that cause UTIs originate in the rectal flora and colonize the vaginal and urethral mucosa before ascending to the bladder.<sup>7</sup> Vaginal colonization has proved to be a crucial step in the pathogenesis of UTI. Many factors that increase the risk of UTI do so by facilitating vaginal colonization with uropathogens.<sup>8</sup> Women (in comparison to men) are particularly at risk based simply on differences in anatomy. Women have a moist periurethral space, a shorter distance between the anus and urethral opening, and a shorter urethra. These factors increase exposure to uropathogens and enhance the ability of these pathogens to colonize the urinary tract.<sup>2</sup>

Why are some women more susceptible to vaginal colonization, and therefore recurrent UTI, than others? There is substantial evidence that vaginal colonization is determined by genetic factors. In 1977, Fowler and Stamey discovered that *E. coli*

**Table 86-1 Host Factors**

Genetic	Anatomic/Functional	Behavioral
Blood group antigen	Congenital abnormalities	Sexual activity
Nonsecretor status	Urinary obstruction	Diaphragm use
Density of adhesin receptors	Urinary incontinence	Spermicide use
Maternal history of UTI	Calculi	Antimicrobial use
	Residual urine	
	Catheters or foreign bodies	
	Atrophic vaginitis	

UTI, urinary tract infection.

Modified from Ronald A: The etiology of urinary tract infection: Traditional and emerging pathogens. *Am J Med* 113(Suppl 1A):14S-9S, 2002.

adhered more avidly to vaginal epithelial cells of women with recurrent UTI.<sup>9</sup> Follow-up studies by Schaeffer showed that high vaginal cell receptivity was correlated with high buccal cell receptivity, suggesting that epithelial cell receptivity is actually a genotypic trait.<sup>10</sup> The concept of hereditary susceptibility was further investigated by Schaeffer and associates, who demonstrated that the prevalence of the human leukocyte antigen (HLA) A3 subtype was greater in women with recurrent UTIs.<sup>11</sup> In addition, carbohydrate structures bound to cell membranes known as blood group antigens make up a significant component of the uroepithelial cell membrane. Certain blood group antigens have been associated with susceptibility to UTI. Sheinfeld and colleagues determined that women with Lewis blood group Le(a<sup>-</sup>b<sup>-</sup>) or Le(a<sup>+</sup>b<sup>-</sup>) (nonsecretor) had a significantly higher incidence of recurrent UTIs than women with the Le(a<sup>+</sup>b<sup>+</sup>) (secretor) phenotype.<sup>12</sup> *E. coli* bind to mannose residues, which are more available in nonsecretor mucosa.<sup>13</sup>

### Sexual Activity

Vaginal and oral intercourse help to propagate potential pathogens into the vagina and urinary tract. Additionally, vaginal intercourse may cause trauma of the vaginal epithelium, rendering it more susceptible to bacterial adherence and vaginal colonization.<sup>14</sup> Several studies have linked sexual activity with vaginal colonization and UTI. Foxman and colleagues found that vaginal colonization with *E. coli* was inversely associated with the number of days since sexual activity.<sup>15</sup> Hooton and coworkers reported that urine cultures in the immediate postcoital period show a transient bacteriuria.<sup>16</sup> It has been proposed that voiding immediately after intercourse is protective, although there are no current data that support this conjecture.<sup>1</sup>

### Spermicide and Diaphragm Use

Spermicide and diaphragm use has been found to greatly increase the risk of vaginal colonization with uropathogens and UTI, independent of sexual activity. Nonoxynol-9, the active ingredient in most spermicides, has a bactericidal effect on the normal vaginal flora and therefore enhances the growth of *E. coli*.<sup>2,8</sup>

### Estrogen

Estrogen withdrawal in postmenopausal women alters the normal vaginal flora. In a randomized, double-blind, placebo-controlled trial of postmenopausal women with recurrent UTI, Raz and Stamm found that topically applied intravaginal estriol cream lowered the vaginal pH, restored lactobacilli in 61% of vaginal cultures, and reduced the incidence of UTI 10-fold. He concluded that intravaginal estrogen replacement restores an acidic environment that is more hospitable to premenopausal flora.<sup>17</sup> However, these results have not been replicated in studies evaluating oral estrogens. Cardozo and associates evaluated the effects of low-dose, oral estrogen replacement but were unable to establish a significant protective effect.<sup>18</sup>

### Recent Antimicrobial Use

Another factor that contributes to UTI susceptibility is recent antimicrobial use. Smith and coworkers, in a prospective study, found that antimicrobial use up to 4 weeks before the onset of a UTI increased the relative risk for that UTI by 2.57 to 5.83 times. It has been proposed that recent antimicrobial use increases a woman's risk of UTI by altering the normal urogenital flora.<sup>19</sup> The most offending antimicrobials are  $\beta$ -lactams, whereas tri-

methoprim and nitrofurantoin seem to have much less of an effect on the normal vaginal flora.<sup>8</sup>

## DIAGNOSTIC TOOLS

### History

A thorough history is an essential component of obtaining the proper diagnosis. It is important to clarify the onset and the presence or absence of symptoms including dysuria, urinary frequency, hematuria, suprapubic tenderness, flank pain, fever, and nausea/vomiting. Has the patient had previous UTIs as a child or as an adult? If so, were her previous UTIs associated with fever?

A complete medical and surgical history is also important. Does the patient have a history of nephrolithiasis or previous urinary tract surgery? Is the patient pregnant? Does the patient diabetic? The answers to these questions will direct further workup and management.

### Physical Examination

The physical examination is not considered diagnostic of UTI but can be helpful in certain cases. The findings may assist in differentiating between lower urinary tract (cystitis) and upper urinary tract (pyelonephritis) infection. Is the patient febrile? Is there costovertebral tenderness? Findings such as a urethral diverticulum may occasionally reveal a potential source of recurrent UTI. The physical examination may also help to rule out other causes of patient symptomatology. For example, the presence of vaginal discharge has a strong association with vaginal infection rather than a UTI.<sup>20</sup>

### Urinalysis

Women should provide a midstream voided urine for analysis after spreading the labia and wiping from front to back with a clean sponge.<sup>7</sup> The urinalysis provides information about pyuria, bacteriuria, and hematuria. Urine dipstick analysis is a quick and inexpensive test that is often used in the clinical setting. Testing for leukocyte esterase, an enzyme produced by polymorphonuclear cells, and nitrite, a byproduct of bacterial growth, it provides an indirect measurement of both pyuria and bacteriuria.<sup>21</sup> If either the nitrite assay or the leukocyte esterase test is positive, the dipstick test has a sensitivity of 75% and a specificity of 82%.<sup>22</sup> False-negative results can occur when the infecting organism does not produce nitrites.<sup>23</sup> It is important to note that, although the dipstick test can be useful for screening, it is not as sensitive as microscopic examination.<sup>7</sup> Pyuria on microscopic examination has a high sensitivity (95%) and a relatively low specificity (71%).<sup>24</sup> The presence of bacteria on microscopic examination has a lower sensitivity (40% to 50%) yet a higher specificity (85% to 95%).<sup>24</sup>

### Urine Culture

The Infectious Diseases Society of America (ISDA) defines cystitis as greater than or equal to 10<sup>5</sup> cfu/mL of midstream urine. However, studies by Stamm and Hooton demonstrated that greater than or equal to 10<sup>2</sup> cfu/mL for a catheterized urine specimen in a symptomatic patient is significant.<sup>25</sup> It is not necessary

to obtain a urine culture in all patients. Appropriate patient selection for urine culture is addressed in a later section.

### Imaging Techniques

Multiple radiographic techniques are available for imaging the urinary tract. Plain abdominal films may demonstrate radiopaque calculi. Intravenous pyelography, although not typically used in the setting of UTI, can be useful to determine the site of an obstruction.<sup>7</sup> Renal ultrasonography may demonstrate stone, hydronephrosis, or perirenal abscess. Advantages of ultrasound are that it does not expose the patient to radiation or contrast material; however, ultrasound results are dependent on operator experience.<sup>7</sup> Computed tomography (CT) and magnetic resonance imaging (MRI) demonstrate excellent anatomic detail and are more sensitive than intravenous pyelography and ultrasonography.<sup>7</sup> Although numerous imaging techniques are available, most UTIs do not warrant radiologic evaluation. The appropriateness of imaging in the setting of a UTI is discussed later.

## TREATMENT

### Antimicrobial Principles

The successful treatment of a UTI depends on two important principles. First, the treatment should result in elimination of bacteriuria. This typically occurs hours after initiation of treatment.<sup>7</sup> Second, the urine concentration of the antimicrobials must exceed the minimal inhibitory concentration (MIC) of the bacteria.<sup>26</sup> It is important to keep in mind that hospital microbiology laboratories typically report bacterial sensitivities based on serum levels that may be several-fold lower than the urine levels of a particular agent.

### Antimicrobial Resistance

The most common reason for unresolved bacteriuria is bacterial resistance to the chosen antimicrobial agent. There are several

ways in which bacteria may be resistant. In natural resistance, certain bacteria simply lack a drug-susceptible substrate, rendering an entire species of bacteria resistant to a particular antimicrobial. Examples include *Proteus* resistance to nitrofurantoin and *Enterococcus faecalis* resistance to cephalexin.<sup>7</sup> Resistance can also occur when the antimicrobial therapy actually selects for resistant mutants. This mode of resistance occurs within the urinary tract and can typically be avoided by choosing an agent with a urine concentration that exceeds the MIC by the greatest margin, adequate dosing, and stressing the importance of compliance with therapy.<sup>7</sup> The third mechanism of resistance is extrachromosomal plasmid-mediated resistance, also known as transferable resistance. This mode of resistance takes place within the bowel and produces multiple resistant strains. To date, transferable resistance has not been demonstrated with nitrofurantoin or fluoroquinolones, and therefore these two drugs are good options for patients exposed to other antimicrobials.<sup>27</sup>

### Antimicrobial Selection

In selecting an antimicrobial agent, it is necessary to understand the efficacy, spectrum of activity, resistance patterns, side effects, dosing, and cost.<sup>28</sup> Individual antimicrobials are discussed later. Costs for a complete course of therapy of the antimicrobials based on 2001 wholesale prices are listed in Table 86-2.

#### Trimethoprim-sulfamethoxazole

Trimethoprim-sulfamethoxazole (TMP-SMX) blocks folic acid metabolism of bacteria, thereby preventing bacterial growth. TMP is effective as a single agent in uncomplicated UTI, has fewer side effects, and is safe for patients with sulfa allergies.<sup>29</sup> SMX has a synergistic bactericidal effect that improves the efficacy of the treatment of upper tract infections.<sup>30</sup> The combination of TMP-SMX is active against most aerobic gram-positive and gram-negative organisms. It is not active against enterococci or *Pseudomonas aeruginosa*.<sup>23</sup> Dosage is one double-strength tablet twice daily for 3 days for uncomplicated cystitis. Side effects may include rash, gastrointestinal upset, and photosensitivity.<sup>31</sup> Serious adverse events may include Stevens-Johnson syndrome.<sup>23</sup>

**Table 86-2 Antimicrobial Cost**

Antimicrobial	Dose (mg)	Cost (\$)
<b>Sulfonamides</b>		
TMP-SMX	160/800 two times daily × 3 days	6.30-8.80
TMP	100 two times daily × 3 days	0.90-1.40
<b>Fluoroquinolones</b>		
Ciprofloxacin	100-250 two times daily × 3 days	17.20-25.00
Levofloxacin	250-500 daily × 3 days	21.90-25.60
Nitrofurantoin macrocrystals		
Macrobid	100 four times daily × 7 days	47.00
Macrobid	100 two times daily × 7 days	23.00
<b>β-lactams</b>		
Amoxicillin	250-500 three times daily × 3 days	6.40-11.50
Cefixime	400 daily × 3 days	23.20
Cefpodoxime	100 two times daily × 3 days	18.30

SMX, sulfamethoxazole; TMP, trimethoprim.

Modified from Jancel T, Dudas V: Management of uncomplicated urinary tract infections. West J Med 176:51-55, 2002.

TMP-SMX should be avoided in pregnant patients as well as those taking warfarin.<sup>7</sup>

TMP-SMX has historically been the most widely used antimicrobial in the treatment of uncomplicated UTI, which may account for its high resistance rates. A recent study by Gupta and colleagues highlighted the fact that antimicrobial susceptibility patterns are dependent on geographic distribution. *E. coli* resistance to TMP-SMX ranged from 10% in the northeastern United States to 22% in the western United States.<sup>32</sup> Risk factors for resistance to TMP-SMX include previous use of TMP-SMX and current use of other antimicrobials, as well as diabetes and recent hospitalization.<sup>23</sup>

### Nitrofurantoin

Nitrofurantoin inhibits several bacterial enzyme systems and is bactericidal. It is active against *E. coli* and most species of *Klebsiella*, *Enterobacter*, *Staphylococcus*, and *Enterococcus*. It is not effective against *Pseudomonas* or *Proteus* species.<sup>33</sup> A 7-day course of therapy is recommended for uncomplicated UTI, and it is also frequently used for UTI prophylaxis.<sup>23</sup> The agent does not penetrate urinary tract tissue or achieve bactericidal levels in blood and therefore is not recommended for complicated UTIs or pyelonephritis.<sup>34</sup> It also should not be used in patients with poor renal function, because adequate urine concentration levels will not be achieved.<sup>7</sup> Side effects may include gastrointestinal upset, peripheral polyneuropathy, hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, and pulmonary reactions ranging from cough to fibrosis.<sup>7</sup> Nitrofurantoin exhibits very low levels of resistance.<sup>23</sup>

### $\beta$ -Lactams

The  $\beta$ -lactam family includes penicillins, aminopenicillins, cephalosporins, and aztreonam. These antimicrobials inhibit bacterial cell wall synthesis.<sup>23</sup>

The aminopenicillins (ampicillin, amoxicillin  $\pm$  clavulanate) are useful against *Streptococcus*, *Enterococcus*, *E. coli*, and *Proteus mirabilis*. Recommended treatment length is 7 days. The most common adverse reactions are hypersensitivity and diarrhea. Extended-spectrum penicillin derivatives including piperacillin are often active against typically ampicillin-resistant gram-negative bacilli.<sup>7</sup>

There are three generations of cephalosporins. Typically, the first-generation agents are active against *Streptococcus*, *Staphylococcus*, *E. coli*, *Proteus*, and *Klebsiella* species. Second-generation cephalosporins have similar activity to first-generation agents with additional activity against anaerobes. Third-generation cephalosporins have decreased activity against gram-positive cocci and increased activity against gram-negative bacilli. Some third-generation cephalosporins are active against *P. aeruginosa* and are often used for nosocomial infections caused by gram-negative organisms. It is important to note that none of the cephalosporins is active against enterococci. Similar to the aminopenicillins, adverse reactions include hypersensitivity and gastrointestinal upset. These agents should not be used in patients with immediate hypersensitivity to penicillins.<sup>7</sup>

Aztreonam is active only against gram-negative aerobes. This drug has a less than 1% incidence of cross-reactivity in penicillin-allergic patients, and its use is mainly limited to those patients with allergies to penicillin.<sup>7</sup>

### Fluoroquinolones

Ciprofloxacin and levofloxacin are the fluoroquinolones most commonly used against UTI in the United States. They are avail-

able in both oral and intravenous forms. The mechanism of action of these drugs is to inhibit DNA gyrase. They are active against enterobacteria and *P. aeruginosa*.<sup>7</sup> These agents are often used as first-line therapy for UTIs in regions with high levels of bacterial resistance to ampicillin and TMP-SMX.<sup>23</sup> Side effects are uncommon but include gastrointestinal upset, dizziness, lightheadedness, photosensitivity, and tendon rupture. Fluoroquinolones should be avoided in pregnant women. Sucralfate should not be used concomitantly, because it decreases oral absorption.<sup>7</sup>

Resistance to fluoroquinolones is low in the United States,<sup>32</sup> but this is not the case worldwide. Spain and Portugal have high rates of resistance to ciprofloxacin, 14.7% and 5.8% respectively.<sup>23</sup> This is perhaps due to the wider use of fluoroquinolones in Europe. In a recent paper, Hooton and colleagues expressed concern regarding increasing fluoroquinolone resistance and recommended discouraging the routine use of fluoroquinolones for treatment of mild-to-moderate acute uncomplicated cystitis.<sup>35</sup>

### Aminoglycosides

Aminoglycosides inhibit ribosomal protein synthesis and are active against *Staphylococcus* and most gram-negative pathogens. They are the drugs of choice in patients with urosepsis when used in combination with ampicillin.<sup>7</sup> Once-daily dosing at 7 mg/kg has been shown to maximize bacterial killing and to reduce nephrotoxicity, a common adverse effect.<sup>36</sup> These agents should be avoided in pregnant patients and in those with impaired renal function or diabetes.<sup>7</sup>

## PRACTICAL APPROACHES TO PATIENT ASSESSMENT

### Classification of Urinary Tract Infections

UTIs can be classified in several different ways. The location of the infection is one method of classification. For example, UTIs may involve the lower tract (cystitis) or the upper tract (pyelonephritis). Texts also describe UTIs as uncomplicated or complicated. Uncomplicated infections occur in healthy women who are without physiologic or anatomic urinary tract abnormalities or recent urologic surgery or instrumentation. Women with uncomplicated infections are not pregnant or immunocompromised and have not recently taken antimicrobials.<sup>7</sup> Complicated infections occur when there is poor response to therapy, the patient is not healthy or is otherwise compromised (e.g., pregnant), or there is a structural or functional abnormality of the urinary tract that increases the risk of therapy failure.<sup>8</sup> Unfortunately, the category into which a patient fits is not always readily apparent. This section attempts to help the clinician recognize patient characteristics that should guide patient categorization.

### Uncomplicated Acute Cystitis

A typical patient with uncomplicated acute cystitis is a premenopausal, sexually active, nonpregnant woman. She reports recent onset of symptoms including dysuria, frequency, urgency, and possibly suprapubic discomfort and hematuria.<sup>37</sup> The differential diagnosis for acute cystitis includes vaginitis and sexually transmitted diseases. Some authors report that a history, physical examination, and urinalysis should be all that is needed to ascertain the appropriate diagnosis.<sup>38</sup> Others report that treating acute, uncomplicated cystitis in low risk women by telephone consultation to be safe and effective.<sup>39</sup>

**Table 86-3 Pathogens Cultured in Uncomplicated Urinary Tract Infections**

<i>Escherichia coli</i>	70-95%
<i>Staphylococcus saprophyticus</i> (premenopausal women)	5-20%
<i>Klebsiella</i> species	
<i>Enterococcus faecalis</i>	
<i>Proteus mirabilis</i>

**Box 86-1 Situations in which it is Appropriate to Obtain a Urine Culture in Acute Uncomplicated Cystitis**

Symptoms and/or urinalysis not consistent with cystitis  
Recent antimicrobial therapy  
UTI symptoms >7 days  
Age >65 yr  
Diabetes  
Pregnancy  
Recurrent UTI

UTI, urinary tract infection.  
Modified from Schaeffer AJ: Infections of the urinary tract. Walsh PC, Retik AB, Vaughan ED Jr, Wein AJ (eds). *Campbell's Urology*. Philadelphia, WB Saunders, 2002, pp 516-602.

**Box 86-2 When to use Fluoroquinolones as First-Line Therapy for Uncomplicated Acute Cystitis**

Allergic to TMP-SMX  
Recent antimicrobial exposure  
High rate of TMP-SMX resistance in the community (>20%)  
Unresolved UTI without prior fluoroquinolone therapy  
Recurrent UTI

TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection.

For the patient with uncomplicated UTI, urine cultures are usually not necessary, because most acute, community-acquired, uncomplicated infections in the United States and abroad are caused by predictable organisms (Table 86-3) and respond to empiric therapy. The routine use of urine cultures in uncomplicated cases has been shown to increase the cost of care by 39% without significant benefit to patient outcomes.<sup>28</sup> However, it is important to recognize situations in which it is appropriate to perform urine cultures in uncomplicated acute cystitis. These are included in Box 86-1.

Evidence-based guidelines for the treatment of acute uncomplicated cystitis were published by the Infectious Diseases Society America (IDSA) in 1999. According to these guidelines, TMP alone or TMP-SMX for 3 days is considered the current standard therapy. However, fluoroquinolones should be used as initial empiric therapy in specific situations, as outlined in Box 86-2.<sup>7,40</sup>

There has been renewed interest in nitrofurantoin in the treatment of uncomplicated cystitis because of its low resistance rates. However, it is not as effective as TMP-SMX or the fluoroquinolones.<sup>41</sup> The IDSA found that nitrofurantoin had lower cure rates (approximately 85%) than other first-line agents (90% to 95%).<sup>40</sup> Most women experience marked improvement in symptoms within 24 hours.<sup>28</sup> Response to therapy is primarily measured by clinical resolution of symptoms, and further follow-up is usually unnecessary.<sup>7</sup>

**Unresolved Urinary Tract Infection**

If the patient's symptoms do not resolve with empiric therapy, the clinician should consider these questions: Has the patient been compliant with treatment? Is the UTI caused by a resistant organism? Are symptoms due to a UTI or another diagnosis altogether? A urine culture should be obtained, and the patient should be switched to a fluoroquinolone if she is not taking one already. The patient should be monitored to ensure that her symptoms resolve and that her urine culture is negative at the end of treatment.

**Recurrent Urinary Tract Infections**

Recurrent UTI is noted when a premenopausal, sexually active, nonpregnant woman presents with her third episode of urgency, frequency, and dysuria in the same year. Reports show that 25% to 50% of women experience recurrent UTI, defined as three or more symptomatic UTIs in 1 year or two UTIs within 6 months.<sup>42</sup> Recurrent UTIs usually occur in the absence of anatomic urinary tract abnormalities and represent a new infection from bacteria outside of the urinary tract.<sup>7</sup> *Reinfections* typically occur at long intervals and usually are caused by different uropathogens, whereas *relapses* secondary to bacterial persistence are commonly caused by the same organism and typically occur at close intervals.<sup>7</sup>

A study by Scholes and colleagues aimed at determining the risk factors for recurrent UTI determined that lifetime sexual activity and sexual activity within the last year were the most important risk factors for recurrence.<sup>42</sup> Other risk factors included spermicide use, a new sexual partner within the past year, first UTI at 15 years of age or younger, and having a mother with a history of UTIs.<sup>8</sup>

As indicated in Box 86-1, when a patient has recurrent UTIs, is appropriate to obtain a urine culture, because it is vital to document that these recurrent episodes are in fact infectious. If the patient's symptoms are not caused by infection, the clinician needs to consider alternative diagnoses, including urethritis, vaginitis, interstitial cystitis, and carcinoma in situ. Further urologic workup is usually not necessary in patients with recurrent UTIs. There are three different strategies for antimicrobial prophylaxis for patients with recurrent UTIs.

**Low-Dose Prophylaxis**

Continuous antimicrobial prophylaxis involves daily administration of a low-dose antimicrobial such as TMP, TMP-SMX, or nitrofurantoin.<sup>1</sup> These agents are ideal because they have minimal adverse effects on the fecal and vaginal flora and have been shown to decrease recurrence rates by 95%.<sup>43</sup> Low-dose prophylaxis is well suited for patients with three or more UTIs annually and is well tolerated.<sup>1</sup>

**Postcoital Prophylaxis**

As mentioned previously, sexual intercourse is a significant risk factor for acute cystitis. Postcoital antimicrobial administration is appropriate for patients with UTI recurrence associated with

intercourse. Single doses of nitrofurantoin, cephalexin, or TMP-SMX have been shown to be effective.<sup>44</sup>

### Self-Start Therapy

A patient on self-start therapy is provided a culture kit as well an antimicrobial preparation so that she may culture her urine and begin therapy promptly after the onset of symptoms. Fluoroquinolones are typically used in self-start therapy. The patient sees her physician after therapy to assess the response. This method has been found to be safe, effective, and economical.<sup>45</sup>

### Uncomplicated Acute Pyelonephritis

A young, sexually active woman without recent antimicrobial use or urologic instrumentation presents with symptoms of flank pain, nausea, vomiting and fever and has costovertebral angle tenderness on examination; this patient most likely has acute pyelonephritis. Treatment for acute pyelonephritis may occur in an outpatient or inpatient setting, depending on patient presentation (Table 86-4).

**Table 86-4 Patient Classification in Acute Pyelonephritis**

Outpatient Therapy	Inpatient Therapy
Not pregnant	Pregnant
Compliant	Noncompliant
Non-toxic-appearing	Septic
No nausea or vomiting	Unable to tolerate oral therapy

From Hooton TM, Stamm WE: Diagnosis and treatment of uncomplicated urinary tract infection. *Infect Dis Clin North Am* 11:551-581, 1997.

Figure 86-1 depicts the appropriate algorithm for the management of acute uncomplicated pyelonephritis, which has a similar etiologic profile to uncomplicated acute cystitis (see Table 86-3). For outpatient therapy, the ISDA recommends a 7-day course of an oral fluoroquinolone.<sup>40</sup> ISDA guidelines for inpatient therapy include a parenteral fluoroquinolone, an aminoglycoside with or without ampicillin, or an extended-spectrum cephalosporin with or without ampicillin. Ampicillin/sulbactam with or without an aminoglycoside is recommended if the offending species is a gram-positive organism.<sup>40</sup> Antimicrobials should be given for a total of 10 to 14 days. The patient may be switched to oral antimicrobials once there has been documented improvement within 72 hours.<sup>7</sup>

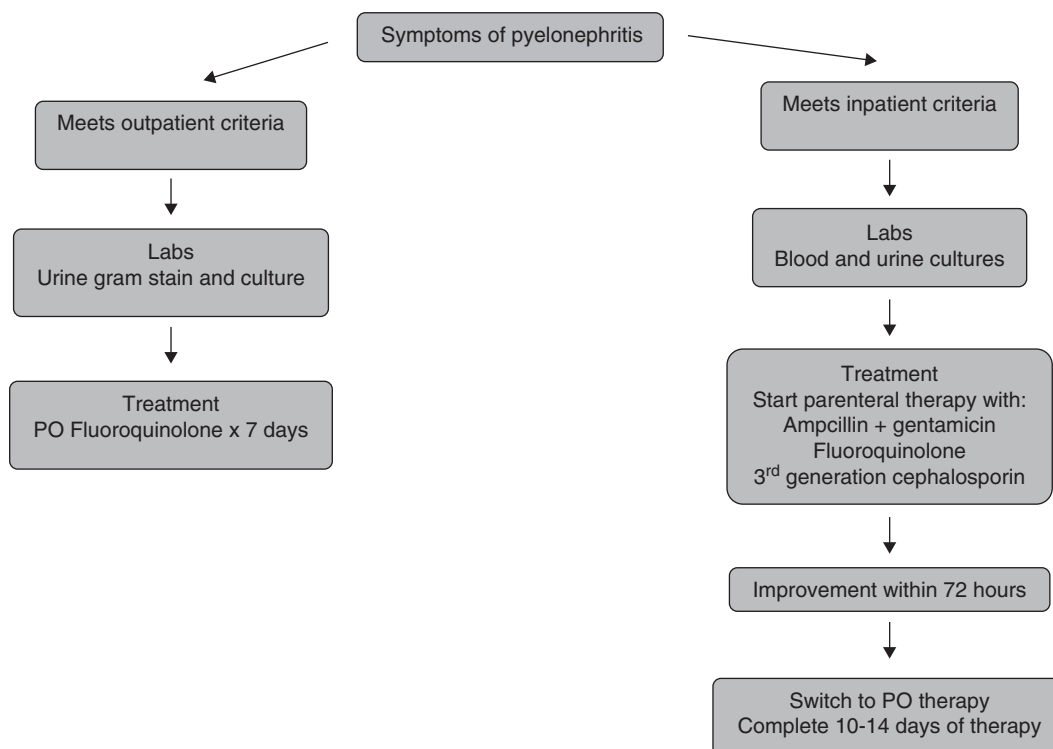

### When is it Appropriate to Obtain Imaging?

If the patient does not improve clinically within 72 hours, the clinician should give serious consideration to obtaining a CT scan or ultrasound study.<sup>46</sup> Some patients may require intervention in addition to antimicrobials. This may include ureteral stenting or placement of a percutaneous nephrostomy to bypass an obstruction, or perhaps drainage of a perinephric abscess.

Imaging may also be helpful in determining whether there is a urologic abnormality, such as struvite stones, foreign bodies, urethral diverticula, or perivesical fistula, that is causing bacterial persistence.<sup>7</sup> A complete list of patient characteristics that should direct the clinician to obtain imaging is included in Box 86-3.

### Complicated Urinary Tract Infection

As mentioned previously, a complicated infection is classified as either an infection that has responded poorly to therapy or one that is associated with host factors that increase the risk of therapy

**Figure 86-1** Algorithm for uncomplicated pyelonephritis. (Adapted from Schaeffer AJ: Infections of the urinary tract. In Walsh PC, Retik AB, Vaughan ED Jr, Wein AJ [eds]: *Campbell's Urology*. Philadelphia, WB Saunders, 2002, pp 516-602.)

**Table 86-5 Host Risk Factors for Complicated Urinary Tract Infection**

Structural/Functional Abnormality	Compromised Host by History	Virulent Bacteria
Obstruction Congenital urinary tract abnormality	Pregnancy Diabetes Spinal cord injury	Recent antimicrobial use Hospitalized or nursing home patient Recent urinary tract instrumentation

Data from Hooton TM: Pathogenesis of urinary tract infections: An update. *J Antimicrob Chemother* 46(Suppl 1):1-7; discussion 63-65, 2000; Bent S, Nallamothu BK, Simel DL, et al: Does this woman have an acute uncomplicated urinary tract infection? *JAMA* 287:2701-2710, 2002; Ronald A: The etiology of urinary tract infection: Traditional and emerging pathogens. *Am J Med* 113(Suppl 1A):14S-19S, 2002.

**Box 86-3 When Is It Appropriate to Obtain Imaging?****On initial assessment, history or findings suggestive of:**

- Ureteral obstruction (may include stone, stricture, tumor, history of genitourinary surgery, or congenital obstruction)
- Sepsis/fever
- Severe diabetes mellitus
- Neurogenic bladder
- Papillary necrosis (sickle cell, diabetes, analgesic abuse)
- Polycystic kidney disease on dialysis

**After initial treatment:**

- Pyelonephritis with poor response to therapy after 72 hr
- Unusual infecting organism (urea-splitting organism, tuberculosis, fungus)

Modified from Schaeffer AJ: Infections of the urinary tract. Walsh PC, Retik AB, Vaughan ED Jr, Wein AJ (eds): *Campbell's Urology*. Philadelphia, WB Saunders, 2002, 516-602.

failure.<sup>8</sup> It is important to recognize patients with complicated UTIs, because there are implications for the workup and treatment. What are the factors that lead to the classification of a complicated UTI? These factors may be classified as structural or functional abnormalities, conditions that compromise host response, and conditions that promote infection with virulent bacteria (Table 86-5).

The pathogenic organisms cultured in complicated UTIs vary from those seen in uncomplicated UTIs (Table 86-6).

If the patient is well enough to be treated as an outpatient, then a fluoroquinolone should be chosen as first-line therapy. However, if the patient has a severe infection requiring admission, then broad-spectrum antimicrobials should be initiated.<sup>7</sup> In general, treatment requires at least 14 to 21 days of antimicrobial therapy.<sup>40</sup> Individual scenarios of complicated infections are discussed in the following paragraphs.

**Obstruction**

*Case:* A 32-year-old woman with a history of nephrolithiasis presents with right-sided flank pain and fever.

Calcium oxalate stones can cause ureteral obstruction and may become secondarily colonized. Other than stones, urinary tract obstruction may also be caused by tumor, clot, or papillary necrosis.

**Urea-Splitting Bacteria that Cause Struvite Stones**

*Case:* A 25-year-old woman with recurrent UTI has recently completed a course of antimicrobials after suffering from a UTI

**Table 86-6 Pathogens Cultured in Complicated Urinary Tract Infections**

Gram-negative organisms	
<i>Escherichia coli</i>	21-54%
<i>Proteus mirabilis</i>	1-10%
<i>Klebsiella</i> species	2-17%
<i>Citrobacter</i> species	5%
<i>Enterobacter</i> species	2-10%
<i>Pseudomonas aeruginosa</i>	2-19%
Other	6-20%
Gram-positive organisms	
Coagulase-negative staphylococci	1-4%
Enterococci	1-23%
Group B streptococci	1-4%
<i>Staphylococcus aureus</i>	1-2%
Other	2%

From Nicolle LE: Recurrent urinary tract infection in adult women: Diagnosis and treatment. *Infect Dis Clin North Am* 1:791-806, 1987.

caused by *P. mirabilis*. A post-therapy urine culture is obtained and grows the same organism. She is currently asymptomatic.

*P. mirabilis* causes alkalinization of the urine, leading to precipitation of calcium, magnesium, ammonium, and phosphate salts and subsequent struvite stone formation. These stones have become known as staghorn calculi because they tend to be large stones that take on the shape of the renal collecting system. Bacteria persist within these struvite stones, and bacteriuria tends to recur almost immediately on discontinuation of antimicrobial therapy. Struvite stones often contain minimal calcium and may not be evident on plain film radiographs.<sup>7</sup>

**Congenital Urinary Tract Anomalies**

*Case:* An 18-year-old woman with a known history of uretero-pelvic junction obstruction presents with a history of recurrent UTIs.

In patients with anomalies of the urinary tract and UTI, recurrent bacteriuria with the same organism typically occurs until the anomalous structure is surgically corrected. Such anomalies include ureteral duplication with ectopic ureter, pericalyceal diverticula, urachal cysts, unilateral medullary sponge kidneys, and congenital obstructions with nonfunctioning kidneys.<sup>7</sup>

**Pregnancy**

*Case:* A 29-year-old pregnant woman in her third trimester presents with fever, left-sided flank pain, nausea, and vomiting.

**Box 86-4 Urinary Tract Changes in Pregnancy****Collecting system**

- Decreased peristalsis of the collecting system and ureters
- Mechanical obstruction of the ureters secondary to enlarging uterus

**Bladder**

- Displaced superiorly and anteriorly

**Kidneys**

- Increased glomerular filtration rate (GFR) by 30-50%

From Waltzer WC: The urinary tract in pregnancy. *J Urol* 125:271-276, 1981.

Although it has been shown that the incidence of bacteriuria in pregnant women is similar to that in their nonpregnant counterparts, the incidence of acute pyelonephritis is significantly increased in pregnant women compared with nonpregnant women.<sup>47</sup> This is perhaps due to the numerous anatomic and physiologic changes that occur in the urinary tract during pregnancy (Box 86-4). Not surprisingly, pyelonephritis is most commonly seen in the third trimester, when stasis and hydronephrosis are most evident.<sup>7</sup>

Before the advent of antimicrobial therapy, pregnant women with pyelonephritis had an increased rate of infant prematurity and perinatal mortality. Today, there is continued debate in the literature as to whether gestational pyelonephritis leads to prematurity and subsequent perinatal mortality. In any case, patients with pyelonephritis during pregnancy should be admitted and treated with parenteral agents.<sup>7</sup> Antimicrobials that are safe to use during pregnancy include penicillins, cephalosporins, and nitrofurantoin. The latter, however, should not be used in pyelonephritis, because it does not achieve adequate tissue penetration. Agents that may be harmful to the developing fetus should be avoided. Fluoroquinolones may impair cartilage development, and TMP-SMX is associated with antifolate teratogenicity in the first trimester and with neonatal hyperbilirubinemia in the third trimester.<sup>48</sup> After treatment, women should either be given prophylaxis or monitored closely throughout the remainder of the pregnancy, because there is an increased risk of repeated episodes of pyelonephritis.<sup>49</sup>

**Diabetes Mellitus**

*Case:* A 45-year-old woman with poorly controlled diabetes is admitted to the hospital with acute pyelonephritis. Despite parenteral antimicrobial therapy for 3 days, she continues to have high, spiking temperatures.

The incidence of UTI in diabetic women has been shown to be substantially higher than in nondiabetic women.<sup>50</sup> Treatment may be more difficult if glomerulopathy is present, because urine concentration of antimicrobials may be less than optimal.<sup>7</sup> Diabetes is also associated with specific entities such as intrarenal and perirenal abscess, emphysematous pyelonephritis and cystitis, xanthogranulomatous pyelonephritis, and papillary necrosis.<sup>8</sup> Further discussion of these entities is beyond the scope of this chapter.

**Spinal Cord Injuries**

*Case:* A 27-year-old woman with a history of a thoracic spinal cord injury presents with fevers and foul-smelling urine. She manages her bladder with clean intermittent catheterization.

The method of bladder management plays a large role in UTI in these patients. Patients with indwelling urethral or suprapubic catheters have high rates of infection.<sup>51</sup> Clean intermittent catheterization was introduced in 1972 and revolutionized bladder management of patients with spinal cord injury. It has been shown to reduce the risk factors for UTI by decreasing intravesical pressure and the incidence of stones.<sup>52</sup> Nevertheless, UTI is a common problem in spinal cord-injured patients and is often difficult to diagnose. Because of loss of sensation, patients do not present with the typical symptoms of frequency, urgency, or dysuria. Additionally, urinalysis in these patients often demonstrates bacteriuria and pyuria regardless of the presence of infection. Therefore, the diagnosis is often clinical, based on symptoms of flank, back, or abdominal discomfort; leakage between catheterizations; fever; increased spasticity; and/or cloudy, malodorous urine.<sup>7</sup> A urine culture must be obtained before therapy is initiated, because there is a high probability of bacterial resistance.<sup>7</sup> Spinal cord-injured patients with recurrent UTI should undergo urinary tract imaging, urodynamic testing, and a review of their bladder management program.<sup>53</sup>

**SPECIAL CONSIDERATIONS****Urinary Tract Infection Prophylaxis**

A nonantimicrobial treatment that prevents UTIs would be extremely useful for women who suffer from recurrent UTIs.

**Cranberry**

Two compounds in cranberries, fructose and proanthocyanidin, have been found to inhibit *E. coli* adhesins in vitro.<sup>54</sup> This finding is likely the basis for the widespread belief among laypersons that cranberries prevent UTIs. Despite a number of clinical trials, at this time there is no compelling evidence that cranberries or cranberry products prevent UTIs.<sup>55</sup>

**Lactobacilli**

Lactobacillus probiotics have been proposed as means of enhancing the natural host defenses by restoring the presence of a normal vaginal microflora.<sup>56,57</sup> Various properties of lactobacillus are believed to be protective against uropathogenic organisms. These include maintenance of an acidic pH, direct killing of pathogens through the production of H<sub>2</sub>O<sub>2</sub>, and competitive inhibition of bacterial adherence.<sup>58</sup>

Multiple small trials have been conducted using *Lactobacillus* species to recolonize the vaginas of women with recurrent UTI. These studies have produced mixed results, and further research in this area is needed.<sup>57</sup>

**Vaccine**

Several vaccines to provide protection against UTI caused by *E. coli* or other uropathogens are currently under development. Preliminary studies are promising for short-term protection from recurrences, but it remains to be seen whether long-term efficacy can be demonstrated.<sup>57</sup>

**Asymptomatic Bacteriuria of Pregnancy**

Asymptomatic bacteriuria occurs in 4% to 6% of both pregnant and nonpregnant women.<sup>59</sup> Despite these similar rates, the number of pregnant women who develop pyelonephritis is sig-

nificantly higher than in nonpregnant women. It has been reported that as many as 20% to 40% of pregnant women with asymptomatic bacteriuria subsequently develop acute pyelonephritis.<sup>60,61</sup> Treatment of bacteriuria early in pregnancy has been shown to decrease the incidence of pyelonephritis by 90%.<sup>62</sup>

The American College of Obstetricians and Gynecologists currently recommends screening for asymptomatic bacteriuria in

pregnancy.<sup>60,63</sup> Obtaining a urine culture once at the end of the first trimester is sufficient. Repeated screening of women with initial negative urine cultures is not recommended, because the risk of pyelonephritis is low.<sup>63</sup> If the urine culture is positive, a repeat specimen for culture should be obtained and treatment initiated. After treatment, women should have periodic urine cultures to identify recurrent bacteriuria throughout the remainder of the pregnancy.<sup>64</sup>

# VULVAR AND VAGINAL PAIN, DYSPAREUNIA, AND ABNORMAL VAGINAL DISCHARGE

Andrea J. Rapkin and Monica Lee

### DEFINITION OF VULVODYNIA AND CURRENT NOMENCLATURE

The purpose of this chapter is to outline the anatomy and physiology of vulvar and vaginal pain syndromes and to explore the differential diagnosis and management of vulvar and vaginal pain and dyspareunia (Tables 87-1 and 87-2), including the roles of medication, surgery, psychotherapy, and multidisciplinary pain management. The differential diagnosis and management of abnormal vaginal discharge is also discussed.

Vulvar pain syndromes are characterized by unexplained burning or any combination of stinging, irritation, itching, pain or rawness anywhere from the mons pubis to the anus that causes physical, sexual, and psychological distress. A multitude of terms have been used in the literature to describe vulvar pain syndromes. Vulvodynia was first described in 1889 by A. J. C. Skene<sup>1</sup> but received little attention until the 1970s. The International Society for the Study of Vulvovaginal Diseases (ISSVD) abandoned the term “burning vulva syndrome,” first described in 1984,<sup>2</sup> and introduced a classification wherein the two principal divisions were vulvar vestibulitis syndrome (VVS) and dysesthetic or essential vulvodynia.<sup>3</sup> The most recent classification of vulvar pain, which was agreed on at the October 2003 Congress of the ISSVD, consists of two major categories<sup>4</sup>:

1. *Vulvar pain* related to a specific disorder
  - a. Infection
  - b. Inflammation
  - c. Neoplasm
  - d. Neurologic disease
2. *Vulvodynia*: vulvar discomfort, usually described as burning pain, occurring in the absence of a specific disorder
  - a. *Generalized* (involving the entire vulva) or *localized* (involving a portion or component of the vulva, such as the vestibule, clitoris, or hemivulva)
  - b. *Provoked* (i.e., by sexual and/or nonsexual contact), *unprovoked* (i.e., spontaneous), or *mixed* (provoked and unprovoked).

The term *vestibulitis* signifies the presence of inflammation, which was thought to be misleading because much evidence suggests no such presence. Therefore, the ISSVD voted to discontinue use of this term.

### INCIDENCE AND EPIDEMIOLOGY OF VULVODYNIA

The typical patient with vulvodynia used to be described as a nulliparous woman in her 20s or early 30s who often may have developed symptoms suddenly.<sup>5</sup> The true prevalence of vulvo-

dynia is uncertain due to its recent recognition; however, a 1991 study of 210 consecutive patients seen at a private practice for general gynecology found that 37% had some degree of positive testing for vulvar discomfort, and 15% met full criteria.<sup>6</sup> A survey of more than 4900 women aged 18 to 64 years reported that 16% of the 3000 respondents had experienced vulvar pain lasting at least 3 months; 7% had vulvar pain at the time of the survey, and many had seen up to five different doctors for this problem.<sup>7</sup> Unexplained vulvar pain was found to be of similar incidence among white and African American women. Hispanic women were 80% more likely than white women to have experienced chronic vulvar pain.

### ANATOMY OF THE VULVA AND VAGINA

The vulva is the part of female anatomy located between the genitocrural folds laterally and between the mons pubis anteriorly and the anus posteriorly (Fig. 87-1).<sup>8</sup> It is composed of the labia majora, labia minora, mons pubis, clitoris, vestibule, urinary meatus, vaginal orifice, hymen, Bartholin's glands, Skene's ducts, and vestibulovaginal bulbs.

The labia majora form the lateral boundaries of the vulva and consist of two large folds of adipose and fibrous tissue. Anteriorly, the labia majora fuse into the mons pubis; posteriorly, they become narrower and flatter and terminate 3 to 4 cm anterior to the anus, where they are united by the posterior commissure or fourchette. The skin of the labia majora is usually darker than the adjacent skin. The skin has an outer lining of stratified squamous epithelium. Within the dermis are numerous hair follicles and sebaceous, sweat (eccrine), and apocrine glands.

The labia minora lie between the labia majora and consist of two flat folds of connective tissue containing little or no adipose tissue. They are covered by skin on their lateral aspects and partially so on their medial aspects. Hart's line separates the medial boundary of the minora from the vestibule and is the line of demarcation between the skin and mucous membrane; it runs along the base of the inner aspect of each labia minora, passes into the fossa navicularis, and separates the skin boundary of the fourchette from the mucous membrane of the hymen. The labia minora are 4 to 5 cm in length and 0.5 cm in thickness. Anteriorly, each divides into two parts, one passing over the clitoris to form the prepuce and the other joining the clitoris to form the frenulum. Posteriorly, they tend to become smaller and blend with the medial surfaces of the labia majora or unite anterior to the posterior commissure to form the fourchette. The skin and mucosa of the labia minora are extremely rich in sebaceous glands. During sexual excitement, the labia minora frequently

become swollen and congested and take on the appearance of erectile tissue.

The clitoris is the female homologue of the penis. It consists of two cylindrical erectile bodies, called the corpora cavernosa, that terminate in the vestibule as the glans. The body of the clitoris is approximately 2 cm long, is formed by the fusion of the two corpora cavernosa, and extends posteriorly from the pubic arch to the glans. The glans of the clitoris is covered by a mucous membrane containing many special nerve end organs.

The vestibule is the portion of the vulva that extends from the clitoris to the fourchette and is visible on separation of the labia majora. Hart's line represents the outer perimeter of the vulvar vestibule, and the inner margin of the vestibule is the hymen. The vestibule is covered by nonpigmented, nonkeratinized squamous epithelium and is devoid of skin adnexa. It contains mucus-secreting minor vestibular glands. The ductal orifices of Bartholin's glands, the periurethral gland complexes of Skene, and the urethral meatus all empty onto the vestibular surface. The vagina opens into the vestibule. The hymen is the thin membrane of

**Table 87-2 Evaluation of Patients with Vulvar or Vaginal Pain**

History	Detailed pain history, obstetric/gynecologic, sexual, medical, surgical, psychosocial, medications, allergies, habits, trauma
Vulvar examination	Inspection: lesions (macules, papules, ulcers, nodules), fissures, fistulas, inflammation (edema, erythema), discharge, tumors, anatomic abnormalities (surgical, congenital, traumatic). Palpation: localize pain with cotton swab, identify specific neural distribution, vestibule, Bartholin's, Skene's, hymenal caliber, urethra Biopsy and/or culture suspicious lesions (e.g., VIN, ulcers, verrucae, white or red plaques); colposcopic magnification of lesions if indicated
Vaginal examination	Speculum examination: inspect mucosa (color, rugations, lesions) pH of discharge Wet mount saline and KOH: infection, atrophy Culture (fungal, bacterial): vagina, cervix Cystocele, rectocele, enterocele, uterine prolapse, cervical discharge, lesions Palpate, attempt to reproduce pain: hymen, bladder, individual pelvic floor muscles, ischial spine area for pudendal nerves, inferior hypogastric plexus (paracervical), cervical motion tenderness
Bimanual examination	Assess ability to contract and relax muscles Uterus: size, shape, position, mobility, tenderness, uterosacral ligament thickening/nodularity, tenderness, adnexal masses, tenderness, mobility Cervical motion tenderness
Rectovaginal examination	Rectal masses, stool guaiac, nodules/fibrosis in cul-de-sac
Additional diagnostic tests as needed	Pelvic floor MRI, pelvic ultrasound, pudendal nerve conduction velocity, diagnostic nerve blocks (local, pudendal, inferior hypogastric), cystourethroscopy, sigmoidoscopy, physical therapist evaluation of pelvic floor, psychological/stress/couples evaluation, HSV serology, urine analysis and culture
Create differential or specific diagnoses	Specific infectious, inflammatory, or anatomic pathology. Treat per diagnosis (e.g., pharmacologic, surgical)
	Neuroplastic or neuropathic/neuromuscular pain requires a multidisciplinary approach: physical therapy, psychology (cognitive/behavioral/biofeedback/sexual), series of specific nerve blocks, pharmacologic (medications to alter nerve conduction or for depression/anxiety, such as antidepressants, anticonvulsants, local anesthetics, or muscle relaxants [Botox])

HSV, herpes simplex virus; KOH, potassium hydroxide; MRI, magnetic resonance imaging; VIN, vulvar intraepithelial neoplasm.

connective tissue over the entrance of the vagina into the vestibule. Bartholin's glands lie deep beneath the fascia, one on each side of the vestibule, posterolaterally to the vaginal orifice. The cells lining the acini contain mucin, which is secreted during sexual excitement and contributes to lubrication of the vaginal orifice. The main ducts of Bartholin's glands open into the vestibule at approximately the 5 and 7 o'clock positions, outside the hymenal ring. The urethra opens into the vestibule just anterior to the vaginal introitus.

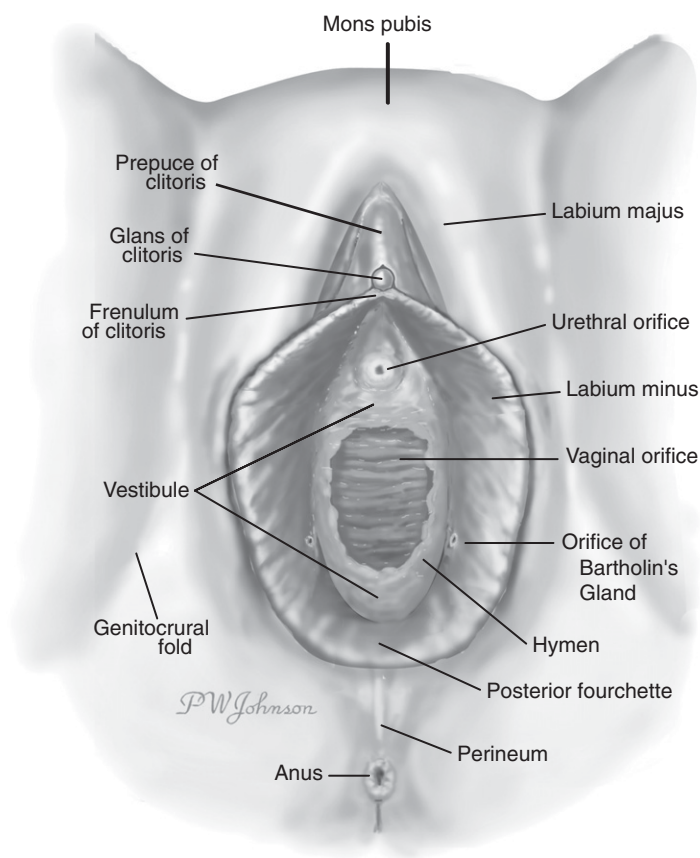

Arterial blood supply to the vulva comes from the internal pudendal artery, which derives from the internal iliac artery (hypogastric artery), and from branches of the external pudendal artery, which derives from the femoral artery. The veins of the vulva form a large plexus, which empties into the internal and external pudendal veins.

Innervation of the vulva is supplied by the cutaneous branches of the ilioinguinal nerve anterosuperiorly and by the pudendal branches of the femoral cutaneous nerve posteroinferiorly (Fig. 87-2). The three roots of the pudendal nerve derive from the second, third, and fourth sacral nerves; they unite approximately 1 cm proximal to the ischial spine, then leave the pelvic cavity by passing through the greater sciatic foramen.<sup>9</sup> The pudendal nerve subsequently passes posterior to the junction between the ischial

spine and the sacrospinous ligament, then reenters the pelvic cavity through the lesser sciatic foramen and proceeds anteriorly through Alcock's canal. The major cutaneous nerve supply of the perineum is provided by the branches of the pudendal nerve.<sup>9</sup> The inferior hemorrhoidal nerve supplies the posterior portion; the superficial branch of the perineal nerve divides into medial and lateral parts known as the posterior labial nerves, and the dorsal nerve of the clitoris innervates the clitoral area.

The vagina extends from the vestibule to the uterus and is directed obliquely upward and backward at an angle approximately 45 degrees to the horizontal axis. Its long axis is parallel to the plane of the pelvic brim and at a right angle to the uterus. The upper one third of the vagina is in contact with the base of the bladder, and the entire lower two thirds is in contact with the urethra. The vagina consists of three principal layers: an outer fibrous layer that derives from pelvic fascia, a middle muscular layer, and an inner mucosal layer.

The pelvic floor muscles include the levator ani, pubococcygeus, and coccygeus muscles. All of the fasciae investing the muscles form a continuum of connective tissue that joins the fascial covering of the pelvic viscera above with the fascia of the perineum below.<sup>9</sup> The levator ani muscle is a broad, thin structure that is attached to the inner surface of the side of the

**Figure 87-1** Vulvar anatomy. (Redrawn from Kaufman RH: *Benign Diseases of the Vulva and Vagina*, 5th ed. St. Louis, Elsevier Mosby, 2005.)

true pelvis.<sup>9</sup> It is attached anteriorly to the pelvic surface of the body of the pubis, lateral to the symphysis; behind, to the medial surface of the spine of the ischium; and between these two points, to the obturator fascia. Morphologically, the levator ani can be divided into the pubococcygeus and the iliococcygeus muscles.

The pubococcygeus muscle arises from the posterior surface of the pubis and from the anterior part of the obturator fascia. Its fibers are directed backward, almost horizontally, along the line of the anal canal and become attached to the front of the coccyx by a tendinous plate that is continuous with the anterior sacrococcygeal ligament. The medial coccygeal muscle arises from the ischial spine and from the posterior part of the tendinous arch of the levator ani muscle. Its fibers attach to the sides of the coccyx and to the opposite muscle in the median raphe on the undersurface of the tendinous plates of the pubococcygeus that contribute to the anococcygeal ligament. The superior or pelvic surface of the levator ani is separated by its covering fascia from the bladder, rectum, and perineum, whereas its inferior and or perineal surface forms the medial boundary of the ischioanal fossa and is covered by the inferior fascia of the pelvic diaphragm. Its posterior border is free and is separated from the coccygeus muscle by areolar tissue, whereas the medial borders of the two muscles are separated by the visceral outlet, an interval through which the urethra, vagina, and anorectum pass from the pelvis. The nerve supply of the levator ani muscle includes a branch from the S4 nerve, a branch that arises either from the inferior

rectal nerve or from the perineal branch of the pudendal nerve. The function of the levator ani muscle is constriction of the lower end of the rectum and vagina, and probably fixation of the perineal body as well. The levator ani, together with the coccygei, form a muscular diaphragm that supports the pelvic viscera and opposes itself to the downward thrust produced by any increase in intra-abdominal pressure.

The coccygeus muscle is posterosuperior in the same tissue plane as the levator ani muscle. It consists of a triangular sheath of muscular and tendinous fibers, arising by its apex from the pelvic surface of the spine of the ischium and sacrospinous ligament. It is attached at its base to the margin of the coccyx and the side of the S5 segment. The muscle receives its nerve supply through branches of the S4 and S5 spinal nerves. The coccygeus functions in pulling forward and supporting the coccyx after it has been pressed backward during defecation or parturition. The coccygeus, together with the levator ani and piriformis muscles, closes the posterior part of the pelvic outlet.

The chief sources of blood supply to the vagina are the uterine, pudendal, and middle hemorrhoidal arteries, which arise from the internal iliac arteries. They form a plexus around the vagina. The upper portion is supplied by a descending branch of the uterine artery, the cervical-vaginal artery. The lower half of the vagina is supplied by ascending branches of the middle hemorrhoidal arteries; the dorsal artery, which originates from the internal pudendal, supplies the clitoris.

## EVALUATION

### History

Obtaining a thorough history is critical in the evaluation and management of vulvar or vaginal pain and dyspareunia (see Table 87-2). Pain symptoms must be well characterized to assess the onset, type of pain (burning, itching, stinging, irritating), timing (constant or cyclic), associated activities (e.g., intercourse, exercise, stress), inciting agents (perfume, lotions, detergents, clothing), and relieving factors (e.g., antifungal medications). A daily pain diary may better define these characteristics. Pain should be quantified on each visit on a scale of 1 (no pain) to 10 (maximal pain imaginable). Concurrent gynecologic, genitourinary, and gastrointestinal symptoms should be identified.

In addition, past or current infections (human papillomavirus [HPV], herpes, *Candida*), medications, local and systemic dermatologic disorders, neurologic disorders (e.g., herniated disk, herpes zoster, pudendal or genitofemoral neuralgia), urologic disorders (interstitial cystitis, urethral syndrome), physical trauma (vaginal deliveries, episiotomy, vaginal surgery), and fibromyalgia should be ascertained. Sexual history evaluating arousal, lubrication, ability to achieve orgasm, whether pain is primary or secondary, and a history of sexual, physical, or emotional abuse should be addressed.<sup>10</sup>

### Physical Examination

In many cases, the vulva appears normal. However, careful inspection should be performed to evaluate for discoloration (erythema, hypopigmentation, or hyperpigmentation), lesions (ulcers and fissures) and atrophy (white epithelium consistent with lichen sclerosis or absence of well-estrogenized tissue). On examination, tenderness (hyperesthesia) at the periurethral or

**Figure 87-2** Nerves of perineum and external female genitalia. (Redrawn from © Netter images “Nerves of Perineum and External Genitalia Female.” www.netter images.com).

Bartholin’s glands and the vulvar vestibule should be outlined using a cotton-tipped swab, scored (on a scale from 0, no pain, to 10, severe pain), and recorded.

The hymeneal ring should be assessed for remnants or tight annular hymen which could tear with intercourse and cause dyspareunia. Tone and tenderness and trigger points of the pelvic floor muscles should be assessed. Pudendal nerves proximal to the ischial spines should be palpated for tenderness. It should be determined whether the pain is within the distribution of a particular branch of the pudendal, genitofemoral, ilioinguinal, or inferior hypogastric nerve.

Vaginal pH, whiff test, and microscopic examination of the vaginal secretions with saline and potassium hydroxide (KOH) should be performed to rule out vaginitis, vaginosis, and vaginal atrophy. Vaginal fluid may be cultured for *Candida* (because microscopic evaluation reveals candidiasis in only 50% of cases), bacterial culture and immunoglobulin E (to evaluate for local allergy). All lesions or discolorations should be further evaluated

by colposcopy or biopsy to evaluate for an underlying dermatosis or an infectious or neoplastic process.<sup>10</sup>

## DIFFERENTIAL DIAGNOSIS OF VULVAR OR VAGINAL PAIN

### Vaginitis

The vaginal mucosa has only a few nerve endings needed for the sensations of pain and light touch.<sup>11</sup> For this reason, many vaginal infections are asymptomatic until the discharge reaches the vulva, where there is abundant somatic innervation. The problem is then perceived as vulvar itching, burning, or pain.

### Vaginal Ecology

In childhood and menopause, in the absence of estrogen, the vaginal epithelium is thin and undifferentiated.<sup>11</sup> Estrogen causes

thickening of the epithelium and a differentiation into well-recognized layers (basal, intermediate, and superficial). The percentage of superficial cells on a vaginal smear is indicative of the amount of estrogen activity. The vagina has a large amount of glycogen, second only to the liver, and it is most available in the superficial layers. Estrogen effects the formation and deposition of glycogen in the vagina.

Glycogen is important as a substrate for a series of enzymatic and fermentative processes that result in the production of lactic and acetic acid. Normal vaginal flora, consisting largely of lactobacilli and acidogenic corynebacteria, produce lactic and acetic acid from glycogen and its breakdown products. These organisms exist in a delicate balance with a small amount of *Candida*. The result of this symbiosis is a low vaginal pH, a milieu that is highly selective for bacterial growth and favors only the lactobacilli, corynebacteria, and *Candida* organisms. Changes in the vaginal flora pH or inoculum of a large amount of foreign bacteria can change this delicate equilibrium and lead to overgrowth of foreign invaders. At a low pH (3.5 to 4.1), normal vaginal flora predominate, but as the pH rises, various pathogens replace them. Interruption of the delicate balance of the vaginal flora can result from antibiotic treatments, pregnancy, oral contraceptives, intercourse, and menses. The vaginal pH is increased with vaginitis, bacterial vaginosis, and atrophy.

### Vaginitis: Description, Diagnosis, Treatment

#### Bacterial Vaginosis

Bacterial vaginosis, the leading cause of abnormal vaginal discharge (according to the American College of Obstetricians and Gynecologists [ACOG], 1996) is a polymicrobial syndrome in which synergistic activity occurs among a characteristic set of bacterial species (*Gardnerella vaginalis* and anaerobic bacteria).<sup>12</sup> Risk factors for bacterial vaginosis infection include multiple or new sexual partners (male or female), early age at first coitus, douching, cigarette smoking, and use of an intrauterine contraceptive device. Approximately 50% to 75% of women who have bacterial vaginosis are asymptomatic. Symptomatic bacterial vaginosis is associated with a “fishy” odor, thin white or gray discharge, absence of pruritus, and inflammation with rare dysuria and dyspareunia.

Diagnosis of bacterial vaginosis is by clinical criteria. Three of the four Amstel criteria have been traditionally needed for diagnosis of bacterial vaginosis. However, a recent study showed that use of only two of the four criteria does not change the specificity or sensitivity of diagnosis.<sup>13</sup> The Amstel criteria include the following:

1. Homogeneous, grayish-white discharge
2. Vaginal pH greater than 4.5
3. Positive whiff-amine test, defined as the presence of a fishy odor when 10% KOH is added to vaginal discharge samples
4. Clue cells on saline wet mount. (Vaginal culture plays no role in diagnosis, because the organisms are detected in 50% to 60% of healthy asymptomatic women.)

Treatment of bacterial vaginosis is indicated for patients with symptomatic infection, those with asymptomatic infection before abortion or hysterectomy, and asymptomatic women with previous preterm births. It is not necessary to treat sexual partners. The condition spontaneously resolves in up to one third of

women. Treatment regimens include metronidazole or clindamycin, orally or intravaginally. Metronidazole is the most successful therapy, with cure rates of greater than 90% in 1 week and 80% at 4 weeks.<sup>14,15</sup> The recommended dose is 500 mg twice a day for 7 days.<sup>16</sup> Topical vaginal therapy with 0.75% metronidazole gel, 5 g once daily for 5 days, is just as effective as the oral regimen.<sup>16,17</sup> A single oral dose of 2 g of metronidazole is an alternative regimen with higher relapse rate but a similar immediate rate of response.<sup>16</sup> Clindamycin appears to be less effective but is a reasonable alternative to metronidazole. It is available as topical vaginal therapy 2% cream, 5 g once daily for 7 days, or oral therapy at 300 mg twice daily for 7 days, or ovules 100 mg once daily for 3 days. Other, less effective therapies include triple-sulfa creams, erythromycin, tetracycline, acetic gel, povidone-iodine pouches, ampicillin, and amoxicillin.

#### *Candida*

*Candida* vulvovaginitis accounts for approximately one third of vaginitis cases. Studies suggest that 75% of women will suffer an attack at least once in their life.<sup>8</sup> The infection is less common in postmenopausal women unless they take estrogen therapy. About half of those infected experience more than one episode.

*Candida albicans* infection accounts for 80% to 90% of candidiasis cases; the remainder are evenly split between *Candida glabrata* and *Candida tropicalis*. The presence of estrogen, directly or indirectly, enhances candidal growth.<sup>18</sup> The organism thrives in many body locations, such as vaginal fluid,<sup>19</sup> as well as unsterile saliva.<sup>20</sup> In one study, one half of infected patients were found to harbor *Candida* in the mouth, and about one third had *Candida* in the anorectal tract; one fourth were found to be colonized in the vagina.<sup>21</sup> Besides the gut and vagina, intertriginous skin areas are especially susceptible including the vulva, groin, axillae, coronal sulcus, and the skin folds of the breast and panniculus. The organism needs warmth and moisture and does not survive long on dry skin. Tight-fitting clothing, especially if made of synthetic fabric, is more conducive to *Candida* than loose clothing is.

The mechanism by which *Candida* species cause symptomatic disease is complex, and includes the host inflammatory response to invasion and yeast virulence factors (e.g., elaboration of proteases). Factors predisposing to symptomatic infection include diabetes, immune suppression, pregnancy, oral contraceptives, antibiotics, metabolic factors (hypothyroidism, anemia, zinc deficiency), and diet. Pregnancy is the most common predisposing factor, with the incidence and severity of infection increasing with the duration of gestation. The increased glycogen content and high hormone levels constitute a favorable environment for the growth of candidal organisms. The newer oral contraceptives have lower estrogen levels and do not seem to predispose patients to *Candida* infection. Furthermore, one study found that only pill-using women with active herpetic, condylomatous, or anaerobic vaginal infections had increased prevalence of candidiasis.<sup>22</sup> Antimicrobials are thought to act as predisposing factors by reducing the number of protective resident bacteria. Some studies have shown that those patients who go on binges of dietary sweets suffer from recurrence of candidiasis and have high levels of urinary sugars derived from lactose and sucrose. By restricting lactose intake, 90% of these patients were able to maintain disease free intervals for longer than 1 year. If a patient has chronic refractory candidiasis, one may consider the possibility of acquired immunodeficiency syndrome (AIDS). Candidiasis has not been traditionally considered a sexually transmitted disease

(STD), especially because it does occur in celibate women. However, it may be linked to orogenital sex.<sup>23</sup>

Vulvar pruritus is the main symptom of candidiasis. Some women notice itching only before menses, and others complain of symptoms only after intercourse. Burning is also a common complaint, particularly on urination, and it is often experienced in those who scratch. Some patients develop reflexive urinary urgency and frequency. The combination of these symptoms can often be mistakenly diagnosed as cystitis. Dyspareunia can be present. Physical examination reveals erythema of the vulva (sometimes with erythematous papules or satellite lesions) and vaginal mucosa. The discharge is classically described as thick, adherent, and “cottage-cheese like,” but it can also be thin and loose.

Diagnosis is by vaginal pH, wet-mount, KOH, and culture. Candidal vaginal pH is 4 to 4.5. A pH value of 4.7 or higher essentially limits the diagnosis to candidiasis or physiologic discharge. The diagnosis is confirmed by KOH wet mount and microscopic examination of vaginal material. The addition of 10% KOH destroys cellular elements and facilitates recognition of budding yeast and pseudohyphae. Because microscopy is negative in up to 50% of patients with confirmed vulvovaginal candidiasis, culture should be performed for patients with persistent or recurrent symptoms.

Treatment of candidiasis is indicated for relief of symptoms. Those who harbor *Candida* but are asymptomatic do not require therapy. Most patients (90%) have uncomplicated infections. The most commonly used antifungal agents are the azoles. There are both oral and vaginal preparations. The only oral preparation recommended is fluconazole: a 150-mg dose of fluconazole is as effective as multiple doses of intravaginal clotrimazole and oral butoconazole. Complicated infections occur in women with uncontrolled diabetes, immunosuppression, or a history of recurrent vulvovaginal candidiasis, and in those who are infected with *Torulopsis (Candida) glabrata*, or *C. tropicalis*. These women are less likely to respond to short courses of antimycotic drugs and may require 7 to 14 days of topical therapy or two doses of oral therapy 72 hours apart. Between 65% and 70% of those infected with *C. glabrata* respond to intravaginal boric acid (600 mg daily for 2 weeks), or a cure rate of more than 90% may be achieved with flucytosine cream (5 g nightly for 2 weeks).<sup>24</sup> Documented recurrent infections warrant testing for human immunodeficiency virus (HIV) infection and glucose tolerance testing and may require weekly and then monthly therapy for 4 to 6 months.

### Trichomonas

The prevalence of *Trichomonas* infection depends greatly on the population studied. *Trichomonas* was found in 3% of unselected, asymptomatic college women,<sup>25</sup> 15% of private patients with leukorrhea,<sup>26</sup> 6% to 8.9% of pregnant women,<sup>27</sup> and 34% of pregnant inner-city adolescents.<sup>28</sup> Nevertheless, there seems little justification for screening low-risk, nonpregnant, asymptomatic individuals.

*Trichomonas vaginalis* is a unicellular protozoan flagellate, round or almond-shaped, slightly larger than a polymorphonuclear leukocyte.<sup>8</sup> Under high-power microscopy, four flagella can be seen to protrude from the forward end of the trichomonad. They are found in the vagina, urethra, and paraurethral glands.

This disorder is almost always sexually transmitted and can be identified in 30% to 40% of male sexual partners of infected

women. The infection is associated with a high prevalence of coinfection with other STDs. There is a positive association between trichomonas infection and HIV infection.<sup>29</sup> Trichomonads can survive in an aqueous environment between 20 and 30 degrees and can remain infectious for up to 24 hours.<sup>30</sup> Women can deposit the trichomonads on toilet seats, on which the organism can survive up to 45 minutes.<sup>31</sup>

There are several signs and symptoms of trichomoniasis. One pathognomonic sign is abundant green, frothy, foul-smelling discharge with an alkaline pH (>6). Sometimes, generalized erythema is the only gross change in the vaginal tissue. “Strawberry vagina” is also associated with trichomoniasis, when the presence of swollen papillae project through a layer of discharge. Pruritus, or itching, is the second most common manifestation of trichomoniasis. Other symptoms include dyspareunia, urinary symptoms from urethrocystitis, discharge from the urethra and Skene’s ducts, and erythema of the vulva.

The most practical and cost-effective diagnostic test available is still the saline wet mount done in a clinic setting.<sup>8</sup> However, motile trichomonads are found only in 50% to 70% of culture-confirmed cases. Culture on Diamond’s medium is 95% sensitive and more than 95% specific but should only be used if there is a high clinical suspicion despite a negative wet mount result, or wet mount is unavailable. Diagnosis with classic Pap smears is not recommended, but diagnosis with liquid-based pap smears has been shown to be highly specific (99%) and sensitive (61%).<sup>32</sup>

Treatment is indicated in all nonpregnant women diagnosed with *Trichomonas* vaginitis and their sexual partners. *Trichomonas* is associated with preterm rupture of membranes and prematurity in pregnant women, but treatment has not been shown to decrease these complications.<sup>33</sup> Oral metronidazole is the treatment of choice; it is preferred over the vaginal route, because systemic administration achieves therapeutic drug levels in the urethra and periurethral glands, which serve as sources for endogenous recurrence. There is no need to identify the source in the male partner before treating him. It has been shown that a single 2-g dose to both sexual partners is as effective as the classic regimen, 500 mg twice a day for 7 days.<sup>34</sup> The advantages of the single-dose regimen include better compliance, a lower total dose, shorter period of alcohol avoidance (due to the disulfiram-like effect of metronidazole), and possibly decreased *Candida* superinfection. In the event of treatment failure, the 7-day regimen should be prescribed before resistance is suspected; many cases of “failure” result from reinfection, possibly from a different or untreated partner.<sup>8</sup>

### Desquamative Vaginitis

Desquamative inflammatory vaginitis (DIV) is not a diagnosis in itself and may be the presentation of a range of blistering disorders, including pemphigus vulgaris, lichen planus, and mucous membrane pemphigoid.<sup>35</sup> The existence of an idiopathic subset of DIV remains controversial. It is a rare but disabling condition and manifests in women of any age with a history of discomfort, irritation, and dyspareunia. Women who develop DIV are different from those who typically develop STDs, being older, married, and with higher levels of education. Patients may complain of increased yellow vaginal discharge.

Examination of the vulva is normal, but erythematous regions on the vaginal walls are evident, with increased vaginal secretion. Repeated cultures are negative for pathogenic bacteria, viruses, and yeast. Microscopic examination of the vaginal discharge shows an increased number of immature epithelial cells, typical

rounded parabasal cells, and an increase in polymorphonuclear leukocytes. Gram staining shows an absence of lactobacilli and occasionally increased levels of gram-positive cocci. The vaginal pH is increased from normal to 7.4. A biopsy of the erythematous portion of the vaginal wall for histology and immunofluorescence is necessary to exclude any underlying cause of DIV.

This sterile inflammatory vaginitis is difficult to treat, but successful therapy has been reported with steroids and clindamycin. Studies have found that 2% clindamycin suppositories or high-potency intravaginal steroids alone or in combination with oral clindamycin for 4-6 weeks have been effective.<sup>36,37</sup> Estrogen deficient women need supplementary vaginal estrogen therapy to maintain remission.

### *Herpes Simplex Virus*

In the United States, the frequency of genital herpes simplex virus (HSV) is increasing. There are two types of HSV infection; it is reported that HSV-2 causes the most genital infections, and HSV-1 causes the most labial infections. However, HSV-1 genital infections are very common. Prevalence of HSV is high: 21.9% were positive among 13,094 individuals surveyed by the Third National Health and Nutrition Examination.<sup>8</sup> HSV is more commonly associated with women, African Americans, single marital status, higher number of sex partners, prior history of an STD, and urban residence.<sup>8</sup>

Infection is transmitted by direct sexual contact, most commonly when an active virus-secreting lesion is present. HSV has been recovered from asymptomatic male carriers and from the cervix of asymptomatic women. Subclinical shedding is common, occurring in 55% of women with HSV-2 and 29% of women with HSV-1.<sup>38</sup> In 70% of patients, transmission was linked to sexual contact during periods of asymptomatic viral shedding. Transmission of genital HSV was documented in 14 couples, and the risk was greater with male than female source partners (17% versus 4%).<sup>12</sup>

The types of genital HSV infection are primary, nonprimary first episode, and recurrent. The clinical manifestations of genital HSV are variable, depending on the type of infection.<sup>39,40</sup> In acute primary and recurrent infections, the initial presentation can be severe, with painful ulcers, dysuria, fever, tender inguinal lymphadenopathy, and headache. Other patients have a mild presentation or are entirely asymptomatic.<sup>39,41</sup> Recurrent infections are typically less severe than primary or nonprimary first-episode infections because of preexisting immunity. In turn, a nonprimary first episode is typically less severe than the primary infection, because the antibodies to one HSV type offer some protection against the other. Recurrent infections are more common with HSV-2 than HSV-1: 60% versus 14% in patients with a first symptomatic episode of genital herpes.<sup>42</sup> Recurrent lesions are fewer in number and are more often bilateral than bilateral.<sup>39</sup>

In a primary infection, the average incubation period is 4 days.<sup>40</sup> Patients usually have multiple, bilateral, ulcerating, pustular lesions that resolve after a mean of 9 days. Other symptoms include systemic headache, malaise, fever, and myalgia (67%); local pain and itching (98%); dysuria (63%); and tender lymphadenopathy (80%). Virus is very often isolated in the urethra and cervix of women with first-episode infection.<sup>39</sup> Extragenital manifestations of HSV include orolabial symptoms, aseptic meningitis, urinary bladder retention, distant skin lesions, herpetic whitlow, and proctitis. The clinical manifestations of HSV in immunocompromised patients are more extensive and include

mucocutaneous involvement, variable appearance of genital lesions, and the development of chronic and recurrent ulcers. Patients may have prolonged viral shedding. In addition to genital symptoms, patients may also have more neurologic complications, such as aseptic meningitis, sacral radiculopathy, and transverse myelitis.<sup>43</sup>

The differential diagnoses of HSV include syphilis, chancroid, Behçet's disease, and drug eruptions. Diagnosis based on history and physical examination is often inaccurate, and laboratory testing is required. Diagnostic tests include viral culture, polymerase chain reaction (PCR), and direct fluorescence antibody (DFA). Viral cultures can be obtained with active lesions; the vesicle should be unroofed for sampling of the vesicular fluid. The overall sensitivity of viral culture is 50%,<sup>44,45</sup> and the highest yield is in the early vesicular stages rather than the later, crusted stages.<sup>46</sup> HSV PCR is a more sensitive method for samples taken from genital ulcers, mucocutaneous sites, and cerebrospinal fluid, and it is particularly useful in detecting asymptomatic viral shedding.<sup>47-49</sup> DFA is specific, reproducible, and less expensive than PCR. Serology is important because it is type-specific and antibodies persist indefinitely in the serum.

Because HSV is a viral disease, there is no cure; however, drug treatment can shorten the duration of symptoms, and, in patients with frequent recurrences, medicine can be used as prophylactic therapy. There are three main drugs used in the treatment of HSV: acyclovir, famciclovir, and valacyclovir. In 2002, the Centers for Disease Control published treatment guidelines for the various types of HSV infection.<sup>16</sup> Recommended regimens for individuals with first episode are acyclovir (400 mg PO three times daily or 200 mg PO five times a day), famciclovir (250 mg PO three times daily), or valacyclovir (1 g PO twice daily) for 7 to 10 days. Recommended regimens for individuals for suppressive therapy are acyclovir (400 mg PO twice daily), famciclovir (250 mg PO twice daily), or valacyclovir (1 g PO daily or 500 mg PO daily). Recommended regimens for individuals with recurrent episodes are acyclovir (400 mg PO three times daily or 200 mg PO five times a day or 800 mg PO twice daily), famciclovir (125 mg PO twice daily), or valacyclovir (1 g PO daily) for 5 days or valacyclovir (500 mg PO twice daily) for 3 to 5 days. Postherpetic neuralgia due to HSV has not been well documented, although the herpes virus can increase the risk of vulvodynia due to recurrent herpes prodromal symptoms or pudendal neuropathy. Prodromal symptoms may be accompanied by positive HSV immunoglobulin M antibody serology; they respond to antiviral agents, whereas the pudendal neuropathy does not.

### *Human Papillomavirus*

HPV infection can lead to vulvar itching and pain through its anogenital manifestations. Condylomata acuminata usually manifest as single or multiple papules on the vulva, cervix, vagina, perineum, or anal region. The most common sites in women are the posterior introitus, followed by the labia majora and labia minora. External HPV lesions are frequently associated with cervical lesions. The lesions are flesh-colored, hyperkeratotic, exophytic, and either sessile or pedunculated.<sup>50</sup> HPV subtypes, other than the low-risk types 6 and 11, are also closely associated with squamous intraepithelial lesions of the cervix.

Diagnosis begins with a clinical examination supplemented with histologic examination of suspicious lesions. Biopsy is recommended in atypical cases or if the benign nature of the lesion is unclear.

There are several treatments for anogenital warts. For home therapy, podophyllotoxin or imiquimod may be used. For office therapy, podophyllin or 40% trichloroacetic acid may be used. Surgical options include cryotherapy, laser therapy, electrosurgery, and surgical excision.

### *Atrophic Vaginitis*

Estrogen-deficient vaginal and vestibular epithelium can be associated with itching, burning, and dyspareunia, due not just to decreased lubrication but also to fissuring from thin epithelium and poor compliance. Perimenopause or postmenopause status, use of hormonal contraceptives, and breastfeeding are the most common circumstances leading to atrophy. The vaginal epithelium loses its glycogen-rich superficial epithelial cells; the vaginal walls lose rugation and become pale or subject to petechial hemorrhage on contact; and the vaginal pH is elevated to 5.5. A yellow discharge reveals increased intermediate and parabasal cells under saline wet mount microscopy. Treatment is with 14 days of vaginal estrogen cream or suppository, followed by therapy twice weekly or use of an estrogen-secreting vaginal ring. Improvement can be expected in 2 months, but full estrogenization may take up to 18 months. Systemic absorption is present but is minimal.

## **Dermatoses**

### *Lichen Sclerosus*

Lichen sclerosus is a benign, chronic, progressive dermatologic condition characterized by marked inflammation, epithelial thinning, and distinctive dermal changes.<sup>51</sup> This disorder usually occurs in the anogenital area (85% to 98% of cases), where it causes itching and burning.<sup>52,53</sup> In 20% of patients, identical lesions appear elsewhere on the body.<sup>8</sup> Extragenital lichen sclerosus is most commonly found on the neck and shoulders and is usually asymptomatic. Pertaining to the vulva, the disorder can involve any or all areas, including the perianal skin, the skin folds adjacent to the thighs, and the inner aspects of the buttocks approximating the anus. The disorder usually occurs in postmenopausal women. However, 10% to 15% of cases occur in children, most of which involve female genitalia.<sup>54</sup> Even though the disease is reported to occur mostly in white females, lichen sclerosus has also been reported in Native Africans, Asians, and dark-skinned patients.

Multiple signs and symptoms are associated with lichen sclerosus. A prodrome to the gross lesions includes nonspecific, dull, painful vulvar discomfort in some women. Other women are asymptomatic. The major symptoms of the disorder include vulvar pruritus (which can be so intense as to disrupt sleep), pruritus ani, painful defecation, anal fissures, rectal bleeding, dysuria, and difficulty voiding. Dyspareunia is associated with introital stenosis, fissures, or posterior deflection of fused labia.

On physical examination, the lesions typically begin as white papules that are irregularly outlined and may coalesce into well-defined plaques.<sup>8</sup> Classic lesions consist of thin, white, "cigarette paper," wrinkled skin localized to the labia minora and/or labia majora, although the whitening may extend over the perineum and around the anus in a keyhole fashion. Fissures may be found perianally, in the intralabial folds, or around the clitoris. Excoriations and lichenification may be observed, often associated with edema of the labia minora and the prepuce. Relatively minor

rubbing or intercourse may lead to hemorrhage and/or petechiae with purpura and ecchymoses due to the fragility of the involved skin. Early in the course of the disease, vulvar architecture remains intact; however, phimosis of the clitoris and obliteration of the labia minora and periclitoral structures may be seen later in the course of the disease.

There is an increased risk of malignancy in patients with lichen sclerosus, of 4% to 6%. However, proof that lichen sclerosus causes cancer as a precursor lesion is lacking. The skin of patients with vulvar lichen sclerosus should be examined at least yearly. Biopsy should be performed of any thickened plaque that fails to thin with corticosteroid treatment or any persistently open or nonresolving lesion.

Diagnosis is by clinical characteristics and histologic confirmation. Before treatment is initiated, it is important that confirmation be made by histologic diagnosis. Multiple punch biopsies should be taken from the vulva, especially from sites of fissuring, ulceration, induration, and thick plaques.<sup>8</sup> Treatment is for relief of symptoms and discomfort, to prevent further anatomic changes, and to possibly prevent malignant transformation. Therapy comprises education, behavioral modification, support, and medication. Surgery is reserved for small subset of cases. Patients should first be educated about the chronicity of the disease and reassured that the condition is manageable. A discussion about the possibility of malignancy and the need for yearly monitoring should take place. Patients should be told about good vulvar hygiene and to stop scratching the lesion. The treatment with the best evidence of efficacy is superpotent corticosteroid ointment, clobetasol propionate 0.05% daily for 6 to 12 weeks and then one to three times a week for maintenance.<sup>55</sup> Long-standing treatment with clobetasol does not appear to cause untoward skin effects. With the eradication of pruritus, hyperplastic lesions may improve or disappear entirely. There is no role for estrogen, progesterone, or testosterone cream in the treatment of lichen sclerosus. Surgical intervention is indicated only for postinflammatory sequelae of the disease and when malignancy is present. Introital stenosis, posterior fissuring, and scarring of the fourchette are treated with perineoplasty. Surgical treatment for lichen sclerosus results in a recurrence rate that is extremely high, making the operation contraindicated in the absence of significant atypia.<sup>8</sup>

### *Lichen Planus*

Lichen planus is a relatively common papulosquamous disorder of unknown etiology. It has its highest incidence in patients 30 to 60 years of age. It occurs most often on flexor surfaces of the extremities and the trunk. It can also affect nails, mucous membranes including the mouth, esophagus, conjunctivae, bladder, nose, larynx, stomach, and anus. It can be isolated to the vulva or be a part of a more generalized skin eruption. The prevalence of vulvar lichen planus is considered uncommon; it occurs in fewer than 10% of women who have lichen planus over a 3-year period.<sup>56</sup>

Patient complaints usually include irritating vaginal discharge, vulvar pruritus, burning, and dyspareunia with postcoital bleeding. Physical examination findings differ depending on the type of lesion. Papulosquamous lichen planus consists of small, intensely pruritic papules with a violaceous hue that arise on keratinized and perianal skin. Hypertrophic lichen planus is characterized by hyperkeratotic, rough lesions on the perineum and perianal region.<sup>57</sup> The appearance is similar to squamous cell carcinoma. Erosive lichen planus refers to glossy, brightly

erythematous erosions with white striae or a white border (Wickham's striae) often visible along the margins. It can occur on the labia minora and vestibule as isolated lesions on an otherwise normal vulva or in association with marked architectural destruction, including loss of the labia minora and narrowing of the introitus. Vaginal involvement is reported in up to 70% of patients with erosive lichen planus, whereas vaginal involvement is not seen in lichen sclerosis.<sup>57</sup> The vaginal lining may be friable, easily bleeding. The vagina may be massively inflamed and denuded with seropurulent exudates, pseudomembrane, or serosanguineous discharge. In severe cases, adhesions and synechiae develop that can lead to narrowing or obliteration of the vagina. The vulvo-vaginal-gingival syndrome is a variant of erosive lichen planus. It involves the epithelium of the vulva, vestibule, vagina, and mouth. The lesions may not be concurrent; for example, lesions in the mouth can proceed or follow lesions in the genital area for months or years.<sup>8</sup>

The diagnosis of lichen planus is based on characteristic clinical manifestations. Classic histopathologic features include irregular acanthosis of the epidermis, liquefactive degeneration of the basal cell layer, and band-like dermal infiltrate of lymphocytes in the upper dermis. Hyperkeratosis is present in areas of keratinized skin. Typical histopathologic features are not found in mucosal lesions. Also, tissue biopsies are not specific except in the erosive type.

The oral and genital lesions of lichen planus, especially lichen planus, are persistent and resistant to therapy. There is no single effective therapy for erosive vulvar lichen planus, which is extremely difficult to treat. On the other hand, hypertrophic and papulosquamous lichen planus respond well to therapy. Patients should be told to maintain good vulvar hygiene and to stop scratching. The first line and mainstay of therapy is corticosteroids: topical, interlesional, and oral corticosteroids are all used. For erosive lichen planus, ultrapotent topical steroids (clobetasol or halobetasol propionate 0.05% ointment) can be applied nightly for 3 to 6 weeks, depending on the severity of disease. The ultrapotent steroid can then be reduced to twice per week, with a midpotency ointment of low potency ointment added, one to three times per week, for maintenance. It may be necessary to experiment to find the best course. Vaginal corticosteroids in the form of suppositories can be used for vaginal lesions. In one study, 16 of 17 patients improved with 25 mg hydrocortisone suppositories inserted in the vagina twice daily for 2 months.<sup>58</sup> In another study of 60 patients, 80% improved by taking 12.5 to 25 mg of hydrocortisone suppositories twice a day for several months, tapering to a symptom-free maintenance dose once or twice weekly.<sup>59</sup>

### *Lichen Simplex Chronicus*

Lichen simplex chronicus is also called leukoplakia and hyperplastic dystrophy.<sup>8</sup> The condition is caused by histologic changes in the vulvar dermis after persistent rubbing or scratching, usually in women who experience chronic irritation and/or pruritus. The condition is characterized by epithelial thickening and hyperkeratosis. There is an enhancement of the normal crosshatch markings of the skin, called lichenification.<sup>60,61</sup> Labial skin folds appear greatly exaggerated, often edematous, and pubic hair can be broken or sparse. The lesions tend to occur on the mons pubis and labia majora.

The most important element about diagnosing lichen simplex chronicus is to perform a biopsy to distinguish it from lichen

sclerosis, lichen planus, and carcinoma. Treatment is discussed in the section on allergic dermatitis.

### *Neoplasm*

Vulvar cancer is the fourth most common gynecologic cancer (after uterine, ovarian, and cervical cancer) and comprises 5% of malignancies of the female genital tract.<sup>62</sup> Vulvar carcinoma is most frequently found in postmenopausal women, with the mean age at diagnosis being 55 to 65 years.

The signs and symptoms of all histologic types of vulvar malignancy are similar. Presentation usually includes a unifocal vulvar nodule, plaque, ulcer, or mass on the labia majora (40%), labia minora (20%), clitoris (10%), mons (10%), or perineum (15%). Lesions are multifocal in 5% of cases. The most common presenting symptom is pruritus. Other symptoms include vulvar bleeding or discharge, dysuria, or enlarged groin lymph node, but many patients are asymptomatic at time of diagnosis.

There are two main categories of vulvar neoplasms, that of the squamous cell type and Paget's disease.<sup>8</sup> In 1984 and 1987, the ISSVD further subdivided these two classifications. Squamous cell type was divided into vulvar intraepithelial neoplasm (VIN) I (mild dysplasia), VIN II (moderate dysplasia), and VIN III (severe dysplasia to carcinoma in situ). The other category included Paget's disease and melanoma in situ.

More than 90% of vulvar malignancies are squamous cell. Two subtypes exist. The first (classic or Bowenoid type, VIN) is predominantly associated with HPV-16 and -18 and is found in younger women.<sup>63,64</sup> Risk factors for this subtype include early coitarche, multiple sexual partners, HIV infection, and cigarette smoking. The second, more common subtype (keratinized, differentiated, or simplex type) occurs in older women and is not related to HPV infection.

The gross appearance of VIN lesions is usually quite distinct: they are well localized, delineated, slightly elevated, white, and rough. The tissues may have a red or brown hue, and both red and white patches may be noted. These changes can be seen anywhere on the vulva but are most commonly found in the region of the fourchette and perineum. Squamous cell carcinoma in situ is a superficial, noninvasive, intraepithelial carcinoma characterized by chronicity, pruritus, burning, and a variable gross appearance.

The diagnosis can be established only by histopathologic study, and biopsies should be taken from more than one site. Some sources say that the biopsy should be taken from the center of the lesion, because those taken from the leading edge do not reflect the most severe histology of the lesion. The best means of detecting an intraepithelial lesion is by careful inspection of the vulva. Surgical extirpation is the primary treatment for early-stage vulvar carcinoma.

### *Paget's Disease*

Pruritus is the most common symptom of Paget's disease, occurring in 70% of patients. The appearance of the Paget's lesion is variable. Typically, it manifests as an erythematous, eczematoid lesion with scales and a crust scattered over the surface. It may also appear as a grayish-white lesion and frequently with moist and oozing ulcerations that bleed readily on contact. The disease is usually multifocal and occurs anywhere on the vulva, mons, perineum/perianal area, or inner thigh.

Diagnosis is by biopsy of the lesion, looking for characteristic histopathology. Vulvar biopsies should be performed for patients with suspicious lesions, including those with persistent

pruritic eczematous lesions that fail to resolve with 6 weeks of therapy.

Patients should also be evaluated for invasive carcinoma: two series found a 4% to 17% rate of invasive carcinoma within or beneath the surface of the Paget's lesion.<sup>65,66</sup> Women with this disease should also be evaluated for synchronous neoplasms, because approximately 20% to 30% of these patients have a non-contiguous carcinoma (breast, rectum, bladder, urethra, cervix, or ovary).<sup>67</sup>

Treatment includes wide local excision of the disease. The local recurrence rate is high, 12% to 58%. Recurrence may occur despite negative margins, probably because of the multicentricity of the disease and microscopic extension of disease beyond clinically visible margins.<sup>66</sup> Recurrence after initial therapy and non-contiguous carcinoma are common.

## Vulvar Infection

### Folliculitis

Folliculitis is a pyoderma of the hair follicles. *Pyoderma* is defined as a localized, purulent streptococcal infection of the skin. Predisposing factors to the development of folliculitis include nasal carriage of *Staphylococcus aureus*, use of swimming pools and hot tubs, and antibiotic administration and corticosteroid therapy predisposing to *Candida*. The most common pathogens are *S. aureus*, *Pseudomonas aeruginosa*, and *Candida* species. Other predisposing conditions include obesity, sweating, maceration, malnutrition, diabetes, seborrhea, poor hygiene, scabies, and pediculosis.<sup>8</sup>

Patients usually present with pain and tenderness, depending on the depth and extent of the lesions. Folliculitis lesions are typically small, less than or equal to 5 mm. They initially appear as papules that develop into vesicles, surrounded by a ring of erythema. Folliculitis does not cause systemic toxicity, and the lesions may spontaneously drain and resolve without scarring.

Treatment includes the use of topical therapies. Warm saline compresses can accelerate pointing, at which time the lesion can be incised. Superficial folliculitis usually responds well to erythromycin-containing antibiotic lotion or cream and use of germicidal soaps. Antifungal agents are useful in the case of *Candida* infections. Mupirocin ointment should be considered for patients with frequent recurrences of folliculitis who are suspected of having nasal colonization with *S. aureus*. The ointment is applied to the anterior nares bilaterally twice a day for 5 days each month.<sup>68</sup>

Complications of folliculitis include recurrence and progression to furunculosis.

### Bartholin's Gland Cyst or Abscess

Bartholin's duct cysts are seen in approximately 2% of new gynecologic patients.<sup>8</sup> They arise in the duct system, and the occlusion is usually near the opening of the main duct into the vestibule. Chronic inflammation can obstruct the orifice and lead to cystic dilation of the duct, but not the gland, proximal to the obstruction.

Bartholin's cysts average 1 to 3 cm in size and are usually asymptomatic. Larger cysts are associated with vulvar pain, dyspareunia, or difficulty sitting or ambulating. Discomfort may be associated with rapid enlargement, as might be induced by repeated or prolonged sexual stimulation.

The diagnosis is clinical and is based on the findings of a soft, painless mass in the medial labia majora or lower vestibular area.

Most cysts are unilateral and are detected during a routine pelvic examination of by the woman herself.

No treatment is necessary for asymptomatic Bartholin's cysts, except in postmenopausal women, in whom a biopsy or excision should be considered to rule out carcinoma. These cysts are usually sterile and therefore do not require antibiotic therapy.<sup>69</sup> A cyst that is symptomatic or disfiguring requires treatment, of which there are several modes. The simplest procedure is an incision and drainage, with or without packing. However, if this procedure is done alone, there is a high likelihood of recurrence when the incised tissue edges reapproximate. Supplementation of the incision and drainage can be performed with a Word catheter. It is a balloon-tipped device that can be placed in the cavity after drainage. The bulb is inflated to keep the catheter in place for 2 to 4 weeks while the duct tract epithelializes. The end of the catheter is tucked in the vagina to minimize discomfort. An alternative procedure after failure of the Word catheter is marsupialization of the gland, whereby a new orifice is created. A fourth method involves sclerotherapy, in which silver nitrate sticks are inserted into the cyst cavity to necrotize the cyst wall after incision and drainage. Mild burning may occur. The patient returns after 48 hours for cleaning of the vulva. A randomized controlled trial found that silver nitrate insertion was as effective as excision of Bartholin's cysts or abscesses.<sup>70</sup> Excision of the entire Bartholin's gland is the definitive procedure for both cysts and abscesses. It is usually considered after other methods have repetitively failed, because it is not an office procedure and has higher morbidity, including excessive bleeding, hematoma formation, cellulitis, and dyspareunia.

Bartholin's gland ducts and cysts can become infected and form abscesses. They are usually the result of polymicrobial infections, with the most common organisms being *Escherichia coli*, *Neisseria gonorrhoeae*, and *Bacteroides* species.<sup>71</sup> Therefore, patients should have both routine cultures and those for gonorrhea and chlamydia.

Symptoms for Bartholin's abscess include pain and tenderness over the affected gland. Usually, these abscesses develop rapidly, within 2 to 3 days, and are associated with acute pain and tenderness. They tend to rupture spontaneously within 72 hours. Patients usually present with pain on intercourse or pain on walking and sitting. Examination reveals a lesion that appears as a large, tender, soft or fluctuant mass in the medial labia majora or lower vestibular area, occasionally with erythema, edema, and pointing of the abscess.

Treatment entails drainage of the abscess, which provides immediate pain relief. Incision and drainage can be performed, followed by Word catheter placement, marsupialization, or silver nitrate insertion. Antibiotic regimens include one dose of ceftriaxone (125 mg IM) or cefixime (400 mg PO) to cover *E. coli* and *N. gonorrhoeae* plus clindamycin (300 mg PO four times a day for 7 days) to cover anaerobes. If *Chlamydia trachomatis* is present, azithromycin (1 g PO in a single dose) should be administered. Treatment with broad-spectrum antibiotics may easily delay ripening of the abscess. For women older than 40 years of age, some recommend complete excision of the gland to exclude underlying carcinoma.<sup>72</sup>

## Allergic Dermatitis

Contact dermatitis is an inflammatory reaction of the skin to a primary irritant or to an allergenic substance. Vulvar dermatitis (vulvar eczema) is the most common vulvar inflammatory skin

disease in women. One third to one half of women's vulvar complaints stem from this problem.<sup>73-75</sup> Patients with this disorder have chronic irritation and pruritus, which leads to persistent rubbing and scratching. There are two types of vulvar dermatitis, endogenous and exogenous. Endogenous dermatitis is also called atopic dermatitis and has a familial disposition. It begins in childhood and may affect other parts of the body. Erythema found in labial folds, perianally, and in the skin between the buttocks suggests endogenous vulvar dermatitis. Exogenous dermatitis is also called contact dermatitis and results from external factors. Allergic dermatitis accounts for 20% of cases and results when an allergen induces an immune response. In irritant contact dermatitis (80% of cases), the trigger directly damages the skin.

The history is important for differentiating among atopic, allergic, and contact dermatitis. What is the intensity of the pruritus, and when is it the worst? What kind of feminine products are used? Does the patient wear occlusive clothing that predisposes to *Candida*? Does she use any type of medication or scented soaps or deodorants?

A patch test may be required to distinguish between atopic and contact dermatitis; biopsy is not helpful. Positive patch tests for relevant substances occur in 25% to 60% of women with vulvar pruritus. Biopsy, however, should be obtained to rule out other possible causes. Coexistent infections should also be diagnosed so they can be treated.

Treatment involves behavioral modification and medications. First, the patient must modify any hygiene or clothing habits that facilitate dermatitis. Then, she must eliminate known or suspected allergens and irritants. She should be warned to refrain from scratching. Wet compresses or soaking in warm water must be undertaken for a day or two in order to restore the natural physiologic environment of the vulva. After this, the patient is ready for topical application of corticosteroid cream or lotion. For mild cases, use of a low- or medium-potency steroid is usually effective (hydrocortisone or triamcinolone), twice a day for 2 to 4 weeks, then twice a week and taper to pruritic symptoms. For severe cases, high-potency steroids may be necessary (clobetasol propionate or betamethasone dipropionate) every night for 30 days and then re-evaluate. Potent steroids can be used for up to 12 weeks on the vulva without adverse effects.<sup>76,77</sup>

## Trauma

Trauma to the vulva and vagina may lead to vulvar pain, dyspareunia, vulvar and vaginal lesions, and discharge. Accidental injuries are seldom seen in the vulva and vagina because of their anatomic location.<sup>8</sup> The injuries seen in prepubertal girls result most commonly from straddling objects such as bench rails, gymnasium equipment, bicycle frames, baths, and toilet seats. In adults, these injuries can be secondary to automobile and motorcycle accidents, bicycle accidents, sexual trauma, snowboarding, or physical assault. Some injuries may result from placing inanimate objects into the vagina. Most of these lesions manifest as hematomas and lacerations.

Lacerations of the vulva or vagina commonly occur from a violent fall on a slender object. Examples include falling on a stake, picket fence, handlebars of a bicycle, or the binding of a snowboard.<sup>78</sup> Lacerations may extend into the rectum, bladder, urethra, or the peritoneal cavity through the cul-de-sac. The area must be inspected carefully for remnants of glass, metal, or plastic. Anterior, posterior, and lateral radiographs including the

vaginal area should be taken to locate metallic or other radiopaque objects. Lacerations can cause profuse hemorrhage, pain, and shock. Treatment includes restoration of normal anatomic relationships. Bleeding vessels should be ligated and tissue edges carefully reapproximated with absorbable suture. Large traumatized areas require copious irrigation and débridement. Other concomitant injuries should be ruled out.

Sexual injuries are a major source of damage to the vulva and vagina. The right and posterior fornices of the vaginal vault are frequent sites of injury for parous women, whereas lower vaginal and introital injuries are often caused by defloration.<sup>79</sup> Rape and insertion of foreign bodies are additional sources of vulvar and vaginal injury. Genital injuries as a result of consensual intercourse are rare.

Most introital injuries associated with consensual first coitus are minor and lead to minimal bleeding.<sup>8</sup> These injuries can be managed conservatively with compression. If the injury involves an extensive laceration of the hymenal ring that extends into the vagina with profuse bleeding, suturing of the laceration is indicated. It has been postulated that vigorous intercourse increases abdominal pressure, causing tensing of the cul-de-sac and decreasing the elasticity of the posterior fornix, which results in a higher likelihood of laceration. Fissuring of the posterior fourchette (vulvar granuloma fissuratum) repeatedly with intercourse may cause a nonhealing granuloma that requires primary excision and closure.<sup>80</sup>

Foreign objects can cause trauma of the vulva or vagina. With certain sexual techniques, patients have been known to insert molded phalluses, glass objects, tops of aerosol cans, and occasionally metal objects into the vagina, which can cause laceration. If glass objects are the cause, it is important to inspect the tissue for the presence of residual foreign bodies, with subsequent irrigation and removal. Patients also occasionally forget to remove tampons. If the tampon remains in the vagina for a long period, there is often a foul, copious, brownish discharge. A simple examination usually demonstrates the presence of the tampon. Removal of the tampon is usually sufficient unless it has been retained for more than 10 days, at which point it is appropriate to give antibiotic therapy. Vaginal pessaries are also a main culprit of vaginal trauma. They are usually used by elderly women with extensive vaginal vault prolapse and may cause erosive conditions in these patients. The patient usually complains of malodor and bloody discharge, which is indicative of abrasion and erosion of the vaginal mucosa. The use of intravaginal estrogen to prevent vaginal tissue thinning helps prevent erosion.

## Prolapse

*Pelvic organ prolapse* refers to a hernia of one of the pelvic organs (uterus, vaginal apex, bladder, rectum) and its associated vaginal segment from its normal location. Pelvic prolapse occurs, in part, because of site-specific fascial defects that result in anterior, apical, or posterior segment weakness. Risk factors include multiparity, operative vaginal delivery, obesity, advanced age, estrogen deficiency, neurogenic dysfunction of the pelvic floor, connective tissue disorders, prior pelvic surgery, and chronically increased intra-abdominal pressure.

The displacement of the pelvic organs is graded on a scale of 0 to 4, with 0 referring to no prolapse; 1, halfway to the hymen; 2, at the hymen; 3, halfway out of the hymen; and 4, total prolapse (procidentia). There are also different prolapsed organs. Cystocele is herniation of the bladder with associated descent of the

anterior vaginal segment. Cystourethrocele is cystocele combined with distal prolapse of the urethra with or without associated urethral hypermobility. Uterine prolapse is descent of the uterus and cervix into the lower vagina, to the hymenal ring, or through the vaginal introitus. Vaginal vault prolapse is descent of the vaginal apex (after hysterectomy) into the lower vagina, to the hymenal ring, or through the vaginal introitus. Rectocele is hernia of the rectum with associated descent of the posterior vaginal segment. Enterocele is herniation of the small bowel/peritoneum into the vaginal lumen, most commonly after hysterectomy in conjunction with vaginal vault prolapse.

The most common symptoms are a sensation of pressure and heaviness or protrusion of tissue from the vagina. Patients may also complain of low back pain and a feeling of heaviness that is relieved with lying down and worsens as the day progresses. Loss of anterior support can lead to urinary stress incontinence. A large anterior vaginal prolapse with vaginal vault eversion can lead to urinary retention. A rectocele can cause defecatory dysfunction. Sexual dysfunction may accompany prolapse of any of the compartments. Because there may be protrusion of the vaginal mucosa, irritation can occur and bleeding may be reported.

Diagnostic evaluation includes examination of the vaginal support from both upright and recumbent positions. The traditional speculum examination should be supplemented with a site-specific examination with a single-bladed speculum or one half of a Graves speculum. This allows for a better view of the vaginal walls when looking for specific defects of vaginal support. A rectovaginal examination should be performed with the patient in standing position for detecting an enterocele, because the small bowel, if present, can be palpated easily in the cul-de-sac between thumb and forefinger. Magnetic resonance imaging is a useful diagnostic tool.

Treatment of mild prolapse is with pelvic floor exercises, physical therapy, or behavioral modification. Women with moderate prolapse or who are not surgical candidates may benefit from a pessary. Surgical treatment is usually necessary for severe prolapse. Surgery can be associated with an up to 30% rate of recurrence/reoperation.<sup>81</sup>

### Rigid Hymenal Ring

The hymen varies in thickness and elasticity. It may be quite elastic and easily stretched without laceration at initial sexual intercourse, or it may be tough and rigid so as to cause dyspareunia or even prevent intercourse. Attention may be drawn to this problem when the patient is unable to insert a tampon. Treatment with appropriate estrogen cream, small dilators, or hymenoplasty can correct the problem and prevent unnecessary laceration of the hymen and introitus due to trauma from intercourse.<sup>8</sup>

### Vulvar Neuroma

Vulvar neuroma, which is usually caused by traumatic or iatrogenic transection of peripheral nerve fibers, can cause dyspareunia and vulvar pain. It is postulated that dyspareunia related to episiotomy may be associated with disorganized proliferation of proximal nerve stumps. Patients can be in all age groups. There have been scarce case reports in the literature, but vulvar neuromas are often associated with episiotomy repairs and, in one case report, with female genital cutting.<sup>82</sup> The patient usually describes

a deep pain of gradual onset that becomes more intense with time. The pain is usually unilateral without dyspareunia. Diagnosis is point tenderness that duplicates the pain. Frequently, a tiny nodule is palpable in the soft tissue, and most often patients can put their finger right on this area. There is no reliable efficacious treatment that ensures no recurrence. Treatment modalities include cryotherapy, chemical ablation, radiofrequency ablation, and surgical excision of the neuroma.<sup>83</sup>

### Localized Vulvar Pain of Vestibule (Vestibulodynia or Vulvar Vestibulitis)

Vulvar vestibulitis syndrome (VVS) or vestibulodynia is characterized by discomfort and hypersensitivity in the vulvar vestibule in the absence of physical findings except for varying degrees of erythema.<sup>84</sup>

Some investigators have proposed that there are two forms, primary and secondary. Primary VVS refers to introital dyspareunia dating from initiation of sexual activity or intolerable pain consistently present on insertion of a tampon or vaginal speculum.<sup>6,85</sup> It accounts for 20% of cases.<sup>86</sup> Secondary VVS describes introital dyspareunia that develops after a period of comfortable sexual relations, tampon use, or speculum examinations.

The standard diagnostic criteria for VVS in the medical literature are as follows: severe pain on vestibular touch or attempted vaginal entry; tenderness to pressure localized within the vulvar vestibule; and no evidence of physical findings except for varying degrees of erythema.<sup>87</sup> Spontaneous pain is minimal or absent. The pain is associated with intercourse, tampon use, binding clothes, and bicycle riding. In one study, one third of women had constant burning in the vestibule, three quarters had excessive vaginal discharge, and 10% had chronic urinary tract symptoms.<sup>88</sup>

This phenomenon is more prominent in premenopausal women.<sup>89</sup> Risk factors related to some aspects of sexual reproductive history have been identified in women with VVS; they include early contraceptive use (before 17 years of age),<sup>90</sup> early intercourse (before 16 years), and early menarche (before 12 years). *Candida* infection and STDs, on the other hand, have not been associated with increased risk of VVS.<sup>84</sup> Other studies have proposed an autoimmune association between *Candida* and VVS.<sup>91</sup>

Excessive urinary oxalate excretion has been proposed as an etiology of vulvar pain, based upon a case report of one patient in whom complete remission of symptoms occurred with low oxalate diet.<sup>92</sup> A controlled study of urinary oxalate excretion, however, did not show differences in women with and without pain.<sup>88</sup> Another theory is that allergy causes VVS, because levels of immunoglobulin E consistent with vaginal allergy have been detected in vaginal fluid; however, treatment with antihistamines has not been effective.<sup>88</sup> It has been suggested that some women have a genetic deficiency that impairs their immune system's ability to stop the inflammatory response triggered by exposure to agents such as infection or chemicals.<sup>94</sup> VVS is also associated with interstitial cystitis, which makes sense when one considers that the vestibule, bladder mucosa, and urethra share a common embryologic derivation from the urogenital sinus.<sup>95,96</sup>

On examination, there is tenderness to gentle cotton swab pressure in the vestibule (allodynia). The diagnosis is made when touching the vulva with a cotton-tipped applicator produces pain only in the vestibule.<sup>85</sup> Some say that the Q-tip test is the sine qua non of diagnosing vestibulitis.<sup>83</sup> While gentle tactile stimulation is applied to specific areas of the vestibule, the patient can rate

her discomfort. Starting at 12 o'clock (just below the clitoris and above the urethra) and proceeding clockwise, the most tender areas may be at 4 and 8 o'clock.

Other diagnoses must be ruled out, and estrogenization should be assessed with vaginal wet mount, looking for predominance of intermediate or parabasal cells instead of the normal, well estrogenized superficial cells. The most common conditions mimicking VVS are *Candida* infection, poor estrogenization, pudendal neuropathy, dermatitis, rigid hymen, and vaginismus/pelvic floor muscle tension myalgia.

The first step in treatment of VVS, once a diagnosis is made, is to validate the patient's pain and reassure her that it is not psychological in nature and is not caused by cancer. The next step is to ensure adequate vulvar care. Patients should avoid scents, dyes, and chemicals, including fabric softener, bubble bath, body wash, and so on. Clothing should be cotton, comfortable and loose. Activities that may be abrasive to the vulvar area, such as biking, should be eliminated. Hydration by sitz baths may help. Use of natural lubricants, such as olive oil and Astroglide, may help. For burning, ice packs may provide relief. Because anecdotal evidence has supported eliminating foods high in oxalate, the patient may want to try this avenue.

Topical anesthetics such as Xylocaine 2% jelly or 5% ointment<sup>89</sup> or the compounded triple therapy (prilocaine, lidocaine, tetracaine: 3.5%/2.5%/1%) in a lipoderm base can provide relief if applied three times per day and liberally 20 minutes before sexual activity. This treatment useful because it "numbs the vulva," but it probably works via its pharmacologic effect of blocking sodium channels and altering neural plasticity. Capsaicin has also been tried in a number of studies, but it has not been widely successful and is painful when first applied.<sup>97</sup> Another study showed great improvement with injections of methyl prednisolone acetate and lidocaine chloride, with complete remission in 7 of 22 women and marked improvement in 3.<sup>98</sup> Triple nerve block therapy using caudal, pudendal, and local anesthetic blocks over 8 weeks has also demonstrated success.<sup>98a</sup>

One of the first-line therapies for VVS, because it appears to be a "neuroplastic pain syndrome," are the tricyclic antidepressants, which are standard therapy for neuroplastic/neuropathic pain.<sup>89</sup> Amitriptyline and desipramine improve pain substantially in patients who can tolerate doses of 50-75 mg.<sup>99</sup> Patients should be counseled that the drug is known primarily for its antidepressant effect but is also widely used for pain, so that patients do not feel deceived. Dosing should start at 10 mg and gradually be increased to minimize side effects, until the total dose is 150 mg or the symptoms are controlled. If patients continue to experience drowsiness with amitriptyline despite decreasing doses for a week, then nortriptyline or desipramine should be substituted, using a similar dosing schedule (less sedation and fewer anticholinergic side effects). Tricyclics take at least 4 weeks to have an effect and should be tried for 3 months at 100 to 150 mg before moving on to another agent.

Gabapentin or other anticonvulsants should be considered in those who cannot tolerate tricyclics or if those medications fail.<sup>89</sup> Patients should be started slowly at 100 mg at bedtime of gabapentin and then increased by 100 mg every 2 days until at least 1800 mg and up to 3600 mg/day is being taken in three divided doses or nightly. Side effects include drowsiness, fatigue, dizziness, and ataxia. Up to 1200 mg can be given at night to decrease drowsiness.

Interferon $\alpha$  has been reported to be beneficial, primarily when injected locally.<sup>100,101</sup> The most common regimen is 1

million units injected three times per week for 4 weeks circumferentially at the periphery of the vestibule. Side effects include flu-like symptoms, fever, malaise, myalgias; pretreatment with acetaminophen or ibuprofen may help. These patients may also experience significant injection-site pain and may benefit from pretreatment for 20 to 30 minutes with a topical anesthetic.

Surgical excision of the vestibule (Woodruff procedure) is another treatment option for patients with VVS. The affected area is mapped and excised, then covered with undermined vaginal epithelium. Many surgeons remove all areas of the vestibule, including those areas that are not painful, because failure can recur in areas of remaining vulvar tissue. One study showed an 85% cure rate.<sup>102</sup> Complications include dehiscence, recurrence of symptoms, and occasionally worsening of pain. So, although vestibulectomy was once the treatment of choice for VVS, the discomfort of the procedure, the possibility of incomplete success or worsening of pain, and the success of less aggressive therapies have relegated this procedure to second- or third-line therapy.<sup>89</sup> One study compared group cognitive-behavioral therapy (12-week trial), surface electromyographic biofeedback (12-week trial), and vestibulectomy in the treatment of dyspareunia resulting from vulvar vestibulitis.<sup>103</sup> This study found that, although vestibulectomy was superior to the other treatment modalities, all three groups significantly improved on measures of psychological adjustment and sexual function. Another study by the same group demonstrated that physical therapy is a promising treatment modality for dyspareunia associated with vulvar vestibulitis.<sup>104</sup>

### Dysethetic Vulvodinia or Generalized Vulvodinia

It is likely that this syndrome is a variant of pudendal neuropathy or, at the least, neuropathic pain, and it is best diagnosed and treated as such.

### Pudendal Neuropathy

Pudendal neuropathy, or "essential vulvodinia," was a label given to patients who complained of constant or almost constant vulvar burning and had a paucity of physical findings.<sup>105</sup> Pudendal canal syndrome (PCS) is induced by the compression or stretching of the pudendal nerve in Alcock's canal.<sup>106</sup> Causes of PCS are by sources of compression (biking, long-time sitting, horseback riding, hematoma) or stretching (descending perineum, surgery, delivery) of the pudendal nerve in the patient's history. A change in the shape or orientation of the ischial spine induced by some athletic activities may also explain some cases.<sup>107</sup> Pudendal neuralgia can also be found in patients with multiple sclerosis and postherpetic neuralgia.

The complete syndrome manifests with pain, hypoesthesia or hyperesthesia, and sometimes anal or urinary incontinence. However, motor symptoms are actually rare. Patients can present with an unprovoked, persistent, superficial, burning sensation that is frequently accompanied by a deep, aching component or a rare, paroxysmal lancinating pain over a large area.<sup>105</sup> Patients with less severe involvement may complain of an itch-burn sensation or a feeling of rawness. Some patients have burning pain with light touch and complain of dyspareunia not only on penile penetration but also during and after intercourse. Patients may also have rare, symptom-free periods that last for days or weeks. Because of the various areas supplied by the pudendal nerve, the following structures can be involved: cutaneous surfaces of the

labia minora and majora, clitoris, urethral meatus, vulvar vestibule, perineum, and perianal skin.

Physical findings are sparse. There is normally no evidence of infection. Focal vestibular erythema with or without tenderness is sometimes seen. Positive findings include thickened surgical scars, presence of palpable tumor, or evidence of genital herpes. Some patients have a weak anal reflex.<sup>108</sup>

Pudendal neuropathy is usually a diagnosis of exclusion. However, a pudendal nerve block can be used as both a diagnostic and a therapeutic measure. The pain usually disappears for only 1 to 2 days after injection. The block is repeated every third day for a total of four blocks. Computed tomography–guided blockade may be more accurate.<sup>109</sup> Other tests sometimes found to be abnormal in PCS include electromyography (EMG) and pudendal nerve terminal motor latency (PNTML). There is diminished EMG activity of the external anal sphincter, external urethral sphincter, and levator ani. There is a significant increase in PNTML in women with severe PCS.

Depending on the severity of the problem, there are several modalities of treatment. Nonsteroidal anti-inflammatory agents are frequently used but are not helpful in most cases. In mild cases, tricyclic antidepressants may be helpful.<sup>105</sup> Anticonvulsants such as carbamazepine, phenytoin, and gabapentin have also been found to be helpful.<sup>110</sup> As described earlier, serial pudendal blocks with a local anesthetic can be used. However, if none of these measures are helpful, another PNMLT is abnormal, there is evidence that surgical decompression of the pudendal canal may lead to improvement.<sup>108,111</sup>

### **Pelvic Floor Muscle Disorders: Myalgia and Trigger Points**

Trigger points are discrete, focal, hyperirritable spots located in a taut band of skeletal muscle.<sup>112</sup> The spots are painful on compression and can produce referred pain, referred tenderness, motor dysfunction, and autonomic phenomena. Acute trauma or repetitive microtrauma may lead to the development of stress on muscle fibers and the formation of trigger points. Patients may have regional, persistent pain resulting in a decreased range of motion in the affected muscles. These include muscles used to maintain body posture, such as those in the neck, shoulders, and pelvic girdle. Trigger points may also manifest as tension headache, tinnitus, temporomandibular joint pain, decreased range of motion in the legs, and low back pain. Trigger points can also be found in the pelvis, causing pelvic pain. Palpation of a hypersensitive bundle or nodule of muscle fiber of harder than normal consistency is the physical finding typically associated with a trigger point. Palpation of the trigger point elicits pain directly over the affected area and/or causes radiation of pain toward a zone of reference and a local twitch response.

Various treatment modalities, such as the spray and stretch technique, ultrasonography, manipulative therapy, and local anesthetic injection, are used to inactivate trigger points. Techniques for rehabilitation include the avoidance of perpetuating factors, rehabilitation of extrapelvic abnormalities, use of manual techniques and needling to promote resolution of connective tissue problems, closure of diastasis recti, and transvaginal/transrectal manual release of muscular trigger points and contractions.<sup>113</sup> Trigger-point injection has been shown to be one of the most effective treatment modalities to inactivate trigger points and provide prompt relief of symptoms.

### **Vaginismus**

Vaginismus is an involuntary spasm of pelvic muscles that partially closes the vagina. The *Diagnostic and Statistical Manual of Mental Disorders, 4th Revision (DSM-IV)*, defines vaginismus as repeated and persistent involuntary spasm of the vaginal muscles that interferes with intercourse. This condition causes penetration to be difficult and painful, or even impossible. Vaginismus is considered a sexual dysfunction although the patient may often have pain with tampon insertion and gynecologic examinations as well. It is a complex condition with several possible causes that may result from past sexual trauma or abuse, other psychological factors, or a history of discomfort with sexual intercourse. Causes can also be congenital or infectious.<sup>114</sup> Sometimes no cause can be determined.

Women with varying degrees of vaginismus often develop anxiety regarding coitus and penetration, and intercourse is usually painful. However, this does not mean that they cannot achieve or sustain sexual arousal. Many are very sexually responsive and can have orgasms through clitoral stimulation.

Difficulty or inability to allow vaginal penetration for intercourse is the primary symptom. Vaginal pain with attempts at intercourse or during attempted pelvic examination is common. A gynecologic examination can confirm the diagnosis of vaginismus. The health care provider will note whether there is an involuntary muscle contraction when fingers are inserted into the vagina, and this usually reproduces the pain the woman feels with intercourse. Other causes of dyspareunia should also be ruled out.

The treatment of choice with vaginismus is an extensive therapy program that combines education and counseling with behavioral exercises. Exercises include pelvic floor muscle contraction and relaxation (Kegel exercises) to improve voluntary control. Vaginal dilation exercises are recommended using plastic dilators. This should be done under the direction of a sex therapist or other health care provider, and treatment should involve the partner. This treatment should gradually include more intimate contact, ultimately resulting in intercourse.

### **Psychosocial Factors**

Psychosocial factors are important in the management of vulvar and vaginal pain, both as a cause and as an effect of the pain. Patients with chronic vaginal or vulvar pain often experience progressively limited professional and social lives. Patients often become frustrated with the multiple physician visits, diagnostic tests, and treatment regimens including surgeries. If the medical treatment is not conclusive or successful, patients may be told it is “all in their head.” This may lead to further stress, depression, and sexual dysfunction.

Most studies indicate that an average of 20% to 30% of women with pelvic pain have experienced childhood trauma or sexual abuse. If the pain is “nonsomatic” or of “unknown etiology,” the frequency of abuse is found to be much higher. The impact of historical factors in causing pain is controversial but may exacerbate a patient’s experience of pain.

### **Chronic Pelvic Pain with Resultant Dyspareunia**

Chronic pelvic pain (CPP) is frequently associated with dyspareunia. CPP is a common problem, and it presents a major challenge to health care providers because of its unclear etiology,

complex natural history, and poor response to therapy. A significant number of these patients have various associated problems, including bladder or bowel dysfunction, sexual dysfunction, and other systemic or constitutional symptoms. Other associated conditions, such as depression, anxiety, and drug addiction, also may coexist. Studies have shown that women with CPP are more likely to have a history of sexual and physical abuse than are other groups of women.<sup>115</sup> The most common causes of CPP are endometriosis, irritable bowel syndrome, interstitial cystitis, abdominal wall and pudendal neuropathy, pelvic floor muscle tension myalgia, and fibromyalgia. Residual symptomatology after accurate diagnosis and focused treatment is best managed with a multidisciplinary approach.<sup>116</sup> The diagnosis and management of CPP is beyond the scope of this chapter.

### Abnormal Vaginal Discharge

Normal vaginal discharge is 1 to 4 mL over 24 hours, white or transparent, thick and odorless. Physiologic discharge is formed by mucoid endocervical secretions in combination with sloughing epithelial cells, normal bacteria, and vaginal transudate. Discharge may be more noticeable during pregnancy, oral contraceptive use, or at midmenstrual cycle, close to the time of ovulation. Physiologic leukorrhea has a pH of 4.0 to 4.5, has a ratio of polymorphonuclear leukocytes to vaginal epithelial cells that is less than 1, and contains many squamous cells.<sup>117</sup> Vaginitis and vaginosis were discussed in earlier sections of this chapter. Cervicitis can lead to abnormal vaginal discharge.

#### Gonorrhea Cervicitis

Gonorrhea is one of the most frequently diagnosed STDs and remains a significant cause of preventable and treatable morbidity. The peak incidence occurs in 15- to 19-year-old women.<sup>118</sup> *N. gonorrhoeae* is a gram-negative diplococcus, first described by Neisser in 1879.<sup>119</sup> The most concerning complications of gonorrhea infection relate to female reproduction. Scarring from pelvic inflammatory disease can interfere with fertilization in 20% of cases. There is also a 9% risk of ectopic pregnancy and an 18% risk of chronic abdominal pain.<sup>120</sup> Women can also infect newborn infants during birth, causing neonatal ophthalmia.

The incubation period for urogenital gonococcal infection is approximately 10 days in the female patient.<sup>8</sup> The typical symptoms are increased vaginal discharge, dysuria, intermenstrual uterine bleeding, postcoital bleeding, and menorrhagia.<sup>50,121</sup> Infection in women is often asymptomatic, whereas men are asymptomatic only 10% of the time.<sup>122</sup>

Gonorrhea in women can infect the cervix, urethra, anus, rectum, or oropharynx or can be disseminated. The most common site of infection is the cervix; approximately 50% of affected women are asymptomatic. Symptoms include vaginal pruritus and mucopurulent discharge from runny or scant to copious. Patients may also complain of new postcoital spotting or dyspareunia. On examination, the cervix may appear normal or show signs of frank discharge. The cervix may be friable, and there may be abdominal pain with upper genital tract disease. Gonococcal vulvitis and vaginitis are infrequent, because the stratified squamous epithelium of the vagina is resistant to invasion by the gonococcus.<sup>8</sup> The symptoms for urethritis are initially urinary frequency and burning.<sup>8</sup> Infection of the trigone is accompanied by increased dysuria, and the patient often has tenesmus. The urethral meatus is often edematous and erythematous with purulent discharge with the urethral epithelium everted.

Patients may have severe pain from Skene's duct abscess and be unable to void. There can also be infection of Bartholin's gland, and pus may drain from that site, but if the duct is occluded, then an abscess will form. Anorectal infection can be asymptomatic or associated with clinical proctitis. In about 4% of patients with anorectal involvement, it is the sole site of infection.<sup>123</sup> Symptoms include anal itching, rectal discharge, rectal fullness, tenesmus, and painful defecation. Pharyngitis results from fellatio with a male partner who has gonococcal urethritis or from cunnilingus.<sup>124</sup> The pharynx is infected in 10% to 20% of individuals. Symptoms include fever and cervical lymphadenopathy.

There are several methods of diagnosing gonorrhea infection. The "gold standard" is culture on modified Thayer-Martin medium. This is very sensitive in symptomatic women but only 65% to 85% sensitive in asymptomatic women.<sup>125</sup> Cultures are 100% specific and allow testing for antibiotic resistance. Gram stains are less sensitive but allow for an earlier diagnosis and treatment. DNA probes have accuracy similar to that of culture, with high sensitivity, specificity, and positive and negative predictive values.<sup>126</sup> Enzyme immunoassay is not widely used, because its positive predictive value is acceptable only in populations with a high prevalence of infection. There are also commercially available nucleic acid amplification tests (NAATs). They are more rapid to perform than culture, returning results within hours, but are much more expensive. NAATs have also been shown to be more sensitive than culture, being able to detect as little as one organism per sample, whereas the threshold for conventional methods is approximately 1000 organisms.<sup>127</sup>

There are many accepted regimens for gonorrhea. The use of one-time, observed therapy is recommended, because compliance with multiple doses is lower. Also, because 42% of patients with gonorrhea are found to have dual infection with chlamydia,<sup>128</sup> concurrent treatment for both organisms is recommended. The recommended treatments of uncomplicated cervical, urethral, or anorectal infection are ceftriaxone 125 mg IM once, ciprofloxacin 500 mg PO once, ofloxacin 400 mg PO once, levofloxacin 250 mg PO once, and spectinomycin 2g IM once.<sup>16</sup> Pregnant women should not be treated with quinolones or tetracyclines. The partner should also be treated.

### Chlamydia Cervicitis

Chlamydia is the most common agent of sexually transmitted genital infections leading to cervicitis and often abnormal vaginal discharge. Chlamydia is a true bacterium, an obligate intracellular parasite. The organism is transmitted primarily by sexual contact. The organism cannot be transmitted across intact skin or mucous membranes. Risk factors for infection are young age, black race, multiple sex partner, recent new sex partner, low rates of barrier contraception, and history of STD.<sup>129,130</sup>

Chlamydia has been implicated in urethritis, Bartholin's abscess, cervicitis, endometritis, salpingitis, conjunctivitis, and pneumonitis of the newborn. The ultimate sequelae in the female that may involve chlamydial infection are ectopic pregnancy, infertility, and complex salpingitis that may lead to formation of a tubo-ovarian abscess and eventually hysterectomy.<sup>8</sup>

Most patients with cervicitis are asymptomatic. If symptoms are present, they may include vaginal spotting with intercourse, vaginal discharge, poorly differentiated abdominal pain, or lower abdominal pain. Examination may reveal the presence of mucopus or hypertrophy of the endocervical epithelium with a copious clear discharge, or the cervix may bleed briskly when

touched with cotton-tipped applicator. Approximately 30% of women with *Chlamydia* infection develop pelvic inflammatory disease if left untreated.<sup>131</sup>

Traditional methods of diagnosis include cervical swabs requiring a full pelvic examination, but new diagnostic techniques include cervical swabs, urine, or self-administered vaginal swabs. Antigen detection by DFA and enzyme-linked immunosorbent assay (ELISA) still requires a swab from the cervix or urethra and is 80% to 95% sensitive compared to culture. Genetic probe methods based on direct specimen swab from the cervix or urethra are also 80% to 95% sensitive compared with culture. Nucleic acid amplification, PCR, and ligase chain reaction (LCR) are being studied and have high sensitivity and specificity.<sup>132</sup> Clinical practice guidelines strongly recommend routine *Chlamydia* screening for sexually active women younger than 25 years of age.<sup>16,133</sup>

Azithromycin (1 g PO as a single dose) and doxycycline (100 mg PO twice daily for 7 days) are the two recommended regimens. Alternative regimens include 7 days of erythromycin base (500 mg PO four times daily), erythromycin ethylsuccinate (800 mg PO), ofloxacin (300 mg PO twice daily), or levofloxacin (500 mg PO once daily).<sup>16,134</sup> Test of cure is not recommended, except for patients with persisting symptoms and those with suspect compliance. Test of cure should be done 3 weeks after the completion of therapy.<sup>16</sup>

## Cervical and Vaginal Lesions

### Vesicovaginal Fistula

Vesicovaginal fistula is a communication between the vagina and a part of the urinary tract (ureter, bladder, or proximal urethra). Continual wetness, odor, and discomfort cause serious social problems. The main causes include obstructed labor and surgical trauma, and 10% of the cases are caused by irradiation, locally advanced pelvic tumors, and pelvic pathologies (e.g., inflammation, foreign bodies).

Classically, vesicovaginal fistulas manifest with continuous incontinence after a recent pelvic operation.<sup>135</sup> If the fistula is small, then watery discharge from the vagina accompanied by normal voiding may be the only symptom. Diagnostic tests can be done by passing a small ureteric catheter through the fistular tract to see if it enters the vagina. Other means of diagnosis are by retrograde and voiding cystourethrography. A high creatinine level of the discharge can confirm urinary leakage.

### Colovaginal, Rectovaginal, and Coloperineal Fistulas

Colovaginal and rectovaginal fistulas are thought to be a relatively uncommon occurrence, but they can cause distressing symptoms depending on the severity, site, location, and etiology.<sup>136</sup> The most common cause of colovaginal fistulas is diverticular disease. They also occur as a result of irradiation, pelvic surgery, malignancy, abdominal hysterectomy, abscess formation, perforation by a foreign body, inflammatory bowel disease, and trauma. Fistulas develop in 2% of patients with diverticulitis. Most patients have colovaginal fistulas secondary to diverticular disease, Crohn's disease, or pelvic surgery, particularly hysterectomy.

The passage of feces per vagina is diagnostic of a fistula between the bowel and internal genitalia. Putting a tampon in the vagina may assist in the diagnosis. Most patients present with abnormal discharge, which may not be recognized as frank feces. Colovaginal fistula may also manifest as vaginal flatus. With small bowel-vaginal fistulas, severe excoriation may be seen secondary to the presence of digestive enzymes. Physical examination with a speculum usually reveals an opening or granular area at the apex of the vagina that appears red and is usually on the left. The next examination usually requested is a barium enema, but this is ineffective. Vaginography may be useful, however. Other diagnostic tools include colposcopy, colonovaginoscopy, and computed tomography.

# BENIGN CYSTIC LESIONS OF THE VAGINA AND VULVA

*Karyn Schlunt Eilber*

Benign cystic lesions of the female external genitalia are frequently encountered in gynecologic and female urologic practices. True cystic lesions of the vagina and vulva originate from vaginal and vulvar tissues, respectively, but lesions arising from the urethra and surrounding tissues can appear as cystic lesions of the vagina and vulva as well. Most cysts of the female genitalia are located within the vagina, and their prevalence has been estimated to be 1 in 200 women; however, this figure is probably an underestimation, because most cysts are asymptomatic and therefore not reported.<sup>1</sup> Cysts arising within the vulvar vestibulum are much less common.

Vaginal cysts typically occur in the third and fourth decades and are rarely found in prepubertal females except in countries where female circumcision is performed.<sup>2</sup> Pradhan and Tobon reviewed the histology of 43 vaginal cysts over a 10-year period. In their study, the incidence of cyst types in decreasing order was müllerian cysts (44%), epidermal inclusion cysts (23%), Gartner's duct cysts (11%), Bartholin's gland cysts (7%), and endometriotic type (7%).<sup>3</sup> The remaining types of cystic lesions include those of urethral or paraurethral origin and other rare lesions (Table 88-1).

## PATIENT EVALUATION

Cysts of the vagina and vulva are usually asymptomatic, and their presence is usually noted as an incidental finding on physical examination. In patients whose cysts are discovered because of symptomatology, mild discomfort, patient detection of a mass, or urinary symptoms such as incontinence or obstructive voiding symptoms are common presenting symptoms. In most cases, the appropriate diagnosis is made by history and physical examination alone; other cases are diagnosed only after excision and histologic examination of the tissue.

Patient history should include the onset and duration of symptoms and the presence of pain, dyspareunia, voiding complaints, and prior urologic or gynecologic procedures. A history of recurrent urinary tract infections and/or intermittent incontinence may indicate the presence of a urethral diverticulum, whereas continuous incontinence may represent an ectopic ureterocele.

During physical examination, the lesion should be assessed for location, mobility, tenderness, definition (smooth versus irregular), and consistency (cystic versus solid). The presence of

**Table 88-1 Vaginal Wall Cyst Location and Histology**

Diagnosis	Location	Histology
Müllerian (paramesonephric) cyst	Anywhere, usually anterolateral vaginal wall	Pseudostratified columnar, mucinous
Gartner's (mesonephric) cyst	Same as müllerian cyst	Low columnar, nonciliated, nonmucinous
Skene's (paraurethral) duct cyst	Floor of distal urethra	Stratified squamous
Bartholin's gland cyst	Lateral introitus, medial to labia minora	Transitional or columnar, mucinous
Adenosis	Vaginal fornices and upper walls	Columnar, ciliated, mucinous
Cyst of canal of Nuck (hydrocele)	Superior to labia majora or inguinal canal	Flat cuboidal
Urethral caruncle	Urethral meatus	Loose connective tissue and vessels
Urethral diverticulum	Periurethral, anterior vaginal wall	Transitional or squamous epithelium
Inclusion cyst	Area of previous surgery	Stratified squamous epithelium around keratinous debris
Endometriosis	Anywhere, usually posterior fornix	Two of three: endometrial glands, stroma, hemosiderin-laden macrophages
Ectopic ureterocele	Periurethral	Transitional or squamous epithelium
Vaginitis emphysematosa	Upper two thirds of vagina	Inflammatory and giant cells
Hidradenoma	Interlabial sulcus	Papillomatous
Dermoid cyst	Paravaginal	Keratinized squamous epithelium and dermal appendages
Aggressive angiofibroma	Vagina and vulva	Hypocellular, myxoid matrix of collagen and capillary-like vessels
Ciliated cyst	Anywhere in vagina, vulvar vestibulum	Müllerian-like columnar ciliated epithelium
Pigmented follicular cyst	Vulva	Stratified squamous epithelium with keratinization and pore

A

B

**Figure 88-1** **A**, Voiding cystourethrogram (VCUG) demonstrates obstruction of distal urethra. **B**, Magnetic resonance imaging (MRI) confirms that the obstructing lesion is a cyst.

malignancy must always be considered. Pelvic organ prolapse, such as cystocele or enterocele, can mimic a vaginal cyst and should be ruled out.

Pelvic imaging by means of ultrasound, voiding cystourethrogram (VCUG), computed tomography (CT), or magnetic resonance imaging (MRI) may be required to characterize the lesion further (Fig. 88-1). Although each of these modalities has been useful in the diagnosis of vaginal cysts, pelvic MRI is the preferred modality for diagnosing both cystic lesions and a variety of other genitourinary abnormalities, including pelvic organ prolapse, urethral diverticula, ovarian abnormalities, and uterine pathology.

### CYSTS OF EMBRYONIC ORIGIN

During the eighth week of embryologic development, the paired müllerian (paramesonephric) ducts fuse distally and develop into the uterus, cervix, and upper third of the vagina, which are lined by a pseudostratified columnar (glandular) epithelium. Wolffian (mesonephric) ducts normally regress in the female, and their remnants include Gartner's duct, epoöphoron and paroöphoron. Beginning at week 12, a squamous epithelial plate derived from

the urogenital sinus begins to grow upward and replace the original pseudostratified columnar epithelium with squamous mucosa. In addition to the lower two thirds of the vagina, the urogenital sinus derivatives in the female are Skene's glands and Bartholin's glands.<sup>4</sup>

### Müllerian Cysts

During the process of replacement of the müllerian (pseudostratified columnar) epithelium with squamous epithelium of the urogenital sinus, müllerian epithelial tissue can persist anywhere in the vaginal wall, although it typically rests within the anterolateral wall. Consequently, müllerian cysts tend to be located along the anterolateral aspect of the vagina.<sup>5</sup> Müllerian derivatives are the most common type of vaginal cyst; they are lined predominantly by mucinous epithelium but may be lined by any epithelium of müllerian origin: endocervical, endometrial, or fallopian.<sup>4,6</sup> Clinically, the distinction between müllerian and mesonephric (Gartner's duct) cysts is of little importance.

Müllerian cysts range in size from 1 to 7 cm.<sup>4</sup> The great majority are asymptomatic and require no treatment. Occasionally, a müllerian cyst may become large enough that symptoms warrant excision.

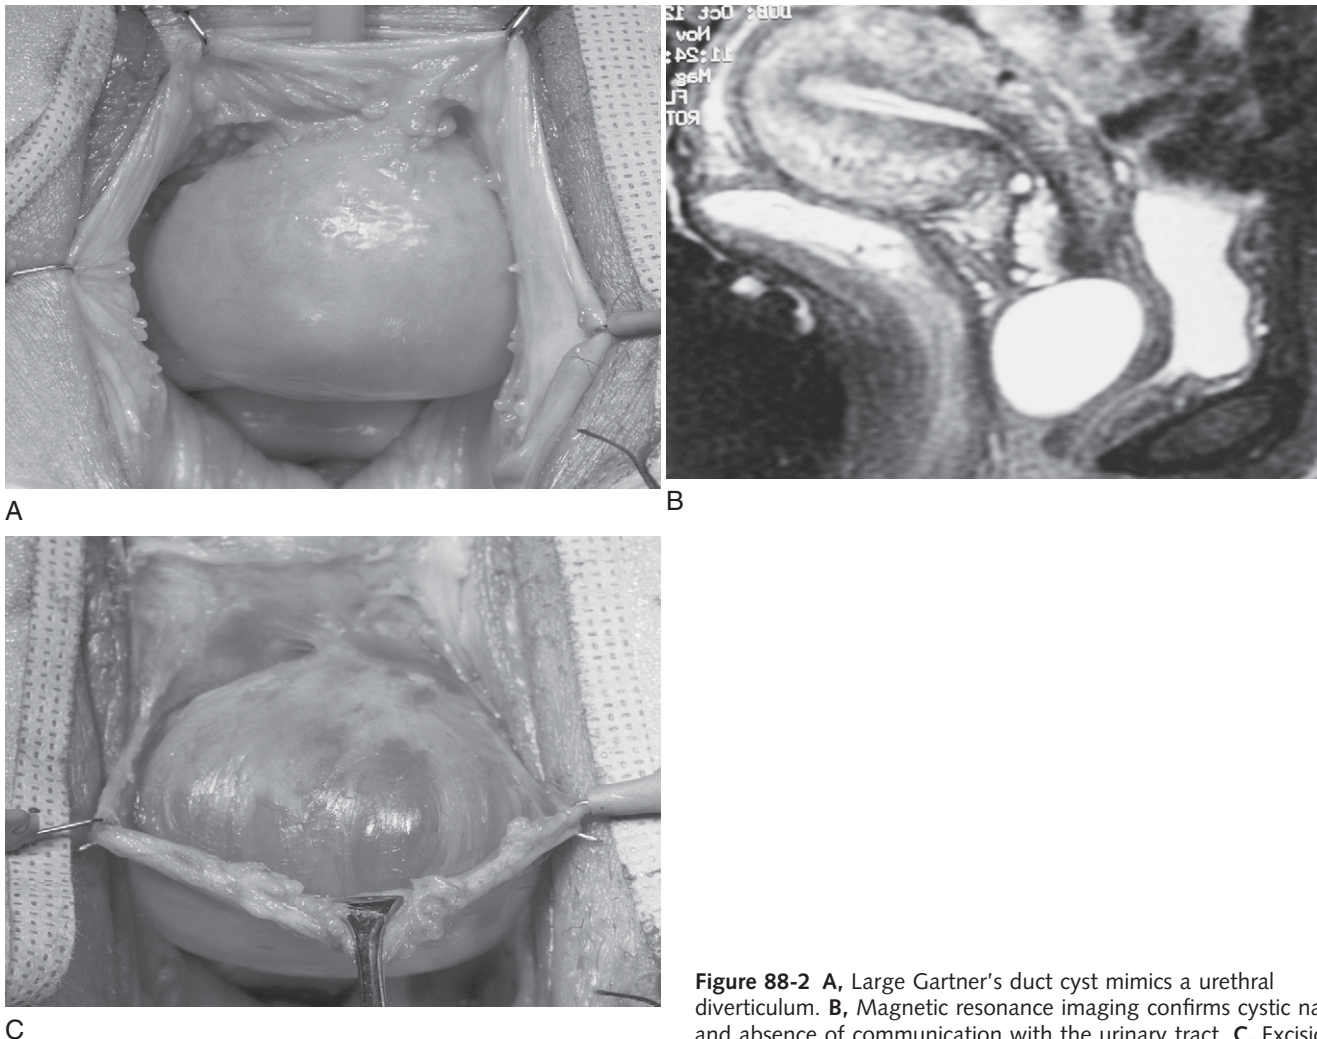

### Gartner's Duct Cysts

Although it is clinically irrelevant to distinguish Gartner's duct cysts from müllerian cysts, true Gartner's duct cysts arise from vestigial remnants of the mesonephric (wolffian) ducts. Gartner's duct extends from the mesosalpinx via the broad ligament to the cervix, so these cysts are usually located along the anterolateral vaginal wall.<sup>4,6</sup> Typically, they are small, with an average diameter of 2 cm, but the cysts may enlarge to the point where they are mistaken for other structures, such as a cystocele or urethral diverticulum (Fig. 88-2A).<sup>4</sup> The largest Gartner's duct cyst reported was 16 × 15 × 8 cm.<sup>7</sup>

An association between Gartner's duct cysts and abnormalities of the metanephric urinary system exists, and cases of ectopic ureter, unilateral renal agenesis, and renal hypoplasia have all been reported in association with Gartner's duct cysts.<sup>8-10</sup> Curra-rino reported on five children with a Gartner's duct cyst and either ipsilateral renal hypoplasia or dysplasia,<sup>9</sup> and Sheih and colleagues found that 6% of female children with unilateral renal agenesis had a Gartner's duct cyst.<sup>10</sup> Although such abnormalities usually present in childhood, awareness of this association should prompt the clinician to image the urinary tract when evaluating adults who present with Gartner's duct cysts. MRI is especially useful, both for evaluation of the characteristics of the cyst and to rule out communication with the urinary tract (see Fig. 88-2B).

Gartner's duct cysts are synonymous with simple cysts and are lined by cuboidal or low columnar, nonciliated, nonmucinous cells. They can be distinguished from müllerian cysts by the presence of a basement membrane and smooth muscle layer; however, clear distinction between the two can be made only on the basis of histochemical staining: müllerian cysts are periodic acid-Schiff (PAS) and mucin positive, whereas mesonephric cysts are devoid of cytoplasmic mucicarmine or PAS-positive material.<sup>5,6</sup>

If a Gartner's duct cyst is large and symptomatic, excision is indicated (see Fig. 88-2C). Successful treatment with cyst aspiration and 5% tetracycline injection has been reported but without long-term follow-up.<sup>11</sup>

**Figure 88-2** A, Large Gartner's duct cyst mimics a urethral diverticulum. B, Magnetic resonance imaging confirms cystic nature and absence of communication with the urinary tract. C, Excision.

### Skene's Duct Cysts

Skene's (paraurethral) glands are bilateral prostatic homologues located in the floor of the distal urethra. Obstruction of the ducts is presumed to occur in response to skenitis, of which gonorrhea is the most common cause.<sup>5,12</sup> Because Skene's ducts are embryologically derived from the urogenital sinus, these cysts are lined by stratified squamous epithelium.<sup>12</sup>

Clinically significant cysts of Skene's ducts are rare, but cysts larger than 2 cm often cause patients to seek treatment for urinary symptoms such as dysuria or obstructive voiding symptoms (Fig. 88-3A).<sup>13</sup> In this situation, a Skene's duct cyst must be distinguished from a urethral diverticulum. Dysuria, history of urinary tract infections, and postvoid dribbling are common in the presence of a urethral diverticulum. Furthermore, on physical examination, compression of a Skene's duct cyst should not result in fluid extravasation. Both MRI and cystourethroscopy are useful to determine whether there is a communication between the lesion and the urethra (see Fig. 88-3B). It is of paramount importance to determine whether a vaginal cyst is of urethral origin. Unless a urethral diverticulum is suspected, urethral injury during cyst excision may occur, and a urethrovaginal fistula can result if the urethra is not adequately repaired and postoperative catheter drainage instituted.

Small Skene's duct cysts can be observed. Excision is recommended for larger, symptomatic cysts. Marsupialization is not necessary, and the duct itself need not be preserved.<sup>5</sup> Acute infection is a contraindication for excision; incision and drainage are advocated in this setting.

### Bartholin's Duct Cysts

Bartholin's glands are also of urogenital sinus origin and are homologous to bulbourethral glands in males. Ductal obstruction, due to previous infection or inspissated mucus, is a prerequisite to cyst formation. Size and rapidity of growth depend on the accumulation of secretions from Bartholin's gland, which is influenced by sexual stimulation.<sup>4</sup> Although most patients have no symptoms or only mild dyspareunia, repeated sexual stimulation may be associated with rapidly enlarging, painful lesions. Pain may also indicate infection of the cyst.

Bartholin's gland is composed of acini lined by columnar, mucus-secreting epithelium and ducts lined by transitional epithelium.<sup>4</sup> The origin of a Bartholin's duct cyst is indicated by its histology: cysts arising from the main duct are lined by transitional or squamous epithelium, whereas cysts originating in an acinus are lined by mucinous columnar epithelium.<sup>5,14</sup>

A

B

**Figure 88-3** A, Vaginal mass causing distal urethral obstruction which proved to be a Skene's duct cyst. B, Preoperative magnetic resonance image demonstrates a cystic lesion arising in the urethra, consistent with a Skene's duct cyst.

Bartholin's duct cysts typically range from 1 to 4 cm in diameter. Most are unilateral, nontender, cystic masses located in the lateral introitus, medial to the labia minora (Fig. 88-4A). These lesions are detectable by ultrasound, CT, and MRI (see Fig. 88-4B). If small and asymptomatic, they require no treatment.

Cysts associated with pain, recurrent abscess formation, or introital obstruction require surgical intervention. Excision of Bartholin's duct cysts has been described, but the preferred treatment is marsupialization to preserve function and prevent cyst or abscess reformation (see Fig. 88-4C). Incision and drainage is indicated for Bartholin's abscesses, with definitive treatment deferred until a period of quiescence.

### Vaginal Adenosis

Vaginal adenosis is the presence of glandular epithelium within the vagina. It is attributed to failure of the squamous epithelium to replace the columnar epithelium in the vagina and ectocervix during embryogenesis.<sup>15</sup> It can be found in infants, children, and adults, and it is the most common lesion in women exposed to diethylstilbestrol (DES).<sup>16</sup> As with müllerian cysts, the lesions may represent any müllerian derivation and may include endocervical, endometrial, or tubal-type mucous cells (Fig. 88-5).<sup>6,17</sup>

Vaginal adenosis is commonly an incidental finding on examination of a DES-exposed woman and may resemble cervical ectropion. The classic appearance of adenosis is red, grape-like mucosa in the vaginal fornices and upper walls.<sup>5</sup> Identification of adenosis may be facilitated by its lack of staining with iodine solution.<sup>4,5</sup> Symptoms may include excessive mucoid vaginal discharge or mild postcoital bleeding.

No specific therapy is recommended for the treatment of adenosis, because the lesion may spontaneously regress. Routine examination of these lesions is recommended, because metaplastic conversion is well documented.

### Cysts of the Canal of Nuck (Hydrocele)

The processus vaginalis, also referred to as the canal of Nuck, is a rudimentary peritoneal sac that accompanies the round ligament through the inguinal canal into the labia majora. During the first trimester, the canal of Nuck normally becomes obliterated. Persistence of the canal is associated with inguinal hernias, and occlusion at any point can lead to the formation of a cyst that is analogous to a hydrocele of the spermatic cord.

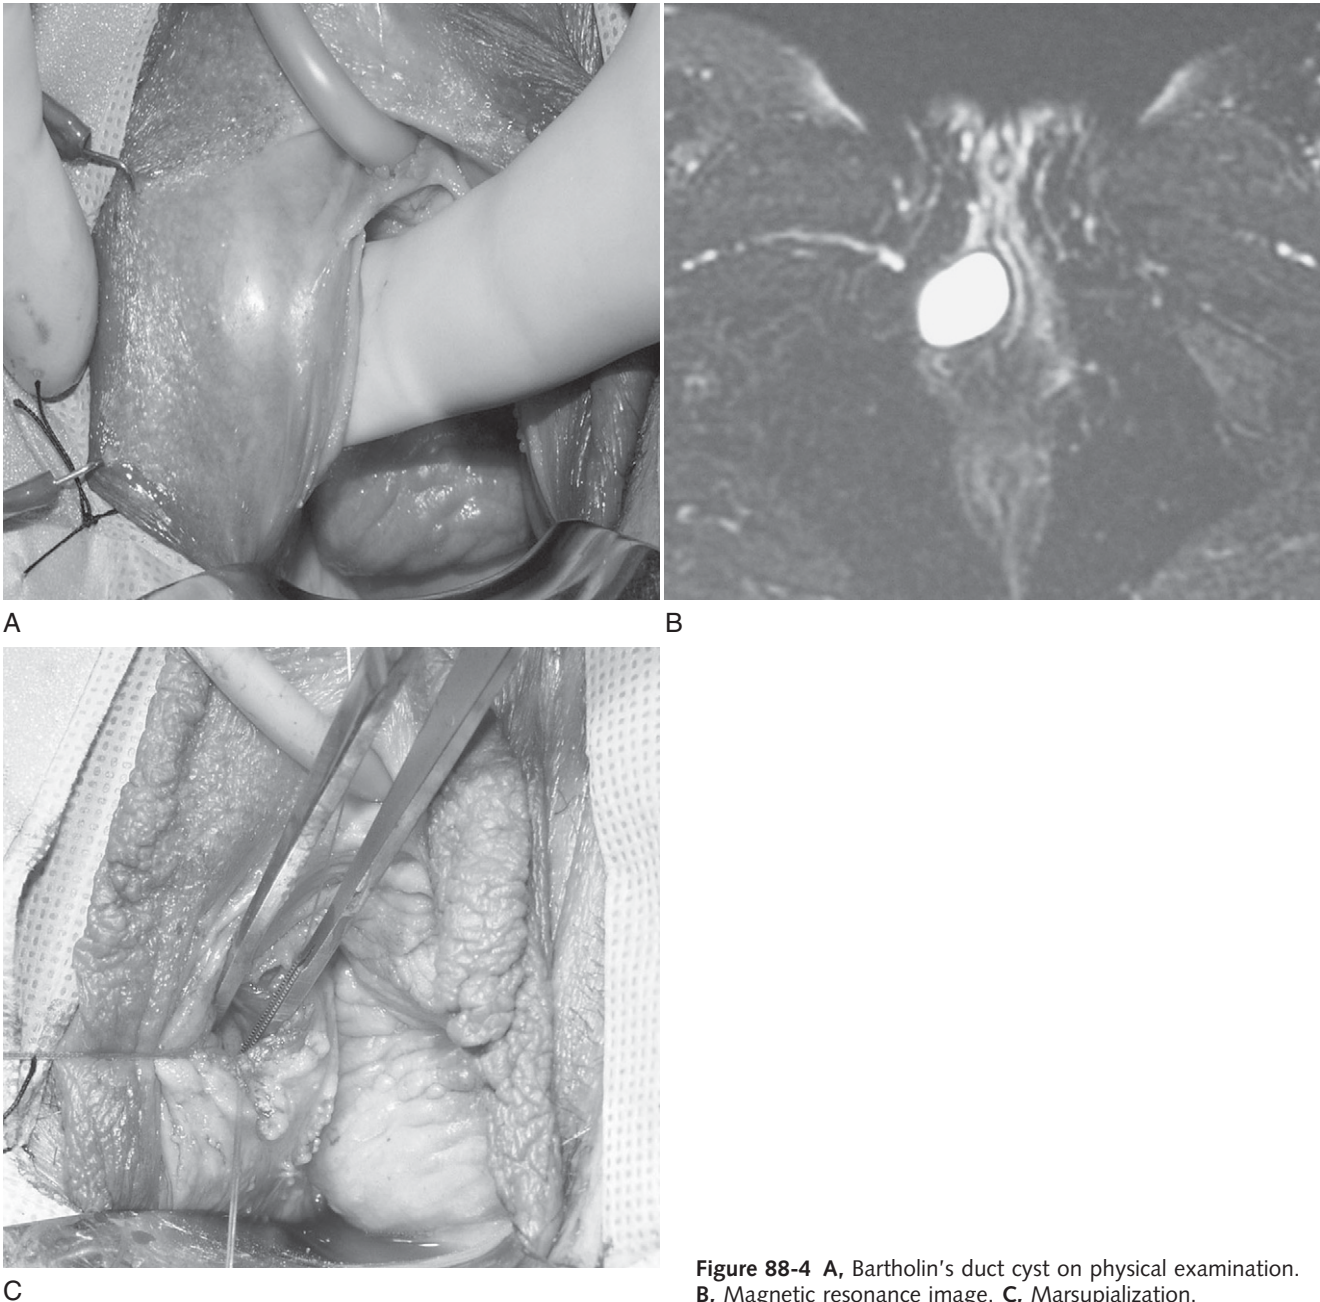

Cysts of the canal of Nuck are found in the superior aspect of the labia majora or inguinal canal. Their size may be several centimeters, and they are associated with an inguinal hernia in one third of cases.<sup>18</sup> Most of these cysts are diagnosed intraoperatively, but if a cyst of the canal of Nuck is suspected preoperatively, the surgical approach should be that for an inguinal herniorrhaphy.

### CYSTS OF URETHRAL ORIGIN

It is important to determine whether a cystic lesion in the vagina is of urethral origin, because excision of urethral lesions requires postoperative catheter drainage to prevent fistula formation.

### Urethral Caruncle

The term *caruncle* refers to a wide variety of lesions protruding from the urethral meatus. Urethral caruncles typically occur in postmenopausal women and most likely represent ectropion of the urethral wall due to postmenopausal regression of the vaginal

**Figure 88-4** A, Bartholin's duct cyst on physical examination. B, Magnetic resonance image. C, Marsupialization.

mucosa. Urethral prolapse is often mistakenly diagnosed as a caruncle in a child.

On physical examination, a urethral caruncle is seen as a solitary, red, polypoid lesion protruding from one segment of the urethral meatus (Fig. 88-6). Most caruncles measure only a few millimeters in diameter. Symptoms range from mild bleeding to extreme discomfort.

Based on histology, caruncles are classified as either papillomatous, angiomatous, or granulomatous.<sup>4</sup> All types consist of a core of loose connective tissue and blood vessels covered by a transitional or squamous epithelium. Classification depends on the degree of associated inflammatory reaction.

Treatment is expectant for small, asymptomatic lesions. Excision is performed for lesions with significant symptoms or in cases in which carcinoma must be ruled out.

### Urethral Diverticulum

A urethral diverticulum typically manifests as a cystic lesion in the anterior vaginal wall along the distal urethra (Fig. 88-7A). It most likely forms as a consequence of the rupture of infected periurethral glands into the lumen. Common symptoms include postvoid dribbling, dyspareunia, and recurrent urethritis or cystitis. Compression of the cyst may cause expulsion of urine or purulent material.

Cystourethroscopy is often the initial test when evaluating a patient with a suspected urethral diverticulum, but it may not be diagnostic if the neck of the diverticulum is small. In this case, imaging is invaluable. Neitlich and colleagues demonstrated that high-resolution, fast-spin echo technique MRI has a high sensitivity for detecting diverticula and a higher negative

Figure 88-5 Microscopic appearance of vaginal adenosis.

Figure 88-6 Urethral caruncle.

predictive rate than double-balloon urethrography.<sup>19</sup> A combination of both VCUG and MRI can be used to accurately diagnosis the condition and localize the lesion or lesions (see Fig. 88-7B,C).

Transvaginal excision with postoperative urethral catheter drainage is the preferred treatment, although endoscopic incision has been described.

### EPIDERMAL CYSTS

Epidermal inclusion cysts secondary to buried epithelial fragments after episiotomy or other surgical procedures are the most common nonembryologic type of vaginal cysts.<sup>4</sup> In Nigeria, epidermal inclusion cysts are common in the first decade of life, and this has been attributed to the practice of prepubertal female circumcision.<sup>2</sup>

Inclusion cysts vary in size from a few millimeters to several centimeters in diameter. Their location correlates with an area of previous surgery, and their contents appear cheese-like and may even resemble a thick, purulent exudate. Imaging of these lesions by MRI reveals a cystic structure containing heterogeneous fluid.

On histologic examination, inclusion cysts are lined with stratified squamous epithelium and contain sebaceous-appearing material that represents desquamated epithelial cells. Cysts lined by squamous epithelium but not associated with buried skin fragments are simply termed *epidermal cysts*. Because these cysts are usually asymptomatic, they may be observed.

### ENDOMETRIOSIS

Endometriosis is the ectopic implantation of endometrial glands and stroma. Primary occurrence in the vulva and vagina is rare and usually represents a secondary manifestation of pelvic disease. On gross examination, these cysts are mucoid and may appear brown or black. Nodules of endometriosis are located in the posterior fornix and appear red-blue to yellow-brown (“chocolate cyst”). The patient may complain of cyclic enlargement, dysmenorrhea, dyspareunia, pelvic pain, or dysuria.

Two of the following three characteristics must be present to make the diagnosis: endometrial glands, stroma, and hemosiderin-laden macrophages. Foreign body giant cells may be found.<sup>4</sup> Treatment is destruction or excision of the lesions.

### ECTOPIC URETEROCELE

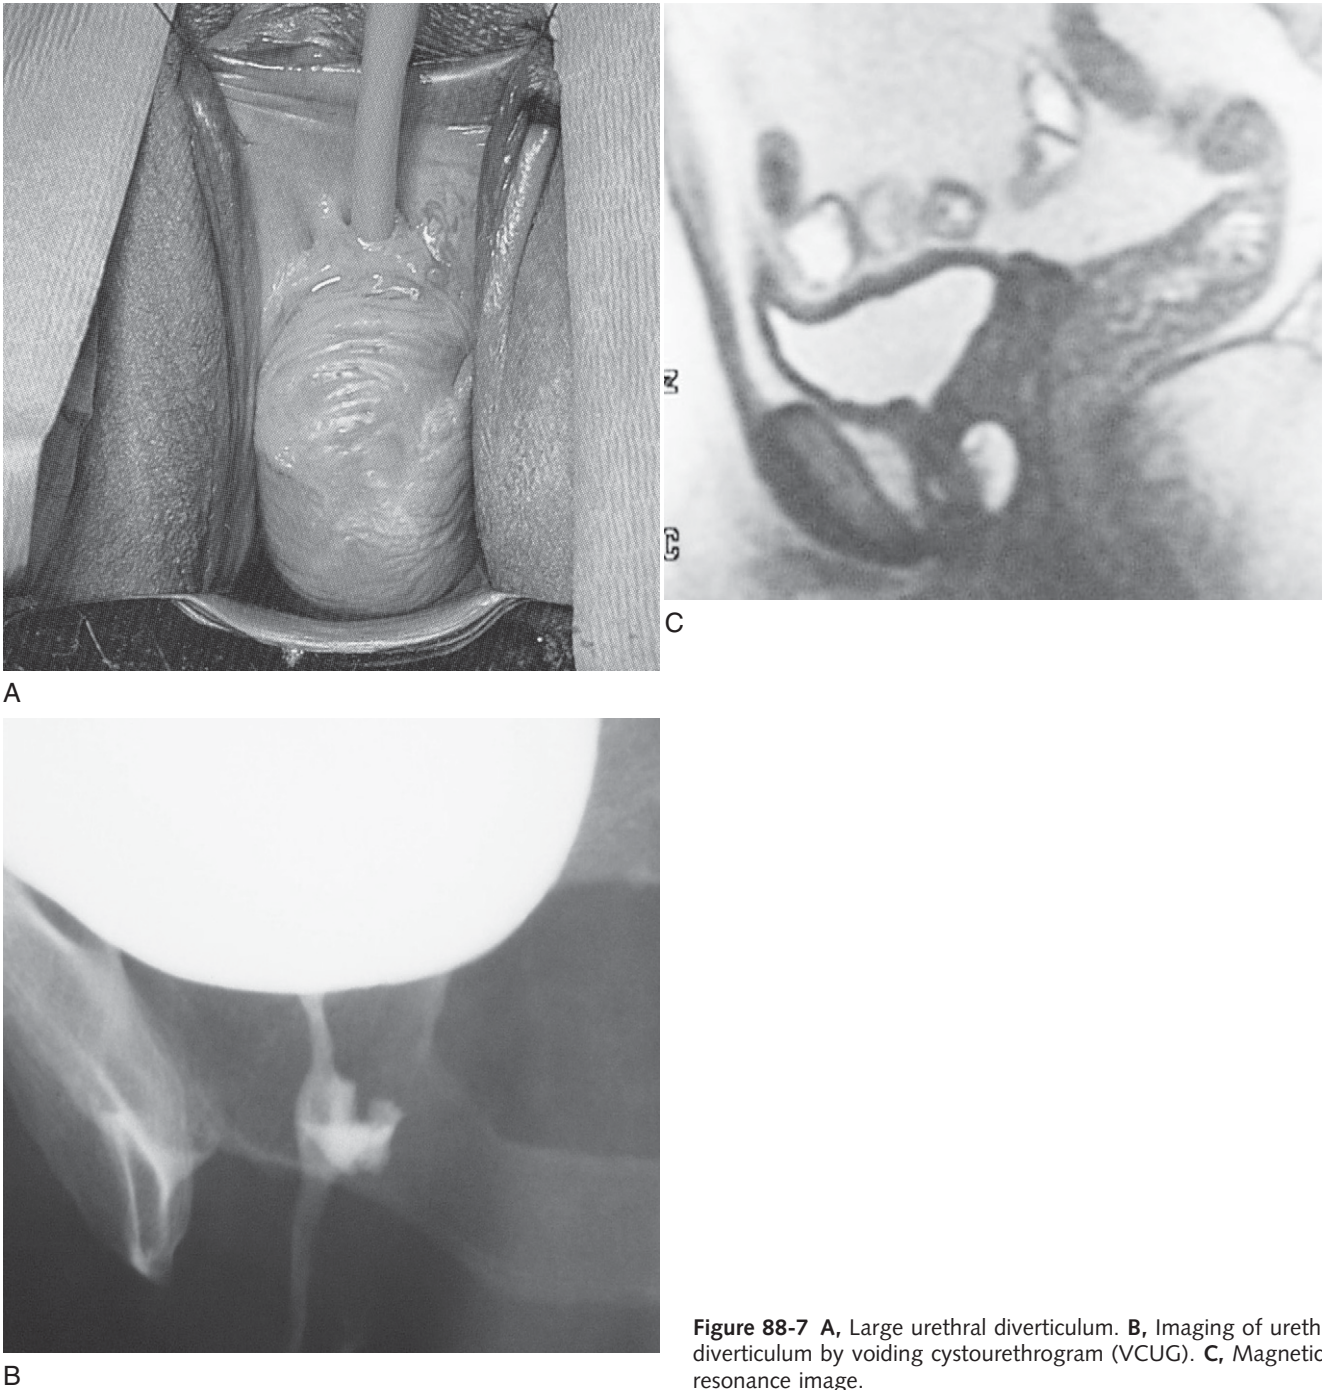

A ureterocele is a cystic dilatation of the distal ureter. Ureteroceles are commonly associated with the upper pole of a duplicated collecting system; if present with an ectopic ureter, they may manifest as a cystic vaginal mass. Although diagnosis is usually made at an early age, an ectopic ureterocele may manifest as incontinence in an older female child or young woman.

Clinically, most ureteroceles are diagnosed by prenatal ultrasound examination, but they may also be found as a cystic vaginal mass on physical examination. An endoscopic or open surgical approach is dictated by factors such as the presence of duplication, reflux, and parenchymal function of the upper pole associated with the ectopic ureterocele.

### PELVIC ORGAN PROLAPSE

Prolapse of pelvic organs (e.g., cystocele, rectocele) can manifest as a vaginal cystic lesion. Symptoms can range from mild vaginal pressure to urinary incontinence or retention. Diagnosis is by history and physical examination. MRI is often helpful. All of the options for treatment are beyond the scope of this chapter and

**Figure 88-7** A, Large urethral diverticulum. B, Imaging of urethral diverticulum by voiding cystourethrogram (VCUG). C, Magnetic resonance image.

will not be discussed, but in general treatment depends on the patient's symptoms, health status, and degree of prolapse.

### RARE CYSTIC LESIONS

#### Vaginitis Emphysematosa

Vaginitis emphysematosa is a rare, benign process characterized by gas-filled cysts in the vaginal wall, first described by Zweifel in 1877.<sup>20</sup> Fewer than 200 cases have been reported in the literature. Most patients present with symptoms of vaginitis, but an audible popping sound during intercourse has been reported by some.<sup>21</sup>

No definitive infectious etiology has been found, but most cases are associated with *Trichomonas vaginalis*.<sup>22</sup>

Diagnosis can be made by physical examination. The cysts are usually found in the upper two thirds of the vagina but may extend to the lower vagina, and rarely to the vulva. On physical examination, the cysts are seen to be discrete, tense, and smooth, and they may create a popping sound when ruptured during a vaginal examination. On histologic examination, the cysts are found to contain pink hyaline-like material, and they are lined by foreign body giant cells and other inflammatory cells.<sup>23</sup> The condition is self-limited and does not require specific treatment.

### Hidradenoma

Hidradenomas of the vagina are well-circumscribed, freely mobile nodules found mainly on the medial aspect of the labia majora in the interlabial sulcus. The majority are smaller than 1 cm. The presence of granular, papillomatous tissue is suggestive of the diagnosis. Microscopic examination is remarkable for a cystic lesion filled with papillomatous growths.<sup>4</sup> Treatment is by local excision.

### Dermoid Cyst

Only two cases of dermoid cysts involving the vagina have been reported.<sup>24,25</sup> In both cases, the cyst originated in the paravaginal space and diagnosis was delayed. Histology is remarkable for a cyst lined by keratinized squamous epithelium and containing dermal appendages.

### Aggressive Angiomyxoma

Aggressive angiomyxoma is a rare myofibroblastic tumor of the pelvic and genital soft tissues with just over 110 cases reported in the literature. It is typically found in women 35 to 40 years of age, although it can develop in men and children as well.<sup>26</sup> The term "aggressive" refers to its pattern of local infiltration and recurrent growth. Most are large (>10 cm), and surgical resection after imaging to determine the extent of disease is recommended.

### Ciliated Cyst

A ciliated cyst is a cyst lined with columnar ciliated epithelium. Ciliated cysts are rare and are probably of müllerian origin. They occur in women 25 to 35 years of age and have been associated with pregnancy, exogenous progesterone, and chronic inflammation.<sup>27</sup> Resection is indicated for symptomatic lesions.

### Pigmented Follicular Cyst

Pigmented follicular cysts are rare, occur predominantly in adult men, are composed of stratified squamous epithelium with epidermoid keratinization, and have a pore-like opening to the skin surface. Only one case of pigmented follicular cyst of the vulva has been reported, and treatment of this lesion was with CO<sub>2</sub> laser.<sup>28</sup>

### CONCLUSIONS

Cystic lesions of the vagina and vulva are a relatively common occurrence and represent a spectrum of disease from embryologic derivatives to preneoplastic lesions. Familiarity with the different diagnoses is essential for any clinician involved in gynecologic or female urologic practice in order to arrive at the correct diagnosis and treatment plan.

# PATHOPHYSIOLOGY OF PELVIC PAIN

*Ursula Wesselmann*

Chronic pelvic pain syndromes belong to the category of visceral pain. Chronic pelvic pain is a common and debilitating problem that can significantly impair a woman's quality of life. Patients with chronic pelvic pain are usually evaluated and treated by urologists, gynecologists, gastroenterologists, and internists. The clinical presentation is often considered to be a diagnostic dilemma, because many urologic, gastrointestinal, and gynecologic disorders appear to cause or are associated with chronic pelvic pain.<sup>1</sup> Although these patients seek medical care because they are looking for help to alleviate their pelvic discomfort and pain, in clinical practice much emphasis has been placed on finding a specific cause and specific pathologic markers for pelvic disease. These patients typically undergo many diagnostic tests and procedures. Often, however, the examination and workup remain unrevealing and no specific cause of the pain can be identified. In these cases, it is important to recognize that pain is not only a symptom of pelvic disease, but that the patient is suffering from a chronic pelvic pain syndrome, in which "pain" is the prominent symptom of the chronic visceral pain syndrome.<sup>2,3</sup>

The purpose of this chapter is to review the pathophysiology of chronic nonmalignant pelvic pain, a chronic visceral pain syndrome. Because of the anatomic location of the viscera, they do not lend themselves easily to experimental manipulation, but recognition of the existence of the chronic pelvic pain syndromes has resulted in the development of novel animal models to study the pathophysiologic mechanisms of chronic pelvic pain<sup>4</sup> and of clinical studies to assess pain treatment options. Knowledge of the neurophysiologic characteristics of visceral pain will guide the physician in making a diagnosis of chronic pelvic pain and in sorting it out from the lump diagnosis of idiopathic pain.<sup>3</sup> A basic understanding of the neurobiology is paramount to gain further insights into the mechanisms of the pelvic pain disorders and contributes greatly to the development of effective clinical management strategies for patients presenting with these syndromes.

## DEFINITIONS: WHAT IS CHRONIC PELVIC PAIN?

Definitions are important if a body of reliable information is to be built up in the scientific literature that will eventually lead to a better understanding of the pathophysiology of chronic pelvic pain. At present, one of the major problems of research into chronic pelvic pain is the lack of agreed definitions, which would allow comparisons among studies. On the other hand, lack of understanding of the pathophysiologic mechanisms of the pelvic pain syndromes makes it difficult to decide on criteria to define chronic pelvic pain conditions.<sup>5</sup>

Pain is defined by the International Association for the Study of Pain (IASP) as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or is described in terms of such damage.<sup>6</sup> There is no generally accepted definition of chronic pelvic pain. The IASP defines chronic pelvic pain without obvious pathology as chronic or recurrent pelvic pain that apparently has a gynecologic origin but for which no definitive lesion or cause is found.<sup>6</sup> This definition is problematic from a clinical perspective, because it implies absence of pathology, which might not necessarily be the case (for example, many patients with endometriosis suffer from pelvic pain). It also excludes cases in which pathology is present but not necessarily the cause of pain (for example, some patients with endometriosis do not have pelvic pain). As in many other pain conditions, the relationship of the pain complaint to the presence of pathology is often unclear in patients with chronic pelvic pain. The proportion of women with chronic pelvic pain and a specific diagnosis (or diagnoses) varies greatly in the literature. A large primary care study from Great Britain found that diagnoses related to urinary and gastrointestinal tracts are more common than gynecologic causes (30.8% urinary, 37.7% gastrointestinal, 20.2% gynecologic). Further, 25% to 50% of women with chronic pelvic pain who received medical care in primary care practices had more than one diagnosis.<sup>7,8</sup>

Several medical societies have recently published consensus statements revising definitions of chronic pelvic pain. The International Continence Society has defined "pelvic pain syndrome" as the occurrence of persistent or recurrent episodic pelvic pain associated with symptoms suggestive of lower urinary tract, sexual, bowel, or gynecologic dysfunction in the absence of proven infection or other obvious pathology.<sup>9</sup> The European Association of Urology suggested extending this definition by considering two subgroups based on the presence or absence of well-defined conditions that produce pain.<sup>10</sup> In the gynecologic literature, chronic pelvic pain is often referred to as pelvic pain in the same location for at least 6 months. The American College of Obstetricians and Gynecologists has proposed the following definition: chronic pelvic pain is noncyclic pelvic pain of 6 or more months' duration that localizes to the anatomic pelvis, anterior abdominal wall at or below the umbilicus, the lumbosacral back, or the buttocks and is of sufficient severity to cause functional disability or lead to medical care. A lack of physical findings does not negate the significance of a patient's pain, and normal examination results do not preclude the possibility of finding pelvic pathology.<sup>1</sup> Definitions of chronic pelvic pain will probably continue to be revised, as knowledge about the pathophysiology of pelvic pain is increasing based on basic science and clinical research. When reviewing literature on chronic pelvic pain, it is crucial for the reader to realize which definition of chronic pelvic was actually used for the study.

### HOW COMMON IS CHRONIC PELVIC PAIN? EPIDEMIOLOGIC DATA

Chronic pelvic pain is more common than previously thought. Epidemiologic data from the United States showed that 14.7% of women in their reproductive years reported chronic pelvic pain, and the estimated number of female pelvic pain sufferers was 9.2 million in the United States alone.<sup>11</sup> Analysis of a large primary care database from the United Kingdom demonstrated that the annual prevalence rate of chronic pelvic pain in women was 38/1000, which is comparable to the prevalence rates of asthma and low back pain.<sup>7</sup> Although this study found a high prevalence of pain, many women had never had the condition diagnosed.<sup>12</sup>

### NEUROANATOMY OF THE PELVIS

The purpose of this section is to provide an overview of the innervation of the pelvis and urogenital floor.<sup>13,14</sup> Although this summary attempts to derive as much information as possible from investigations involving humans, it is important to note that some generalizations are necessarily taken from animal studies, recognizing that much research in this field is still in its infancy.

All viscera, including the pelvic visceral organs, are dually innervated by both divisions of the autonomic nervous system, the sympathetic and parasympathetic divisions, as well as by the somatic and sensory nervous systems. In a broad anatomic view, dual projections from the thoracolumbar and sacral segments of the spinal cord carry out this innervation, converging primarily into discrete peripheral neuronal plexuses before distributing nerve fibers throughout the pelvis (Fig. 89-1). Interactive neuronal pathways routing from higher origins in the brain through the spinal cord add to the complexity of neuronal regulation in the pelvis. Although it is important to appreciate the influence of supraspinal centers in the coordination of pelvic organ activities, it is beyond the scope of this section to discuss these interactions in further detail; for review, see Bors and Comarr,<sup>15</sup> Morrison,<sup>16</sup> de Groat et al,<sup>17</sup> de Groat,<sup>18</sup> and Berkley and Hubscher.<sup>19</sup>

The nomenclature of the various plexuses, ganglia, and nerves in the pelvic cavity (see Dail<sup>20</sup>) is varied, and sometimes there are confusing presenting designations from both *Nomina Anatomica*<sup>21</sup> and clinical usage (see Baljet and Drukker<sup>22</sup>). In this review and in Figure 89-1, the anatomic nomenclature is used, with the clinical usage given in parentheses: superior hypogastric plexus (presacral nerve), hypogastric plexus (hypogastric nerve), inferior hypogastric plexus (pelvic plexus), and pelvic splanchnic nerve (pelvic nerve).

Within the pelvis, the inferior hypogastric plexus is regarded as the major neuronal integrative center. Neuroanatomic studies have confirmed its retroperitoneal location adjacent to each lateral aspect of the rectum, with interconnections between the left and right inferior hypogastric plexuses at the posterior aspect of the rectum.<sup>23-26</sup> It innervates multiple pelvic organs, including the urinary bladder, proximal urethra, distal ureter, rectum, and internal anal sphincter, as well as genital and reproductive tract structures.<sup>27</sup> The anterior part of the inferior hypogastric plexus, which is associated with the distal extent of the hypogastric plexus (hypogastric nerve), is referred to as the paracervical ganglia in females.<sup>28</sup> The paracervical ganglia part of the inferior hypogas-

tric plexus in the female, situated in the parametrium lateral to the cervix and the upper part of the vagina, distributes nerve fibers to the corpora cavernosa of the clitoris, vagina, and periurethral tissues.<sup>28</sup>

Neuronal input to the inferior hypogastric plexuses involves dual input through the sympathetic and parasympathetic divisions of the autonomic nervous system. Sympathetic nerves originate in the thoracolumbar segments of the spinal cord (T10-L2) and condense into the superior hypogastric plexus located just inferior to the aortic bifurcation. Preganglionic efferents originate largely in the intermediolateral cell column, whereas afferents have their cell bodies located in dorsal root ganglia of these segments. Nerve fibers project from the superior hypogastric plexus as paired hypogastric plexuses (hypogastric nerves) and fuse distally before diverging bilaterally into branches destined for the inferior hypogastric plexuses. Additional sympathetic innervation to genitourinary organs may involve preganglionic nerves that synapse on postganglionic nerves originating in sympathetic chain ganglia; these postganglionic nerves join sacral nerves and course to their destinations via pelvic somatic neuronal pathways.<sup>29</sup> Parasympathetic preganglionic nerve efferents are thought to arise from cell bodies of the sacral parasympathetic nucleus located in the intermediolateral gray matter of the sacral spinal cord (S2-S4) and to fuse as the pelvic splanchnic nerve before entering the inferior hypogastric plexus.<sup>30,31</sup> Parasympathetic afferents have cell bodies located in the S2-S4 dorsal root ganglia and course also within the pelvic splanchnic nerve. In addition to its parasympathetic efferent and afferent component, the pelvic splanchnic nerve also receives postganglionic axons from the caudal sympathetic chain ganglia.<sup>18</sup>

A distinctive distribution of pelvic autonomic innervation is recognized at the urogenital organ level. Lower urinary tract smooth muscle, including that of the proximal urethra, urinary bladder, and lower ureter, receives direct postganglionic efferent projections from the inferior hypogastric plexus, although vesical or intramural ganglia also serve as origins for postganglionic axons.<sup>32</sup> The inferior hypogastric plexus additionally provides afferent input to the lower urinary tract and internal reproductive organs, with proximal afferent fibers predominantly projecting through the hypogastric plexuses (hypogastric nerves) (see Jänig and Koltzenburg<sup>33</sup>).

The autonomic innervation of the female genitalia has been less well studied than the male counterpart. It involves inferior hypogastric plexus projections deriving primarily from the paracervical ganglia part of the plexus. Conspicuous nerve trunks run in the adventitia of the vagina parallel to its long axis, sending off anterior branches that course to the clitoris and periurethral tissues and local branches that enter the vaginal smooth muscle walls.<sup>22,34</sup> A network of nerve fibers tends to follow vascular distributions and conspicuously terminates at the junction between the subepithelial connective tissue and the vaginal epithelium as well as within the epithelium.<sup>34</sup> Nerve density is observed to be greater in the distal vagina than in the proximal regions.<sup>34</sup>

Although the rectum and the anal sphincters are closely situated anatomically, their exact sources of innervation differ. Not surprisingly, a division of neural control is characterized on the basis of morphologic and functional differences. The smooth muscle of the rectum and internal anal sphincter (a thickened continuation of the circular smooth muscle fibers of the rectal wall) is influenced by the autonomic nervous system and receives innervation directly from sympathetic and parasympathetic

**Figure 89-1** Schematic drawing showing the innervation of the pelvic area in the human female. CEL, celiac plexus; DRG, dorsal root ganglion; HGP, hypogastric plexus (hypogastric nerve); IHP, inferior hypogastric plexus (pelvic plexus); PSN, pelvic splanchnic nerve (pelvic nerve); PUD, pudendal nerve; SA, short adrenergic projections; SAC, sacral plexus; SCG, sympathetic chain ganglion; SHP, superior hypogastric plexus (presacral nerve); Vag = vagina. (From Wesselmann U, Burnett AL, Heinberg LJ: The urogenital and rectal pain syndromes. *Pain* 73:269-294, 1997. With permission of the International Association for the Study of Pain.)

origins coursing through or synapsing within the inferior hypogastric plexus.<sup>35</sup> Rectal branches from this plexus accompany the middle rectal vessels to the lateral sides of the rectum, within condensations of connective tissue referred to as the lateral ligaments of the rectum.<sup>35</sup> At the level of the intestinal wall, innervation continues according to the pattern observed throughout the gastrointestinal tract, which involves two ganglionic plexuses, the myenteric plexus lying between the longitudinal and circular muscle layers and the submucosal plexus.<sup>27</sup> In contrast, the striated muscle of both the external anal sphincter and the levator ani (including the puborectalis muscle) is generally under the control of the somatic nervous system.

Somatic efferent and afferent innervation to the pelvis is generally understood to involve the sacral nerve roots (S2-S4) and their ramifications. Somatic efferents arise within Onuf's nucleus situated in the ventral horn of the S2-S4 spinal cord, and afferents reach the dorsal horn with their cell bodies in dorsal root ganglia

of these segments.<sup>32</sup> Central projections of somatic afferents overlap with pelvic nerve afferents within the spinal cord, which theoretically allows coordination of somatic and visceral motor activity.<sup>29</sup>

The sacral nerve roots emerge from the spinal cord, forming the sacral plexus,<sup>36</sup> from which the pudendal nerve diverges (S2-S3) along with the sciatic nerve, between an initial division of sacral nerves that branch to the levator muscle and a subsequent division of fibers that intermingle with autonomic pelvic nerves coursing to the inferior hypogastric plexus.<sup>37-39</sup> The pudendal nerve also receives postganglionic axons from the caudal sympathetic chain ganglia.<sup>18</sup> In general, the pudendal nerve runs medial to the internal pudendal vessels along the lateral wall of the ischioanal fossa, dorsal to the sacrospinous ligament. An initial branch then splits off destined to innervate the clitoris, and the remaining pudendal nerve fibers distribute branches in various directions, which include medial branches to

the anal canal (external anal sphincter and puborectalis muscle), dorsal branches to the urethral sphincter, and dorsolateral branches primarily to anterior perineal musculature (including bulbospongiosus and ischiocavernosus muscles). Nerves originating predominantly from sacral level S4 supply the posterior perineal musculature, and branches of S4-S5 nerve roots forming the coccygeal plexus distribute to perineal, perianal, and labial skin.<sup>39</sup>

Nociception and pain arising from within the pelvis and pelvic floor involve diverse neuronal mechanisms. In general, sensations from the pelvic viscera are conveyed within the sacral afferent parasympathetic system, with a far lesser afferent supply from thoracolumbar sympathetic origins.<sup>33</sup> Functionally, this dual innervation contributes to differential processing of visceral stimuli by different regions of the neuraxis. For example, in a model of colonic pain it was demonstrated that the pelvic nerve and lumbosacral spinal cord process acute or transient colorectal pain with recruitment of the splanchnic innervation during inflammation of the colon.<sup>40,41</sup> Pelvic nerve afferents innervate the deeper layers of hollow organs, including mucosa and submucosa as well as the muscle and serosa.<sup>42</sup> Receptive fields in the perineum are understood to be carried out primarily by sensory-motor discharges associated with pudendal nerve afferents.<sup>17,33</sup> While the interactions of sensory afferents are quite complex, likely possibilities by which these pathways exert effects on autonomic efferent function include mediatory effects on spinal cord reflexes and modulatory effects on efferent release in peripheral autonomic ganglia and in peripheral organs. These neural structures in the periphery comprise the first of numerous relays of sensory neurons that transmit painful sensations from the abdominal/pelvic cavity to the brain.

Traditionally, it was thought that ascending pathways for visceral and other types of pain were mainly the spinothalamic and spinoreticular tracts. Recently, three previously undescribed pathways that carry visceral nociceptive information have been discovered: the dorsal column pathway, the spino(trigemino)-parabrachio-amygdaloid pathway, and the spinohypothalamic pathway (see review in Cervero and Laird<sup>43</sup>). The dorsal column pathway plays a key role in the processing of pelvic pain, and neurosurgeons have successfully used punctate midline myelotomy to relieve pelvic pain due to cancer (see review in Willis and Westlund<sup>44</sup>). In addition, descending facilitatory influences may contribute to the development of maintenance of hyperalgesia, thus contributing to the development of chronic pelvic pain.<sup>45</sup>

#### VISCERAL NOCICEPTION: VISCERAL NOCICEPTORS, VISCERAL SENSITIZATION, AND REFERRED PAIN MECHANISMS

Chronic visceral pain is a much greater clinical problem than that from skin, however, until relatively recently, the focus of experimental work on pain mechanisms mainly related to cutaneous sensation. Although it was often assumed that concepts derived from cutaneous studies could be transferred to the visceral domain, there are emerging experimental data indicating that the neural mechanisms involved in pain and hyperalgesia of the skin are different from the mechanisms involved in painful sensations from the viscera.<sup>46,47</sup> This is supported by differences between somatic and visceral pain based on clinical observation. In contrast to somatic pain, visceral pain cannot be evoked from all

viscera and is not necessarily linked to visceral tissue injury. Further, visceral pain tends to be a diffuse and poorly localized sensation, whereas somatic pain can be localized exactly. Different from somatic pain, visceral pain can be referred to other visceral structures and somatic structures of the same segmental level. For example, patients with chronic pelvic pain typically report multiple pelvic pain problems, and they present with pain radiating to the lower back and legs.<sup>7,8</sup>

The visceral innervation is not as dense as the somatic innervation. It is assumed that at most 5% to 8% of the total afferent input to the spinal cord is contributed by spinal visceral nerves.<sup>48</sup> This rather sparse afferent input to the spinal cord from the viscera is compensated for by an extensive divergence in the central nervous system. In addition, recent studies have suggested that some visceral afferents innervate more than one organ. About 20% of dorsal root ganglion cells retrogradely labeled from the colon were double-labeled from the bladder.<sup>49</sup> The physiologic role of the bifurcating afferents is not clear, because recordings from colon or bladder afferents failed to provide evidence of excitation of the other organ.<sup>50,51</sup> It is possible that these bifurcating afferents become active after inflammation. This hypothesis is supported by the observation that colonic inflammation in a rat model results in plasma extravasation in an otherwise normal bladder.<sup>52</sup> These neuroanatomic and neurophysiologic observations might explain why visceral pain tends to be diffuse and poorly localized, providing a diagnostic challenge to the health care provider who is trying to ascertain the origin of the pain.

There are two components of visceral pain, which were already described more than 100 years ago<sup>53</sup>: “true visceral pain,” which is deep visceral pain arising from inside the body, and “referred visceral pain,” which is pain that is referred to segmentally related somatic and also other visceral structures. Secondary hyperalgesia usually develops at the referred site.<sup>4</sup> Although several mechanisms have been entertained to explain the referred pain phenomenon over the last 70 years, the most convincing experimental evidence is provided by the observation of convergence. Convergence of afferent input is a typical characteristic of second-order neurons in the spinal cord that receive visceral input. These visceroreceptive spinal neurons receive convergent somatic input from skin and musculature.<sup>54</sup> In addition, viscerovisceral convergence of input onto second-order spinal neurons is common (e.g., colon and bladder). This mechanism offers a ready explanation for the segmental nature of referred pain, but it does not address explicitly the issue of hyperalgesia in the referred zone. To interpret “referred pain with hyperalgesia,” two main theories have been proposed, which are not mutually exclusive. The first is known as convergence-facilitation theory. It proposes that the abnormal visceral input produces an irritable focus in the relative spinal cord segment, thus facilitating messages from somatic structure. The second theory postulates that the visceral afferent barrage induces the activation of a reflex arc whose afferent branch is presented by visceral afferent fibers and efferent branch by somatic efferents and sympathetic efferents toward the somatic structures (muscle, subcutis, and skin). The efferent impulses toward the periphery sensitize nociceptors in the parietal tissues of the referred area, thus resulting in the phenomenon of hyperalgesia.

When examining and treating a woman with chronic pelvic pain, it is important to consider the true and referred aspects of the visceral pain syndrome, including the pain deep in the pelvic cavity and pain referred to somatic structures (lower back and

legs) and other visceral organs. The mechanisms of referred viscerovisceral pain might explain the substantial overlap observed in epidemiologic studies between chronic pelvic pain and other abdominal symptoms.<sup>12,55</sup> Considering the concept of referred visceral pain and realizing that the visceral innervation is sparse, but compensated for by extensive divergence in the central nervous system, will allow the health care provider to look at the global picture of visceral dysfunction, rather than “chasing” one aspect of the visceral pain syndrome out of context.

The existence of visceral nociceptors has been debated for a long time, in part because of the difficulty of defining and applying physiologically relevant noxious stimuli to the viscera (for review, see Bielefeldt and Gebhart<sup>54</sup>). The functional properties of visceral afferent neurons have been studied by recording afferent fiber activity and responses to controlled visceral stimuli in teased fiber preparations in which one or a few axons are recorded. These experiments have shown that several kinds of sensory receptors exist in most internal organs and that different pain states are mediated by different neurophysiologic mechanisms.<sup>56</sup> Acute, brief visceral pain seems to be triggered initially by the activation of high-threshold visceral afferents and by the high-frequency bursts that these stimuli evoke in intensity-coding afferent fibers, which are afferents with a range of responsiveness in the innocuous and noxious ranges. However, more prolonged forms of visceral stimulation, including those leading to hypoxia and inflammation of the tissue, result in sensitization of high-threshold receptors and the bringing into play of previously unresponsive afferent fibers, termed “silent nociceptors.” This is a special class of mechano-insensitive C-fiber nociceptors that has been found in almost all tissues, including in animal models of visceral pain.<sup>57</sup> Silent afferents are activated only in the presence of tissue damage or inflammation, which might explain why visceral pain cannot be evoked from all viscera and is not necessarily linked to every type of visceral tissue injury.

There are several potential molecular substrates that may play key roles in the peripheral sensitization of nociceptor terminals in viscera. Messengers for tetrodotoxin (TTX)-resistant sodium channels, specifically Na 1.8, are primarily found in small-diameter neurons with unmyelinated axons, which typically play an important role in nociception. Essentially all visceral sensory neurons have unmyelinated or thinly myelinated axons. Capsaicin and protons bind the vanilloid TRPV1 receptor. TRPV1 is coexpressed with calcitonin gene-related peptide (CGRP) and substance P in 60% to 80% of visceral afferents.<sup>58</sup> TRPV1 expression in sensory fibers was correlated positively with the degree of hypersensitivity in patients with rectal hypersensitivity.<sup>59</sup> In addition, urothelial cells (non-neuronal tissue) have been shown to express TRPV1 receptors as well, and these can be activated by vanilloids to produce the release of adenosine triphosphate (ATP), which then can activate P2X3 receptors in sensory afferent fibers.<sup>60</sup> (Birder et al. 2001). This mechanism might account for the enhanced bladder sensitivity observed in patients with interstitial cystitis. Prostaglandins are synthesized in response to tissue injury by cyclooxygenase. They sensitize sensory fibers to mechanical and thermal stimuli and contribute to spinal processing of visceral pain.<sup>61</sup> In studies of central contributions to visceral sensitization, the main focus has been the spinal cord. Intrathecal application of *N*-methyl-D-aspartate (NMDA) and non-NMDA receptor antagonists significantly attenuates visceral hypersensitivity in behavioral models, and spinal application of NMDA agonists increases the magnitude and duration of visceral

pain responses.<sup>62,63</sup> NMDA receptors are expressed in primary afferents and in dorsal horn neurons.

### SEX, GENDER, AND GONADAL HORMONAL STATUS

A distinguishing feature of many of the pelvic pain syndromes is the overwhelming burden reported by women in their reproductive years. For example, population prevalence estimates in patients with interstitial cystitis indicate a female-to-male ratio of 9:1.<sup>64</sup> Interestingly, and in support of the hypothesis that the gonadal hormonal milieu influences pain perception, several pain syndromes are more common in women than in men.<sup>65,66</sup> There is growing evidence from studies in animals and humans that the response to noxious stimuli may be influenced by the gonadal hormonal milieu and varies across different phases of the estrous (rodents) or menstrual (humans) cycle.<sup>65,67-69</sup> However, the variations observed in different studies are inconsistent<sup>70</sup> and cannot be linked to only one phase of the cycle.

### CLINICAL IMPLICATIONS

Because epidemiologic data have confirmed the widespread existence of chronic pelvic pain in the female population in last 10 years, there is growing interest in the pharmaceutical industry to expand basic science and clinical research efforts for this underserved patient population. Controlled clinical trials are desperately needed to design improved pharmacologic treatment strategies. To date, most reports on the pharmacologic treatment of chronic pelvic pain are anecdotal. Currently used pharmacologic treatment approaches have mainly been evaluated for other chronic pain syndromes, and not specifically for chronic pelvic pain. Several different pharmacologic classes of medications have been demonstrated to be effective in alleviating pain in patients with chronic pain syndromes: nonsteroidal anti-inflammatory drugs (NSAIDs), antidepressants, anticonvulsants, local anesthetic antiarrhythmics, and opioids (for review, see Wesselmann<sup>71</sup>). Although clinical trials and case reports on the pharmacologic management of chronic pain syndromes provide general guidelines as to which drug to choose, currently we have no method to predict which drug is most likely to alleviate pain in a given patient. Therefore, it is a “trial and error” method of prescribing drugs.

As the pathophysiologic mechanisms of visceral pain explored in basic science research have provided explanations for some of the clinical phenomena observed in patients, additional, revived and new concepts of chronic pelvic pain have emerged. First, a spectrum of different insults might lead to chronic pelvic pain. Second, different underlying pathogenic pain mechanisms may require different pain treatment strategies for patients presenting with pelvic pain. And third, multiple different pathogenic pain mechanisms may coexist in the same patient presenting with chronic pelvic pain, requiring several different pain treatment strategies (perhaps concomitantly) to successfully treat visceral pain.<sup>3</sup>

# NEUROENDOCRINE ROLE IN INTERSTITIAL CYSTITIS AND CHRONIC PELVIC PAIN IN WOMEN

C. A. Tony Buffington

The International Association for the Study of Pain defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” The awareness of acute pain motivates those experiencing it toward withdrawal and guarding to permit avoidance of further injury and activation of repair processes. In some cases of chronic pain, however, the situation may be somewhat different, in that the severity of signs loses its usual tight correlation with symptoms. In chronic visceral pain states such as interstitial cystitis (IC) and chronic pelvic pain (CPP), the endocrine system also may be involved in maintaining the sensation of pain (Fig. 90-1),<sup>1,2</sup> although the extent to which (or in which patients) this results from an underlying genetic or developmental predisposition and to what extent it results from the etiology of the disease process cannot yet be determined.

The aims of this chapter are to describe some of the neuroendocrine abnormalities that occur in women with IC and CPP and to suggest the possibility of underlying neuroendocrine abnormalities in some of these patients.

IC is a lower urinary tract syndrome of unknown cause and no generally accepted treatment.<sup>3</sup> The symptoms of IC include variable combinations of pain referable to the urinary bladder, as well as increased frequency and urgency of urination. IC may affect more than 700,000 American women,<sup>4</sup> and a significant (potentially comparable) number of men diagnosed with sterile prostatitis or prostatodynia.<sup>5</sup> The quality of life of IC patients is significantly degraded; in one study, these patients scored much lower ( $P < .001$ ) than healthy control subjects did in all eight domains of health assessed by the Medical Outcomes Study Short Form-36 Health Survey.<sup>3</sup>

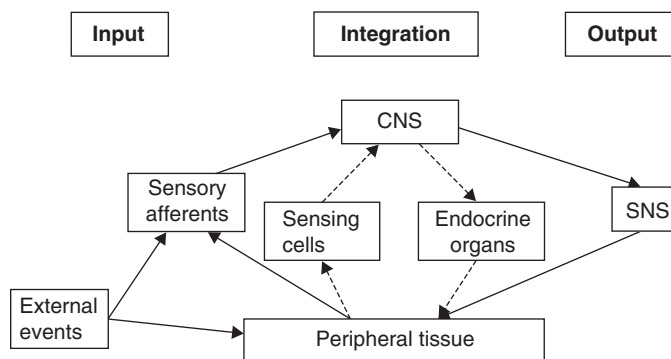

Since 1993, my laboratory has investigated a common lower urinary tract disorder of domestic cats, feline interstitial cystitis (FIC), that represents a naturally occurring model of IC. We have found that cats with FIC meet all the criteria promulgated by the National Institutes of Health for diagnosis of IC that can be applied to animals, and we have shown that cats with FIC and humans with IC have comparable bladder, sensory afferent, central, sympathetic, and endocrine abnormalities, to the extent they have been investigated. Recent findings in these cats<sup>3,6</sup> are consistent with and extend the neuroendocrine abnormalities identified in humans with IC.

The National Institutes of Health classifies IC as a CPP syndrome, which has been defined as nonmenstrual pain of at least 6 months' duration that is severe enough to cause functional disability or necessitate medical or surgical treatment.<sup>7</sup> As many as 39% of women of reproductive age seen by primary care physicians report the presence of CPP “always,” “often,” or “some-

times.”<sup>8</sup> Women with CPP use more medications, have more nongynecologic operations, and are five times more likely to have a hysterectomy than are women without CPP. These patients also are more likely to have a history of abuse and to suffer from depression, impaired sexual functioning, and reduced overall quality of life.<sup>9</sup>

A recent comprehensive review<sup>7</sup> listed some 70 disorders (15 extrauterine and 8 uterine, 11 urologic, 8 gastrointestinal, 17 musculoskeletal, and 11 “other”) that may be associated with CPP in women, including IC, irritable bowel syndrome, and fibromyalgia. The comorbidity of some of these diseases was suggested by the results of a recent mail questionnaire survey in England, which found that 24% of women aged 18 to 49 years reported CPP during the previous 3 months. Of these women, 52% had CPP only, 24% had CPP and irritable bowel syndrome, 9% had CPP and urinary frequency and urgency, and 15% had all three.<sup>10</sup> These results suggest that patients with CPP have variable combinations of organ involvement, raising the question of the extent to which a different etiology affects each organ individually, or whether some common underlying etiology affects a variety of organs, which then respond in their own characteristic ways.

Two subtypes of IC currently are recognized based on cystoscopic evaluation of the bladder. In most patients (90%), only submucosal petechial hemorrhages (glomerulations) are observed (type I), whereas mucosal (“Hunner’s”) ulcers, with or without glomerulations, are identified in a minority (type II). The two types also appear to differ in patient epidemiology, histologic findings, and response to treatment, further suggesting that they

**Figure 90-1** General plan of communication between the central nervous system and peripheral structures. CNS, central nervous system; SNS, sympathetic nervous system.

may be distinct entities.<sup>11</sup> One important difference between the two types is that many patients with type II IC report significant symptomatic relief after supratrigonal cystectomy and cystoplasty, whereas the pain in patients with type I IC is not usually diminished by this procedure.<sup>12</sup> This difference in patient response to removal of the bladder may provide an important clue to the underlying causes of pain associated with IC: the cause of the pain in patients with type II disease may be nociceptive, whereas the pain of patients with type I IC may be neuropathic.

Nociceptive pain results from persistent activity of sensory afferent fibers innervating the affected area and is relieved by removal of the stimulus. Examples of nociceptive pain include toothache, which is relieved by extraction, and osteoarthritis of the hip joint, which is relieved by hip replacement.<sup>13</sup> In contrast, neuropathic pain arises from some abnormality related to the nervous system; although generally attributed to a body structure, it can remain after desensitization of nociceptive afferents<sup>14,15</sup> or even removal of the structure.<sup>16,17</sup> Such results have been reported for endometriosis, where removal of identified abnormalities does not always lead to resolution of the CPP.<sup>18</sup>

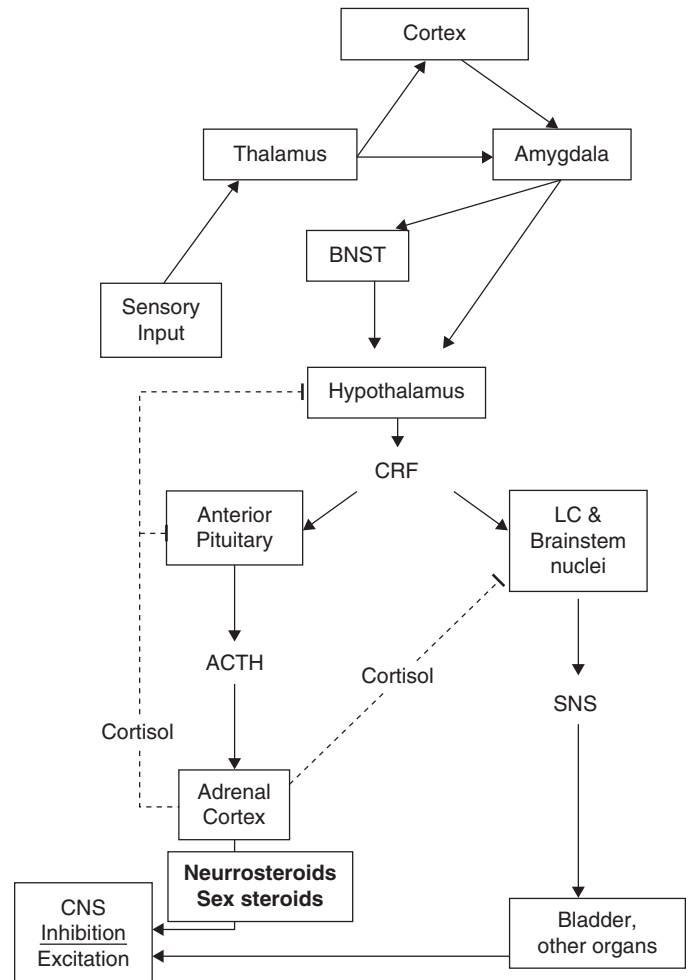

### THE STRESS RESPONSE SYSTEM

The presence of neuropathic pain may be related to abnormalities and imbalances of the neuroendocrine system, which is activated in response to threats to homeostasis. One commonality among some IC and CPP patients appears to be a relative predominance of activation of the sympathetic nervous system (SNS) limb of the stress response system (SRS), compared to the responses of the hypothalamic-pituitary-adrenal (HPA) and -gonadal (HPG) axes.<sup>19</sup> A schematic diagram of some of the features this complex system<sup>20</sup> is presented in Figure 90-2. Once the system is stimulated by central nervous system structures responding to sensory inputs (conscious or unconscious<sup>21</sup>) that are perceived as a threat to homeostasis, corticotropin-releasing factor (CRF) is released from the paraventricular nucleus of the hypothalamus. CRF acts as a neurotransmitter, to activate sympathetic premotor neurons in the pontine locus coeruleus and brainstem nuclei, and as a hormone, to stimulate the anterior pituitary. In some patients, the SNS arm of the response appears to be uncoupled from the HPA and HPG axes in that SNS outflow increases in the absence of activation of the HPA axis and in the presence of reduced HPG function.

### Sympathoneural Output

Even though the neuroendocrine features of the stress response have not been thoroughly studied in humans with IC and CPP, the available data support the presence of a comparable abnormality in at least a subset of these patients. Although plasma catecholamine concentrations have yet to be reported patients with IC, the findings of abnormal vasomotor tone,<sup>22</sup> increased density of bladder neurons staining for tyrosine hydroxylase (the rate-limiting enzyme for catecholamine synthesis),<sup>23,24</sup> and increased urine norepinephrine excretion<sup>25</sup> that have been reported suggest increased SNS activity.

Recent studies have begun to map the pathways that transduce activation of the SRS into cellular dysfunction via the SNS. Events external to the central nervous system, from both within and without the body, are transmitted to the brain by the sensory

**Figure 90-2** Afferent (sensory input), integrative (thalamus, cortex, amygdala, BNST, and motor (hypothalamus and beyond) components of the stress response system. ACTH, adrenocorticotropic hormone; BNST, bed nucleus of the stria terminalis; CRF, corticotropin-releasing factor; LC, locus coeruleus; SNS, sympathetic nervous system.

neurons. These signals are conveyed to the thalamus, where they are evaluated and usually forwarded to the cerebral cortex for further processing before activation of the appropriate motor program (see Fig. 90-2).<sup>26</sup> Potentially threatening events, however, can activate the SRS directly via the thalamic activation of the amygdala, bypassing cortical inhibitory control.<sup>27</sup>

Activation of the SNS results in sympathoneural release of norepinephrine. A 2003 study<sup>28</sup> traced this pathway from the external environment through to norepinephrine-mediated induction of the transcription factor nuclear factor kappa B (NF- $\kappa$ B), which is thought to play a role in mediating the urothelial inflammatory response of IC.<sup>29</sup> In vitro stimulation of human promonocytic (THP-1) cells with physiologic amounts of norepinephrine for 10 minutes resulted in a dose- and time-dependent induction of NF- $\kappa$ B and NF- $\kappa$ B-dependent gene expression; only norepinephrine induced this response, which was reduced by both  $\alpha_1$ - and  $\beta$ -adrenergic receptor antagonists. The authors concluded that norepinephrine-mediated activation of NF- $\kappa$ B represented a downstream effector of the neuroendocrine response to stressful psychosocial events, linking changes in

the environment to a bewildering array of cellular responses through activation of the SRS.<sup>30</sup>

Activation of the SRS also can increase epithelial permeability, permitting environmental agents greater access to sensory afferent neurons,<sup>31</sup> which could result in both increased sensory afferent firing and local inflammation. Sympathetic neural-epithelial interactions appear to play an important role in urothelial permeability. For example, Birder and colleagues showed that application of  $\beta$ -adrenergic receptor agonists to urinary bladder strips induced release of nitric oxide (NO) from urinary bladder epithelium, raising the possibility that norepinephrine from adrenergic nerves in the bladder (which may not be present in normal individuals)<sup>23,24</sup> or circulating catecholamines could influence bladder function by acting on  $\beta$ -adrenergic receptors in the urothelium to release NO and possibly other neurotransmitters, such as adenosine triphosphate (ATP).<sup>32</sup> Application of capsaicin, the pungent principle in hot peppers, also resulted in release of NO from epithelium as well as nervous tissue in the urinary bladder.<sup>33</sup> In light of reports that NO may increase urothelial permeability,<sup>34,35</sup> these results suggest that some of the sympathetically mediated alterations in permeability may be mediated by norepinephrine via this mechanism.

The increased permeability related to increased SNS activation does not require direct interaction with epithelial cells, nor is it restricted to the urinary bladder.<sup>36</sup> Moreover, neural release of norepinephrine<sup>37</sup> is but one of a variety of mechanisms whereby SRS-induced increases in efferent SNS output can activate local inflammatory cells such as mast cells, which can in turn also increase epithelial permeability.<sup>36</sup> Afferent sensory neurons, too, may increase epithelial permeability by releasing neurotransmitters at the peripheral process of the nerve via sympathetic-sensory coupling, dorsal root reflexes, and axon reflexes.<sup>38</sup> Recently, increased sensitivity to potassium chloride instillation, a test thought by some to indicate increased urothelial permeability, was reported in 244 female patients with CPP. Eighty-one percent of patients, with clinical diagnoses that included endometriosis, vulvodynia, and pelvic pain, showed a positive (painful) response to potassium instillation into the bladder.<sup>39</sup> However, patient's sensitivity to potassium instilled into other organs (vagina, uterus, colon, or peritoneum) was not assessed, so the specificity of the response cannot be evaluated. This may be an important control procedure, because a number of studies have reported that abnormalities in one visceral organ may affect responses in another, a process called viscerovisceral convergence.<sup>40-42</sup> In cats with FIC, we recently reported<sup>43,44</sup> sensitization and abnormal properties of dorsal root ganglion cells of axons that provide innervation not only to the bladder but throughout the lumbosacral (L4-S3) region, suggesting that generalized hypersensitivity may be a mediating mechanism for viscerovisceral convergence in animals with naturally occurring as well as induced disease.

Moreover, one must recall that the presence of inflammation, or altered permeability, is not well correlated with pain, as anyone who has had a superficial bruise knows from personal experience. In the bladder, we have reported the presence of submucosal petechial hemorrhages in cats with no signs referable to the lower urinary tract,<sup>45</sup> and others have identified petechial hemorrhages in healthy women,<sup>46</sup> as well as urothelial disruption and increased presence of inducible nitric oxide synthase (iNOS), and presumably increased permeability, in elderly men with bladder outlet obstruction.<sup>47</sup>

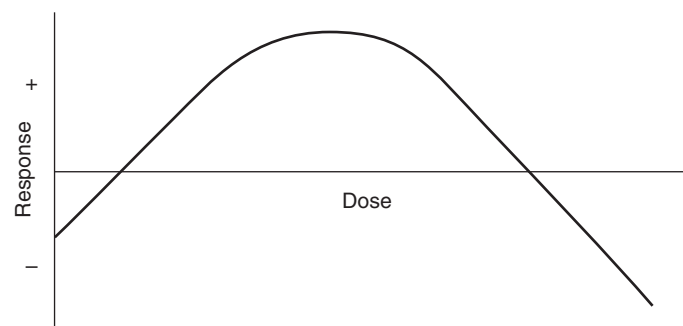

Moreover, emotional and environmental factors such as stress or depression can modulate the experience of pain through

descending pathways from the midbrain.<sup>48</sup> Therefore, even the recently reported increased firing rate of afferent nerves noted in cats with FIC<sup>49</sup> could result in differences in perceived sensations arising from the bladder, depending on the effects of the emotional state of the animal on descending inhibitory and facilitatory balance.

### Hypothalamic-Pituitary-Adrenal Axis

The HPA axis of the SRS acts at multiple levels to coordinate and modulate the body's response to perceived threats. Glucocorticoids tend to antagonize the effects of the SNS, both centrally and peripherally,<sup>20</sup> and they appear to play a complex role in epithelial permeability. Corticosterone has long been known to decrease capillary permeability to proteins in the brain,<sup>50</sup> skin,<sup>51</sup> and lung,<sup>52</sup> and cortisol has been shown to reduce *in vitro* permeability by enhancing tight junction integrity.<sup>53</sup> The effects of stress on glucocorticoid-mediated alterations in permeability are more complex and may be dose dependent. For example, stress created by a brief forced swim increased the permeability of the blood-brain barrier in adult FVB/N mice, whereas no evidence of a stress-potentiated effect was found when restraint, forced swim, or a combination of restraint and forced swim stressors were applied to Long-Evans or Wistar rats.<sup>54</sup> Moreover, stress-induced increases in intestinal epithelial permeability disappeared after adrenalectomy or pharmacologic blockade of glucocorticoid receptors, and dexamethasone treatment of control animals increased gastrointestinal permeability and mimicked the effects of stress.<sup>55</sup> Differences in tissues studied, rodent strain, type of stress, glucocorticoid studied, and the specifics of the experimental protocol all could influence interpretation of these discordant results.

The response to glucocorticoids also is likely to be hormetic (Fig. 90-3); that is, there is an inverse-U-shaped function wherein both deficiencies and excesses may produce abnormalities, which sometimes are relatively similar, further complicating interpretation of the results.<sup>56</sup> Glucocorticoids also tend to inhibit activation of NF- $\kappa$ B.<sup>57,58</sup> This and other adrenocortical steroid-related protective mechanisms, such as inhibition of the SRS and modulation of neuronal excitability,<sup>59-61</sup> may be less efficient in states of reduced function of cortisol and other steroids (see later discussion) such as IC and other stress-related bodily disorders.<sup>62</sup>

**Figure 90-3** Hormetic responses are those that move from inadequate function with deficient doses of a substance, to satisfactory function at intermediate doses, to inadequate function again with excessive doses. This pattern is common to many nutrients and hormones.

In a 2002 study of IC patients and healthy controls, Lutgendorf and colleagues<sup>63</sup> reported that, although mean urinary or salivary cortisol did not differ between the groups, IC patients who had higher morning salivary cortisol concentrations had significantly reduced pain and urgency, and those with higher urinary free cortisol concentrations reported less overall symptomatology ( $P < .05$ ). This relationship also was observed when comorbid conditions such as fibromyalgia, chronic fatigue syndrome (CFS), and rheumatoid arthritis were controlled for. Patients with morning salivary cortisol concentrations less than 12.5 nmol/L (0.45  $\mu\text{g/dL}$ ) were 12.8 times more likely to report high urinary urgency than those with values above this cutoff point. An increased ratio of adrenocorticotropic hormone (ACTH) to cortisol also was reported in women with IC by Lutgendorf and associates.<sup>64</sup>

Hypocortisolism has been reported in women with CPP, CFS and a variety of other disorders, often related to increased activity of the SRS.<sup>62</sup> The causes of the decrease in cortisol have yet to be identified in patients with IC but have been investigated in patients with CPP<sup>62,65</sup> and CFS.<sup>66</sup>

Although diagnostic laparoscopy may be normal in some patients with CPP, psychological studies have identified a high frequency of psychopathology and increased prevalence of chronic stress and traumatic life events, such as sexual and physical abuse, in women with CPP, suggesting a relationship between post-traumatic stress disorder (PTSD) and CPP. Heim and colleagues<sup>65</sup> explored stress history, psychopathology, and HPA axis alterations in 16 female patients with CPP and 14 pain-free, infertile controls. An increased prevalence of abuse experiences and PTSD was identified in women with CPP, as well as a higher total number of major life events, although symptoms of depression were within the normal range. Women with CPP also had normal to low diurnal salivary cortisol concentrations and normal plasma ACTH but reduced salivary cortisol response to a CRF stimulation test and enhanced suppression of salivary cortisol by dexamethasone. The authors concluded that a lack of protective properties of cortisol may be of relevance for the development of bodily disorders in chronically stressed or traumatized individuals, although other hormones were not measured. It is not necessary to show such extreme examples of abuse to find correlations between early adverse experience and disease, which also may result from environmental instability and parenting variables.<sup>67,68</sup>

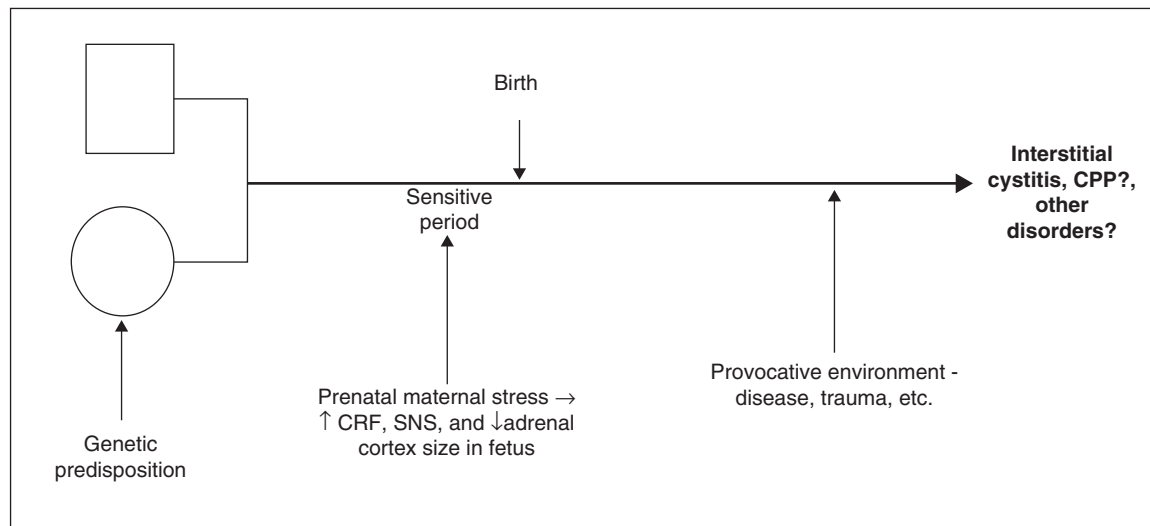

In patients with CFS, Demitrack and associates<sup>66</sup> concluded, after comprehensive study of the HPA axis, that the data were most compatible with a mild central adrenal insufficiency secondary to either a deficiency of CRF (although this was not identified) or some other central stimulus to the pituitary-adrenal axis. Scott and coauthors later reported that the adrenal glands of patients with CFS were some 50% smaller than those of control subjects based on computed tomography.<sup>69</sup> Although they studied patients who had low cortisol responses to ACTH, these authors subsequently found comparable results in CFS patients with normal cortisol responses to ACTH.<sup>70</sup> A more recent study did not find any difference from normal in adrenal gland volume in another group of CFS patients,<sup>71</sup> leaving the question of the role of adrenal volume in the observed abnormalities still open. Additionally, Kizildere and associates<sup>72</sup> recently identified a  $\beta$ -adrenergic receptor-mediated inhibition of CRF-stimulated adrenal steroid secretion in healthy humans. They found that administration of 10 mg propranolol (a nonspecific  $\beta$ -adrenergic receptor antagonist) 2 hours before administration of 100  $\mu\text{g}$  human CRF

decreased heart rate and diastolic blood pressure by 20%. Propranolol treatment also reduced plasma ACTH concentrations by about 40% and increased serum cortisol by approximately 70%, which decreased the ACTH-to-cortisol ratio by twofold. These results suggest that increased sympathetic tone also may reduce adrenocortical responsiveness to ACTH. Moreover, ACTH release can be enhanced by  $\alpha$ -adrenergic receptor activation, as well as by vasopressin, which also can modulate SRS activity.<sup>73</sup>

There is convincing evidence that the adrenal cortex is hypoactive in some circumstances in a variety of chronic disorders other than IC and CPP, including asthma, chronic fatigue syndrome, fibromyalgia, panic disorder, PTSD, and rheumatoid arthritis. Moreover, flares in disease activity in these disorders have been related to stress. Although hypocortisolism appears to be a frequent and widespread phenomenon, the nature of the underlying mechanisms and the homology of these mechanisms within and across clinical groups remain speculative. Potential mechanisms underlying the observed hypocortisolism include dysregulation of function at any level of the HPA axis, genetic vulnerability, previous stressful experiences, and individual coping and personality styles.<sup>62</sup>

In neuroendocrine investigations comparing healthy cats to cats with FIC in a basal state, we found higher plasma catecholamine concentrations in cats with FIC but could not identify a difference in response of ACTH and cortisol to CRF between affected and healthy cats.<sup>74</sup> Based on some anomalous responses to a naturalistic stressor obtained during experiments with a CRF receptor antagonist in cats with FIC,<sup>75</sup> we began to look more closely at adrenal function during activation of the SRS and found increased concentrations of CRF<sup>76,77</sup> and ACTH<sup>75</sup> in the absence of a comparable increase in plasma cortisol concentrations, suggesting the presence of mild primary adrenal insufficiency or decreased adrenocortical reserve. We also found that adrenal gland size was significantly smaller in cats with FIC than in healthy cats.<sup>78</sup> Microscopic examination of the glands did not reveal any obvious hemorrhage, inflammation, infection, fibrosis, or necrosis as causes of the reduced size. The primary abnormality identified was a reduced size of the fasciculata and reticularis zones of the adrenal cortex. These results suggest that any adrenocortical abnormality might be unmasked more readily in response to a moderate, salient stressor and may not be identifiable in patients studied under basal circumstances, a conclusion about these systems that has also been drawn by others studying human patients.<sup>79,80</sup>

The simplest explanation for the combination of increased CRF, ACTH, and SNS activity in the presence of reduced adrenocortical response and small adrenal fasciculata and reticularis zones without other apparent abnormalities seems to be the presence of an underlying genetic disorder or developmental anomaly (or some combination of the two). These relationships are depicted in Figure 90-4. When a woman is exposed to a sufficiently harsh stressor during pregnancy, the hormonal products of the ensuing stress response may cross the placenta and affect the course of fetal development. Prenatal and postnatal stressors can result in persistently increased central CRF activity in animals.<sup>81</sup> For example, in both continuous and last-trimester paradigms, prenatal dexamethasone (0.1 mg/kg) treatment increased CRF messenger RNA levels specifically in both the hypothalamus and central nucleus of the amygdala, key loci for the effects of the neuropeptide on the expression of fear and anxiety.<sup>82</sup>

**Figure 90-4** Potential trajectories to some cases of interstitial cystitis and chronic pelvic pain (CPP). Variable combinations of these factors could result in differences in disease severity among patients. CRF, corticotropin-releasing factor; SNS, sympathetic nervous system. (Adapted from Compagnone NA, Mellon SH: Neurosteroids: Biosynthesis and function of these novel neuromodulators. *Front Neuroendocrinol* 21:1, 2000.)

Matthews recently suggested that the biological “purpose” of transmitting this response to the fetus is to program the development of the fetal SRS and associated behaviors toward enhanced vigilance to increase the probability of survival.<sup>83</sup> The effects of stressors on the fetal HPA axis seem to depend on the timing and magnitude of exposure to products of the maternal stress response in relation to the developmental “programs” that determine the maturation of the various body systems during gestation and early postnatal development. If the fetus is exposed before initiation of a developmental program, there may be no effect. With exposure during the critical period while the adrenocortical maturation program is running, however, adrenal size in the developing fetus may be reduced, as shown by studies in Long-Evans rats,<sup>84</sup> guinea pigs,<sup>85</sup> blue fox,<sup>86</sup> rhesus monkeys,<sup>87</sup> and baboons.<sup>88</sup> If a sufficiently severe stress response occurs after the critical period of adrenocortical development, including during postnatal development, subsequent adrenocortical responses to stress and adrenal size may be increased.<sup>83</sup>

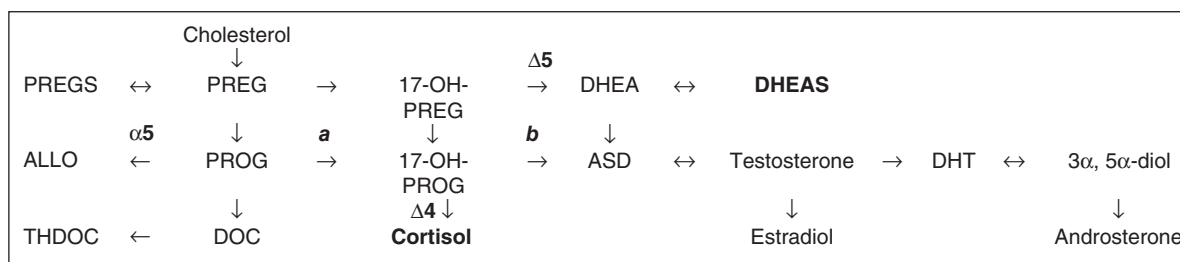

In either case, however, the biologic outcome might be similar. Raison and Miller<sup>56</sup> recently concluded from a review of the pertinent literature that inadequate biologic activity of glucocorticoids can occur either as a result of decreased hormone bioavailability or from reduced hormone sensitivity due to agonist-mediated receptor desensitization. Regardless of the cause, decreased biologic activity of adrenocortical steroids may have a variety of adverse effects on bodily function, possibly related to their role in restraining activation of the immune system and other components of the stress response, including the SNS and CRF.

The lack of long-term benefit of glucocorticoid therapy in most patients with IC<sup>89</sup> (but see Hosseini and colleagues<sup>90</sup> for results of a small, uncontrolled study of patients with type II IC given 5 mg/day oral prednisolone) suggests that the most appropriate dose has not yet been identified, that inadequate production of other steroids also might play a role in the pathophysiology of IC, and/or that SNS output needs to be attenuated. Most doses of glucocorticoid, although possibly appropriate for acute phases

of the disease,<sup>91</sup> may be excessive for chronic therapy. As shown in Table 90-1, the daily production of cortisol in humans is in the range of 8 to 25 mg, much lower than doses of glucocorticoid sometimes suggested. In a recent open trial, 10 mg/day hydrocortisone was administered orally for 1 month to three patients with PTSD in a double-blind, placebo-controlled, crossover design. A significant treatment effect was observed in all patients, with cortisol-related reductions of at least 38% in one of the daily rated symptoms of traumatic memories, as assessed by self-administered rating scales. Although very preliminary, these results suggest that physiologic glucocorticoid replacement may have a role in some patients with CPP, if only in those with concurrent PTSD.<sup>92</sup>

Available evidence also suggests that part of the stress response may include maintaining production of cortisol ( $\Delta 4$  pathway) at the expense of the 17,20-lyase ( $\Delta 5$  pathway) products of the 17- $\alpha$  hydroxylase enzyme (Fig. 90-5) such as dehydroepiandrosterone sulfate (DHEAS, the longer-lived metabolite of DHEA)<sup>72</sup> if the stressor is severe or adrenocortical reserve is inadequate.<sup>93,94</sup>

DHEAS also is a neurosteroid, a term used to describe steroids that are synthesized in the central and peripheral neurons and in glial cells. The concept of neurosteroids was introduced by Baulieu in 1981<sup>95</sup> to describe a steroid hormone (DHEAS) he found at high levels in the brain long after gonadectomy and adrenalectomy. Androstenedione, pregnenolone, and a variety of other steroids were later also identified as neurosteroids.<sup>96</sup> These compounds can act as allosteric modulators of ion-gated neurotransmitter receptors, such as  $\gamma$ -aminobutyric acid (GABA)-A and *N*-methyl-D-aspartate (NMDA) receptors, which are the primary inhibitory and excitatory receptors, respectively, in the nervous system. Neurosteroid concentrations vary according to environmental and behavioral circumstances, such as stress, sex recognition, and aggressiveness. In the peripheral nervous system, neurosteroids also may play a role in neuronal repair after injury. Abnormal neurosteroid function may underlie some functional disturbances of the nervous system.<sup>96-98</sup>

**Figure 90-5** The output of the adrenal cortex includes variable combinations of glucocorticoids, sex steroids, and neurosteroids. Other sources of sex steroids and neurosteroids include the gonads and neural tissue. Some examples in women are presented in Table 90-1. The cytochrome P450 c17 enzyme (a) performs the  $17\alpha$ -hydroxylase reaction equally well using PREG or PROG as substrate, but the  $17,20$ -lyase reaction (b) occurs 50 to 100 times more efficiently using 17-OH-PREG as substrate, rather than 17-OH-PROG. Therefore, conversion of 17-OH-PROG to ASD is minimal, and DHEA is the principal precursor of sex steroid synthesis.  $3\alpha,5\alpha$ -diol,  $3\alpha$ -androstenediol; ALLO,  $3\alpha,5\alpha$ -tetrahydroprogesterone; ASD, androstenedione; DOC, 11-deoxycorticosterone; DHEA, 11-dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate; 17-OH-PREG, 17-hydroxy-pregnenolone; 17-OH-PROG, 17-hydroxy-progesterone; PREG, pregnenolone; PREGS, pregnenolone sulfate; PROG, progesterone; THDOC,  $3\alpha,5\alpha$ -tetrahydrodeoxycorticosterone. (Adapted from Compagnone NA, Mellon SH: Neurosteroids: Biosynthesis and function of these novel neuromodulators. *Front Neuroendocrinol* 21:1, 2000.)

**Table 90-1 Sources, Production Rates, and Plasma Concentrations of Selected Steroids in Women**

Steroid	Source	Production (mg/day)	Plasma Concentration Range (nmol/L)

We recently measured serum free cortisol and DHEAS concentrations in patients with moderate to severe IC during flare and remission. During flare, the concentration of serum free cortisol was half, and that of DHEAS was 20%, of the concentration found in patients not in a flare (Fig. 90-6). During their flare, two patients were deficient in serum free cortisol, and four patients were deficient in DHEAS (adjusted for age).<sup>99</sup> In addition to suggesting that neuroendocrine function may be altered in IC during flare, the results of studies of cats with FIC, and of human patients with IC and other unexplained clinical conditions,<sup>100</sup> document that neuroendocrine abnormalities may not be identifiable by evaluation of basal neuroendocrine function and may be unmasked only by appropriate provocative testing paradigms.

Adrenocortical function also has been evaluated in patients with CFS by measuring the cortisol-to-DHEAS ratio,<sup>101</sup> which

was twofold to threefold higher in CFS patients than in controls. Kizildere and colleagues<sup>72</sup> suggested that serum levels of DHEAS may be low in patients with inflammatory and noninflammatory diseases due to an activated SNS. They concluded that sympathetic hyperactivity may be a common denominator for low levels of DHEAS in both inflammatory and noninflammatory diseases. These abnormalities also suggest that some patients may have decreased availability of adrenocortical sex steroids and neurosteroids (see Fig. 90-5),<sup>98</sup> which could adversely affect normal neural function.<sup>102,103</sup>

### Hypothalamic-Pituitary-Gonadal Axis

Patients with IC and CPP also may be at increased risk for inadequate biologic activity of the sex hormones, for a variety of reasons. Some patients in both groups have decreased circulating

**Figure 90-6** Effects of flare (F) and remission (R) of interstitial cystitis symptoms on serum free cortisol (SFC) and dehydroepiandrosterone sulfate (DHEAS). Parentheses (= no. of patients = no of dots in graph). (Adapted from Compagnone NA, Mellon SH: Neurosteroids: Biosynthesis and function of these novel neuromodulators. *Front Neuroendocrinol* 21:1, 2000.)

glucocorticoid concentrations, suggesting decreased adrenocortical availability of sex steroid precursors<sup>99,104</sup>; some have undergone oophorectomy and/or hysterectomy; and some may have inadequate pituitary function. Kalantaridou and associates<sup>105</sup> recently reviewed the complex effects of activation of the SRS system on the female reproductive system. Increased CRF and  $\beta$ -endorphin release as a consequence of chronic activation of the SRS can inhibit release of gonadotropin-releasing hormone (GnRH), thus decreasing sex hormone availability. Increased glucocorticoid activity also can suppress function at all levels of the gonadal axis.<sup>105</sup>

Decreased estrogen activity has been recognized in some patients with CPP, as well as in patients with irritable bladder symptoms,<sup>106</sup> and replacement therapy may be beneficial. Androgen activity also may be inadequate in some patients.<sup>107,108</sup> Reported causes of androgen deficiency in women are presented in Table 90-2. Any of these causes may lead to variable combinations of the deficiency symptoms listed in Table 90-3.

Dessein and colleagues<sup>109</sup> investigated the concentrations of adrenal androgen metabolites and their relationship with health status in women with fibromyalgia, a syndrome that commonly occurs comorbidly with CPP and IC. Responses to the Fibromyalgia Impact Questionnaire and fasting blood samples were obtained from 57 women with fibromyalgia for measurement of DHEAS, free testosterone (T), cortisol, serotonin, and insulin-like growth factor-1. Normal values for DHEAS and T were obtained from 114 controls. Individual results for all patients were reported and are plotted in Figure 90-7. The individual values were divided by the uppermost value from the reference range to allow the results to be plotted as quartiles of the reference range. DHEAS concentrations were decreased significantly in both premenopausal and postmenopausal patients ( $P < .0001$  and  $P < .0005$ , respectively). T concentrations were decreased significantly in premenopausal patients ( $P < .0001$ ), and a trend could be identified in postmenopausal patients ( $P = .06$ ). After

**Figure 90-7** Fasting blood concentrations of selected hormones in women with fibromyalgia syndrome. DHEA-S, dehydroepiandrosterone sulfate; IGF-1, insulin-like growth factor 1. (Adapted from Dessein PH, Shipton EA, Joffe BI, et al: Hyposecretion of adrenal androgens and the relation of serum adrenal steroids, serotonin and insulin-like growth factor-1 to clinical features in women with fibromyalgia. *Pain* 83:313, 1999.)

**Table 90-2 Causes of Androgen Insufficiency in Women**

Presentation	Causes
Inadequate adrenal function	Decreased adrenal reserve, adrenal failure, surgery
Inadequate ovarian function	Oophorectomy, hysterectomy, premature menopause after radiation therapy or chemotherapy
Inadequate pituitary function	Chronic stress response, hypercortisolism
Iatrogenic	Exogenous oral estrogen, antiandrogen therapy, chronic glucocorticoid treatment
Normal aging	Low bioavailable free testosterone

Data from Cameron DR, Braunstein GD: Androgen replacement therapy in women. *Fertil Steril* 82: 273, 2004; and Rivera-Woll LM, Papalia M, Davis SR, et al: Androgen insufficiency in women: Diagnostic and therapeutic implications. *Hum Reprod Update* 10: 421, 2004.

adjustment for age, the only significant correlations between hormone concentrations and Fibromyalgia Impact Questionnaire scores were between DHEAS and pain ( $r = -0.29$ ,  $P < .001$ ), and between T and physical functioning ( $r = .34$ ,  $P = .002$ ). Body mass index correlated positively with pain ( $r = .38$ ,  $P < .001$ ) and inversely with DHEAS level ( $r = -0.33$ ,  $P = .006$ ).

Androgen insufficiency can occur even in regularly menstruating women. Guay recently reported measurement of total and free serum testosterone levels in 12 premenopausal women with complaints of decreased libido.<sup>110</sup> Eight of the women had low or immeasurable levels of both testosterones despite having regular menstrual periods. Concentrations of DHEAS and androstenedione were in the low-normal to high-normal range. Treatment

**Table 90-3 Symptoms of Androgen Deficiency and Excess in Women**

Hormone	Deficiency		Excess	
	Signs	Symptoms	Signs	Symptoms
Estrogen	Hot flashes Dry vagina Lowered libido Painful intercourse Irritable bladder symptoms Fatigue Headache/migraine Night sweats Vaginal infections Urinary tract infections Incontinence Difficulty falling asleep Decreased concentration Episodes of rapid heart rate Decreased verbal skills Irregular vaginal bleeding	Depression Minor anxiety Emotional instability Feelings of despair Crying easily	Breast pain PMS Irregular bleeding Fluid retention Headache Breast adenoma Gall bladder problems Blood sugar problems Sugar cravings Fibroids Hormonal cancers Heavy menstruation Bloating Weight gain Nausea Endometriosis Thyroid problems Sleep disturbances	Nervousness Irritability Low libido Mood swings
Progesterone	Breast cysts/pain Fluid retention Reduced body temperature Hair loss Heavy periods Menstrual cramps Fibroids Hypothyroidism Bone loss Irregular cycle/Infertility	Anxiety Over-reacting Easily alarmed Easily stressed Feelings of confusion Mood swings Irritability Nervousness Depression PMS Headaches/migraine Endometriosis Sleep disturbances		
Testosterone	Decreased pubic hair Reduced lean body mass Osteopenia or osteoporosis Incontinence Thinning skin Genital thinning Reduced muscle tone	Blunted motivation Diminished well-being Flat mood Reduced libido	Acne/oily skin Facial hair Deepened voice Ovarian cysts Low blood sugar Midcycle pain Low HDL cholesterol Thinning scalp hair Increased breast cancer risk Painful nipples	Agitation Anger Irritability

HDL, high-density lipoprotein; PMS, premenstrual syndrome.

with oral DHEA, 50 to 100 mg per day, restored sexual desire in six of the eight women, gave partial improvement in one, and failed in one.

It is important to note that DHEA currently is marketed as a “dietary supplement,” which means that the U.S. Food and Drug Administration does not certify the amount or quality of DHEA in the many commercially available preparations. Thompson and Carlson recently reported that determination of the DHEA content of 54 such supplements using a liquid chromatographic method revealed variation from 0% to 109.5% of the declared amount, with an overall mean value of 91%.<sup>111</sup> This variability suggests that circulating DHEA concentrations should be moni-

tored in patients taking these products to ensure that intake is not inadequate or excessive. The most frequently reported side effects of excessive DHEA intake are increased facial hair and acne.<sup>107</sup>

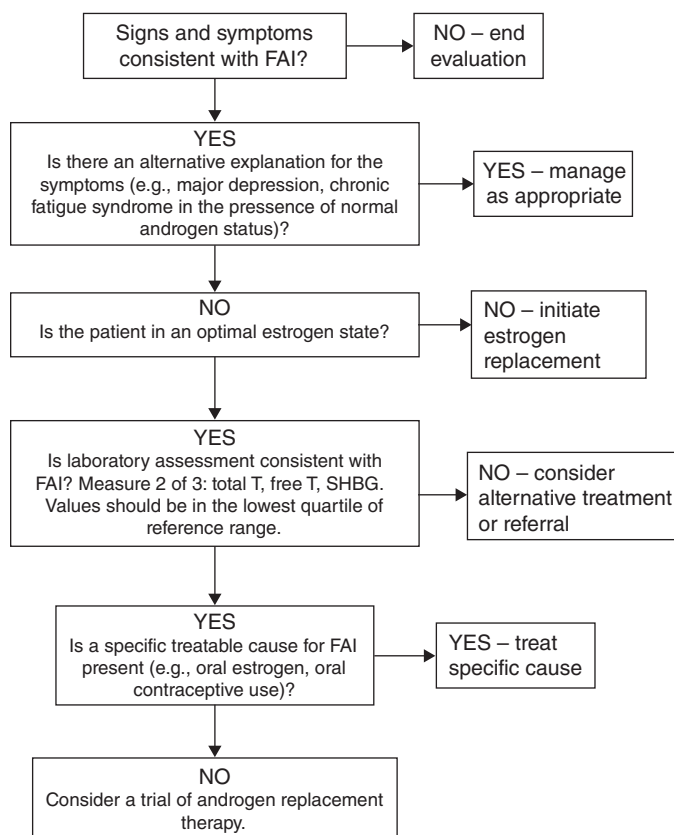

Additionally, conversion of DHEA or DHEAS to androgens and estrogens may not occur normally in some patients.<sup>112</sup> Most of the androgens in women, especially after menopause, are synthesized in peripheral tissues from adrenal DHEA and DHEAS by 17 $\beta$ -hydroxysteroid dehydrogenase enzymes in a process called intracrinology.<sup>113</sup> Once synthesized, the sex steroids exert their action in the cells where they are synthesized without significant diffusion into the circulation, thus seriously limiting

the ability to interpret serum sex steroid concentrations. They also are inactivated locally into more water-soluble compounds that diffuse into the general circulation, where they can be measured.<sup>113,114</sup> Dysfunctions in human 17 $\beta$ -hydroxysteroid dehydrogenases result in disorders of biology of reproduction and neuronal diseases, and these enzymes also are involved in the pathogenesis of various cancers. Abnormalities of this complex peripheral system may underlie some of the discordant results found in studies of DHEA and DHEAS replacement therapy.

Recently, concern has been expressed that excessive biologic activity of estrogen and testosterone, both essential hormones, can increase the risk for breast cancer in women.<sup>115,116</sup> On the other hand, patients with documented symptoms and laboratory evidence of hormone insufficiency have been shown to benefit from appropriate physiologic replacement therapy.<sup>107,117</sup> The occurrence of abnormalities with both inadequate and excessive biologic activity of hormones demonstrates the hormetic nature of the biologic response to steroid hormones (see Fig. 90-3).<sup>118</sup> The “dose-response” for hormones is similar to that for many essential nutrients, with deficiency signs occurring with inadequate intake, a variable plateau of satisfactory intake, and symptoms of toxicity with excessive intake.<sup>119</sup> The diagnosis of androgen insufficiency should be made only in adequately and satisfactorily estrogenized women, because estrogen therapy alone may be sufficient to alleviate the symptoms in some patients.<sup>120</sup> *Adequately* means replacement with physiologic doses that avoid potentially detrimental excesses. *Satisfactorily* means avoidance of oral preparations in this patient population, due to the effects on the liver of oral conjugated equine estrogens (or oral contraceptives). Oral forms of estrogens appear to stimulate hepatic production of both cortisol and sex hormone-binding globulin, reducing the availability of the free, biologically active forms of cortisol and testosterone. Oral conjugated equine estrogens also have been reported to increase high-density lipoproteins, triglycerides, and C-reactive protein, which may adversely affect cardiovascular health. Transdermal delivery of estradiol has not been associated with these potentially adverse changes.<sup>121</sup> The Princeton consensus statement<sup>122</sup> proposed the algorithm presented in Figure 90-8 for initiating androgen therapy in women.

The age at onset of symptoms also supports the hypothesis that hormone deficiency may play a role in IC. Prevalence was greatest in age categories 41 to 45 years and 71 to 75 years, with the highest prevalence (266 per 100,000) observed in those age 41 to 45 years.<sup>123</sup> Koziol also reported an average age at the time of onset of symptoms of IC of approximately 41 years, although almost 30% of patients were younger than 30 years of age at the time of onset.<sup>124</sup> Further support comes from the observation that some patients with IC and CPP have significant symptom improvements during pregnancy, a time when concentrations of many of the steroid hormones increase.<sup>125</sup>

Inadequate sex hormone biologic activity in women also may increase SNS activity. Stoney and coworkers<sup>126</sup> tested the effects of elective hysterectomy and/or bilateral salpingo-oophorectomy on cardiovascular risk factors, blood pressure, lipids, weight, and physiologic responses to stress in 29 middle-aged premenopausal women. After surgery, the 10 women who had undergone oophorectomy only had higher concentrations of stress-induced lipids and tended to have higher circulating concentrations of epinephrine and higher stress-induced systolic and diastolic blood pressure than did the 19 women who had undergone hysterectomy including removal of their ovaries. In rats, Ting and colleagues<sup>127</sup>

**Figure 90-8** Algorithm proposed by the Princeton consensus statement for initiating androgen therapy in women. FAI, female androgen insufficiency; SHBG, sex hormone-binding globulin; T, testosterone. (Adapted from Bachmann G, Bancroft J, Braunstein G, et al: Female androgen insufficiency: The Princeton consensus statement on definition, classification, and assessment. *Fertil Steril* 77:660, 2002.)

recently reported that ovariectomy resulted in a 59% elevation in vaginal nerve density. This change was attributable to increased densities of sympathetic (70%), cholinergic parasympathetic (93%), and nociceptive sensory nerves (84%); myelinated sensory innervation did not appear to be affected. Sustained administration of 17 $\beta$ -estradiol reduced innervation density to an extent comparable to that of estrus, suggesting that estrogen deficiency had mediated the increments in innervation. These findings indicate that some aspects of vaginal dysfunction during menopause may be attributable to changes in innervation. Increased sympathetic innervation may augment vasoconstriction and promote vaginal dryness, and nociceptive sensory afferent proliferation may contribute to symptoms of pain, burning, and itching associated with menopause and some forms of CPP.

Documentation of widespread involvement of other organ systems<sup>124,128-132</sup> also suggests a role for neuroendocrine involvement in at least some patients with IC and CPP. In particular, the prominence of autonomic symptoms in some patients with type I IC provides further evidence for the presence of persistently increased SNS activity in these patients. Even the somewhat unusual bladder histopathology found in patients with IC, vasodilatation, and vascular leakage in the absence of any significant mononuclear infiltrate could be the result of high local concentrations of norepinephrine.<sup>133,134</sup>

IC and CPP are so complex that it seems unlikely that all, or even most, cases will be explained by a single underlying etiology. Separation of type I from type II patients in data analyses appears to be an important distinction and may suggest different underlying neuroendocrine abnormalities. Even if neuroendocrine imbalance explains only a subset of cases of IC, however, it could result in improved care for those patients. In the case of CPP, patients who have had their reproductive organs removed to treat the pain, without success, may be most likely to be affected.<sup>104</sup>

In susceptible individuals with IC or CPP, it may be prudent to assess adrenocortical function before elective surgical procedures or after significantly stressful experiences and to consider providing replacement therapy as indicated.<sup>135</sup> Although Addisonian-like events have not been reported in these patients to the my knowledge, studies in other patient populations have suggested that inadequate adrenocortical function in stressed patients may predispose some individuals to development of PTSD.<sup>56,136</sup>

The direct and circumstantial evidence that neuroendocrine abnormalities may play an important role in the etiology, pathophysiology, and therapy of IC and CPP in some patients is tantalizing and incomplete. There are so many genetic, environmental,

and individual variables that finding a single “smoking gun” does not seem likely. To begin to tease apart the relative contributions of the SNS, HPA, HPG, and other systems may require measurement of a “panel” of markers of neuroendocrine function in patients, much like a serum biochemical profile. The most appropriate sample source (e.g., saliva,<sup>137</sup> serum<sup>138</sup>), timing of collection (during flare or remission periods), and assay methodology<sup>139</sup> for diagnosis and follow-up of neuroendocrine abnormalities remain unresolved questions, as do the amount, balance, and route of replacement therapy, when indicated. The sex and adrenal steroids arose hundreds of millions of years ago,<sup>140</sup> and we are left to sort out the ensuing complexity. It may be that, by broadening our perspective, at least initially, to include additional systems, we may be better able to understand syndromes that at first appear to be restricted to isolated organs but in some patients are revealed on closer inspection to be system wide.<sup>141</sup>

# FOCAL NEUROMUSCULAR THERAPIES FOR CHRONIC PELVIC PAIN SYNDROMES IN WOMEN

Rodney U. Anderson

Women have been suffering from chronic pelvic pain (CPP) syndromes presumably since the age of primate evolution. Except for endometriosis, there is little in the way of objective biologic findings to explain the pathophysiology of these complaints. In most instances, the diagnostic terms for disorders of pain in the pelvis relate to a specific organ with no identifiable mechanistic relationship. This chapter attempts to identify the common urologic/gynecologic disorders commonly considered CPP syndromes, explores the evidence for neuromuscular disorder, and reviews most of the local and focused therapeutic approaches that may be beneficial in the management of these conditions. I am specifically avoiding consideration of any pharmaceutical therapy. The objective is to suggest an integration of both physical and behavioral treatments to elicit relief from these life-altering conditions while we await more elucidation about the biologic mechanisms involved.

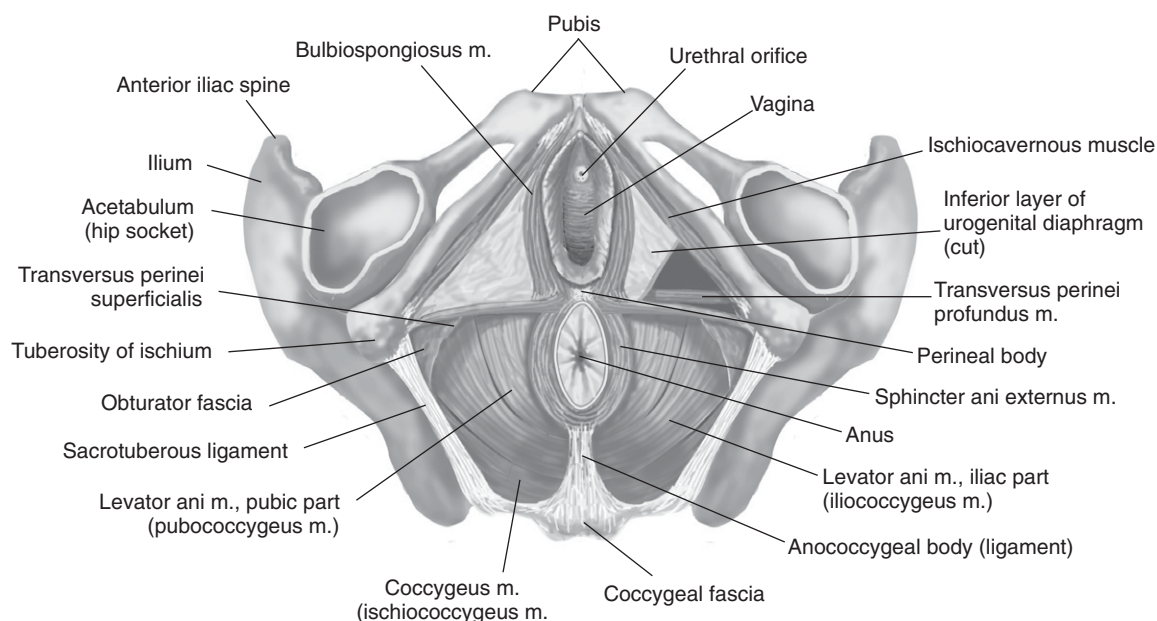

## BIOFEEDBACK THERAPY

Biofeedback therapy for pelvic disorders has primarily been used to manage pelvic floor disorders and urinary incontinence, but

it has also become quite valuable for patients with pelvic pain disorders. Biofeedback and behavioral changes can play a role in effecting clinical improvement in urologic problems including pelvic pain (vulvar vestibulitis), irritative voiding symptoms, recurrent urinary tract infections, and urinary incontinence. Biofeedback for pelvic floor dysfunction involves the use of surface internal (vaginal and rectal) electrodes that transduce muscle potentials into visual and auditory signals; by this means, patients learn to be aware and control (increase or decrease) voluntary muscle activity. Physical exercises are then used to affect the pelvic floor muscles (Fig. 91-1).

In the late 1940s, Dr. Arnold Kegell, an obstetrician/gynecologist, invented the first feedback device that was used for pelvic muscle rehabilitation to treat female urinary incontinence. The processes and procedures of biofeedback therapy have been described.<sup>1,2</sup> A general overview for application to pain management was summarized by Tan and colleagues.<sup>3</sup>

Two major subtypes of biofeedback therapy are currently in practice. The traditional form is known as peripheral or somatic feedback, which assists in teaching patients to be more physiologically aware of abnormal muscle tension and adjust accordingly. Surface electromyography (EMG), heart rate and blood

**Figure 91-1** Pelvic floor muscles as seen from below in the supine female subject. (Redrawn from Travell JG, Simons DG: *Myofascial Pain and Dysfunction: The Trigger Point Manual*, Vol 2, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1998.)

pressure, skin temperature, and galvanic skin responses are used. Applications of peripheral biofeedback include neuromuscular re-education (for patients after stroke), musculoskeletal therapy, urinary<sup>4</sup> and fecal incontinence, and pelvic pain including CPP syndromes in men,<sup>5,6</sup> vulvodynia,<sup>7</sup> and dysmenorrhea.<sup>8,9</sup> A second subtype of biofeedback therapy uses electroencephalography (EEG) and is classified as central biofeedback, neurofeedback, or neurotherapy. With the exception of migraine, most of the research with this therapy has been in areas other than pain, such as treatment of alcohol or addictive disorders.

Glazer and coworkers reported their experience in two separate open-ended, uncontrolled studies using EMG biofeedback of the pelvic floor musculature to treat patients with vulvar vestibulitis syndrome, a subset of vulvodynia.<sup>7,10</sup> The rationale for study was based on the knowledge that patients with vulvar vestibulitis usually have hyperirritability of the pelvic floor muscles.<sup>7,11</sup> The hypothesis has been put forward that destabilization of pelvic floor muscles is a factor in perpetuating the vulvar skin disturbances and accompanying pain. Travell and Simons reported that muscle disturbances are reflected in discord of EMG recordings.<sup>12</sup> In the studies by Glazer and associates, patient diagnosis was confirmed by physical examination, and the initial pelvic floor EMG assessments were performed with a surface EMG single-user vaginal sensor; monthly evaluations followed during clinic visits.<sup>7,10</sup> A portable EMG biofeedback device and instructions for pelvic floor rehabilitation exercises were provided to each patient for twice-daily in-home practice. Patient demographics were similar in both studies; average duration of symptoms was 3.5 years (range, 2 to 6 years), and most had abstained from sexual intercourse for an average of 1 year.

In the first Glazer study of 33 women, symptoms ranged from only introital dyspareunia to chronic, intense pain provocation.<sup>7</sup> After 16 weeks of practice, pelvic floor contraction increased by 95%, resting tension levels decreased by 68%, and muscle instability at rest decreased by 62%. Based on subjective reporting at each evaluation, maximum pain decreased from the previous evaluation to an average of 83%. Many patients (22 [79%] of 28) resumed intercourse. Half of the women remained pain free at follow-up 6 months later. In the second study, 29 women with level 2 and 3 vulvar vestibulitis were enrolled.<sup>10</sup> Level 2 includes women who have pain with intercourse that requires interruption or discontinuance of coitus, and level 3 includes those who have pain with intercourse that prevents any attempt at insertion or coitus.<sup>13</sup> With biofeedback therapy, increased muscle stabilization was associated with decreased pain; as pain decreased, patients were more likely to resume intercourse. After therapy, 85% (24 of 29) had negligible or mild pain, and 69% resumed sexual activity.

Neuromuscular education of the pelvic floor muscles to ameliorate chronic pain has been supported by the studies in men with CPP syndromes. In a preliminary study of 19 patients using biweekly sessions of biofeedback and home exercises, significant decreases (approximately 50%) in pain and urgency scores were reported by Clemens and colleagues.<sup>5</sup> However, only about half of the patients completed the full course of therapy. In the study by Cornel and colleagues, biofeedback rehabilitation of 25 men with type III CPP involved verbal guidance and feedback through palpation of pelvic floor muscles and EMG measurements to teach correct muscle contraction and relaxation.<sup>6</sup> Significant improvements in the National Institutes of Health–Chronic Prostatitis Symptom Index (NIH-CPSI) total scores, with pain and micturition domains decreasing an average of 50%, were

associated with a significant 35% decrease in pelvic muscle tonus after treatment.

## MYOFASCIAL TRIGGER POINT RELEASE THERAPY

### Definition and Basic Science Investigation

A long list of disorders in women has been shown to involve the musculoskeletal system; these include the levator ani syndrome, vulvodynia, vulvar vestibulitis syndrome, dyspareunia, vaginismus, coccygodynia, interstitial cystitis (IC) or painful bladder syndrome, pelvic floor tension myalgia, urge-frequency syndrome, urethral syndrome, inflammatory bowel disease, proctodynia, proctalgia fugax, and pudendal nerve entrapment,<sup>7,14-18</sup> and, in men, nonbacterial prostatitis and CPP syndromes.<sup>19,20</sup> Often overlooked and misunderstood as a musculoskeletal source of pelvic pain are myofascial trigger points (MTrPs). More than 50 years ago, Dr. Janet Travell introduced the phenomenon of referred pain and referred motor activity attributed to trigger points (TrPs) in skeletal muscles, which were later shown to be a causative factor in myofascial pain and dysfunction. Our understanding of MTrPs and their relation to myofascial pain syndromes continues to evolve, as shown in Table 91-1.

**Table 91-1 Progress of Discovery and Understanding of Chronic Pain Syndromes and Myofascial Trigger Points**

- 1838 Recaimer—First describes syndrome of tension myalgia of pelvic floor in “Stretching massage and rhythmic percussion in the treatment of muscular contractions”
- 1937 Thiele—Describes tonic spasms of levator ani, coccygeus, and piriformis muscles and their relationship to pain
- 1942 Travell et al—First describes myofascial trigger points as common cause of chronic muscle pain
- 1951 Dittrich—First recognizes pelvic pain occurring as a result of referral from trigger points in subfascial fat and perifascial tissue
- 1963 Thiele—Successful uses digital massage of spastic levator muscles subsequently described as “Thiele massage”
- 1977 Sinaki et al—Consolidates various syndromes of pelvic musculature under one terminology: tension myalgia of the pelvic floor; uses combined treatment with rectal diathermy, Thiele’s massage, and relaxation exercises
- 1983 Travell and Simons Publishes the first edition of *Myofascial Pain and Dysfunction: The Trigger Point Manual*; identifies external and internal muscles and areas of referred pain from myofascial trigger points
- 1984 Slocum—Treats trigger points related to the abdominal pelvic pain syndrome in women using locally injected anesthetic; indicates that emotional stress is frequently a potentiating factor, not a cause for chronic pelvic pain
- 1994 Hong—Develops rabbit animal model to identify myofascial trigger points; with colleagues, subsequently publishes 36 animal clinical and 12 basic science articles to advance understanding of myofascial trigger point
- 2004 Simons—Reviews the present understanding of myofascial trigger points as they relate to musculoskeletal dysfunction

An MTrP is defined as a highly localized and hyperirritable spot in a palpable taut band or tender nodule of skeletal muscle fibers.<sup>16,21</sup> MTrPs can be located in one or more muscles, and common clinical characteristics exist.<sup>22-26</sup> Muscles can become “knotted” and inelastic and unable to contract or relax. Stimulated by digital palpation or needling, active MTrPs characteristically elicit local pain or a referred pain similar to that of the patient’s complaint of pain or aggravation of existing pain. A local twitch response is also a confirmatory sign of an MTrP. Latent MTrPs are clinically asymptomatic and do not cause pain with compression. Both active and latent MTrPs are associated with muscle weakness on active contraction and reduced range of motion, and MTrPs can be perpetuated or aggravated by mechanical stress, metabolic, endocrine, and nutritional inadequacies, as well as psychological factors.<sup>21</sup> Depression and chronic pain are often closely associated, and it should be appreciated that depression and anxiety are frequently consequent to unresolved symptoms.

Recent reviews present the current understanding of MTrPs and an historical summary of the development of these concepts.<sup>27,28</sup> An integrated hypothesis of the etiology of TrPs implicating local myofascial tissue, the central nervous system, and mechanical factors is proposed in the 1999 edition of *Travell and Simons’ Myofascial Pain and Dysfunction: The Trigger Point Manual*.<sup>29</sup> The hypothesis postulates that a central MTrP has multiple fibers with end plates releasing excessive acetylcholine and shows histopathologic evidence of regional sarcomere shortening. The positive-feedback loop of events perpetuates these changes until the loop is interrupted. The putative steps were elegantly explained by Simons.<sup>28</sup> Evidence contributing to the etiology of TrPs has evolved from two early studies. Mense and Simons reported that histologic examination of biopsied muscle tissue in the vicinity of TrPs reveals large, rounded, and darkly stained muscle fibers, as well as increased muscle fiber diameters.<sup>30</sup> At physical examination for MTrPs, these changes are manifested as taut bands and palpable nodules. An EMG study by Hubbard and Berkoff showed greater activity in MTrPs than in adjacent nontender muscle.<sup>31</sup> EMG activity was significantly higher in TrPs of patients with chronic tension headaches than in normal patients and could be reduced by injection of sympathetic blockers such as phenoxybenzamine. In another study, McNutley and colleagues reported that EMG activity within an MTrP was significantly increased in subjects involved in an experimental stress test, whereas contiguous nontender muscle showed no changes.<sup>32</sup> This finding may have implications for the psychophysiology of stress contributing to pain and the association with MTrPs.

### Physical Examination and Mapping of Trigger Points

A distinguishing feature of MTrPs is their location within a taut band of muscle or fascia as identified by palpation. They can be discovered with a careful external and internal pelvic examination. Compression of the MTrP results in a twitch response, a transient contraction from the band of fibers, and referred sensory and motor responses (e.g., tenderness, pain) occurring distant to the TrP. Two objective methods have been used to document MTrPs. Algometry provides a quantitative measurement of pressure thresholds to document the sensitivity of TrPs. Results from several studies have confirmed that MTrPs are more sensitive than contralateral muscle areas without TrPs or surrounding healthy tissue.<sup>33,34</sup> A difference in pressure threshold

exceeding 20 newtons per square centimeter (2 kg/cm<sup>2</sup>) between a TrP and a contralateral point is considered abnormal.<sup>33</sup> A second method, thermography, employs a noninvasive imaging technique to detect infrared radiation from body surfaces and heat distribution.<sup>35</sup> Comparative imaging of subjects with clinical TrPs and asymptomatic controls revealed discrete thermal responses in muscles with suspected TrPs. Sensory referral areas for TrPs in symptomatic subjects showed significantly reduced temperatures from precompression levels during ischemic compression; no significant temperature changes were noted in asymptomatic areas after compression. It was assumed that the colder area was caused by a reduction in blood flow due to a sympathetic autonomic change associated with the myofascial pain syndrome.

A review of the neuroanatomy of the pelvis, such as that provided by Wesselmann and colleagues, assists in understanding the pathophysiology of urogenital and rectal pain syndromes and their management.<sup>36</sup> The involvement of MTrPs in CPP can thereby be taken in perspective. Travell and Simons published the first manuals on TrPs and myofascial pain and dysfunction and provided specific details of the pelvic muscles to check internally.<sup>16,22</sup> A subsequent edition of this manual was published in 1998.<sup>12</sup>

All of the muscles of the pelvis, both internal and external, must be thoroughly evaluated and subsequently treated. Muscles known to contain TrPs referring pain to an area that the patient is complaining about should be examined with extra care.

Testing for MTrPs within the pelvis depends on the palpation skills of an experienced examiner, because no diagnostic standard has been established to identify intrapelvic MTrPs. The therapist must be trained in identifying TrPs and be able to feel for superficial and deep TrPs located in the belly and the attachments of the muscles. For the purpose of locating these MTrPs, the pelvic muscles can be grouped into three categories—perineal muscles, pelvic floor muscles, and pelvic wall muscles. Examination of intrapelvic muscles for MTrPs requires a vaginal or rectal approach, as appropriate for each muscle by establishing bony and ligamentous landmarks, and relating the direction of palpation to the direction of the muscle fibers. This was explained in detail by Travell and Simons, as was the relationship between symptoms and the location of associated MTrPs.<sup>12</sup> Other MTrP associations have been gleaned from the experience of many physical therapists. Table 91-2 summarizes the internal pelvic muscles and external muscles referring pain to pelvis from MTrPs.

### Approaches for Inactivating Myofascial Trigger Points

A variety of manual massage techniques have been reported to inactivate MTrPs.<sup>29</sup> Manual therapy may involve active and passive rhythmic muscle releases based on the principle that tight or poorly relaxed muscles can exhibit released tension after moderate voluntary contraction. The active and passive release maneuvers take up the slack in the muscle by stretching it to the point of beginning resistance or discomfort. This is then followed by a patient-performed isometric contraction that is held in position by the patient or therapist.

Direct transrectal massage was reported by Thiele for patients with coccygodynia with pain localized to the coccyx and the presence of spasms of the levator ani and coccygeus muscles.<sup>14</sup> A modified Thiele massage was used by Oyama and colleagues in 21 women to treat IC and high-tone dysfunction of the pelvic

**Table 91-2 Internal and External Muscles and Referred Pain to Pelvis from Myofascial Trigger Points**

Muscle	Referred Pain Site	Symptom
<b>Pelvic floor muscles</b>		
Levator ani	Sacrococcygeal region, perineal region	Pain in perineum, vagina, anal sphincter; pain with sitting; aggravated by lying on back and by defecation
Bulbospongiosus Ischiocavernosus Transverse perinei Coccygeus	Perineal region and adjacent urogenital structures	Pain in vagina, dyspareunia, perineal ache
Sphincter ani Obturator internus	Poorly localized aching in anal region Perineal region, outward toward hip, whole pelvic floor, posterior thigh, and hamstrings	Pain in coccyx, hip, or back; ischiococcygeus is likely cause of backache in late pregnancy and early labor Anal pain, painful bowel movement Pain in vagina, vulva, urethra, coccyx, posterior thigh; pain and feeling of fullness in rectum
<b>Muscles referring pain into pelvis</b>		
Piriformis	Sacroiliac joint, hip girdle, hamstrings, pelvic floor, buttock, low back	Pain in rectum during defecation, dyspareunia; pain in referred areas worsens with palpation, standing, sitting, walking
Gluteus Iliopsoas Quadratus lumborum	Hip girdle, buttock, sacrum, hamstrings Groin, anterior thigh, low back Sacroiliac joint and buttock, lower abdomen, groin	Pain in low back, hip, inguinal area Pain in groin, down anterior thigh, and in low back Pain in low back and with coughing, sneezing, and walking
Abdominals Transverse	Entire abdomen up into ribs Groin, inguinal ligament, detrusor, and urinary sphincter	Groin pain, bladder pain, urinary frequency or retention
Rectus	Across thoracolumbar back, xiphoid process, sacroiliac joints, and low back	Somatovisceral response, nausea, vomiting, diarrhea, intestinal colic, dysmenorrhea
Pectineus Pyramidalis Thoracolumbar Paraspinals	Groin area, bladder, and pubis Abdomen	Pain in groin, bladder, urethra, and pubic area Visceral pain, sacral pain, pain in middle and lower back; pain can resemble renal colic

Data from references 12, 37, 38, and 39.

floor (e.g., dyspareunia, impaired bladder and bowel evacuation, pelvic pain exacerbated by physical activity or prolonged sitting).<sup>40</sup> Subjects underwent 5 weeks of twice-weekly Thiele intravaginal massage, with massages of the affected hypertonic pelvic muscles, 10 to 15 times per session, from origin to insertion along the direction of muscle fibers. Additional short ischemic compression of tender points was applied as needed. IC symptom scores and pelvic floor muscle tone showed significant improvements, and pelvic tone remained improved at 4.5 months of follow-up in three of the four treated pelvic muscles, excepting the coccygeus.

Weiss reported amelioration of symptoms in 42 patients with urgency-frequency syndrome with or without urethral pain (and in some patients with IC) using manual therapy of discrete MTrPs in the pelvic floor.<sup>18</sup> Treatment continued one to two times weekly for 8 to 12 weeks until MTrPs and muscle tension decreased. A program of home therapy involving muscle stretches and strengthening, biofeedback, and Kegel exercises was also part of the treatment. In the 42 patients (39 women, 3 men) with urgency-frequency syndrome, 83% had moderate to marked improvements or complete resolution. Of the 10 patients with IC (6 women, 4 men), 70% had moderate to marked improvements.

Injection with local anesthetics, saline, or water has been used for inactivation of MTrPs. An important sign of precise needle

placement in an MTrP is elicitation of a local twitch response. The resulting MTrP inactivation should result in immediate relief of pain and tightness.<sup>24</sup> Specific targeted therapy with local anesthetic injections of TrPs in the abdominal wall has been used for treatment of CPP in women.<sup>41,42</sup> Slocumb reported that approximately 50% of 122 women with pelvic pain had relief after treatment that consisted of TrP blocks in all patients; additional surgeries were performed in 13 women.<sup>41</sup> Most patients (89%) had abdominal wall TrPs; pain was relieved in 89% after anesthetic injection. Patients with only vaginal TrPs had a response rate of 85% after injections. TrP identification with needling and therapy of active MTrPs with 0.5% procaine injections was reported to provide symptomatic relief in four female patients with pelvic pain, IC, and irritative voiding symptoms.<sup>37</sup>

### Associated Stress and Psychological Factors

CPP in women is a perplexing problem. Frequently, a physical cause of pain cannot be established, and, consequently, it is difficult to treat successfully. In the absence of a discrete physical cause, a psychopathologic causation has been considered.

Many reports have associated CPP with personality and mood disturbances, childhood events including sexual abuse, and difficulties in sexual relationships; evidence, however, is inconclusive.<sup>43</sup> Among the causes of CPP is tension myalgia of the pelvic

floor. Recent evidence indicates that TrPs associated with myofascial problems are not the cause of CPP but a sign of somatization of neurotic or psychosomatic problems in the pelvis.<sup>44-47</sup> For example, Miller used stress management *alone* to effect symptom improvements in men with chronic prostatitis.<sup>48</sup> Eighty-six percent (110 of 218) of the patients reported that they were better, much better, or cured. Miller focused on the person and not the prostate, reinforcing the relationship between managing stress in the patients' lives and their symptoms.

One hypothesis for CPP is that acute and chronic stress induces neuroendocrine disturbances and consequent neuro-inflammatory stimulus-activating receptors and cytokines via neuropeptide release that give rise to CPP symptomatology. Stress triggers a cascade of pathophysiologic events that involve activation of two pathways: the hypothalamic-pituitary-adrenal (HPA) axis and the autonomic nervous system. Chronic activation of the physiologic stress response induces putative glucocorticoid resistance and altered immunity, release of proinflammatory cytokines and prostaglandins that may contribute to pelvic tension myalgia, and, ultimately, cycling psychological distress. No systematic evaluation of the physiologic role of acute and chronic stress in pathogenesis of CPP in women has been undertaken. Over the years, clinicians have anecdotally observed that stress exacerbates symptoms, as has been shown for prostatitis,<sup>48</sup> and chronic stress was shown to induce inflammatory histologic changes in the prostate of a rat model.<sup>49</sup> Certain inherent personality traits (genetic and developmental factors) modulate reactivity to stress. Researchers at my institution have strong preliminary evidence from our male patients with CPP syndrome indicating that physiotherapeutic myofascial release and cognitive behavioral therapy, proven methods to relieve stress, can provide both curative and partial relief of pain in some patients with CPP syndrome.<sup>50,51</sup>

### Physical and Mental Exercises Complementary to Management of Chronic Pelvic Pain

Emerging evidence suggests the influence of psychosocial factors on physiologic function and health outcomes. Mind-body therapeutic interventions, including yoga (a body-based therapy), cognitive behavioral therapy, relaxation therapy, meditation, and imagery, have shown efficacy in several common conditions. A recent systematic analysis showed that mind-body therapy can serve as an effective adjunct to conventional medical therapies for chronic low back pain, headaches, incontinence, and cardiac rehabilitation.<sup>52</sup> Hatha yoga has been proposed as a complimentary therapy for chronic urologic conditions involving pelvic floor dysfunction, to provide improved pain control and stress reduction. Specific yoga postures can contribute to the strengthening and relaxation of muscles that are associated with urologic symptoms resulting from hypotonicity (stress urinary incontinence) and hypertonicity (vulvodynia, IC) of pelvic floor muscles.<sup>53</sup>

In 1929, Edmund Jacobson published his method of "progressive relaxation," which has been used in various forms in Western medicine ever since.<sup>54</sup> He provided instructions to contract and relax muscles at the beginning of relaxation and, with Bell Telephone Laboratories, codeveloped the electromyograph to objectively verify the physiologic effects of tension and relaxation. He introduced the concept that relaxation of the gastrointestinal tract and arousal of the autonomic system, thought to be out of one's control, could be voluntarily reduced. A modification of

progressive relaxation, the practice of "*paradoxical relaxation*" according to David Wise,<sup>39</sup> has been used successfully in conjunction with MTrP release therapy to produce symptomatic relief in men with CPP syndrome.<sup>51</sup>

Operant behavioral and cognitive-behavioral approaches to chronic pain were introduced in the 1960s and 1980s, respectively, and often serve as a component of multidisciplinary treatment dealing with anatomic and physiologic factors.<sup>55</sup> Aspects of these treatments include relaxation training, cognitive restructuring, interventions to change perception and emotional responses to pain, habit reversal, and maintenance and relapse prevention. These approaches are complementary for management of the psychosocial influences on a patient's response to pain. Because pain is not entirely a response to nociception, therapies such as these attempt to influence the behavior of a patient in chronic pain.

### Clinical Experience with Combined Myofascial Trigger Point Release Therapy and Paradoxical Relaxation Therapy

A recent study at Stanford University has integrated physiotherapy with myofascial trigger point release therapy (MFRT) to relieve pelvic floor myalgia and paradoxical relaxation therapy to achieve autonomic and pelvic floor self regulation.<sup>51</sup> This study, although conducted in men with refractory CPP syndrome is nevertheless germane to both genders; it used multimodal therapy based on the potential etiology of pelvic pain as a manifestation of a neurobehavioral disorder.<sup>7,19,20,56</sup> A team approach to therapy included a urologist, a physical therapist experienced in pelvic pain treatment, and a psychologist.

The physiotherapist applied treatment to the patient in the lateral position. Individual muscle groups were palpated, and myofascial TrPs were identified. Positive myofascial TrPs induced pain on palpation that tends to reproduce symptoms at the site or referred to a nearby anatomic location. Pressure was held to each TrP for about 60 seconds to release.<sup>39</sup> Additional physiotherapy techniques also used in conjunction with MFRT sessions included voluntary contraction and release, hold and relax, contract and relax, and reciprocal inhibition as well as deep tissue mobilization including stripping, strumming, skin rolling, and effleurage. MFRT physiotherapy was given weekly for 4 weeks, then biweekly for 8 weeks.

Paradoxical relaxation therapy conducted by the psychologist coincided with physiotherapy. Patients received 1 hour of individual verbal instructions and a supervised practice session weekly for 8 weeks in progressive relaxation exercises. Training included the respiratory sinus arrhythmia breathing technique to quiet anxiety and relaxation training to have the patient focus attention on the effortless acceptance of tension in specific areas of the body. The therapy is called "paradoxical" because patients are directed to accepting their pelvic tension as a way of relaxing/releasing it.<sup>39</sup> Daily home practice relaxation sessions of 1 hour were recommended for a minimum of 6 months using a series of audiotaped lessons. Symptoms were assessed with a Pelvic Pain Symptom Survey and the National Institutes of Health-Chronic Prostatitis Symptom Index (NIH-CPSI). Patient-reported perceptions of overall effects of therapy were documented on a Global Response Assessment (GRA) questionnaire.

A total of 138 men with refractory chronic pain or CPP syndrome (CP/CPPS) and median disease duration of 31 months

were treated; their average age 40.5 years. Symptoms were rated as markedly improved or moderately improved by 72% of patients on the GRA questionnaire at the conclusion of therapy. This was associated with commensurate clinically significant decreases in NIH-CPSI total scores of 10.5 (46%) and 6.5 (24%), respectively. The number of treatments was variable; some patients had rapid responses occurring as early as after 1 week of treatment and either further improved or remained the same. After a median of five MFRT treatments, clinical improvements ( $\geq 25\%$  decrease in symptom scores) were first observed. A few patients had intermittent therapy, based on need, throughout recurring episodes of pelvic pain. The combined MFRT and paradoxical relaxation therapy provided an effective approach for these chronic pain patients, resulting in pain and urinary symptom relief at least comparable to or better than that achieved with traditional pharmacologic therapy.

The aspects of this treatment approach are amenable to the various expressions of pelvic pain in women. Each patient is unique in her objective and subjective clinical presentation. Thus, release of specific MTRPs that tend to recreate a patient's symptoms and behavior modification to relax the pelvic muscles and modify the habit of focusing tension in the pelvis under stress could help to ameliorate pain. The patient can also become an active participant, partnering with her therapists in the healing process.

### ELECTRICAL STIMULATION FOR NEUROMODULATION

Electrical stimulation has been entertained as a modality for treating pain since the distant past, when a man stepped on an eel at the beach and experienced an electrical shock that relieved his gout pain. Multiple attempts to introduce electrical energy have arisen, from Chinese acupuncture, through surface application using transcutaneous electrical nerve stimulation (TENS), to implantation of electrodes for continuous electrical stimulation of peripheral and spinal nerve roots and electrodes applied on the surface of the spinal cord itself.

The gate control theory of controlling pain assumes that afferent nerve fibers may be influenced by continuous high-frequency electrical stimulation and thereby modulate the transmission of pain impulses. TENS has been used most successfully and was introduced for bladder urgency and urinary frequency as well as stress urinary incontinence. One disadvantage of this method may be the lack of specificity of the nerve branch or bundle of the afflicted nerve. Direct stimulation of the S3 nerve as it exits the sacrum has recently received approval from the U.S. Food and Drug Administration for management of frequency, urgency, and urge urinary incontinence refractory to medical therapy. Because pelvic pain, particularly that arising from IC, may represent a neuroinflammatory pathogenic condition, electrical modulation promises to exert favorable outcomes in pain management.

The application of intravaginal electrical stimulation to treatment of CPP in women with levator ani syndrome was evaluated in a retrospective study of 66 patients.<sup>57</sup> After digital vaginal palpation of the levator ani muscles for tenderness, a probe was placed in the patient's vagina and pulsed electrical stimulation was given to muscles at variable settings (up to 50 mA for up to 20 minutes per session) for one to seven sessions. Pain symptoms were reported as improved in 34 (52%) of 66 patients; benefit

was sustained for more than 6 months after the last treatment. Electrical stimulation for management of vulvar vestibulitis including dyspareunia and vaginismus has been shown to be effective.<sup>58</sup> A group of 29 women participated in a 10-week therapy program of stimulation (20 minutes once weekly) at the vestibular area and vagina introitus. Contractile ability and resting ability of the pelvic floor muscles significantly improved; pain was significantly reduced, and half of the women with vaginismus resumed coital activity.

The therapeutic effects of high-frequency electrostimulation were also assessed in men with noninflammatory CPP syndromes using a urethroanal stimulation device.<sup>59</sup> This approach was based on the supposition that chronic prostate pain may represent a chronic visceral pain,<sup>36</sup> and the authors' speculation that electrical stimulation might block afferent nerves supplying the pelvic floor and pelvic organs, thereby providing pain relief. This premise was supported by another study showing that sacral nerve stimulation can provide a dramatic and durable improvement in pain symptoms and urgency-frequency.<sup>60</sup> The neuronal mechanisms associated with bladder inhibition during intravaginal electrical stimulation have been documented experimentally in the cat.<sup>61</sup>

Sacral neuromodulation is an approved treatment for management of refractory detrusor instability and nonobstructive voiding dysfunction; it has also been shown to be effective for amelioration of pelvic pain.<sup>62-64</sup> An early study with TENS indicated the possibility for treatment of the chronic painful bladder syndrome, IC.<sup>65</sup> Favorable responses to a percutaneous trial stimulation of the S3 sacral roots for as few as 5 days or up to 10 days have been shown for IC patients.<sup>66,67</sup> Significant improvements occurred in urinary dysfunction, pelvic pain, and quality of life parameters. The test neuromodulation normalized urinary levels of heparin-binding epidermal growth factor and antiproliferative factor activity—factors known to be altered in patients with IC.<sup>66</sup> The temporary nature of the percutaneous stimulation evaluation permits assessment of the potential efficacy and desirability of permanent sacral neurostimulation.

Neuromodulation is the physiologic process by which the activity in a neural pathway alters preexisting activity in another pathway. It is theorized that sacral neurostimulation causes afferent inhibition of sensory processing in the spinal cord. The S2-S4 nerve roots provide the primary anatomic and somatic innervations to the pelvic floor, bladder, and urethra. Comiter indicated that the mechanism associated with the effectiveness of sacral nerve stimulation for IC involves both afferent (pelvic pain and sensory urgency) and efferent (motor frequency and urgency) modulation.<sup>68</sup>

Comiter evaluated the efficacy of sacral nerve stimulation for treatment of refractory IC in 25 patients.<sup>68</sup> After a trial of nerve stimulation, 17 patients demonstrating at least 50% improvement in pain and urinary dysfunction qualified for permanent nerve stimulator implantation. Improvements were sustained in 16 of 17 patients for an average of 14 months' follow-up after permanent implantation. In a retrospective study, the efficacy of long-term sacral neuromodulation was evaluated in 21 patients with refractory IC by Peters and Konstandt.<sup>69</sup> Eighteen patients had used chronic narcotics for pain. After an average follow-up of 15 months after surgery for implantation of a permanent nerve stimulator, 20 patients reported marked improvements in pain, with a significant decrease (36%) in narcotic requirements; all narcotics were stopped in 4 of 18 patients.

Siegel and colleagues used sacral nerve stimulation to treat intractable pelvic pain in 10 patients (9 women, 1 man) without a primary complaint of voiding dysfunction.<sup>70</sup> After successful percutaneous trial nerve stimulation, a neuroprosthetic sacral nerve stimulator device was surgically implanted, with leads placed in the S3 or S4 foramen. Follow-up was after a median of 19 months. Nine of 10 patients had decreased severity and frequency of pelvic pain; 6 had significant improvements in pain symptoms. No serious device complications were reported.

Spinal cord stimulation (SCS) has been used since 1967 for the treatment of chronic lower back or lower extremity pain of diverse causes that is refractory to numerous conventional therapies. The work of Shealy and colleagues led to the development of this pain therapy, which was then used exclusively for failed back syndrome.<sup>71</sup> As the clinical applications of SCS expanded in the following years, the outcomes were poor due to a lack of understanding of the appropriate clinical indications, SCS equipment technical failures, and the need for a trial stimulation period to identify patients who might achieve a long-term benefit. Based on increased knowledge, SCS outcomes throughout the last 2 decades were found to provide reasonable (>45% to 60%) long-term pain relief.<sup>72-75</sup> There is a better understanding of the psychological factors that are predictive of SCS outcomes.<sup>74</sup> Avoidance of implants in patients with severe untreated depression, untreated drug abuse, or borderline personality disorder has led to improved outcomes.<sup>76</sup> A recent review presents the current and future trends of SCS.<sup>77</sup>

Technologic advances, which have widened the scope of applications for SCS, include multichannel leads, dual-lead configurations, multichannel devices, totally implantable generators, and new procedures for programming stimulators. The primary indication for treatment with SCS is neuropathic pain that has failed to be relieved by other conservative approaches. With the discovery of the dual-lead technology, the clinical applications have expanded. Acceptable relief was attained in 70% of patients with chronic axial low back and extremity pain.<sup>78</sup> Several patients with intractable pain of the pelvis and rectum have been treated with the dual leads.<sup>79</sup> SCS is a relatively simple and reversible treatment using greatly improved and clinically reliable equipment. It may serve as an option for patients with moderate to severe pain of the trunk or extremities when other pain relief methods have failed or are unacceptable. Studies of SCS for amelioration of CPP warrant further investigation.

## BOTULINUM A TOXIN

Botulinum A toxin (BTX-A) is a neurotoxin derived from *Clostridium botulinum* that binds irreversibly to cholinergic, presynaptic membranes of the neuromuscular junction. When a minute amount is injected into a muscle, it prevents release of acetylcholine, thereby blocking neurotransmission and temporarily paralyzing affected muscles. It can provide symptomatic relief for up to 3 months. In the United States, BTX-A is approved for treatment of blepharospasm, strabismus, hemifacial spasm, and cervical dystonia in adults. In Europe, labeled indications are for cervical dysplasia and cerebral palsy. BTX-A has received much notoriety for its cosmetic use for facial wrinkles and in pain therapy to treat myofascial pain, low back pain, and headaches including migraine.

BTX-A has been used clinically for more than 2 decades: there is continued accumulation of evidence for its application for a

variety of urologic conditions.<sup>80</sup> Experience with BTX-A in neurourology began in the early 1990s with treatment of neurogenic-sphincter dyssynergia after spinal cord injury, neurogenic and non-neurogenic detrusor hyperactivity, and other dysfunctional voiding disorders.<sup>81</sup> BTX-A injections have been used to treat voiding symptoms related to CPP syndromes in men.<sup>82</sup>

It has been hypothesized that interruption of the junction of somatic nerves with striated muscles may affect the central pain cycle. Zermann and coworkers used transurethral perisphincteric injections of BTX-A in 11 patients with chronic prostatic pain.<sup>83</sup> Injections resulted in pelvic floor muscle weakening and relief of pelvic pain and urethral hypersensitivity.

A pilot study explored the use of BTX-A in the treatment of CPP associated with spasm of the levator ani muscles.<sup>84</sup> The 12 women had a minimum 2-year history of pelvic pain and pelvic floor hypertonicity. BTX-A at one of three dilutions (10, 20, or 100 IU/mL) in groups of four patients was injected bilaterally into the puborectalis and pubococcygeus muscles under conscious sedation. Visual analogue pain scale scores were significantly improved for dyspareunia and dysmenorrhea at the 12-week follow-up. Pelvic floor muscle manometry had a 37% maximal reduction at week 4 and a statistically significant 25% reduction at week 12. Marked improvement in sexual activity was associated with significant reductions in discomfort and improved habit. No differences in response were noted with different dilutions of BTX-A; no medically adverse reactions occurred.

A multicenter case series of 13 patients with recalcitrant IC was described using intravesical BTX-A.<sup>85</sup> This study was based on evidence from a rat somatic pain model suggesting that BTX-A may have an antinociceptive effect on both acute and chronic pain.<sup>86</sup> Patients were injected submucosally with 10 RA to 20 RA IU/mL of BTX-A through a cystoscope into 20 to 30 sites to target dense sensory innervations in the trigone and bladder floor. Pain, daytime frequency, and nocturia measured by visual analogue scale scores decreased significantly ( $P < .01$ ) by 79%, 44%, and 45%, respectively. First desire to void and maximal cystometric capacity also increased by more than 50% ( $P < .01$ ). These observations, although preliminary, suggest the potential application of BTX-A for symptomatic and functional improvements in IC.

BTX-A for treatment of urologic conditions has had a good safety profile with relatively few significant side effects. Leippold and colleagues have expressed their perspective on BTX-A as follows: "One cannot deny human ingenuity in transforming the lethal poison into a modern day therapeutic medicine."<sup>87</sup> Possible systemic side effects of BTX-A injection, although unusual, include nausea, vomiting, dysphagia, dry mouth, diplopia, and blurred vision, which may be due to unintentional distribution of the toxin. The incidence of systemic side effects treated in a variety of urologic conditions was reviewed by Maan and colleagues.<sup>80</sup> A limited number of papers have reported on localized side effects associated with toxin diffusion and possible overdosing of the targeted tissue, including temporary stress incontinence in female patients treated for chronic retention, or urinary retention, or severe generalized muscle weakness (as reviewed by Leippold and colleagues<sup>87</sup>). Contraindications for BTX-A injections are pregnancy, breastfeeding, myasthenia gravis, muscular dystrophy, use of aminoglycosides or any drugs that interfere with neuromuscular transmission, and hemophilia or hereditary clotting factor deficiencies.

Further research on BTX-A for treatment of CPP is warranted. Additional, larger studies are needed to explore the biologic and

clinical effects of BTX-A including a placebo-control arm. Because the effects of the drug are temporary and most patients require repeat treatments, evaluation of the safety, benefits, and cost of repeated injections of the toxin are needed. In some cases, BTX-A given at high doses (>100 IU) for neurologic conditions has been shown to induce the development of antibodies (occurring in <5% of patients), making further treatment ineffective.<sup>88</sup> Seven serologically different types of BTX exist, each with distinct properties and actions. A new product containing botulinum B toxin has been effective in treating pain and other symptoms of cervical dystonia in patients who developed antibodies and stopped responding to BTX-A.

### MANAGEMENT OF PUDENDAL NERVE ENTRAPMENT SYNDROME

Compression entrapment of pudendal nerves in the pelvis may be the cause of urogenital and anorectal pain syndromes.<sup>89-93</sup> Robert and colleagues conducted anatomic and clinical studies and elucidated three possible entrapment sites along the pudendal nerve: between the sacrotuberous and sacrospinous ligaments, in the pudendal canal of Alcock, and during the straddling of the falciform process of the sacrotuberous ligament by the pudendal nerve and its branches.<sup>92</sup> Female patients may complain of perineal, anal, and/or vaginal pain while sitting, which is diminished when standing, when in the recumbent position, or when sitting on a toilet seat. It is the positional nature of the pain and its relief when standing that are the most important diagnostic clues. Pain is not related to urination or defecation, although chronic constipation and straining with bowel movement may contribute to the condition.<sup>93</sup> Pudendal neuropathies secondary to pressure effects on the perineum have been reported in competitive bicyclists due to seat positions.<sup>94</sup> Because pudendal nerve entrapment causes symptoms similar to other pain syndromes, including coccygodynia, levator ani syndrome, urethral syndrome, and idiopathic proctalgia, misdiagnosis is possible.<sup>95</sup> Cases of idiopathic vulvodinia have been subsequently attributed to pudendal neuralgia.<sup>96-98</sup>

Physical examination of patients with symptoms of pudendal nerve entrapment typically reveals little about the cause. Reproduction of pain can be generated by digital rectal or vaginal examination along the course of the pudendal nerve deep within the pelvis. Robert and colleagues stated that the "richness of the subjective manifestation contrasts with the poverty of the clinical examination and the normality of the radiologic examination."<sup>99</sup> Electrophysiologic tests may be performed to measure the distal latency time of the pudendal nerve (upper limit of normal, 2.5 msec). This procedure has been described using a St. Mark's Hospital pudendal electrode that incorporates stimulating and recording electrodes on an adhesive sheet that fits on a gloved index finger for intrarectal placement.<sup>95</sup>

Pudendal nerve block with local anesthetics, alone or with corticosteroids, has been used for diagnosis and treatment of various perineal pain syndromes and may yield temporary pain relief. Computed tomography (CT) has been described as the best technique for good appreciation of the anatomy and precise location of anatomic points to guide blocking of pudendal nerves at potential entrapment sites.<sup>100-103</sup> In other instances, use of an insulated electrode to localize the pudendal nerve with electrical stimulation allows local infiltration of long-acting bupivacaine

with or without corticosteroid. In some reports, the pain relief continued for 1 year after the last anesthetic block in more than 60% of patients.<sup>92,102</sup> McDonald and Spigos treated 26 women with severe pelvic pain with CT-guided nerve blocks once monthly for 5 months.<sup>104</sup> Improvement was reported by 73% (19/26), and 16 women (62%) had substantial pain reduction based on pain scale scores. The favorable results were attributed to correct placement of the local anesthetic. No response duration was reported.

Patients with pudendal neuralgia caused by involvement of the pudendal nerve may be appropriate candidates for surgical decompression after confirmation of the diagnosis by electrophysiologic tests and diagnosis and temporary pain relief with nerve block injections. Robert and coworkers reported their experience with more than 200 procedures for neurolysis and transposition over the sciatic spine of one or both pudendal nerves.<sup>92,99,102</sup> The success rate was 67% (45% complete pain relief and 22% significant improvement). In another series by Amarenco and colleagues, in 170 cases of perineal neuralgia treated with pudendal nerve block, 57% of patients had pain relief, but only 15% had sustained relief after 1 year.<sup>91</sup> Subsequent surgical decompression in 27 patients yielded a good to excellent result in 17 (62%). Shafik reported the disappearance of vulvar pain in 9 (82%) of 11 women after pudendal canal fasciotomy to release the pudendal nerve in the ischiorectal fossa.<sup>98</sup> An algorithm for treating pudendal neuralgia has been developed from 212 cases, approximately half of which involved surgical decompression after negative responses to nerve block; 86% of the patients were free of pain or had a significant pain reduction after 1 year of follow-up.<sup>105</sup>

Predictive factors related to the postoperative success of patients with pudendal nerve entrapment include duration and clinical characteristic of pain and signs of pudendal neurogenic lesions with electrophysiologic testing. From a series of patients reported by Robert and coworkers, factors associated with improved success included shorter duration of pain before surgical treatment, age younger than 50 years, and discovery of a damaged nerve.<sup>92,102</sup> Factors associated with decreased success were pudendal nerve distal motor latency of greater than 7.0 msec, age older than 70 years at surgery, and the finding of a normal nerve. Depression is known to be a component of pain syndromes. It has been suggested that surgery should be avoided in patients in whom a depression is manifested as chronic anal/perineal pain.<sup>106,107</sup> Neurolysis-transposition of the pudendal nerve failed in 5 of 6 depressed patients treated by Maullion and associates.<sup>108</sup>

Maullion and coworkers examined the efficacy of pudendal nerve blocks as a predictive factor for the subsequent efficacy of nerve decompression surgery.<sup>108</sup> Twelve patients with urogenital and rectal pain were initially treated with CT-guided injections of lidocaine/corticosteroids in the pudendal nerves. Surgical treatment was proposed if pain recurred after temporary improvements or after nerve block failure. All patients underwent surgery for decompression of the sacrotuberous and sacrospinous ligaments and either unilateral or bilateral transposition of pudendal nerves proximal to the ischial spine. After 21 months, 25% (3 of 12) patients remained asymptomatic, and one had partial improvement; eight remained in pain. The three patients cured by surgery had complete pain relief for at least 2 weeks after neurolysis repeated twice before nerve transposition. This was considered the best criterion to predict the success of surgery.

# PAINFUL BLADDER SYNDROME AND INTERSTITIAL CYSTITIS

*Christopher Kennerly Payne*

### EVOLUTION OF TERMINOLOGY: PAINFUL BLADDER SYNDROME AND INTERSTITIAL CYSTITIS

The last 20 years has produced an explosion of interest in the diagnosis and treatment of bladder pain. Although the attention is welcomed by patients, clinicians, and researchers alike, there is a simultaneous sense of insecurity and confusion as traditional ideas are challenged. Even the name identifying the condition, interstitial cystitis (IC), has been questioned. The original description of Hunner's ulcers characterized a very small group of patients with a clearly defined disease defined by erythematous, bleeding areas on the bladder wall and physically diminished bladder capacity.<sup>1</sup> In 1949, Hand<sup>2</sup> described 223 patients, both men and women, with what would now be called IC; only 13% had severe cystoscopic findings. Nevertheless, it was left to Messing and Stamey<sup>3</sup> to focus attention on the disorder; they described an "early diagnosis" of IC based on cystoscopic identification of glomerulations after bladder distention. This dramatically increased the population of patients considered to have IC while simultaneously raising a question as to whether these patients really had the same underlying disease. Most patients with glomerulations have normal cystoscopic findings before distention, normal bladder capacity during distention, and relatively little inflammation on bladder biopsies. Can these patients have the same condition as those with frank ulceration? In recent years, the population has been further expanded by a move to diagnose patients based on symptoms without performing bladder distention and biopsy.

The International Continence Society (ICS) proposed useful definitions to promote clarity in discussing the problem of bladder pain.<sup>4</sup> First, it is recognized that bladder pain is part of a larger problem of genitourinary pain or pelvic pain syndromes. The document states, "The syndromes described are functional abnormalities for which a precise cause has not been defined. It is presumed that routine assessment (history taking, physical examination, and other appropriate investigations) has excluded obvious local pathologies such as those that are infective, neoplastic, metabolic or hormonal in nature." The term *painful bladder syndrome* (PBS) was introduced and defined as "the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology." It was suggested that the term *interstitial cystitis* be reserved for those with specific objective findings, stating that it is "a specific diagnosis and requires confirmation by typical cystoscopic and histological features. In the investigation of bladder pain it may be necessary to exclude conditions such as carcinoma in situ and endometriosis."

Although PBS does not have objective diagnostic criteria, it does provide a simple, unambiguous description of a disease that is useful when discussing the problem with patients. It allows for a classification of patients who chose to undergo treatment without invasive investigations. At the same time, it includes patients who undergo investigation but do not have the "typical cystoscopic and histologic features." Thus, there are actually three separate groups:

1. *Interstitial cystitis*—symptoms of PBS with typical cystoscopic and histologic features
2. *Painful bladder syndrome* (uninvestigated)—symptoms of PBS with unknown cystoscopic and histologic features
3. *Painful bladder syndrome* (investigated)—symptoms of PBS with negative cystoscopic and/or histologic features

Furthermore, patients with IC actually comprise at least three readily identifiable subgroups:

1. Bladder ulcers seen on baseline cystoscopy and confirmed by distention with biopsy
2. Normal baseline cystoscopy, glomerulations after distention, inflammation on biopsy, reduced bladder capacity
3. Normal baseline cystoscopy, glomerulations after distention, no inflammation on biopsy, normal bladder capacity

These groups may substantially overlap; at this time there is essentially no information that can be used to define distinct differences in etiology, pathophysiology, treatment, or prognosis for either subgroup of nonulcer IC patients. However, there is clearly a difference in pathophysiology between ulcer and nonulcer patients. Future studies with careful characterization of symptoms, objective findings, and longitudinal follow-up could produce important insights into the utility of these somewhat artificial distinctions.

An important limitation of the ICS terminology is that these definitions of disease do not translate readily into entry/exclusion criteria for clinical research. Ever since the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) sponsored a conference to review the accumulated knowledge of IC in 1987, the consensus statement from this meeting<sup>5</sup> has been considered the "official" research definition of IC. The definition encompasses inclusion criteria (Box 92-1) that describe the syndrome and exclusion criteria (Box 92-2) that serve to create a relatively homogeneous patient population. The exclusion criteria can be subdivided into two groups: first, other diseases that, if present, could engender doubt about the source of symptoms, and second, various symptoms or patient factors used to eliminate subjects that might be problematic to evaluate in a clinical trial.

### Box 92-1 NIDDK Inclusion Criteria: Two Positive Factors Are Necessary for Inclusion in the Interstitial Cystitis Study Population

Hunner's ulcer-automatic inclusion  
 Pain on bladder filling relieved by emptying  
 Pain (suprapubic, pelvic, urethral, vaginal, or perineal)  
 Glomerulations on endoscopy  
 Decreased bladder compliance on CMG

CMG, cystometrography; NIDDK, National Institute of Diabetes and Digestive and Kidney Diseases.

### Box 92-2 NIDDK Exclusion Criteria for Interstitial Cystitis Study Population

#### Other diseases

Benign or malignant bladder tumors  
 Uterine, cervical, vaginal, or urethral cancer  
 Other cystitis: radiation, tuberculous, bacterial, or cyclophosphamide  
 Vaginitis  
 Symptomatic urethral diverticulum  
 Active herpes infection  
 Bladder or ureteral calculi  
 Involuntary bladder contractions (UDS)

#### Practical issues in research

Age <18 yr  
 Waking frequency <5 times in 12 hours  
 Nocturia <2 times per night  
 Symptoms relieved by antibiotics, urinary antiseptics, urinary analgesics  
 Duration <12 mo  
 Bladder capacity >400 mL, absence of sensory urgency

NIDDK, National Institute of Diabetes and Digestive and Kidney Diseases.

The NIDDK criteria were criticized in a retrospective study from the NIDDK IC Database.<sup>6</sup> It was observed that, when patients with a wide range of symptoms were recruited for this longitudinal study, the NIDDK criteria achieved the purpose of defining a homogeneous patient population, because 90% of the database subjects meeting NIDDK criteria were believed by the experts to have IC. On the other hand, more than 60% of the patients diagnosed clinically with IC by the same experts did not meet the strict NIDDK criteria. Because use of these criteria greatly limits the available patient population and hampers clinical research; it has been argued that research trials should draw from the full spectrum of the clinical population, so that the results will be maximally generalizable.<sup>7</sup>

It has been proposed that this obstacle could be overcome by using the constellation of symptoms that defines PBS as inclusion criteria. However, at this time, there have been no published clinical trials of PBS and no published criteria for selecting patients for such trials. There is also a lack of worldwide agreement on the standard diagnostic evaluation of patients with bladder pain. In the United States, patients are often diagnosed by symptoms, and even when bladder distention is performed, biopsies are often not obtained. In Europe and other parts of the

world, most patients undergo distention and biopsy, and diagnosis follows ICS terminology closely.<sup>8</sup> Therefore, it can thus be difficult to conduct an international study. Furthermore, even when similar entry criteria are used, it may be difficult to ensure that patients from U.S. and European trials are similar, given the varying diagnostic philosophies. A recent NIDDK subcommittee charged with reviewing the literature to update the diagnostic criteria was unable to find an evidence base to improve on the earlier NIDDK criteria.<sup>9</sup> This problem may not be solved until a reliable biomarker is developed. Until such time, the NIDDK criteria will continue to be used to provide an accepted homogeneous IC population representing a subset of the affected population; this definition is appropriate for trials of more toxic treatments for those with refractory symptoms. More inclusive criteria will be proposed to facilitate additional research, particularly for the more recently diagnosed and less severely affected patients. However, the lack of universally accepted research criteria for PBS will hamper research efforts in the short term.

## EPIDEMIOLOGY, ASSOCIATIONS, AND IMPACT

The diagnosis of IC/PBS is controversial and is based primarily on symptoms; there is as yet no objective test or marker to establish the presence of the disease, so studies to define its prevalence and incidence are difficult to conduct. Such epidemiologic studies use one of three methods: patient self-reported history, physician diagnosis, or identification of symptoms that suggest IC/PBS. The estimates of prevalence obtained vary widely, depending on when the study was performed (recognition of the disease is much greater in recent years), which methodology was used (symptoms are very prevalent, physician diagnosis relatively uncommon), and where the study was performed (physician and patient attitudes differ by culture, and there may be environmental or hereditary risk factors). The major published studies examining the incidence of IC/PBS are summarized in Table 92-1. Reports employing physician diagnoses report a much lower incidence, but the methodologies of such studies still vary considerably: some consist of surveys sent to urologists,<sup>10,11</sup> whereas others involve review of medical records from broad, population-based samples.<sup>12,13</sup> Each methodology has its inherent biases and limitations. Leppilahti and colleagues<sup>13</sup> used a powerful technique in which patients were contacted from a representative population-based sample, diagnosed based on presence of symptoms, and then invited to participate in a physician evaluation to confirm the diagnosis. Even without including potential patients who could not be examined, the group estimated that the prevalence of IC in Finnish women was 230/100,000 for probable cases and 530/100,000 for possible/probable cases. The power of the study was limited by the facts that the population examined was very homogeneous and that only a small number of cases were actually diagnosed (three probable, four possible), but the results are informative and in marked contradistinction to the initial report of IC epidemiology by Orovisto,<sup>14</sup> who found only 18 cases per 100,000 women in the same type of population. Orovisto required the presence of a confirmatory biopsy.

Two studies using self-reported histories of IC/PBS employed the same definition of disease.<sup>15,16</sup> Participants were asked, "Have you ever had symptoms of a bladder infection (such as pain in your bladder and frequent urination) that lasted more than 3 months?" Those who answered "Yes" were then asked, "When

**Table 92-1 Estimates of the Prevalence of Interstitial Cystitis**

Publication	Years Surveyed	Methodology	Population	Total No. Surveyed	Prevalence (per 100,000)
Jones 1997	1988-1991	Self-report	U.S. national (overall)	20,561	501

HMO, health maintenance organization; NHS, National Health Service (U.K.).

you had this condition, were you told that you had interstitial cystitis or painful bladder syndrome?" An affirmative answer to both questions was considered to define the presence of IC/PBS. The Curhan study<sup>15</sup> also included review of medical records and found a much lower prevalence of disease in these records than was found by self-reported histories.

Overall, there is greater than 100-fold variation in the diagnosis of IC/PBS among studies. Whether this represents an actual difference in the presence of disease in different populations or an artifact from study design is unknown. Patient recollection is inaccurate due to confusion between IC/PBS and other forms of cystitis. At the same time, most of these studies do not capture patients who have no access to care due to economic or other social pressures and therefore may underestimate the presence of disease. Physician diagnosis similarly may underestimate the true prevalence due to selection biases.

Recent studies that assess the presence of symptoms suggestive of IC/PBS provide methods of identifying undiagnosed patients. Clemens and colleagues<sup>17</sup> used three different clinical definitions of IC/PBS symptoms in a study that included a questionnaire and review of medical records. Definition 1 consisted of self-reported pelvic pain along with urinary urgency or frequency lasting for at least 3 months. Definition 2 included the definition 1 criteria plus the presence of pain increasing as the bladder fills or pain relieved by urination. Definition 3 used results from a validated condition-specific questionnaire. Presence of IC/PBS for this definition was defined as a score of 12 or higher on the Interstitial Cystitis Symptom Index and Problem Index, including two or more episodes of nocturia per night and a pain score of 2 or greater. The resulting prevalence estimates were 11,200 per 100,000 women and 6,200 per 100,000 men by definition 1; 3300 and 1400, respectively, by definition 2; and 6200 and 2300,

respectively, by definition 3. Interestingly, using only definition 3, a different study in Finnish women<sup>18</sup> demonstrated a prevalence of 450 per 100,000. Finally, investigators using a very controversial approach based on the presence of symptoms and potassium sensitivity testing in a subset of patients suggested that between 10% and 30% of women in a third-year medical school class had IC and that 25 to 30 million U.S. women could be affected.<sup>19</sup> Although this study was based on several questionable assumptions, there is no doubt that pelvic pain and lower urinary tract symptoms are exceedingly common and most likely are underappreciated in the general population. It is not yet clear that these patients actually have a unifying diagnosis. The need for an objective diagnostic marker for IC/PBS is obvious.

Only two investigators have estimated the incidence of IC/PBS. In a community-based study in Olmsted County, Minnesota, physician-assigned diagnoses of IC/PBS were identified using medical records from the Rochester Epidemiology Project.<sup>20</sup> The overall age- and sex-adjusted incidence rate was 1.1 per 100,000 per year for the interval from 1976 to 1996. The age-adjusted incidence rates were 1.6 per 100,000 women and 0.6 per 100,000 men. The median number of episodes of care-seeking for symptoms before diagnosis was 1 for women and 4.5 for men. In this study, the cumulative incidence rate (an estimate of prevalence) was 114 per 100,000 by age 80 years. A subsequent review of physician diagnoses of IC/PBS among Kaiser Permanente Northwest enrollees identified a much higher yearly incidence: 21 per 100,000 women and 4 per 100,000 men.<sup>12</sup> These two estimates present a rather large difference that cannot be resolved without further research. The methodologies and patient populations are quite different. It would be exciting to know that there is a substantial difference in incidence between different ethnic groups but we cannot conclude that at the present time.

Koziol and colleagues<sup>21,22</sup> first examined the impact of IC in a population of patients treated at a single center. They found that more than 60% of the patients were unable to enjoy usual activities or were excessively fatigued, and 54% reported depression. Travel, employment, leisure activities, and sleeping were adversely affected in more than 80% of the patients. The quality of life for these IC patients (likely a very severely affected group) was worse than that of chronic dialysis patients. Another survey of 495 IC patients in the United Kingdom demonstrated similar findings.<sup>23</sup> Sixty-seven percent of patients reported “considerable impact” or worse on their lifestyle, and 46% reported moderate depression or worse. Half of the patients reported at least considerable difficulties with sexual intercourse. There is no doubt that IC/PBS can greatly diminish quality of life in all domains (physical, social, emotional, relationships) and that the combination of chronic pain and lower urinary tract dysfunction places a burden that is matched by few other conditions.

An initial effort to determine the financial impact of IC/PBS on the U.S. healthcare system was produced from the Urologic Diseases in America project sponsored by the NIDDK. This endeavor compiled several national databases, including Medicare, Medicaid, and the Veteran’s Administration health care system, as well as private sources. The search strategy included identifying costs associated with patients diagnosed with IC (*International Classification of Diseases, 9th Revision* [ICD-9] code 595.1) as well as attempting to identify patients who may have PBS (the combination of code 788.41 for urgency-frequency with either 625.8 or 625.9, which code for female pelvic pain). Because there is no current diagnostic code for PBS, this was the first attempt to identify such patients through coding. Among the most important findings were the following:<sup>24</sup>

- Between 1992 and 2001, there was a twofold increase in the rate of hospital outpatient visits and a threefold increase in the rate of physician office visits related to IC. The annual-

ized rate was 102 office visits per 100,000 population. The rate of ambulatory surgery visits for IC declined.

- A diagnosis of IC was associated with a twofold increase in direct medical costs compared with the costs for individuals without the disorder (Table 92-2).
- Between 1994 and 2000, the annual national expenditure for IC was stable at approximately \$37 million, but the annual costs for PBS increased from \$481 million to \$750 million (Table 92-3).
- More than 80% of the outpatient care was provided by urologists.

The data are consistent with observations that fewer patients undergo procedures under anesthesia; the growing expenditures on PBS most likely represent an increased awareness of the condition combined with the trend away from performing cystoscopy, bladder distention, and biopsy. The economic impact of disease detailed in this report includes direct costs paid to the medical system and indirect costs borne by the individual and society. Direct costs include payments to physicians for inpatient and outpatient care, payments to hospitals for inpatient care, payments for outpatient procedures and tests, and the costs of prescription drugs, among others. Indirect costs include potentially measurable items such as the consequences of time away from work (borne by the individual, employers, and colleagues) and lost productivity when at work. The condition also has substantial impact through indirect costs that are more difficult to measure: work, education, and social opportunities not pursued; general decrements in quality of life; loss of family and social support; and even depression, divorce, and, for some IC/PBS patients, suicide. It is probable that these indirect costs would overwhelm the direct costs.

There are a number of intriguing associations with IC. Clauw<sup>25</sup> and Erickson<sup>26</sup> independently surveyed patients and controls for the presence of a wide variety of physical symptoms. They found

striking parallels, with IC patients reporting increased cardiac, gastrointestinal, and rheumatologic symptoms, but both investigators noted that these patients with chronic pain did not simply report the presence of somatic complaints in every organ system (Table 92-4). Alagiri and colleagues<sup>27</sup> surveyed 2405 patients with a diagnosis of IC for the presence of other diagnosed diseases plus symptoms that would suggest the presence of disease. Allergies were the most common condition, occurring at twice the rate in the general population, but more striking differences were seen in dramatically increased rates of irritable bowel syndrome, fibromyalgia, Crohn's disease, and lupus. Endometriosis, incontinence, chronic fatigue, and migraines occurred in IC patients at about the same rate as in the general public. This finding is important, because the presence of anything more than mild stress incontinence is unusual in IC/PBS patients and should prompt a more comprehensive evaluation. In contrast to this large population-based study, examination of patients in a single center showed that IC and endometriosis may frequently coexist in patients with chronic pelvic pain.<sup>28</sup> A total of 178 female patients with chronic pelvic pain underwent both cystoscopy with bladder distention and laparoscopy. Endoscopic findings supported a diagnosis of endometriosis in 134 patients (75%),

and cystoscopy confirmed a diagnosis of IC in 159 patients (89%); 115 patients (65%) were diagnosed with both IC and endometriosis. The question here is whether the specific endoscopic findings are meaningful. Perhaps these patients had a generalized hypersensitivity disorder, and the glomerulations and deposits of endometriosis were not specifically related to the pathophysiology. Only more detailed research with longitudinal follow-up can answer this question.

These associated symptoms are particularly fascinating when viewed in the context of a report from Weissman and colleagues,<sup>29</sup> who described a genetic linkage study demonstrating associations between IC and panic disorder, thyroid disorders, mitral valve prolapse, and chronic headaches/migraines. These associations parallel the increased incidence of palpitations, heart pounding, chest pain, and rapid heart rate in the reports of Clauw<sup>25</sup> and Erickson.<sup>26</sup> These researchers, however, did not find an increase in headaches in IC patients compared with controls. Although such a genetic syndrome would likely only involve a fraction of the typical IC patients, this discovery could ultimately produce insights about the pathophysiology of disease and lead to new medical treatments. Another view on this issue was provided by Buffington<sup>30</sup>; in his review of published associations between IC

and other disorders, he pointed out that many of the associations could be explained by a common dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis. Buffington has carefully documented such abnormalities in a series of publications using the Feline Interstitial Cystitis model<sup>31-33</sup> and has begun studying the response to stress in these animals. Preliminary results suggest there is dissociation between the sympathetic nervous system and HPA-axis responses to stress (see Chapter 90). This is a promising area for further research, because it could lead to improved understanding of the pathophysiology and present new avenues for treatment.

A critical question in defining the future of IC/PBS and other pelvic pain syndromes is whether there are meaningful distinctions between different syndromes. Wessely and colleagues<sup>34</sup> performed a literature review in 1999; they found that a substantial overlap existed between the individual syndromes and that the similarities between them outweighed the differences. Similarities were apparent in case definition, reported symptoms, and nonsymptom associations such as gender, outlook, and response to treatment. They concluded that the existing definitions of these syndromes in terms of specific symptoms were of limited value and proposed that a dimensional classification would probably be more productive. They further postulated that the existence of specific somatic syndromes is largely an artifact of medical specialization; that is to say, the differentiation of specific functional syndromes reflects the tendency of specialists to focus on only those symptoms pertinent to their specialty, rather than any real differences among patients. There may be no more important question than this. For both research and treatment, it is critical to determine whether IC/PBS is really a primary disease of the bladder or part of a larger predisposition to chronic pain.

## ETIOLOGY AND PATHOPHYSIOLOGY

The name “interstitial cystitis” implies a chronic bladder inflammation, and most of the theories about the pathophysiology of this disorder involve inflammation. Abnormally increased numbers of detrusor mast cells and/or abnormal mast cell function<sup>35,36</sup> have been suggested to be key features of the disease. The hypothesis is attractive because of the symptoms of the disease and the association with allergies and food sensitivities. However, although ulcer patients clearly have classic chronic inflammation on biopsy, the majority of subjects in the NIDDK Interstitial Cystitis Database study did not have significant histologic inflammation.<sup>37</sup> Moreover, treatment with mast cell inhibitors has been largely disappointing, and urinary histamine and its metabolites have not been reliable markers for the disease.<sup>38</sup>

Autoimmune dysregulation and chronic inflammation have also been proposed as an etiology. The demographic distribution of young female patients parallels that of other autoimmune diseases, and several autoimmune disorders are associated with IC, as discussed earlier. However, it does not seem possible that IC is an autoimmune disease in the classic sense, because many histologic studies have failed to demonstrate the expected pathologic changes. Positive clinical results from recent studies using cyclosporine have generated renewed interest in this hypothesis.

For many years, the primary theory of IC pathogenesis was a deficiency in the protective glycosaminoglycan (GAG) layer of the bladder. Parsons and others suggested that GAGs are quan-

tatively and qualitatively diminished. A unifying theory of urologic pelvic pain centered on epithelial cell dysfunction was proposed by Parsons.<sup>39</sup> The concept is that the defective urothelial barrier allows potassium and other solutes to diffuse back into the bladder, stimulating pain nerves and creating local inflammation. IC patients are clearly more sensitive to intravesical potassium (see later discussion), but actually proof of abnormal bladder permeability has been elusive. In addition, treatment aimed at restoring the GAG layer has been relatively disappointing. The clinical or basic science breakthrough that would substantiate this attractive theory has yet to arise.

The most promising scientific research in IC involves antiproliferative factor (APF). The presence of a substance in the urine of IC patients that inhibits urothelial cell growth in culture (but is not cytotoxic) was first described in 1996 by Keay and colleagues.<sup>40</sup> Subsequent work from the same group demonstrated that APF was found in bladder urine but not in urine taken from the renal collecting system,<sup>41</sup> that it was found in almost all IC patients but rarely in normal controls or in patients with other urologic disorders,<sup>42</sup> and that abnormally high levels of APF reverted to normal after patients were treated by bladder distention and sacral nerve stimulation.<sup>43,44</sup> APF activity also has been shown to correlate with other known epithelial growth factors EGF and HB-EGF.<sup>45</sup> The structure of APF was finally elucidated in 2004 by Keay and colleagues<sup>46</sup>; it belongs to the family of frizzled 8–related sialoglycopeptides and has 100% homology to the sixth transmembrane segment of the G protein–coupled Wnt ligand receptor. At this time, there is no easy test to assess APF, because the assay still depends on a cell culture. If an antibody-based assay can be developed in the future, it could have a major impact on the diagnosis of IC/PBS. This in turn would greatly facilitate both clinical and epidemiologic research. The ultimate question is whether APF is a simply a marker associated with the disease or is integrally involved in its pathophysiology.

Warren and colleagues have investigated the possibility that susceptibility to IC is inherited. One study involved a pilot mail-in study of members of the Interstitial Cystitis Association.<sup>47</sup> The participants were asked about the presence of IC symptoms and a diagnosis of IC in all first-degree relatives. Diagnosis was not confirmed in the probands or relatives. The survey found that women, aged 31 to 73 years, who were first-degree relatives of patients with IC, themselves had a prevalence of IC of 995/100,000. This suggests a relative risk of up to 17 times that in the general population, based on Curhan’s study of IC prevalence.<sup>15</sup> This team also investigated IC in twins. Of the co-twins of 8 monozygotic twin respondents, 2 had probable and 3 had confirmed IC, compared with none of the co-twins of the 26 dizygotic twin respondents (including 15 female co-twins). Although this is a very small sample, the striking results suggest that there may be a genetic susceptibility to IC.<sup>48</sup>

## CURRENT DIAGNOSTIC TESTS AND STRATEGIES

As discussed earlier, the 1988 NIDDK research criteria are the product of “expert opinion” and were intended to ensure that the populations in research studies would be comparable. The criteria were not intended for clinical practice; even in the research setting, they function suboptimally by excluding too many appropriate subjects. Because of this controversy, the NIDDK charged a subcommittee to examine the evidence

supporting current diagnostic strategies and knowledge and identify the gaps to be filled. This was intended to be the first step in moving toward an evidence-based definition of IC and to include specific recommendations for future research that would create the necessary evidence. Individual participants reviewed the published data on urodynamics, biomarkers, potassium sensitivity testing, cystoscopy with distention and biopsy, and questionnaires. The conclusions of each reviewer were discussed and modified by the whole subcommittee. Each author then presented the conclusions for public comment at the 2003 NIDDK Interstitial Cystitis Research Symposium on November 1, 2003, in Alexandria, Virginia. This meeting was attended by more than 250 international experts in IC, including clinicians from many different specialties and basic science researchers. The subcommittee found that, in the 15 years since publication of the original NIDDK guidelines, no high-quality evidence had been developed to support the routine use of any diagnostic test in defining IC. The specific findings and recommendations are included in the following sections.

### Urodynamics

Urodynamic studies are required to diagnose IC by the NIDDK entry criteria. Despite this fact and the many papers that purport to study IC based on the NIDDK criteria, the reviewers in 2003 identified only 10 papers that described urodynamic findings. The NIDDK criteria include the presence of noncompliant filling as a positive factor in the diagnosis and the presence of involuntary detrusor contractions (IDCs) as an exclusionary factor. However, although diminished compliance appears to occur in a subset of patients with IC/PBS, this feature of the disease has not been characterized sufficiently to be of any clinical value. At the same time, IDCs are consistently reported in a subset of IC/PBS patients and correlate with symptom severity. No data were found to suggest that these patients are different from patients who do not have IDCs. It was concluded that IDCs should not be used to exclude a diagnosis of IC/PBS. One important point presented was that most of the reports did not include any assessment of pain during bladder filling and that the standard urodynamic terms of “first desire to void” and “urgency” may not be adequate to describe urodynamics in patients with IC/PBS.<sup>49</sup>

My colleagues and I use urodynamic testing selectively, with the primary indications being the presence of significant incontinence, prominent voiding difficulty or high residual urine, and failure to respond to treatment. The test is adapted from the technique described by Teichman and colleagues.<sup>50</sup> We typically perform a baseline filling/voiding cystometrogram. This is followed by a potassium sensitivity test (PST) as described by Parsons.<sup>51</sup> The bladder is then anesthetized with alkalinized lidocaine, as described by Henry,<sup>52</sup> and cystometry is repeated. It is important that voiding be adequately evaluated before the PST and lidocaine instillation, because there is a significant incidence of voiding abnormalities, much of it related to pelvic floor dysfunction, and this may offer a separate avenue for therapy (see later discussion of pelvic floor therapy).

### Cystoscopy with Bladder Distention and Biopsy

More than 50 papers including data on cystoscopy, bladder distention, and bladder biopsy were reviewed.<sup>53</sup> Although the presence of glomerulations after bladder distention has long been

considered to be the sine qua non of IC, there is no body of evidence to support this hypothesis. The sensitivity of glomerulations as a marker for IC was questioned by Awad and colleagues.<sup>54</sup> This group defined patients with subjective symptoms of IC and supportive urodynamic findings. They found no difference between those who did and did not have glomerulations after bladder distention in histology or in response to treatment. The specificity of glomerulations was questioned by Waxman and associates.<sup>55</sup> They photographed bladder distentions performed on asymptomatic women presenting for elective tubal ligation. The photographs were reviewed by outside experts along with similar photographs taken from distentions of IC patients. The study conclusively demonstrated that the bladder mucosal lesions characteristically associated with irritative voiding symptoms and pelvic pain in patients diagnosed with IC were also observed in asymptomatic women. More recently, Erickson and colleagues<sup>56</sup> prospectively evaluated 36 patients undergoing bladder distention using the NIDDK cystoscopic criteria. They found no difference in symptoms or in response to the procedure between those who did and did not meet cystoscopic criteria for IC. There was no difference in histology or urine markers. They concluded that, “cystoscopic criteria do not appear to identify a distinct pathophysiologic subset of patients with IC symptoms.”

It would thus appear that cystoscopy under anesthesia with bladder distention cannot be recommended as a mandatory test. At the same time, patients with chronic disease are often concerned about cancer and crave more information about their disease. Either the patient or the clinician may feel a need for further evaluation. IC does not appear to predispose patients to bladder cancer. On the other hand, several authors have published cases series of patients who were misdiagnosed with either IC or chronic pelvic pain and actually had bladder cancer or carcinoma in situ.<sup>57-59</sup> This is of great concern because of the trend away from examining all patients with cystoscopy. It is certainly important to maintain a high index of suspicion in these patients and to use diagnostic studies such as cystoscopy and cytology prudently. In selected patients, office cystoscopy can be well tolerated and can provide the necessary information to exclude other diseases (although the bladder can rarely be distended enough to produce glomerulations without severe pain in the absence of anesthesia). If cystoscopy is performed under anesthesia, abnormal or suspicious areas should certainly be biopsied, but there is as yet no evidence that routine biopsies of normal areas or glomerulations provide useful diagnostic or therapeutic information. At the present time, it seems rational to conclude that cystoscopy should still be used for patients with PBS and microscopic hematuria or pyuria, risk factors for bladder cancer, and for those patients for whom empiric therapy has failed. Two investigators have suggested that the likelihood of identifying any specific cause for microscopic hematuria in young women with PBS is very low.<sup>60,61</sup> Perhaps such low-risk patients might be initially evaluated with ultrasonography and cytology.

### Biomarkers

APF was discussed in detail earlier. Currently, there is no clinically useful biomarker for IC/PBS. There is a need for large, multicenter prospective studies, including a broad spectrum of patients with lower urinary tract symptoms and pelvic pain, in which APF (and other putative biomarkers) can be tested on all

patients at enrollment and correlated with eventual diagnosis and response to therapy.

### Potassium Sensitivity Testing

The most controversial tool in the IC/PBS diagnostic armamentarium is the PST. First described by Parsons,<sup>51,62</sup> the PST has been studied more extensively than any other test. In this test, 50 mL of sterile water and 50 mL of 0.4N KCl are instilled into the patient's bladder sequentially, and the patient is asked to rate the degree of pain and urgency on a scale of 0 to 5. An increase of 2 points in either symptom is considered a positive test. It should be noted that the PST assesses sensitivity to intravesical instillation of potassium. The concentration used is pharmacologic, not physiologic. A positive test may indicate increased permeability of the urothelium to potassium, increased sensitivity of the bladder nerves, or some combination of the two.

Many investigators using very different patient populations have unanimously concluded that this test separates IC patients from normal subjects. The question is whether the test meaningfully separates patients with IC/PBS from those with other diseases. Reports document high rates of positive testing in patients with prostatitis, urethral syndrome, and a wide variety of gynecologic disorders, as well as a substantial minority of patients with detrusor overactivity (Table 92-5).<sup>63-65</sup> As discussed earlier, Parsons<sup>39</sup> has proposed that the test accurately identifies a large group of patients with undiagnosed IC/PBS who share a common uroepithelial dysfunction. Another explanation for the wide positivity of the test is the concept of neural cross-sensitization and referred pain. FitzGerald and colleagues<sup>66,67</sup> studied pain responses in PBS patients. They first demonstrated that subjects with PBS exhibit bladder hyperalgesia and may sense bladder discomfort at sites other than suprapubic. They were able to show that the rating of bladder discomfort and sensory mapping during cystometry usefully distinguishes between PBS subjects and controls (no pain, stress incontinent or continent). A second study examining patients with PBS, overactive bladder, or stress incontinence and normal controls found that most of the patients

with PBS and some of those with overactive bladder experienced their bladder discomfort or urgency at referred sites other than suprapubic. They postulated that the etiology of widespread sensation may include an expansion of dermatomes of referral of bladder sensation, and/or the presence of associated somatic abnormalities.

Even more intriguing is the work by Pezzone and colleagues in a rat model of referred pelvic pain. In the first study, after acute bladder irritation, dramatic increases in abdominal wall electromyographic activity in response to rectal distention were observed, indicating colonic afferent sensitization. Analogously, after acute colonic irritation, bladder contraction frequency increased by 66%, suggesting sensitization of lower urinary tract afferents.<sup>68</sup> In the second study, colonic irritation was shown to sensitize urinary bladder afferents to noxious mechanical and chemical stimuli (including bladder distention, capsaicin, bradykinin, and substance P). Interruption of the neural input to the bladder minimized this effect, suggesting a local afferent pathway from the colon. This work suggests the stimulating hypothesis that the overlap of chronic pelvic pain disorders may be a consequence of pelvic afferent cross-sensitization.<sup>69</sup>

The PST was examined in two prospective double-blind trials to determine the utility of the test in predicting response to therapy aimed at improving the bladder GAG layer. A three-armed study investigating different doses of pentosanpolysulfate sodium (PPS; 300, 600, or 900 mg daily) enrolled patients based on symptoms and performed PST on all subjects at entry. In the 377 patients evaluated at baseline, the PST was positive in 302 (80.1%), negative in 51 (13.5%), and indeterminate in 24 (6.4%). The PST had no predictive value, because significant responses to treatment were seen in 92 (60%) of the 153 patients who were PST-positive at entry and in 20 (64%) of the 33 who were PST-negative.<sup>63</sup> In contrast, Gupta and colleagues<sup>70</sup> performed the PST on 36 patients who went on to receive intravesical sodium hyaluronate. They found that 20 (55%) of 36 patients reported an improvement after six doses, but 17 (74%) of those with a positive PST result improved, compared with only 5 (22%) of those with a negative test ( $P = .03$ ). Further examination of the role of PST in identifying patients for such intravesical therapy seems appropriate.

In summary, the PST is not a physiologic test, and it assesses bladder sensitivity, not necessarily permeability; development of a practical test to conclusively measure urothelial permeability in humans would be enormously helpful in directing clinical care and research efforts. The specificity of the PST has not been established. However, the test is simple and inexpensive and clearly separates IC patients from normal controls; it is possible that further research will define a role for the test in the diagnosis of IC/PBS. In a large-scale, prospective randomized controlled trial (RCT), the PST did not predict response to PPS therapy, but in a smaller trial it did seem to predict response to intravesical sodium hyaluronate.

### Questionnaires

Three questionnaires are in common use in IC/PBS: the University of Wisconsin, O'Leary-Sant, and PUF scales. Although all may be used to monitor patients longitudinally, there is no evidence that any questionnaire can be used to diagnose IC. Many epidemiologic studies are investigating the use of all or part of these instruments as screening tools to estimate prevalence in large populations.

**Table 92-5 Results of Testing for Epithelial Dysfunction in Populations of Symptomatic Patients**

Population	N	No. Positive for Epithelial Dysfunction (%)
Interstitial cystitis	1629	1285 (79)
Urethral syndrome	116	64 (55)
Chronic pelvic pain (gynecologic patients)	365	288 (79)
Category IIIA-III B prostatitis (chronic pelvic pain syndrome)	44	37 (84)
Lower urinary tract symptoms		
Men	526	83 (16)
Women	25	2 (24)
Acute bacterial cystitis	4	4 (100)
Detrusor instability	16	4 (25)
Radiation cystitis	9	9 (100)

**Table 92-6 Oral Therapy Level of Evidence\***

Treatment	Level of Evidence	Grade of Recommendation
Amitriptyline	2	B
Cyclosporine	4	C
Analgesics	5	C
Hydroxyzine	1	D
Cimetidine	4	D
Methotrexate	4	D
Misoprostol	4	D
Montelukast	4	D
Nifedipine	4	D
Quercetin	4	D
Behavioral modification	5	D
Dietary manipulation	5	D
IPD 1151T	4	N/A
Sodium pentosanpolysulfate	1	-C
Antibiotics	4	-C
L-Arginine	-1	-A

There are several different systems of Levels of Evidence. For example the Oxford CEBM gives:

- Level A: consistent Randomised Controlled Clinical Trial, Cohort Study, All or None, Clinical Decision Rule validated in different populations.
- Level B: consistent Retrospective Cohort, Exploratory Cohort, Ecological Study, Outcomes Research, Case-Control Study; or extrapolations from level A studies.
- Level C: Case-series Study or extrapolations from level B studies
- Level D: Expert opinion without explicit critical appraisal, or based on physiology, bench research or first principles

## THERAPEUTIC OPTIONS

### Overview

The inherent difficulty in managing a disease of unknown etiology characterized by chronic pain can produce a therapeutic nihilism, because there are few treatments that produce significant benefit for the majority of patients and little guidance for the physician or patient. Patient management is further compromised by the lack of quality RCTs. The evidence base supporting various treatments for IC/PBS was summarized by the International Consultation for Incontinence (ICI).<sup>71</sup> Oral and intravesical treatments commonly used are listed in Table 92-6, along with their associated level of evidence and grade of recommendation. The highest level of evidence comes from randomized clinical trials and the lowest level from “expert opinion.” The highest grade of recommendation stems from consistent level 1 evidence (multiple RCTs or meta-analysis). These criteria follow the standards of the Oxford Centre for Evidence-Based Medicine (<http://www.cebm.net>).

These treatments are discussed in more detail in the following sections, along with neuromodulation techniques and surgical therapy. Although a common approach is to start with behavioral therapies, followed by oral treatment and then intravesical therapy, I prefer to give the patient significant leeway in selecting

the treatment that seems most appropriate to his or her individual situation; the ICI Committee recommendations are similar. Because there are no useful comparative trials that can be used to direct therapy for an individual patient, there is considerable room to individualize treatment. Oral therapy is simple and convenient; however, the patient must accept long-term treatment and the attendant side effects. Intravesical therapy is invasive and produces considerable anxiety for many patients; this is balanced by the lack of systemic side effects as treatments are delivered directly to the bladder. The frequent trips to the doctor’s office can be very inconvenient. However, many patients learn to self-administer treatments, providing a tremendous sense of control over the disease. The time required for a response to intravesical therapy is typically shorter than what may be seen with oral medications, and intravesical therapy is attractive if the diagnosis is in doubt. A clear response to intravesical therapy supports a diagnosis of IC/PBS as opposed to other causes of pelvic pain.

The hierarchy of goals in treating IC/PBS is as follows:

1. Relieve symptoms
2. Restore normal bladder function
3. Maintain response after withdrawal of treatment

Too often, only the first goal is addressed. The key to managing these cases is keeping the goal of normal bladder function in mind. The clinician should start with three pieces of information: the primary symptoms, a bladder diary with volumes, and a symptom score. These should be assessed at the outset of every new treatment and reassessed at an appropriate point during or after treatment. This, along with the presence or absence of side effects, informs the decision as to whether the treatment should be continued or abandoned and whether additional treatment is indicated. In many cases, a patient feels great relief after a particular course of therapy and has little interest in adding more treatment. The patient may not appreciate that there is room for further improvement, may be wary of potential adverse effects, or may simply not want to “rock the boat” after experiencing improvement. Regular use of the symptom scores can alert the clinician that the patient, although reporting a great response, still has significant ongoing symptoms. In other cases, the symptom score is low but the bladder diary demonstrates that the functional capacity remains small. In such cases, true bladder rehabilitation has not been achieved, and ongoing treatment is indicated, even if its focus is limited to bladder training/behavioral modification. Normalization of bladder function—achieving a normal voiding pattern, normal capacity, and normal control without pain—should be the ultimate focus. If this can be achieved and maintained, then there is a realistic chance that treatment can be withdrawn successfully and the bladder will be rehabilitated. If bladder function is not normalized, it is unlikely that treatment can be withdrawn, regardless of the symptomatic success. A rule of thumb is that medication titration can begin after 6 months with no pain and normal functional bladder capacity.

### Behavioral Therapies

Behavioral therapies include bladder training and various forms of behavioral modification, including dietary restrictions, urinary alkalization, fluid management, relaxation/stress management, and so on. Although behavioral therapies have been almost uniformly recommended as being helpful and harmless, there has

been almost no useful research into the true efficacy of these treatments or the optimal way of delivering them. Bladder training was shown to be effective in at least two uncontrolled clinical studies<sup>72,73</sup> and should be part of the prescription for almost all patients. The initial bladder diary is used to establish baseline function and set goals. The patient should practice delaying urination for 10 to 20 minutes after experiencing a normal urge, but not holding to the point that pain is induced. Many patients have too much pain to use bladder training initially. Other treatments and general pain management can be used initially, with bladder training added after adequate pain relief has been achieved. Basic science research showing that production of APF is inhibited by bladder distention (Chai 2000)<sup>43</sup> suggests a mechanism by which bladder training might ultimately be instrumental in reversing the underlying pathophysiology of disease.

Dietary restriction has been recommended as a first and essential step in managing all cases of IC/PBS. However, there is no good evidence to support the efficacy of dietary management. The most common reported sensitivities are to “acidic” foods such as citrus and tomatoes, spicy foods, alcoholic beverages, and coffee/caffeine. Others have suggested that high-protein diets can induce pain through high urine urea concentrations, that food allergies stimulate the disease, and that additives such as dyes are the cause of pain. Indeed, a large proportion of these patients do report sensitivities to various foods, but there is no evidence that eating suspect foods leads to progression of disease or that restrictions improve the course of the disease. Therefore, the benefit of any dietary management must be weighed against the diminished quality of life associated with dietary restriction. The so called “IC diet” eliminates an enormous number of foods and results in a bland, unattractive regimen that does not promote good overall health. Because many patients never identify any dietary items that provoke symptoms, the diet cannot be universally recommended except as a tool to aid in the search for potential sensitivities. After 1 to 2 weeks on the restricted diet, the patient can assess any improvement and then begin adding back foods to look for reactions. If sensitivities are identified, the patient can reasonably weigh the increase in symptoms against the pleasure obtained from the particular menu item. Acid sensitivity can sometimes be managed by use of dietary supplements such as Prelief, various neutraceutical, and oral antacids. It is regrettable that many patients are forced to give up some of their favorite foods, such as tomato sauce, red wine, and spicy ethnic cuisines, due to sensitivities. It is tragic that others are forcefully instructed to give up such foods without ever experiencing any benefit.

In the same way that dietary measures are recommended in a common-sense approach without substantive data, patients are often advised to drink more water to keep the pH higher and dilute irritating components. Some patients do respond favorably, and some benefit from urinary alkalinization. However, one randomized trial<sup>74</sup> showed no difference in sensitivity between instillations of acidic urine and buffered urine. It would seem reasonable to examine the effect of urine alkalinization and increased free water critically for individual patients but to realize that, for many, this may only produce an increase in urinary frequency.

Stress management can be useful in most chronic pain conditions. There is an accumulating body of evidence that the hypothalamic-pituitary axis is abnormal in patients with pelvic pain and also in the spontaneously occurring feline cystitis model. Although there are no good clinical trials to support the effectiveness of these therapies, it seems reasonable to consider counsel-

ing, yoga, meditation, and other techniques that might allow the patient to reduce stress and anxiety. General pelvic muscle relaxation employing biofeedback has been used successfully (see later discussion).

### Oral Therapies

The mainstay of therapy for IC/PBS has been oral medications. As pointed out earlier, the level of evidence for almost all oral medical therapies is low. The most commonly recommended agents are PPS (Elmiron), hydroxyzine (Vistaril and Atarax), and amitriptyline (Elavil). Interestingly, a survey of practice patterns from the INGENIX database indicates that anticholinergic medications are actually the most commonly prescribed drugs for IC/PBS. Although it seems logical that medications designed to treat the frequency and urgency of overactive bladder might be effective for the frequency and urgency of IC/PBS, there is no evidence that this is true. Given that patients with overactive bladder are presumed to have IDCs as the source of the symptoms and that such findings are uncommon in patients with IC/PBS patients, one might even postulate that anticholinergic medications could produce as much harm as good, by making it more difficult to empty the bladder. Antibiotics are similarly prescribed very commonly, but there is no good evidence that intensive therapy is beneficial<sup>75</sup> and “no evidence to suggest that antibiotics have a role in the treatment of IC in the absence of culture-documented infection.”<sup>71</sup> There are patients who clearly have recurrent bacterial cystitis but also suffer significant bladder symptoms in the absence of infection. In such cases, a 3- to 6-month course of antibiotic prophylaxis along with supportive therapy for the lower urinary tract symptoms would seem to be appropriate.

PPS is the only oral medication that is approved by the U.S. Food and Drug Administration (FDA) for treatment of IC. It is structurally similar to components of the urothelial GAG layer and is intended to repair a postulated GAG defect that allows toxic and inflammatory components of the urine to diffuse back into the bladder. The recommended dose is 100 mg three times daily. Unlike most other medications, it has been examined in a number of RCTs of reasonable quality. The ICI committee concluded that the evidence shows that PPS is ineffective in treatment of IC/PBS with a C level recommendation. The results of the three placebo-controlled, randomized clinical trials are summarized in Table 92-7. The results are reasonably consistent, with three of the four studies demonstrating efficacy or a strong trend toward efficacy for PPS over placebo. The overall utility is not great, with only about one third of patients responding, but the low response rate is balanced by a low incidence of side effects. In the RCTs, the overall incidence of adverse events with PPS was similar to that with placebo. Hair loss is an infrequent but potentially distressing problem affecting 2% to 3% of patients. It can sometimes be managed by reducing the dose and is reversible when the drug is discontinued. Safety has been confirmed in long-term, open-label continuation studies, and the benefit obtained by responders appears to be durable.<sup>76,77</sup> Van Ophoven and colleagues reported that patients with a minor response to PPS might see additional benefit from the addition of subcutaneous heparin, also an analogue of the bladder GAG layer.<sup>78</sup>

PPS should be administered for a minimum of 3 and preferably 6 months before it is abandoned as ineffective. If a clear effect is seen, then the response can be cumulative and improvement may continue gradually over 1 year or longer. It is therefore

**Table 92-7 Results of Three Placebo-Controlled, Randomized Clinical Trials of Pentosanpolysulfate Sodium (PPS) for Treatment of Interstitial Cystitis**

Author	Year	Design	N	Dosage	Duration	Outcome Measure	Results
Holm-Bensten	1987	Double-blind, placebo, RCT	114	200 mg bid	4 mo	More than "slight improvement"	28% vs 13%
Mulholland	1990	Double-blind, placebo, RCT	110	100 mg tid	3 mo		
Parsons	1993	Double-blind, placebo, RCT	148	100 mg tid		50% Overall improvement	32% vs 16%
Sant	2003	2 × 2 with hydroxyzine and PPS	121	100 mg tid			34% vs 18%

RCT, randomized controlled trial.

critically important to establish baseline symptoms clearly and to define the treatment plan at the outset of therapy, because many patients are confused as to whether to persist on medications, and some inappropriately continue the medication for years in the absence of any benefit. In summary, PPS is a safe medication that offers a reasonable chance of improving the symptoms of IC/PBS, and it can be offered to those patients who are willing to commit to a fairly long course of therapy. It is, again, the only oral medication specifically approved by the FDA for IC/PBS and certainly should be offered to all patients at some point in their treatment. PPS was developed specifically to cure the proposed pathophysiology of IC. As such, clinical results with the drug have been quite disappointing. However, new research is providing insights into the pharmacology of the drug and may ultimately lead to improved efficacy. PPS is a heterogeneous mixture of molecules with varying sizes and charges. Only recently has a reliable laboratory assay been developed to track PPS excretion. Erickson and colleagues<sup>79</sup> determined that the median urine PPS level in 34 patients with IC was 1.2 µg/mL (range, 0.5 to 27.7 µg/mL) and that all PPS recovered from the urine patients with IC who were taking oral PPS comes only from the low-molecular-weight fraction.<sup>79</sup> In contrast, rabbit studies have shown that the high-molecular-weight fraction of PPS is recovered in small amounts from urine after intravenous administration but not at all after oral administration. The authors concluded that the low-molecular-weight fraction has greater gastrointestinal absorption and urine excretion. They speculated that IC patients with low PPS levels could have achieved better symptom relief if their PPS levels had been higher and that improved PPS bioavailability might come from using only the LMW fraction of PPS or by placing PPS into different vehicles. The same group went on to test this theory by attaching galactosyl residues to PPS to promote binding to the endogenous lectins in the bladder.<sup>80</sup> The hypothesis is that increased binding may improve efficacy for treating IC. They were able to show that only 2% to 4% of PPS and heparin binds to the bladder but that this can be substantially increased by using lactose-PPS and lactose-heparin. In the future, clinical trials of modified drugs may demonstrate improved effectiveness for IC than the parent compounds. Another group examined a different approach, putting PPS into a novel formulation with a lyotropic liquid and an absorption enhancer. The liquid converts to mucoadhesive gel with water. In a rat model, the absolute bioavailability increased from 1.9% at baseline to 46.4% with the new model. Again, the ultimate test is whether improved bioavailability will improve outcome, but the preliminary research is very promising.<sup>81</sup>

Amitriptyline and other tricyclic antidepressants have been commonly used in the treatment of IC/PBS as well as for a wide variety of other chronic pain syndromes. Although individual clinicians may have "favorite" drugs from this category, only amitriptyline has strong evidence to support its efficacy. Several uncontrolled studies suggested that amitriptyline was effective for those patients who were able to tolerate it,<sup>82-84</sup> although discontinuation of therapy due to adverse events was common. Van Ophoven<sup>78</sup> reported a single-center RCT demonstrating a greater than 30% reduction in symptom score for 42% of patients treated with amitriptyline, compared with only 13% for those treated with placebo. Surprisingly, the dropout rate was only 1 of 25 in each arm of the study. A National Institutes of Health-sponsored clinical research group is investigating the use of amitriptyline in the treatment of newly diagnosed PBS.

Amitriptyline is typically started at either 10 or 25 mg taken nightly at bedtime and titrated up to a maximum of 75 mg as tolerated. The mechanism of action is not known, but it does not appear that the effect is due to treatment of an underlying mood disturbance; the dose used for depression is usually greater than 150 mg. Most clinicians do not monitor blood levels when these lower doses are used. Amitriptyline has strong antihistaminic effects (see later discussion) and has central antinociceptive actions. The primary side effects are sedation along with other central nervous system problems, constipation, dry mouth, and weight gain. Palpitations and arrhythmias are associated with this class of medication, and the drug should be used cautiously, if at all, in patients with underlying cardiac rhythm disturbances. Careful, slow dose titration can provide an opportunity for patients to accommodate to the side effects and continue therapy. Sedation can be beneficial for patients with problematic nocturia, and constipation can generally be prevented or easily managed if it is anticipated. Some patients respond favorably to very low doses of 10 to 20 mg but, I recommend continuing titration to side effects then dropping back to the comfortable dose. The goal, as always, is to get the most out of every treatment and to aim for not only relief of symptoms but normalization of bladder function. Once the optimal dose is determined, about 6 to 8 weeks should be allowed to see a response before discontinuing treatment. It is safest to titrate down when discontinuing the drug, although this can be done more rapidly than when titrating up. Amitriptyline is a good choice for IC/PBS patients with pain as a predominant symptom, for those with bothersome nocturia, and, of course, for those with concomitant depression (although collaboration with a psychiatrist in choosing the dose is recommended).

Hydroxyzine and other antihistamines are commonly used to treat IC/PBS, based on the theory that abnormal mast cell function is a key part of the disease pathophysiology. However, the quality of research and evidence to support the effectiveness of these drugs is lacking. Hydroxyzine has been touted as the most effective mast cell–stabilizing agent. It was reported to be effective in a series of IC patients selected because of associated problems with allergies<sup>85</sup> but was not superior to placebo (31% versus 20%) in the one multicenter RCT that has been performed.<sup>86</sup> Hydroxyzine is typically dosed at 50 mg every night and 25 mg during the day. Some patients respond to lower doses, and some physicians prescribe a single 75-mg dose to be taken at bedtime. Dose titration is usually employed, starting at 25 mg nightly. The most common side effect is sedation but nighttime dosing can convert this into an advantage for those patients with nocturia and/or difficulty sleeping. Other side effects are generally mild. A 6- to 8-week course of therapy after full-dose titration is recommended. Although there are anecdotal reports of success with diphenhydramine and with the selective (nonsedating) antihistamines, there is a paucity of data, and these agents should probably be reserved for patients who are intolerant of hydroxyzine. The histamine 2 blocker, cimetidine, has been reported to be effective in some uncontrolled studies, and one RCT comparing cimetidine at 400 mg twice daily to placebo suggested that cimetidine was superior in reducing pain and frequency.<sup>87</sup> Although more data are needed before the drug can be recommended routinely, it is a generally safe medication and does not cause sedation, so it might be useful if other antihistamines are not tolerated. It is particularly appropriate for the large group of IC patients with seasonal allergies, hay fever, and other atopic disorders. Cimetidine can affect the metabolism of many other medications, and this needs to be considered, because many IC/PBS patients suffer from polypharmacy. When patients do have a complete response, they can often titrate the dose down, but it seems less likely that they will be able to completely stop therapy without experiencing a relapse.

As noted in the ICI report,<sup>71</sup> many other oral medications have been used in treating IC/PBS. Nonsteroidal anti-inflammatories, steroids, and other agents that modulate inflammation, such as quercetin, montelukast, and misoprostol, have all been associated with anecdotal success. There is special interest in immune system–modulating agents, because it has been postulated that IC may have an autoimmune etiology. Small case series have been reported using prednisone and other agents, but a controlled study comparing cyclosporine to PPS has stimulated interest in this form of treatment.<sup>88</sup> Sixty-four patients were recruited and were randomly assigned to receive either cyclosporine at 3 mg/kg (twice daily in divided dosing) or PPS 100 mg three times daily in an open-label study. Cyclosporine was clearly superior to PPS, with a clinical response rate (according to a patient global response assessment) of 75%, compared with 19% for PPS ( $P < .001$ ) after 6 months of treatment. It should be noted that these were relatively severely affected patients; their mean symptom index was 16 out of 20, 15 of the 64 subjects had ulcers, and their mean age was  $56.2 \pm 14.7$  years. The quality of the response was also impressive, with an increase in awake bladder capacity of 81 mL, a decrease in symptom score of 7.9 points from baseline 15.7, and a decrease in nocturia of 2.2 episodes from a baseline of 3.9—all clearly clinically meaningful changes. A previous uncontrolled series by the same author<sup>89</sup> reported that 11 of 20 responders stopped taking their cyclosporine, but symptoms recurred within months in 9 of them. The primary

toxicity of cyclosporine is hypertension and diminished renal function, so careful monitoring is required. All immunosuppressive agents can potentially expose patients to opportunistic infections and even malignancies, but the risk is probably much less than in the transplant population, in whom multiple agents are used simultaneously. There is clearly a need for a great deal more work to confirm and expand these results to other agents and even combination therapy. In the meantime, cyclosporine appears to be a reasonable treatment option for patients with refractory disease if regular follow-up and careful monitoring can be assured.

### Intravesical Therapies

Intravesical therapy is an attractive option for the treatment of IC because of the opportunity to deliver therapy while minimizing side effects. Treatments are limited by patient discomfort, expense, and the relatively poor absorption of most drugs through the bladder. Nevertheless, intravesical therapy is an important part of the therapeutic armamentarium and still presents a great opportunity for further research. Intravesical therapy is preferred by some patients and is an important second-line tool for those who do not respond to oral agents.

Although many agents and combinations of drugs have been given in the bladder for IC/PBS, the only agent specifically FDA-approved for intravesical therapy is dimethylsulfoxide, or DMSO (RIMSO-50). The mechanism of action of DMSO is unknown, although the drug has a number of properties that could be beneficial, including anti-inflammatory, analgesic, muscle relaxation, and collagen dissolution. There has been little quality research on DMSO because it is an older drug and it also has a strong odor that makes blinding very difficult, if not impossible. Perez-Marrero and colleagues<sup>90</sup> performed a placebo-controlled, crossover study involving 33 patients. They found that 53% of DMSO-treated patients were markedly improved, compared with 18% of the placebo-treated patients. Of the DMSO group, 93% had objective improvement, compared with 35% of the placebo group. Peeker and colleagues<sup>91</sup> compared DMSO to bacillus Calmette-Guérin (BCG) in 21 patients using a crossover trial, finding some response to DMSO but none to BCG. However, this study was criticized for not allowing adequate time for BCG to take effect. Many other uncontrolled studies have suggested that more than 60% of patients with IC/PBS will respond to intravesical DMSO, although the relapse rate is high, perhaps up to 50% in the first year. My colleagues and I typically use a cocktail of DMSO with alkalized lidocaine and steroids, giving six weekly treatments. It seems reasonable to add steroids to the DMSO solution, because it is unlikely that they can be absorbed without DMSO. Patients are assessed with the use of symptom scores and voiding diaries. Those with objective and subjective responses then continue on monthly maintenance therapy and may be gradually titrated off therapy. It is common for patients to have a mild increase in symptoms during the first two treatments, and they should be counseled about this possibility. Most patients tolerate the treatments quite well; those who do not have usually been given “straight” DMSO instead of a “cocktail,” which reduces the initial pain, or they have been instructed to hold the solution for an extended period of time. Absorption of DMSO is rapid, and retaining the solution for 15 minutes is probably more than adequate.

Many other agents have been proposed for intravesical use. Heparin, PPS, and hyaluronic acid/sodium hyaluronate are all

GAG layer analogues that have been used with anecdotal success. However, two large controlled trials of sodium hyaluronate apparently showed no efficacy,<sup>92</sup> and no controlled studies have been done with the other agents. We typically use 20,000 units of heparin with alkalized lidocaine administered daily to three times per week for patients who are intolerant of DMSO or who like the ability to gain symptom control with daily self-instillations. It is essential that the clinical utility of intravesical GAG therapy be carefully analyzed, because oral bioavailability of GAGs is poor. It is critically important to determine whether GAG therapy can actually be used to treat most patients with IC/PBS. At this time, essentially nothing is known about the optimal agent or combination of agents, the optimal dose or dosing schedule, or the long-term safety and efficacy of treatment. These questions are amenable to RCTs if a collaborative group with adequate funding would take up the challenge.

Most other intravesical therapies fall into the category of initial hope followed by disappointment. Intravesical BCG showed promise in a controlled pilot study<sup>93</sup> and seemed to produce a durable response in a few patients.<sup>94</sup> However, a multicenter randomized study conducted by the NIDDK research network did not confirm the early work. A total of 265 patients were randomized to receive six weekly BCG instillations or saline instillation. The adjudicated response rates, based on the patient's global response assessment plus medication usage, were 12% for placebo and 21% for BCG ( $P = .062$ ). The primary reason for the observed difference in response rates was that 15 of the patients taking BCG reported being "markedly improved," compared with only 5 of those taking placebo.<sup>95</sup> Similarly, capsaicin and its ultrapotent analogue, resiniferatoxin (RTX), appeared to offer great promise in the laboratory and in uncontrolled pilot trials,<sup>96-98</sup> but RTX failed in a pivotal phase II study. A randomized, double-blind, placebo-controlled study was conducted in 163 patients with IC; the participants were randomly assigned to receive a single intravesical dose of 50 mL of RTX at 0.01  $\mu\text{mol/L}$ , 0.05  $\mu\text{mol/L}$ , or 0.10  $\mu\text{mol/L}$  or placebo. At the primary end point, RTX did not improve overall symptoms, pain, urgency, frequency, nocturia, or average void volume during 12 weeks of follow-up. RTX resulted in a dose-dependent increase in

the incidence of instillation pain but was otherwise generally well tolerated.<sup>99</sup> Both of these studies had a significant effect on the IC research community in directing efforts away from these areas.

Currently, there has been interest in using botulinum toxin for IC/PBS, based on excellent results in patients with detrusor overactivity and the possibility of similar activity on sensory nerves. A small, uncontrolled pilot study included 13 patients in the United States and Poland who received either 100 or 200 units of botulinum A toxin (BTX-A) or Dysport. Nine (69%) showed a subjective response, and there was no urinary retention. In contrast, Kuo<sup>100</sup> injected 10 IC patients with either 100 units into the detrusor or 100 units in the detrusor plus an additional 100 units into the trigone. None of the patients was symptom free, and only limited improvements in bladder capacity and pain score were achieved in 2 patients. In this group, 7 of the 10 patients had subjective emptying symptoms, although there was no overt retention. In my own experience, one woman required intermittent self-catheterization for 2 months after a single injection. Although there is ample scientific rationale to be interested in botulinum toxin for treating IC/PBS, the ICI group concluded that, "Botox cannot be recommended for clinical use outside of carefully controlled studies."<sup>71</sup>

### Physical Therapies

There is a clear clinical association between IC/PBS and muscular abnormalities of the pelvic floor.<sup>101</sup> It is not clear whether the pelvic floor myofascial abnormalities are primary or secondary, but the presence of such physical findings has encouraged a number of investigators to pursue pelvic floor physical therapies, including biofeedback, myofascial release, and trigger point injections. Vaginal and anorectal biofeedback therapy has sometimes shown beneficial effect,<sup>102</sup> but the current focus is on active internal physical therapy aimed at specific trigger points. Most preliminary studies have been very positive (Table 92-8). The NIDDK clinical trials group is currently preparing a controlled feasibility study to further investigate the possibility of using PT in men and women with PBS/IC and chronic pelvic pain.

**Table 92-8 Published Effectiveness of Transvaginal Manual Physical Therapy (PT) for Painful Bladder Syndrome**

Author & Year	Subjects & Intervention	Success Rate	How Determined
Weiss, 2002*	52 with IC or urgency/frequency, treated with manual PT to pelvic floor weekly for 8-12 wk	70% of IC patients and 83% of urgency/frequency patients had moderate to marked improvement	Subjective rating of percent improvement over baseline
Lukban, 2001 (abstract only, Whitmore group)	16 female IC with high-tone pelvic floor dysfunction and sacroiliac (SI) dysfunction treated with manual PT of SI joints, hip girdle, and pelvic floor for 2-15 visits	"94% improvement" in Oswestry disability score, symptom score; mean ICSI fell from 16 to 8	Modified Oswestry disability index, symptom scores, ICSI.
Oyama, 2004	21 female IC with high-tone pelvic floor dysfunction, treated with transvaginal Thiele massage <sup>†</sup> twice weekly for 5 wk	Overall rate not reported.	ICSI/ICPI decreased from 9 to 7; urgency VAS decreased from 4 to 3; pain VAS decreased from 5 to 3

\*The methods reported by Weiss are typical of most pelvic floor physical therapists working in this field.

<sup>†</sup>Thiele massage does not require advanced pelvic floor PT training.

IC, interstitial cystitis; ICPI, IC problem index; ICSI, IC symptoms index; VAS, visual analogue score.

Physical therapy presents a very promising avenue for alleviation of symptoms in patients with chronic pelvic pain. A great deal of research is needed to confirm initial results, to refine patient selection, and to determine the optimal and necessary treatment regimen. At this time, there is a severe shortage of qualified physical therapists with interest and expertise in pelvic pain. Only by proving the efficacy of the treatment can more therapists be attracted to the field.

### Nerve Stimulation

Neuromodulation is the most promising new avenue for treatment of refractory IC, and several different techniques are under active investigation. Sacral neuromodulation is clearly the best established treatment modality. Although it has not been formally studied for IC, the Medtronic InterStim device has been approved by the FDA for urinary urgency and frequency since 1997, and many IC patients have benefited from implants. Maher and coauthors<sup>103</sup> first reported on the use of the device in 15 patients with IC. The patients were older (mean, 62 years) and had a dramatic acute response, with 73% going on to receive a permanent implant. Mean bladder pain decreased from 8.9 to 2.4 on a 10-point scale, and mean voided volume increased from 90 to 143 mL. Similar improvements were seen in bladder diary and symptom scores. Results of chronic stimulation were not reported. Comiter<sup>104</sup> described the results in 25 IC patients (mean age, 47 years) who had a trial of percutaneous nerve stimulation or a staged technique. Seventeen (68%) were successful and went on to a permanent implant. Success was much higher with the staged technique (13 of 15 patients) than with the percutaneous evaluation (4 of 10 patients). Striking improvement was seen in symptom scores, pain, and bladder diary variables. Peters<sup>105</sup> also compared the standard percutaneous approach to the new staged implantation technique with similar conclusions. In a separate report, Peters<sup>106</sup> examined the results of sacral neuromodulation for IC after 6 months. Moderate or marked improvement in pain was reported by 20 of 21 patients, and 4 of 18 became free of narcotics. For those taking narcotics at the outset, the morphine dose equivalent decreased from 82 to 52 mg/day. There is a great need to determine the durability of sacral neuromodulation in the IC population and to identify optimal candidates. I recommend patients who have primary urge-frequency and adequate bladder capacity under anesthesia for this therapy, but better data would be welcome.

Other forms of nerve stimulation have not been as impressive. Posterior tibial stimulation was ineffective in 14 patients with refractory IC,<sup>107</sup> and a randomized study of transdermal pulsed laser therapy to the posterior tibial nerve showed no difference between active and sham devices in the treatment of IC.<sup>108</sup> An exciting technology under development is pudendal nerve stimulation. Although no device is yet approved for this use, Peters<sup>105</sup> conducted a randomized trial in which 30 patients underwent simultaneous placement of electrodes at S3 and the pudendal nerve. Twenty-four (80%) of the subjects responded and had a permanent implant placed. The pudendal nerve was chosen as a superior lead in 79.2%; the sacral site was superior in 20.8%. The order in which the leads were simulated had no impact on the final lead implanted, and no carryover effect was seen. Overall reduction in symptoms was 63% for the peripheral nervous system and 46% for the sympathetic nervous system ( $P = .02$ ). This is particularly exciting work, because devices are being tested that could be placed percutaneously in an office setting.

### Surgical Therapies

Surgery is often employed early in the management of IC/PBS; traditionally, bladder distention has been the first treatment most IC patients experience, with the “diagnosis” of IC made by cystoscopy, distention, and biopsy. However, as discussed earlier, the role of cystoscopy in the diagnosis of IC is undergoing a major reevaluation; this, in turn, forces bladder distention to be considered more on its own merits as an IC treatment. Overall, it appears that bladder distention is a marginally effective therapy. Although the quality of reporting is generally poor and dominated by retrospective, highly selected case series, there is general agreement that hydrodistention has a modest and transient value in the treatment of IC/PBS symptoms, with 20% to 60% of patients experiencing partial or complete resolution of symptoms, almost always for less than 6 months.<sup>79,109-111</sup> Because bladder distention is the most expensive and invasive of the primary IC treatments, it seems reasonable to employ it selectively rather than universally.

I recommend selecting patients for distention who either are more likely to benefit from the procedure or may benefit from the diagnostic and prognostic information obtained. There is weak evidence that patients with a large bladder capacity under anesthesia (>600 mL) are less likely to respond to distention.<sup>109</sup> Although functional bladder capacity by voiding diary correlates poorly with bladder capacity under anesthesia, some patients with IC symptoms have fairly normal maximum void volumes on diary (>250 mL). These patients seem to be more likely to have a large capacity under anesthesia and are therefore less likely to benefit from the procedure. In addition, it is probable that these patients might be adequately assessed by office cystoscopy when an evaluation is required for hematuria or some other reason. Patients with very small capacities on void diary (<150 mL) are less likely to tolerate office cystoscopy and somewhat more likely to benefit from a bladder distention. Bladder distention allows the clinician to stratify the findings, giving some objective sense of severity of disease. Although one cannot say that the objective findings directly correlate with prognosis in an individual patient, they do allow for identification of a subgroup of patients with severe disease that might be treated more aggressively and provide some reassurance for those with clearly normal bladder capacity under anesthesia.

Regarding the technique of distention, the critical issues are to adequately characterize the baseline cystoscopy, the findings on distention, and the bladder capacity under anesthesia. Our method is delineated as follows, but it is most important that the clinician be internally consistent in technique.

1. The distention should be performed with the patient under a deep general or regional anesthesia. Local anesthesia and sedation do not allow for a full therapeutic distention. The patient experiences the trauma of the procedure without the potential benefit.
2. The entire urothelium is carefully visualized before distention. Abnormalities present at this time usually represent ulcers that will crack and tear during distention. If abnormal areas are seen, bladder wash cytology and bladder biopsies should be obtained.
3. We distend the bladder for 7 minutes under direct vision at 80 cm H<sub>2</sub>O pressure. In women, digital pressure at the bladder neck may be required to prevent leakage around the cystoscope, which would both produce inaccurate information about the bladder capacity and lessen the

potential therapeutic impact of the procedure. Linear cracking seen during distention after an initially normal cystoscopy is an intermediate-level finding indicating more severe disease with loss of elasticity.

4. The bladder is then drained. At least the first part of the drainage procedure should be done under direct vision through the side port of the cystoscope. Capillary bleeding (glomerulation) may be dramatic but transient and is best seen during the drainage. If possible, photographs taken sequentially during this time help to document the findings for future reference and provide validating information for the patient. The cystoscopic fluid is collected and measured. Terminal hematuria is subjectively graded.
5. If any lesions were seen on the initial cystoscopy, they are biopsied at this time. Ulcers should be completely fulgurated, because this may provide the patient a dramatic response with relief of pain. The value of biopsy when the initial cystoscopy is normal is unclear. Many clinicians prefer to look for detrusor mastocytosis and to treat such patients aggressively with antihistamines. Patients often appreciate the objective data removing the fear of cancer. On the other hand, biopsy adds trauma and risk of complication and has not been shown to affect outcome.
6. A complete report of the procedure includes the baseline findings, the findings during distention, subjective grading of glomerulations and terminal hematuria, and the bladder capacity under anesthesia.

Although the role of cystoscopy and bladder distention has been markedly diminished, it is still an important procedure with some diagnostic, prognostic, and therapeutic value. It does not need to be the initial procedure or treatment, but it should always be performed if the picture is confusing or there is no response to standard treatments.

Special attention is directed to the treatment of ulcers. As mentioned earlier, patients with ulcers often respond dramatically to a variety of local treatments; in fact, Hunner advocated partial cystectomy in such cases.<sup>1</sup> One danger related to the declining role of cystoscopy in the diagnosis of IC is the possibility of overlooking this group of patients, who actually have an excellent prognosis for at least intermediate- to long-term pain relief. Almost all reports agree that complete treatment of ulcers by any of a variety of techniques (partial cystectomy, endoscopic resection, cauterization) produces almost uniform pain relief. Laser treatment without distention has been advocated for ulcer patients, with 13 of 24 subjects having a mean response duration of 19 months after only a single treatment.<sup>12</sup> I agree that ulcer treatment can be performed without distention, but I have not seen any advantage in using the laser over standard electrocautery.

Despite the wide variety of treatment options already discussed, a substantial minority of IC patients suffer from severe frequency and debilitating pain that is refractory to all therapy. Many are disabled by their disease. These patients are candidates for radical surgery. As with other IC treatments, the options are myriad and confusing, and the data to support any particular treatment are suspect. Reasonable minimum requirements for considering radical surgery include the following:

1. An adequate trial of all standard IC treatments and appropriate secondary therapies
2. A concerted effort at pain management, ideally by a specialist in the field

3. Realistic understanding of the nature of the surgical procedure, the risks of the procedure itself, and the possibility that pain may persist even after diversion or complete cystectomy

There is a general sense that patients with objectively severe disease (reduced capacity under anesthesia) are better candidates for surgery. A capacity of less than 350 mL clearly represents a major (and possibly irreversible) change in the bladder. The bladder has lost elasticity and may become progressively fibrotic. If sequential hydrodistentions demonstrate progressive loss of capacity, the picture is even more ominous. Very low capacity can be associated with hydronephrosis, reflux, and intractable frequency and/or pain. Even as new treatments for IC are developed, it is not clear that these bladders can be salvaged. If the bladder capacity is greater than 600 mL under anesthesia, the patient clearly has the potential for complete rehabilitation, and radical surgery should be approached with trepidation. Although the published literature lacks adequate detail and power, there is a strong suggestion that a bladder capacity of less than 350 mL is a predictor for success with surgery. If a surgical approach is chosen, there are a number of options. Some of the published data on the various operations are reviewed in Table 92-9. These approaches are briefly reviewed here, with the key decision making factors for each.

1. *Supratrigonal cystectomy and augmentation*: For a period of time, this procedure was considered standard treatment for severe IC, and there is much more data about it than about other operations. Most of the early enthusiasm has waned, despite good published results. The primary advantage of this approach is simplicity, because there is no need for ureteral reimplantation. Risks include the development of urinary retention and ureteral reflux. Patients should be willing to accept self-catheterization, because the development of retention is unpredictable.
2. *Conduit diversion with or without cystectomy*: I consider conduit urinary diversion to be the standard surgical treatment for patients with refractory IC. The patients can be assured of relief of urinary frequency. Pain relief should be at least as high as with any other surgical therapy, and the risk of recurrent symptoms may be the lowest. It is probable that mere diversion of the urine will produce adequate pain relief in most cases; cystectomy is not routinely required. Some surgeons believe that the diseased organ must be removed to prevent other local complications.<sup>113</sup> The negative aspects of conduit diversion include problems related to the stoma (e.g., skin complications, hernia formation) and the altered body image.
3. *Total cystectomy and neobladder*: The primary alternative to conduit diversion is total cystectomy plus neobladder. The obvious advantage is the possibility of a completely normal lifestyle—normal voiding and a normal body image. On the other hand, this operation is technically more demanding; cystectomy is required and must be carefully performed to provide an appropriate field for the neobladder. The short-term complications of the procedure are therefore higher than with a conduit. The long-term complications are probably less, except for the possibility of recurrent pain. It has been theorized that contact between IC urine and intestine can lead to disease in the intestinal segment; this is not well supported by data, but if it is true, the contact time is much greater with a

Table 92-9 Radical Surgery for Interstitial Cystitis

Author	Year	Operation	N	Initial Response	Follow-up (Mean [Range])	Comments
Begany and Politano	1995	Neobladder	5	100% pain free	52 mo (3-78 mo)	All had <250 mL anesthetic capacity and were continent; 2 were on self-catheterization
Nurse et al.	1991	Neobladder	8	NR	NR	Offered to patients with IC in trigone by biopsy, one patient with SUI
Costello et al.	2000	Supratrigonal cystectomy and ileocystoplasty	5	100% pain free	18 mo (3-69 mo)	Anesthetic capacity 120-350 mL, all patients continent, 2 patients on self-catheterization; only 2 had follow-up >3 mo
Webster and Maggio	1989	Supratrigonal cystectomy and augmentation	19	12 no symptoms, 4 pain free but with frequency, 2 self-catheterization	39 mo (12-76 mo)	Anesthetic capacity 150-550 mL, 16/19 right colon, some not detubularized, 4 with reflux
Peeker et al.	1998	Supratrigonal cystectomy and ileocystoplasty	13	10/10 with classic disease successful, but all with nonulcer disease failed	5 yr (6 mo-8 yr)	7/10 voided, 3 self-catheterized; all nonulcer patients successfully treated with Kock pouch and resection of trigone
Nurse et al.	1991	Supratrigonal cystectomy and augmentation	24 unselected	16 successful, 8 with persistent frequency/urgency	NR	—
			12 selected by biopsy	10 successful	Less than above	Only patients without disease on trigone biopsy offered procedure
Kontturi et al.	1991	Supratrigonal cystectomy and colocystoplasty	12	9 successful	4.7 yr (1.2 to 11 yr)	2 cystectomy/conduit (persistent pain, SUI); 3 BNI for retention; 2 urge incontinence
Nielsen et al.	1990	Supratrigonal cystectomy and ileocystoplasty	8	2 successful, 6 with recurrent pain; 4/6 with retention requiring self-catheterization	10 mo (8-22 mo)	Median bladder capacity 435 mL (range, 200-675 mL); all failures >400 mL; 5/6 failures had cystectomy and diversion
Lotenfoe et al.	1995	Cystectomy and continent diversion	22	73% "surgical cure"; 7 patients with persistent pain postoperatively	NR	14/17 (82%) success if <400 mL, 1/5 if >400 mL; recommend epidural to localize pain & psychological evaluation

SUI, stress urinary incontinence.

continent form of diversion than with a conduit. As with supratrigonal cystectomy and augmentation, this form of reconstruction must be strictly limited to patients who are willing to perform self-intermittent catheterization. I have performed six neobladder operations in women with IC and contracted bladders. Five of the six are continent and pain free but have to self-catheterize three to six times per day due to incomplete voiding. The other patient developed persistent pain and stress incontinence very early in the postoperative period.

4. *Continent diversion with or without cystectomy:* Continent urinary diversion is the most complex reconstructive procedure and has the highest complication rate. The catheterizable stoma requires revision due to problems with catheterization or incontinence in approximately 20% to 30% of patients. The procedure is primarily indicated for the patient who seeks a more normal body image, without an external appliance, but is not able to perform self-catheterization (due to urethral pain). The same issue as to whether a cystectomy should be performed applies as with a conduit diversion.

In summary, radical surgical procedures offer tremendous relief to a small subset of IC patients with severe, refractory disease. These patients must be carefully screened in order to select those with the highest likelihood of benefit. There is no clear “best” reconstructive procedure, so the decision must be made based on individual patient preferences and the judgment of the surgeon.

### Pain Management

Not all patients with IC complain of pain. Some describe an uncomfortable “pressure” in the bladder that generates urinary frequency while denying any “pain.” Nonetheless, most IC patients suffer from some degree of pain, and for many the pain is debilitating. Given that IC is not a curable disease at the current time, pain control becomes a legitimate and important goal in and of itself. Nevertheless, pain management tends to be poorly handled in IC (as in many chronic diseases) for a variety of reasons, some legitimate and some not. The impediments to proper pain control and strategies for improving pain management in IC/PBS are discussed in this section.

Physicians are often reluctant to prescribe pain medication to IC patients. In contrast, most physicians feel comfortable prescribing pain medication to their postsurgical patients. This simple dichotomy highlights some of the important issues about pain in IC. Surgeons are trained in the management of acute pain. They understand the disease process, the expected course, and the range of responses that might be expected with various medications. Still, postoperative pain is often undertreated due to individual variation. Surgeons are much less comfortable treating chronic pain. Even when the disease process is understood, there is a reluctance to use adequate doses of chronic analgesics; this is in large part due to a lack of training and relatively limited exposure to this type of patient. The IC patient faces an even greater hurdle, the hurdle of “invisible disease.” In our current state of knowledge, IC is a diagnosis of exclusion, raising the specter of the patient as a malingerer and/or drug seeker. This is relevant because urologists have long been the target of such behavior, in the guise of the recurrent stone patient. Suspicion of motive, uncertainty of diagnosis, and a feeling of inadequacy can

interfere with the physician’s role. Finally, although lip service is paid to the importance of adequate pain control, physicians continue to see colleagues cited for improper prescription of controlled substances. Lawsuits have been filed for inadequate pain treatment but also for contributing to addiction. Many states place significant additional burdens on providers of common therapeutic narcotics.

At the same time, we must acknowledge that treatment of acute pain in IC is quite difficult. Narcotics and nonsteroidal medications are often ineffective. It is therefore incumbent on the patient to try and address the issue of pain control proactively. In many instances, the “best” arrangement is for the patient to be referred to a pain specialist, typically an anesthesiologist or oncologist skilled in the evaluation and management of chronic pain. In this setting, the urologist continues to work with the patient with standard bladder treatments while the pain specialist uses alternative approaches. In the best of cases, this involves multimodality therapy, including narcotic and non-narcotic analgesics, physical therapy, and psychological counseling, nerve blocks, and so on.

Some of the principles used in working with chronic pain are as follows.

1. Long-acting narcotics are preferable to short-acting narcotics. The dose of the long-acting drug is titrated up to a satisfactory level, and the patient is given a small amount of short-acting medication for breakthrough pain.
2. Combination medical therapy is usually superior to narcotics alone. Nonsteroidal anti-inflammatory medications, tricyclic antidepressants, and a wide variety of novel medications (often anticonvulsants) can be used to achieve a synergistic response.
3. Analgesic medications should be tied to concrete, functional outcomes. It is unlikely that a medication will provide complete resolution of the problem. Objective improvements can be assessed in any of a variety of role functions (e.g., work, home, sexual) as well as in urinary frequency and pain control.

The most important principle is for the physician to care for the patient as a family member, using all diagnostic skill, all reasonable therapeutic modalities, and the utmost compassion.

### CONCLUSIONS

IC presents a formidable challenge to the urologist. The disease continues to create diagnostic problems and to defy the development of universally effective therapy. Although it is easy for the clinician and patient to become frustrated, most patients can achieve substantial amelioration of their symptoms over time.

Teamwork is required in the management of IC, more so than in almost any other disease faced by the urologist. The clinician must respect the integrity of the patient and the burden faced by those living with “invisible disease.” The patient must actively participate in seeking effective therapy. Although it is always reasonable to hope for a cure, realistic goals must be set with an aim to maximizing function.

If behavioral techniques such as dietary modification, stress reduction, and bladder training fail to control the symptoms of IC, medical treatment is indicated. First-line therapies include bladder distention, DMSO bladder instillations, PPS, amitriptyline, and hydroxyzine. Most patients respond to one of these

treatments. New treatments being investigated for refractory disease include instillations of BCG and hyaluronic acid and sacral nerve stimulation. The role of therapy directed at the pelvic floor muscles (myofascial release and biofeedback) is also being defined. Pain management is an underutilized tool for a disease in which daily pain is a common symptom. A multidisciplinary approach using the skills of a urologist, a physical therapist, and a pain specialist can produce excellent results. Ultimately, a small percentage of patients will go on to radical surgical treatment. Limited evidence suggests that those with a low bladder capacity

under anesthesia (<350 mL) do especially well with surgery, although the optimal method of urinary tract reconstruction has not been established.

High-quality RCTs are desperately needed in the study of IC. Only through this type of research will we be able to make progress in discovering which therapies work for which patients and to counsel patients accordingly. Clinicians are encouraged to work together to develop clinical protocols, and patients are urged to participate in research studies whenever possible.

# EPIDEMIOLOGY OF INCONTINENCE AND VOIDING DYSFUNCTION IN THE ELDERLY

*Virgilio G. Petero, Jr., and Ananias C. Diokno*

The understanding of epidemiology—the study of the distribution and determinants of disease—is critical in the search for the risk and protective factors that lead to primary or secondary disease prevention. This is especially true of urinary incontinence and voiding dysfunction, conditions that are multifactorial in origin. Although there is still a major gap in our knowledge about the issues involved in the epidemiology of these conditions, there has been a significant advance in the procurement of epidemiologic information in many parts of the world. This new-found enthusiasm led to the realization that urinary incontinence and voiding dysfunction are highly prevalent and that the consequences can be devastating for the afflicted women and have a tremendous impact on the nation's health care system. Largely because of these research initiatives, treatment and preventive strategies have emerged.

This chapter addresses the epidemiology of incontinence and voiding dysfunction. Although these conditions affect women of all ages, they are generally considered health concerns of the older age group. This review places special emphasis on elderly women.

## URINARY INCONTINENCE

The International Continence Society defines *incontinence* as “the complaint of any involuntary leakage of urine.”<sup>1</sup> The *prevalence* of urinary incontinence is defined as the probability of incontinence within a defined population group within a specified time period. The concept is important for establishing the distribution of the condition in the population and for projecting the need for health and medical services. The prevalence of all cases of urinary incontinence is estimated as the ratio of the number of

incontinence respondents identified in a cross-sectional survey of continent and incontinent subjects. The prevalence of specific types and severity levels is estimated in an analogous manner. Any studies on the epidemiology of incontinence and voiding dysfunction or any condition or disease depend significantly on the definition of the condition and on the method used to obtain the information. The lack of a uniform definition of urinary incontinence is a fundamental problem in assessing and comparing the findings in different studies.

### Prevalence of Urinary Incontinence in the Community

The pioneering studies on the prevalence of incontinence were done in Europe and mainly included subjects living in the community. From these early investigations, it was established that urinary incontinence is much more prevalent among the elderly than in any other age group living in the community. The sentinel paper published in 1968<sup>2</sup> was followed by a comprehensive study by Thomas and colleagues<sup>3</sup> in 1980. The group carried out a postal survey of two London boroughs and assessed 22,430 female subjects 5 years old or older. The survey team defined regular incontinence as two or more episodes of urinary incontinence occurring in the past month, whereas occasional incontinence was defined as less than two incontinence episodes per month. The group reported the prevalence of incontinence in all age groups (5 to more than 85 years) to be 8.5%. The prevalence rates of urinary incontinence in the different age groups are shown in Table 93-1.

When incontinence was correlated with previous pregnancy and with the number of pregnancies, nulliparous women were found to have a lower prevalence than those who had one or more babies. The number of pregnancies did not make any

**Figure 93-1** Prevalence of urinary incontinence by age group and severity in the Norwegian EPINCONT study. (From Hannestad YS, Rortveit G, Sandvik H, et al: A community-based epidemiological survey of female urinary incontinence: The Norwegian EPINCONT study. *J Clin Epidemiol* 53:1150-1157, 2000.)

difference among the incontinent respondents, except those in the 45- to 54-year age group, in which those who had had four or more babies were most likely to report regular incontinence. Incontinence was also reported to be moderate or severe in approximately 20% of the respondents, of whom less than one third received health or social services for the condition.

A European epidemiologic study was conducted by Hunskaar and coworkers<sup>4</sup> in four countries. Based on a mail survey of 29,000 households representing the general population of adult women 18 years or older (mean, 46.3 years) and on incontinence defined as any leakage or involuntary loss of urine during the preceding 30 days, the group reported the prevalence of incontinence to be 15% for women in Spain, 32% in France, 32% in the United Kingdom, and 34% in Germany. The survey also determined the type of incontinence. *Stress urinary incontinence* symptoms were defined as a leak or loss of urine caused by sneezing, coughing, exercising, lifting, or physical activity. *Urge urinary incontinence* symptoms were defined as an urge to urinate but being unable to reach the toilet before leaking or having a strong sudden urge to go to the toilet to urinate with no advance warning. *Mixed urinary incontinence* symptoms were defined as at least one stress and one urge symptom. Among the adult women in four countries, stress (37%) and mixed (33%) types were shown to be more predominant than urge incontinence (20%) and other (10%) types. In the subpopulation of women 60 years old or older, the mixed type predominates (41%), followed by stress incontinence (31%), urge incontinence (22%), and other types (6%).

The prevalence of any type of urinary incontinence by age shows an intriguing pattern. A survey of Norwegian women 20 years old or older found a gradual increase of prevalence across adulthood until age 50, when the prevalence reaches 30%, and then a stabilization or even slight decrease until age 70, when prevalence starts increasing again. The severity of incontinence also increases regardless of the type of incontinence with advancing age (Fig. 93-1).<sup>5</sup>

In the United States, the first comprehensive epidemiologic study on urinary incontinence in the elderly living in the com-

munity was the Medical Epidemiologic and Social Aspect of Aging (MESA) survey, which was conducted in 1983 in Washtenaw County, Michigan, by Diokno and colleagues.<sup>6</sup> This was a cross-sectional and longitudinal study of elderly respondents 60 years old or older sponsored by National Institute of Aging. A multistage stratified area probability sample of the Washtenaw County identified 13,912 households that were screened by household interviewers to identify households containing one or more persons 60 years old or older. The prevalence of urinary incontinence among all women 60 years old or older interviewed was 38%. The severity of urinary incontinence was analyzed according to the quantity of urine loss per day and the frequency of urine loss in 365 days (Table 93-2). The clinical type of urinary incontinence was also detailed in the MESA study. The result showed the mixed type of incontinence was the most prevalent, involving 55% of the incontinent responders, followed by stress (27%), urge (9%), and the other category (9%).

A more recent epidemiologic study in the United States was reported by Kinchen and associates<sup>7</sup> in 2002. The team conducted a national, cross-sectional, mailed survey of 45,000 households to determine the prevalence of urinary incontinence in adult women 18 years old or older. Among the 24,443 female respondents, 37% reported urinary incontinence in the past 30 days. The type of incontinence also depicts a higher prevalence rate for mixed (45%) and stress (41%) incontinence than for urge incontinence (12%). Age of onset differs by the type of incontinence. The median age of women was 48 years old for those reporting stress incontinence, 55 years for mixed incontinence, and 61 years for urge incontinence.<sup>7</sup>

In Asia, an epidemiologic study (cross-sectional, mailed survey) was done by the Asian Society for Female Urology (ASFU) to determine prevalence of overactive bladder symptoms and incontinence in 11 Asian countries.<sup>8</sup> The questionnaire used to establish the prevalence of incontinence, however, was different from the American and European surveys in that it was more focused on urge incontinence than on any type of incontinence. The prevalence of urinary incontinence ranged from 17% for Thailand and 13% for the Philippines to 4% for Singapore and

**Table 93-2 Severity of Urinary Incontinence by Volume and Frequency of Urine Loss in Women 60 Years or Older**

Volume of Urine Loss in 24 Hours	No. of Days with Urine Loss				Total (%)*

\*Percent of women affected.

From Diokno AC, Brock BM, Brown MB, et al: Prevalence of urinary incontinence and other urological symptoms in the noninstitutional elderly. *J Urol* 136:1022, 1986.

China. The Asian survey also reported a much higher prevalence of mixed incontinence of 64%, with urge incontinence at 23% and stress incontinence at 13%.

The discrepancy between the prevalence rates of incontinence in Europe, America, and Asia may be attributed to the study methods and questions used. It is also possible that these differences reflected cultural variations, race, and ethnicity.

### Prevalence of Urinary Incontinence in Institutions

The prevalence of urinary incontinence is much higher among institutionalized women. A survey sponsored by the United States Department of Health, Education, and Welfare about long-term facilities reported that 55% of patients surveyed had some problems with urinary control and that an additional 5% of patients were using a catheter or some collecting device.<sup>9</sup> Similarly, the National Nursing Home Survey sponsored by the National Center for Health Statistics confirmed the prevalence of incontinence of 50% among the more than 1.5 million nursing home facility residents in the United States.<sup>10</sup> Willington<sup>11</sup> estimated that 30% of unselected elderly admissions have urinary incontinence.

Some studies suggest institutional prevalence ranges between 6% and 72%.<sup>12</sup> Several reviews from around the world, some of which sample of institutions rather than individual institutions, suggests a prevalence of 50% or higher.<sup>13-20</sup> The range of prevalence in institutions is probably a consequence of the definition of urinary incontinence and criteria for admission to residential care, which vary within countries and among facilities.<sup>21</sup> The process that results in the relatively high prevalence of urinary incontinence in residential care facilities remains unclear. Thom and colleagues<sup>22</sup> reported that the relative risk of admission to a nursing home was two times greater for incontinent women after adjustments for age, cohort factors, and comorbid conditions. These findings suggest that incontinence may contribute to institutionalization. However, an alternative explanation of residential care contributing in some way to the development of incontinence cannot be excluded with confidence.

### Racial and Ethnic Differences

Most epidemiologic studies of urinary incontinence have been conducted on white populations. The data available on black women indicate that they are less susceptible to urinary incontinence than white women.<sup>23</sup> However, in those who were incontinent, the severity was not significantly different between the two racial groups.<sup>23,24</sup>

It was suggested that black and white women have different factors promoting urinary incontinence.<sup>25</sup> The clinical data in the United States indicate that black women have higher urethral closure pressure, larger urethral volume, and greater vesical mobility compared with white women.<sup>26</sup> This difference in physiologic subtypes was supported by data confirming a significant difference in the predominance of stress incontinence in white women.<sup>27</sup> Black South African women rarely develop stress incontinence and the related disorder of pelvic floor prolapse, at a rate 80 times lower than whites.<sup>28</sup> Later studies later attempted to explain these observations as a function of different urethral pressures and lengths and pubococcygeal muscle strength.<sup>29,30</sup>

The prevalence of urinary incontinence among the Hispanic women 65 years old or older in the United States is lower than the general population. Using a methodology similar to the MESA study, Espino and coworkers<sup>31</sup> reported a prevalence rate of 15%. Similarly, mixed incontinence predominates at a rate of 42%, urge at 33%, and stress incontinence at 10%.

### Incidence and Remission Rates

The incidence of urinary incontinence is the probability of becoming incontinent during a defined period of time. The concept is helpful in determining the onset and in understanding the risk factors for the condition. There are few epidemiologic data on the development or natural history of urinary incontinence and its transition to various levels of severity and type of incontinence. Campbell and associates<sup>32</sup> reported an incidence rate of incontinence among women 65 years old or older in New Zealand to be about 10% in a 3-year period. Moller and colleagues<sup>33</sup> and Samuelsson and coworkers<sup>34</sup> reported an incidence of 6% and 3% in young and middle-aged women, respectively. During the 5-year follow-up, the annual incidence was 2.9%, with severe incontinence at occurring at a rate of 0.5%. The remission rate (i.e., women who were incontinent at baseline and became incontinent at the end of study) was 5.9%.

In the MESA survey, the incidence of elderly women who were continent at the initial baseline interview and became incontinent a year later (i.e., second interview) was 22.4%. The incidence at the third interview of respondents who were still continent during the second interview was 20.2%. The remission rate during the second interview was 11.2%. Similarly, 13.3% of the incontinent respondents at the second interview became continent by the third interview. When a continent woman becomes incontinent the subsequent year, the most likely pattern is a mild form of incontinence. About one half of the cases of mild incontinence at the beginning of survey remained mild; few became

severe. Women with severe incontinence usually remained severely incontinent after 1 year of follow-up. One half of the cases of moderate incontinence remained moderate, and the rest became mild or severe. In terms of the type of incontinence, women who originally had stress incontinence remained the same or developed the mixed type. Women with the mixed type usually stayed the same. Most continent women who became incontinent developed the stress type or a mixed stress-urge type of incontinence.

The current interpretation of the data indicates that the substantial incidence rates are paralleled by equally substantial remission rates. However, it is not clear whether the level of remission reflects active treatment or intervention or it is part of the natural course of incontinence.<sup>35</sup>

### Correlates of Urinary Incontinence

Urinary incontinence is a condition of multifactorial origin. The MESA study investigated and reported the many suspected correlates of incontinence. The factors investigated extended beyond the medical correlates into social and psychological aspects. Among women, the measures of depression, negative affect balance, and life satisfaction reflect to a statistically significant degree the effect of incontinence.<sup>36</sup> Continent older women reported the highest levels of psychological well-being (i.e., the least depression and negative affect balance) and the most life satisfaction. Psychological well-being declines with increasing severity of urinary incontinence; the more severely incontinent women experience higher depression and negative affect balance and lower life satisfaction than the less severely incontinent women or continent women. Changes in the measures of happiness and positive affect balance are not as clear. Herzog and colleagues<sup>37</sup> suggested that these relationships are partly explained by the fact that incontinent respondents are less healthy than the continent respondents.

Miller<sup>38</sup> presented data from the New Haven Established Populations for the Epidemiologic Study of the Elderly (EPESE) study showing that respondents who reported difficulty holding their urine "all the time" or "most of the time" scored highest on a scale of depressive symptoms, followed by respondents who had difficulty "sometimes" or "hardly ever." Continent respondents scored the lowest of the three groups. This pattern persisted when functional disabilities and chronic disabilities were controlled.

Study of the medical correlates of urinary incontinence confirmed that incontinence in elderly individuals is associated with many debilitating medical conditions.<sup>39</sup> Surveys showed that physical mobility problems, specific neurologic symptoms, lower urinary tract problems, bowel problems, respiratory problems, and a history of genital surgery are more prevalent among those who are incontinent than those who are not. Other factors associated with female geriatric incontinence include a history of parent or sibling incontinence, incontinence during pregnancy or postpartum, hearing problems, use of female hormones, and vaginal infections. Mobility problems among the elderly were identified by the use of a wheelchair or walking aids, the presence of diagnosed arthritis or rheumatism, and whether the respondent fell during past year. The results showed that the proportion of respondents who reported mobility limitations was significantly greater among those who were incontinent than among those who were not. Among incontinent women, those with urge symptoms reported more difficulty with mobility than those with other symptoms. For example, among women with urge incon-

tinence, 28.2% had mobility problems, in contrast to only 6.8% of those with stress incontinence.

Incontinence was associated significantly more often with neurologic factors (i.e., disease of the nerves or muscles or numbness in any part of body). Bowel problems, including lost control of stools in the past year, and problems with constipation were significantly more prevalent among the incontinent respondents than among their continent counterparts. Similarly, vaginal infections were reported more frequently by incontinent women. With regard to respiratory symptoms, incontinent women cough or sneeze more often than continent women. More incontinent than continent respondents reported urinary tract problems. The largest differences were found among those who reported urinary tract infections; the presence of blood, cloudiness, or foul smell in the urine; slow and weak stream of urine; and the presence of pain, burning, or stinging during urination.

The MESA respondents were followed for several years to identify causal relationships between urinary incontinence and its correlates. The data suggest a clear relationship among the onset of poor health, mobility problems, and urinary symptoms. These factors appear to be significant risk factors for the development of urinary incontinence in the elderly.

The widespread use of diuretics among the elderly population was also confirmed by the MESA study.<sup>40</sup> One in three women 60 years or older uses a diuretic. Wells and coworkers<sup>41</sup> reported that diuretics were used in 29% of incontinent elderly women seen in a continence clinic. Ouslander,<sup>42</sup> in his study of nursing home patients, observed no significant difference in the use of diuretics between continent and incontinent patients. Shimp and colleagues<sup>43</sup> reported the influence of diuretics on bladder symptoms in a study of 200 incontinent women recruited from a continence program clinic. Incontinent women taking diuretics had a positive correlation with nocturia and a trend toward significant urge incontinence ( $P = .056$ ) compared with incontinent women not taking diuretics.

The MESA study showed that there was no significant difference in the prevalence of incontinence in users and nonusers of diuretics. However, it was found that diuretic users who had uninhibited bladder contractions on cystometry had a significantly higher prevalence of urinary incontinence (85%) compared with nonusers with similar bladder abnormalities (25%). Among respondents who did not have uninhibited bladder contractions on cystometry, the use or nonuse of diuretics resulted in no difference between the two groups ( $P = .085$ ). Although these comparisons were made in men because there were not enough women with uninhibited bladder contraction to compare, there is no reason not to expect similar relationships in women.

The correlation between diuretics and the presence of uninhibited bladder contractions has significant implications. When confronted with an elderly patient who has recently experienced the onset of urinary incontinence, especially the urge type, the physician should specifically ask about the concomitant use of diuretics. If diuretic use correlates with the onset of incontinence, the physician can discontinue the diuretic and change to a non-diuretic therapy if medically feasible. If the diuretic cannot be discontinued, the use of bladder relaxants should be considered as long as the patient has adequate detrusor contractility and can empty the bladder adequately. As part of the overall management of incontinence in patients with mobility and dexterity, easier access to the toilet should be considered; otherwise, provisions for toilet supplements, such as commodes or urinals should be encouraged.

### Urodynamic Parameters for the Continent and Incontinent Elderly

The MESA survey performed urodynamic studies among 167 women who volunteered to undergo the study at the household interview followed by a clinic visit for a free examination, including urinalysis. One hundred incontinent and 67 continent women were studied.

The uroflow measures of peak and average flow rates showed no difference between continent and incontinent subjects or between the different clinical types of incontinence. The mean noninstrumented peak flow rate among women voiding 300 mL or more was 23.3 mL/sec, whereas the mean noninstrumented peak flow rate for a voided volume between 200 and 299 mL was 18.2 mL/sec. The mean average flow rates were 12.0 mL/sec and 8.8 mL/sec, respectively.

The postvoid residual urine volume showed no significant difference between continent and incontinent women respondents. The prevalence of postvoid residual urine volume of 101 to 150 mL among continent women was 9.7%, and for incontinent women, it was 3.5%. The prevalence of uninhibited detrusor contraction on cystometry among the continent respondents was 4.9%, and for the incontinent respondents, it was 12.2%. The overall prevalence rate was 7.9%. The difference in prevalence rates between continent and incontinent subjects was not statistically significant. These rates are more in line with the prevalence of uninhibited detrusor contractions among hospitalized women without urologic symptoms reported by Jones and Schoenberg,<sup>44</sup> but they are lower than the 39% reported by Hilton and Stanton.<sup>45</sup> The difference appears to be related to the general health status of the individual. Healthier subjects are less likely to have uninhibited detrusor contractions.

The urethral pressure profile parameters in the MESA study revealed that assessment performed in the supine position did not reveal any significant difference between the continent and incontinent subjects. However, static and dynamic urethral pressure profilometry performed in the standing position showed a significant difference in the values between continent and incontinent subjects. Although a significant difference existed, there was considerable overlap in the values, and it was impossible to adopt a specific range of values that could be used to identify urethral insufficiency in elderly subjects.

On the lateral stress cystography, the posterior urethra-vesical angle was strongly associated with continence status. However, there was significant overlap in the posterior urethra-vesical angle values that made it impossible to assign a specific value for the diagnosis of incontinence. It appears that this test is of value in the assessment of the type of stress incontinence and in assessing the type of repair to be used.

### Patient Strategies to Control Urine

Because urinary incontinence is not life threatening, many incontinent individuals have found ways of managing their own conditions. Part of the MESA study was to determine how incontinent elderly women manage their urine loss condition.<sup>37</sup> The survey revealed that 69% of incontinent women were using one or more methods to control urine loss. For most incontinent women, absorbent products such as sanitary napkins, toilet tissue, and absorbent garments were the most popular means, as reported by 55% of women respondents. The second most common means of controlling incontinence was to locate a toilet on arrival at an

unfamiliar place. Forty-two percent of women reported using this strategy as part of controlling their incontinence. Voiding manipulation such as scheduled urination, urination before leaving home, and other conscious efforts to plan urination was practiced by 28% of female incontinent respondents who altered their diet and fluid intake to control incontinence and 12% who did pelvic muscle exercises. Only 6% of women reported taking medications for their incontinence.

Forty-two percent of those with severe incontinence had talked with their physicians in the past year, whereas only 25% of those with moderate incontinence and 19% of those with mild incontinence had done so. With regard to the type of incontinence, 30% of those with the mixed type of incontinence had talked with their physicians in the past year, whereas only 20% of those with urge or stress incontinence had done so.

### Continent Surgery and Its Outcomes

An estimated 126,000 operations for incontinence are performed annually in the United States.<sup>46</sup> A review of the literature demonstrates that the median proportion of women cured or improved by surgery at 1 to 2 years was 78% for anterior repair, 86% for retropubic suspension, and 91% for sling procedures.<sup>47</sup> Realizing the value of patient satisfaction as an outcome of continence surgery, the National Family Opinion (NFO) world group panel evaluated the prevalence and outcome of continence surgery among community dwelling women.<sup>48</sup> The group reported that 4% of women living in the community and 8% of women 60 years old or older had a history of continence surgery. One third of the women had their surgery within the past 5 years. The initial satisfaction of surgery was high, but it then decreased as time progressed. Of those who had surgery within the past 3 years, 64% were currently satisfied. Of those who had surgery more than 3 years, satisfaction rates between 42% and 45% were reported. Seventy-three percent of the women who had surgery reported incontinence in the preceding month, 58% had incontinence in the preceding week, and 53% used pads regularly. Of those with recurrent urinary incontinence, 83% continued to have stress urinary incontinence, although 62% experienced stress and urge symptoms, and 14% had urge symptoms only.

### Prevention of Urinary Incontinence

Urinary incontinence is a preventable condition.<sup>49</sup> Behavioral techniques, including pelvic muscle training and bladder training, are safe and effective for stress, urge, and mixed urinary incontinence.<sup>50-53</sup> Only a few randomized, controlled trials have sought to prevent incontinence. Until recently, the randomized, controlled trials assessing a behavioral modification program for prevention of urinary incontinence have been limited to pregnant and postpartum women. None of the randomized, controlled trials previously reported tested the preventive effects of bladder training and pelvic muscle training in older women.<sup>54,55</sup>

Diokno and colleagues<sup>56</sup> reported the first successful randomized, controlled trial of a group behavioral modification program to prevent incontinence in postmenopausal women living in community who were 55 years old or older, compared with the usual care. The program consisted of a 2-hour classroom presentation, followed 2 to 4 weeks later with an individualized evaluation to test knowledge, adherence, and skills in behavioral

techniques and to provide a brief re-enforcement of technique as needed. Both groups (i.e., treated and control or no treatment) were followed for 12 months. Continence status, pelvic muscle strength, voiding frequency, and intervoid interval were significantly better in the treatment group.<sup>56</sup> The result of this trial suggest that women with stronger pelvic muscles have increased awareness of pelvic muscle function, which translates into greater voluntary contraction of the pelvic muscles at the onset of increased physical activity, maintaining or improving continence.<sup>57</sup>

### Socioeconomic Issues

As is true for any chronic health condition, the burden of urinary incontinence reflects experiences of the incontinent individual and those around her, and it puts significant strain on society and the health care system. Between 1984 and 1995, the estimated number of persons 65 years old or older with urinary incontinence increased by 218%.<sup>58</sup> Urinary incontinence is a costly condition, with the annual expenditure similar to other chronic diseases in women, such as osteoporosis, Alzheimer's disease, and arthritis, that vary in their effects on morbidity, mortality, and quality of life.<sup>59</sup>

The estimated cost of urinary incontinence in 1995 for persons 65 years old or older in the United States, based on the calculated 6.32 million community-dwelling and 1.06 million institutionalized elderly patients,<sup>59</sup> was \$24.3 billion, of which direct costs accounted for 97% (\$23.6 billion).<sup>58</sup> The single biggest contributing cost was for routine care among older adults living in the community; this represented 29.4% of total costs. The cost per individual was \$3565, an increase of 174% from \$2052 in 1984.

The indirect costs include income from work lost. Among all workers with urinary incontinence, 23% of women missed work, whereas only 8% of men did so. The reported average annual work absence for women totaled 28.7 hours for inpatients (7.1 hours) and outpatients (21.6 hours). Although women and men have similar numbers of outpatient visits for urinary incontinence, average work loss associated with outpatient care was greater for women, probably because of the availability of outpatient procedures for women.<sup>60</sup>

### VOIDING DYSFUNCTIONS

Few studies have examined the prevalence of urinary symptoms other than incontinence among women. The prevalence of urinary symptoms has been infrequently reported in detail among women of different ages. For example, there are few data for normal values of daytime and nighttime voiding frequencies for women of different ages. Voiding dysfunction is perceived less commonly as an important urinary symptom in women, despite evidence that detrusor function may become less efficient with age.<sup>61</sup>

### Normal Voiding Parameters

The distribution of frequency of voiding among the elderly women in the United States was reported by the MESA survey. It appears that the normal voiding frequency was no more than eight times per day; 88% of all women respondents who were asymptomatic (i.e., no self-reported incontinence or irritative or obstructive symptoms) and 70% of incontinent women reported this daily frequency. In terms of nocturia, 93% of asymptomatic

women and 83% incontinent women void no more than two times at night. The frequency of nocturia increased among women with bladder symptoms. Nocturia of three times or more was reported by 25% of women with irritative bladder symptoms and 24% of women with difficult bladder-emptying symptoms. The increased frequency reported among symptomatic respondents compared with asymptomatic respondents was statistically significant.

Fitzgerald and coworkers<sup>62</sup> reevaluated the definition of urinary frequency by assessing 300 healthy, asymptomatic volunteer women between the ages of 18 and 91 years (median, 40 years). They found a median of 8.3 voids in 24 hours, with 95% of subjects recording fewer than 13 voids per 24 hours. Ninety-two percent of the women voided no more than once per night, including 36% who voided once. Two or more nocturnal voidings were reported by 8% of the volunteers. Among the 133 (44%) subjects who had nighttime voiding, 39% of them did so because they were awakened by the need to void. The group concluded that 8 voids or more per 24 hours as the definition of *frequency* may be inappropriate and suggested that a value 13 voids or more may be more appropriate. However, it can be argued that because the information came from a self-selected group of volunteers who reside in a large metropolitan area, the figures obtained may not be representative of the true voiding frequency in the general community.

### Lower Urinary Tract Symptoms in Women

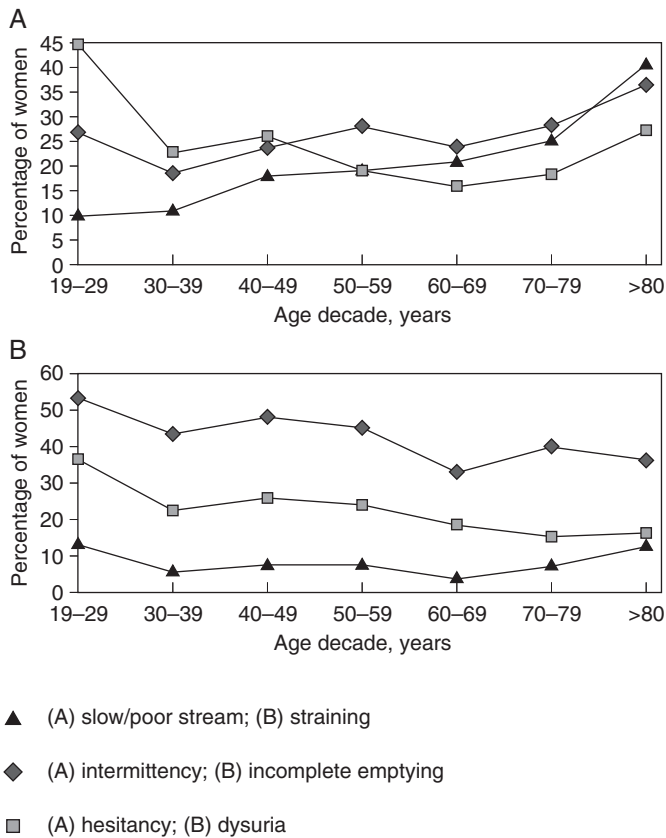

Using the validated Bristol Female Lower Urinary Tract Symptoms (BFLUTS) questionnaire,<sup>63</sup> it was demonstrated that lower urinary tract symptoms were prevalent among and troublesome to a group of community-dwelling women.<sup>64</sup> In the MESA survey, the prevalence of lower urinary tract symptoms (i.e., hesitancy, poor stream, interrupted stream, straining to void, and use of catheter to drain the bladder) among women 60 years old or older was 10.9%. Men of a similar age group reported a 22.1% prevalence. Other surveys report prevalence rates of 18% for women 65 years old or older<sup>65</sup> and 8% for women 81 years old or older.<sup>66</sup> It is believed that the difficult bladder-emptying symptoms in women are more likely a consequence of an underactive bladder, whereas in men, the most likely cause is outlet obstruction.<sup>6</sup>

Voiding symptoms other than poor stream have seldom been assessed in women, although hesitancy has been described as occurring in a small population of younger women.<sup>67</sup> Using the BFLUTS questionnaire, Swithinbank and colleagues<sup>68</sup> reported the age-specific prevalence of voiding symptoms among women, including the character of the stream (i.e., intermittency, hesitancy, and slow stream), incomplete emptying, dysuria, and straining (Fig. 93-2). With the exception of weak stream, these symptoms were more commonly described by younger women.<sup>68</sup>

The high prevalence of lower urinary tract symptoms among women is not surprising. Many other investigators have reported similar prevalence rates for these symptoms in age-matched men and women when testing the International Prostate Symptom Score (I-PSS) as a diagnostic tool.<sup>69-71</sup> As in the case with men, storage symptoms appear to be much more bothersome than voiding symptoms.

### Overactive Bladder Syndrome

Overactive bladder is a common disabling condition that affects health-related quality of life. The International Continence

**Figure 93-2** Relationships between age and type of stream (A) and bladder emptying symptoms (B) in women. (From Swithinbank LV, Abrams P: A detailed description, by age, of lower urinary tract symptoms in a group of community-dwelling women. *BJU Int* 85(Suppl2):19-24, 2000.)

Society (ICS) derived a consensus symptomatic definition of *overactive bladder syndrome* as urinary urgency, with or without urge incontinence, usually with urinary frequency and nocturia, in the absence of pathologic and metabolic factors that would explain the symptoms.<sup>1</sup> Urodynamically, overactive bladder is characterized by the presence of involuntary bladder contractions that occur during bladder filling despite the patient's attempt to suppress them.

The National Overactive Bladder Evaluation (NOBLE) study was initiated to better understand the prevalence and impact of overactive bladder in a broad spectrum of the U.S. population.<sup>72</sup> Using a clinically validated, computer-assisted telephone interview questionnaire, a sample population of adults, who were 18 years old or older and representative of the main population by sex, age, and geographic region, was surveyed.

A surprising result from this study is the equal prevalence of urgency-related bladder control problems in men and women (16.0% and 16.9%, respectively), although more women (13.4%)

suffer from overactive bladder with incontinence than men (2.6%). The prevalence and prevalence ratios were inversely related to increasing education, a pattern that was more apparent among women who had overactive bladder with urge incontinence. In women, but not in men, the prevalence of overactive bladder with urge incontinence increased in relation to increasing body mass index.

The age-specific prevalence of overactive bladder was similar for men and women, but age patterns differed by sex and type of overactive bladder. The age-specific prevalence of overactive bladder without incontinence appears to plateau after age 44 years for women and after age 54 years for men. In contrast, age-specific prevalence of overactive bladder with urge incontinence continues to increase with increasing age, with women having a steeper age-related increase than men. These contrasting patterns suggest that overactive bladder without incontinence may precede the onset of overactive bladder with urge incontinence. Moreover, in the older ages, the transition rate from overactive bladder without to overactive bladder with urge incontinence may exceed the rate of occurrence of new cases of overactive bladder without incontinence. This may explain the plateau in prevalence of overactive bladder without incontinence. Longitudinal studies will be required to test this hypothesis. If confirmed, the incidence of overactive bladder with urge incontinence may be mitigated through secondary prevention efforts directed toward overactive bladder without urge incontinence.

Women and men who have overactive bladder, with or without urge incontinence, have significantly poorer scores for health-related quality of life, mental health, and quality of sleep compared with sex- and age-matched controls. These differences were significant after adjusting for other covariates, including comorbid illnesses.

## CONCLUSIONS

Urinary incontinence and voiding dysfunctions are prevalent conditions that can affect women of all ages. The incidence is especially high among the elderly, whether they are living in the community or in institutions. These conditions are associated with many medical correlates and have a tremendous effect on the psychological well-being of the afflicted. Urinary incontinence and voiding dysfunctions are very costly, with the expenditure similar to the more popularly recognized health concerns of the aging woman.

The explosion of epidemiologic data has led to novel treatment and prevention strategies, although patient satisfaction about the outcome of surgery may not be as high as previously believed. Epidemiologic information about different racial and ethnic populations is now being reported. Our knowledge about the different issues of voiding dysfunctions is still inadequate, and our understanding of normal voiding parameters is still far from complete.

# LOWER URINARY TRACT DISORDERS IN THE ELDERLY FEMALE

*Theodore M. Johnson, II, and Joseph G. Ouslander*

Aging is a continuous and inevitable process that affects everyone. It occurs at various rates in different individuals and in different organ systems within the same individual. The individual organism's responses to the aging process are diverse and depend on many complex factors. The lower urinary tract, as much as any other organ system, is greatly influenced by the interactive and additive effects of age-related changes and the accumulation of many pathologic entities with increasing age. Symptoms of lower urinary tract dysfunction are common in elderly women.

This chapter focuses on the age-related and age-associated changes that underlie lower urinary tract dysfunction in this population. We review in some detail the two most common

disorders of the lower urinary tract in elderly women—urinary incontinence and urinary tract infection (UTI).

## AGING AND THE FEMALE LOWER URINARY TRACT

When considering the effects of increasing age on any organ system, a crucial distinction must be made between true age-related changes that occur in everyone and age-associated changes resulting from the accumulation of pathologic conditions that do not occur in everyone. Table 94-1 lists age-related changes and age-associated factors that can influence lower urinary tract function and symptoms in elderly women. Because determining true

**Table 94-1 Aging and the Female Lower Urinary Tract**

Change or Effect	Potential Effects
<b>Age-related changes</b>	
Altered cell function	Altered interstitial tissues and mucosal surfaces
Decreased estrogen level	Increased likelihood of pelvic prolapse and urinary infection
Altered concentrations of central nervous system neurotransmitters; altered nerve conduction	Thinner and more friable mucosa and interstitial tissues
Altered immune function	Increased likelihood of pelvic prolapse, urinary symptoms, and infection
Altered bladder function	Increased likelihood of bladder and urethral dysfunction
Decreased capacity	
Increased uninhibited contractions	
Increased residual volume	
Lower urethral pressure	Increased likelihood of incontinence
<b>Age-associated factors</b>	
Cognitive and sensory impairment	Decreased ability to relate symptoms
Locomotor disturbances and immobility	More difficulty getting to a toilet; increased likelihood of fecal impaction and incontinence
Stroke	
Hip fracture	
Peripheral vascular disease	
Parkinson's disease	
Poor fluid intake	Increased likelihood of fecal impaction and bacteriuria
Central nervous system diseases affecting bladder function	Increased likelihood of incontinence
Stroke	
Dementia	
Parkinson's disease	
Other diseases affecting bladder function	Increased likelihood of bladder dysfunction
Malignancy	
Atherosclerotic vascular disease	
Drug usage (see Table 94-2)	Increased likelihood of bladder or urethral dysfunction

age-related changes in the female lower urinary tract would involve invasive procedures (e.g., catheterization for urodynamic studies, cystoscopy) in continent elderly women without urinary symptoms, this type of information is rarely sought. Despite these difficulties in obtaining data, several types of age-related changes are known to have a prominent influence on lower urinary tract function.

One of the most important age-related changes affecting the female lower urinary tract is the postmenopausal decline in estrogen. This remains true, even though evidence has suggested that oral estrogen supplementation is linked to worse continence outcomes.<sup>1</sup> The bladder, urethra, and genital tract have a common embryologic origin, and the epithelium of all of these tissues responds to hormonal changes. When the influence of estrogen declines, the epithelium and supporting tissues of the pelvic area atrophy, resulting in a friable mucosa and a tendency toward prolapse. The lower glycogen content in the vaginal epithelium results in less lactic acid metabolism by Doderlein's bacilli and an increase in the pH of vaginal secretions that may increase susceptibility to infection. Changes occur in the concentration of certain neurotransmitters in various locations in the central nervous system with increasing age. Given the important influence of the central nervous system on human bladder function, these age-related changes in central neurotransmitters may play a role in disorders of micturition in the elderly. Alterations in immune function also occur with increasing age. Although these changes have been seen mainly in cellular immunity, age-related changes in immune function, especially local immune activity in the lower urinary tract, may play an important role in susceptibility to bacteriuria and symptomatic UTI in older women.

Certain functional changes appear to occur in the bladder and urethra with increasing age. In one study, abnormal cystometric results were found for 15 of 24 continent elderly women who were free of neurologic disease.<sup>2</sup> Twelve of these 15 showed uninhibited contractions; 10 had a bladder capacity of less than 250 mL. Other studies have shown prevalence rates of 5% to 11% of abnormalities in continent older women.<sup>3,4</sup>

Some work has attempted to elucidate in the underlying anatomic basis of these changes. In a series of investigations in symptomatic and asymptomatic adults older than 65 years using urodynamics and electron microscopy of bladder biopsy specimens, investigators found that patients with detrusor activity had specific anatomic abnormalities, including a dysjunction pattern with protrusion junctions and ultraclose abutments. These changes are believed to be the anatomic explanation for the propagation of involuntary detrusor contractions in older patients.<sup>5-7</sup>

Maximal urethral pressure and functional urethral length are decreased in continent elderly women.<sup>8,9</sup> In one study, the maximal urethral pressure in continent women fell from a mean of 87 cm H<sub>2</sub>O in the third decade to 42 cm H<sub>2</sub>O in the seventh decade, a value that overlapped that of younger women with stress incontinence.<sup>8</sup> These age-related changes in lower urinary tract function should be considered when evaluating urodynamic findings in elderly women. One postmortem study of 25 bladders from women between the ages of 74 and 102 years revealed marked trabeculation, diverticula, and cellular formation.<sup>10</sup> Another study demonstrated continuous loss of striated muscle cells of the rhabdosphincter due to apoptosis, which eventually may reach a critical mass, leading to reduced function of the muscle with resultant urinary incontinence.<sup>11</sup> Histologic section of the bladder outlet showed a high incidence of chronic inflam-

mation, edema, and fibrosis, presumed to be related to chronically infected residual urine. The trabeculation in these bladders was thought to be the result of loss of elastic tissue and coalescence of muscle fiber and of muscle hypertrophy resulting from bladder outlet obstruction or frequent uninhibited bladder contractions against a closed sphincter, or both. Other investigators have reported that the bladder in elderly women is more often decompensated and thin walled and that hypertrophy does not occur with uninhibited contractions.<sup>12</sup> Further research on the anatomic changes that occur in the aging lower urinary tract will help to clarify these issues.

Several age-associated factors (Table 94-1) can have an important influence on lower urinary tract function and symptoms in elderly women. Although most elderly individuals are generally active and healthy, the incidence of several disorders does increase with age. Impairments of cognitive and sensory function are more common in the elderly than in younger populations. These impairments may make it difficult for the elderly to interpret and relate symptoms of lower urinary tract dysfunction accurately. Poor nutritional and fluid intake can predispose the elderly to fecal impaction and urinary infection. The prevalence of asymptomatic bacteriuria increases with age (discussed later), and this situation predisposes to symptomatic urinary infection. Locomotor disturbances are common in the elderly. The incidence of stroke, arthritis, osteoporosis with resultant hip fractures, peripheral vascular disease with claudication or resultant amputations, Parkinson's disease, and other gait disorders increase with age. These disorders can make it difficult for the elderly to reach a toilet, especially in the setting of urinary frequency and urgency. Impaired mobility may play a prominent role in the development of incontinence in elderly women (discussed later). The incidence of diseases of the central nervous system, such as stroke, dementia, and Parkinson's disease, increases with age. Given the important role of higher centers in the control of micturition, these diseases are frequently involved in urinary dysfunction in the elderly.

An associated problem is that as a result of the high prevalence of so many diseases among the elderly, they are also likely to be taking a wide variety of drugs (often several different agents in complex dosage schedules), many of which can affect lower urinary tract function (Table 94-2). An important component of the assessment of older women with lower urinary tract symptoms is evaluation of the potential role of medications in causing or contributing to their symptoms. It is important to understand the potential effects of acetylcholinesterase inhibitors, given for dementia to stabilize cognitive decline, because these procholinergic agents can worsen or cause incontinence. Bladder relaxant agents may worsen cognition in some older adults.<sup>13</sup>

### URINARY TRACT INFECTION IN ELDERLY WOMEN

Asymptomatic and symptomatic UTIs are common in the elderly. The overall expenditures for the treatment of UTIs in women in the United States, excluding spending on outpatient prescriptions, were approximately \$2.47 billion in 2000.<sup>14</sup> The estimated lifetime risk for a woman to have a UTI is greater than 50%.<sup>14</sup> The prevalence of bacteriuria increases with age; it is more common in elderly women than in men and in patients in nursing homes and hospitals than in elderly people residing at home. Compared with younger women, elderly women are at higher risk for hospitalization from a UTI<sup>14</sup> and have twice the risk for

**Table 94-2 Medications That Can Negatively Affect Continence**

Type of Medication	Potential Effects on Continence
Diuretics	Polyuria, frequency, urgency
Anticholinergics	Urinary retention, overflow incontinence, impaction
Acetylcholinesterase inhibitors (for dementia)	Urgency, urge urinary incontinence
Psychotropics	
Antidepressants	Anticholinergic actions, sedation, rigidity, immobility
Antipsychotics	Anticholinergic actions, sedation
Sedatives and hypnotics	Sedation, delirium, immobility, muscle relaxation
Narcotic analgesics	Urinary retention, fecal impaction, sedation, delirium
$\alpha$ -Adrenergic blockers	Urethral relaxation
$\alpha$ -Adrenergic agonists	Urinary retention
$\beta$ -Adrenergic agonists	Urinary retention
Calcium channel blockers	Urinary retention
Alcohol	Polyuria, frequency, urgency, sedation, delirium, immobility

**Table 94-3 Prevalence of Bacteriuria in Elderly Women**

Setting of Population	Women Affected (%)
Community	11-17
Nursing home	23-27
Hospital	32-50

developing bacteriuria after urodynamic procedures,<sup>15</sup> Table 94-3 summarizes several studies of the prevalence of bacteriuria in the elderly.<sup>16-26</sup> Longitudinal studies of bacteriuria among older women have documented that the organisms change over time and that bacteriuria resolves and returns spontaneously in many women.<sup>20,24-26</sup> Several factors have been implicated in the increased prevalence of bacteriuria in the elderly, including atrophic mucosal changes as a result of estrogen deficiency, increased residual urine volumes, immobility, the prevalence of fecal and urinary incontinence, and the relatively common use of indwelling catheters.<sup>27</sup> Risk factors for bacteriuria and UTIs in postmenopausal women include sexual activity, diabetes, urinary incontinence, and past UTIs.<sup>28</sup> Symptoms common in elderly women that are usually associated with UTI, such as frequency, urgency, dysuria, and incontinence, do not reliably predict whether the urine is infected.<sup>17-19,21</sup> Midstream urine specimens from elderly women are highly unreliable in predicting true bladder infection. The white blood cell count on urinalysis correlates poorly with bladder infection,<sup>10</sup> and there is at least a 17% incidence of false-positive cultures when midstream urine specimens are repeated or compared with suprapubic aspirates.<sup>20,29</sup> Growth of between  $10^4$  and  $10^9$  colonies/mL and contaminated specimens are also more common with midstream specimens. Taking two consecutive midstream specimens increases the reliability substantially. These factors can make the accurate diagnosis of true bladder infection difficult in elderly women.

Asymptomatic bacteriuria is generally considered a benign condition in the elderly who are free of catheters. Studies have, however, shown a substantial incidence of potentially correctable lower urinary tract disease that can contribute to bacteriuria in asymptomatic elderly patients.<sup>22</sup> One study found that bacteriuric elderly nursing home residents had a 30% to 50% lower sur-

vival rate (deaths from a variety of causes) when followed for 10 years compared with nonbacteriuric residents matched for age, blood pressure, smoking habits, hematocrit, and blood cholesterol levels.<sup>30</sup> A second study of community-dwelling elderly also showed an association between bacteriuria and mortality,<sup>31</sup> but a cause-and-effect relationship has not been documented. Two studies of treated asymptomatic bacteriuria in older institutionalized<sup>32</sup> and ambulatory<sup>33</sup> women have not documented substantial effects on mortality. In summary, therapy for asymptomatic bacteriuria in older individuals has not produced improvements in survival or amelioration of genitourinary symptoms, but it has correlated with increased antimicrobial resistance and adverse drug effects. For these reasons, guideline consensus statements have recommended against the routine screening for and treatment of asymptomatic bacteriuria in older persons resident in the community elderly institutionalized residents of long-term care facilities.<sup>34</sup>

Symptomatic UTIs in elderly women should be treated with an antimicrobial that achieves a high concentration in the urine. Consensus guidelines recommend that trimethoprim/sulfamethoxazole (TMP/SMX) DS twice daily be first line therapy for UTIs, based on cost and efficacy considerations. Fluoroquinolones (i.e., ciprofloxacin and others) should be reserved for situations in which there are high rates of resistance (10% to 20%) to TMP/SMX.<sup>34</sup> In younger women, a 3-day regimen is associated with a 93% eradication rate. Longer courses are associated with higher eradication rates, which must be weighed against higher rates of adverse drug events.<sup>35</sup> Because of the acknowledged higher rates of failure in 3-day treatment for older women, the consensus statement recommends a 7-day treatment course for uncomplicated symptomatic infections. Drug selection should be modified based on such factors as allergy, renal function, cost, and bacterial sensitivities (especially when infections are recurrent). Although age-related changes do occur in the kidney's ability to eliminate these drugs, dosage adjustments usually are unnecessary unless the serum creatinine level is above 2.0 mg/dL.

Compliance with drug regimens may be a problem for many elderly patients and should be kept in mind as a potential cause of treatment failure. Recurrent infections in elderly women usually are caused by reinfection with a different organism. Relapse with the same organism should prompt a search for a structural abnormality in the lower urinary tract. When relapse

**Table 94-4 Prevalence of Urinary Incontinence Among Older Women**

Setting of Population	Women Affected (%)
Community	Approximately 33%: any incontinence* 4-6%: severe incontinence <sup>†</sup>
Acute care hospital	Approximately 40%
Nursing home	50-70%

\*Positive response to questioning about any uncontrolled urine loss in the past year.

<sup>†</sup>Incontinence that occurs more than once per week or requires the use of pads.

occurs in the absence of a structural abnormality, a 3- to 6-week course of drug therapy should be given. Infrequent symptomatic reinfections should be treated as separate episodes; frequent symptomatic infections can be managed by long-term prophylaxis. Nitrofurantoin (100 mg/day) and TMP/SMX ( $\frac{1}{2}$  of a single strength (40 mg/200 mg) tablet/day) have been shown to prevent recurrent symptomatic infections<sup>36</sup> and appear to be cost-effective, especially in women who have three or more symptomatic infections per year.<sup>37</sup>

## URINARY INCONTINENCE IN ELDERLY WOMEN

### Scope of the Problem

Incontinence is a common, disruptive, and potentially disabling condition in the elderly. The prevalence of urinary incontinence is illustrated in Table 94-4. Incontinence is a heterogeneous condition among older women, ranging in severity from occasional episodes of dribbling small amounts of urine to continuous urinary incontinence with concomitant fecal incontinence. The prevalence of urinary incontinence among women increases with increasing age. The likelihood of having severe urinary incontinence also increases with increasing age; compared with 8% of women between 30 and 39 years old reporting severe urinary incontinence, 33% of women between 80 and 90 years old reported severe urinary incontinence.<sup>38</sup> Although these general trends are clear, there are more subtle trends. The overall prevalence of urinary incontinence increases with rising age, but the prevalence of stress incontinence may peak at age 50 and then decrease slightly.<sup>39</sup> Parity, which is a significant risk factor for stress incontinence in younger women, is a much less important risk factor for stress incontinence in older women.<sup>40,41</sup>

Not all incontinent elderly women are severely demented, bedridden, and in nursing homes. Many in institutions and in the community are ambulatory and have good mental function. Physical health, psychological well-being, social status, and the costs of health care can be adversely affected by incontinence. Physical consequences can include skin breakdown, UTIs, and fractures, which may result if patients fall when they are forced to get up in the middle of the night to urinate. The psychosocial effects can be even more devastating; many elderly patients may suffer intense embarrassment, loss of self-esteem, and feelings of helplessness, depression, and anxiety, resulting in a withdrawal from vital social contacts or at least a reluctance to go places or engage in activities that are not close to toilet facilities.<sup>42</sup> The

financial impact of incontinence is also significant. It has been estimated that the cost of managing incontinence in elderly nursing home residents alone is close to \$3 billion per year.<sup>43</sup> Estimates put the U.S. Medicare cost of inpatient and outpatient treatment of urinary incontinence in women at \$234.4 million (1998). Urinary incontinence as the main reason for physician care for a Medicare visit rose from 845 per 100,000 in 1992 to 1845 per 100,000 persons in 2000.<sup>39</sup>

Urinary incontinence is curable in many elderly patients, especially those who have adequate mobility and mental function. There is growing literature suggesting that for some individuals, urinary incontinence can be prevented or delayed by exercises and behavioral strategies.<sup>44</sup> Even when urinary incontinence is not curable, incontinence can always be managed in a manner that keeps patients comfortable, makes life easier for caregivers, and minimizes the cost of caring for the condition and its complications.

### Acute, Reversible Incontinence versus Persistent Incontinence

The distinction between acute, reversible forms of incontinence and persistent incontinence is clinically important in older women because incontinence is often contributed to or caused by factors outside the lower urinary tract in this population. *Acute incontinence* refers to situations in which the incontinence is of sudden onset, usually related to an acute illness or an iatrogenic problem, and subsides after the illness or medication problem has been resolved. *Persistent incontinence* refers to incontinence that is unrelated to an acute illness and persists over time. The causes of acute and reversible forms of urinary incontinence can be remembered by the acronym DRIP (Table 94-5). Many of the reversible factors listed in this table can also play a role in patients with persistent forms of incontinence. A search for these factors should be undertaken in all incontinent geriatric patients.

Persistent forms of incontinence can be classified clinically into four basic types in the geriatric population: stress, urge, overflow, and functional. These types can overlap each other, and an individual patient may have more than one type simultaneously. Although this classification does not include all of the neurophysiologic abnormalities associated with incontinence (e.g., reflex or “unconscious” incontinence), it is helpful in approaching the clinical assessment and treatment of incontinence in the elderly.<sup>45</sup>

Stress incontinence is the most common type among women younger than 75 years, especially in ambulatory clinic settings.<sup>46-48</sup> It may be infrequent and involve very small amounts of urine, and it may need no specific treatment in women who are not bothered by it. However, it may be so severe or bothersome that it requires surgical correction. It is most often associated with weakened supporting tissues and consequent hypermobility of the bladder outlet and urethra caused by lack of estrogen or by previous vaginal deliveries or surgery. Older adults with stress incontinence, compared with their continent older counterparts, are more likely to be white, have arthritis, be using oral estrogen therapy, have chronic obstructive pulmonary disease, and be obese.<sup>49</sup> Parity appears to be a somewhat weaker risk factor among women 60 years old or older than among women younger than 60 years.<sup>30</sup> Many older women also develop stress incontinence because of intrinsic urethral dysfunction after one or more lower urinary tract surgical procedures.

**Table 94-5 Reversible Factors That May Contribute to Urinary Incontinence**

DRIP Acronym	Definition	Description
D	Delirium	New-onset urinary incontinence (UI) may be associated with delirium because of acute underlying conditions requiring diagnosis and treatment.
R	Restricted mobility Retention	Acute conditions causing immobility may precipitate UI; environmental manipulation and scheduled toileting are appropriate until the condition resolves. Urinary retention may be precipitated by many drugs (see Table 94-2) or may occur acutely because of anatomic obstruction; immobility and large fecal impactions may also contribute.
I	Infection Inflammation Impaction	Acute cystitis may precipitate urge UI. Otherwise asymptomatic bacteriuria may contribute to urinary frequency and should be eradicated before any urodynamic evaluations are carried out. Atrophic vaginitis and urethritis can cause irritative voiding symptoms, including UI. Fecal impaction and fecal incontinence may be associated with UI.
P	Polyuria Pharmaceuticals	Poorly controlled diabetes with glucosuria can contribute to urinary frequency and UI. Edema due to congestive heart failure or venous insufficiency can cause nocturia and exacerbate nocturnal UI (see Table 94-2)

Urge incontinence is the most common symptomatic and urodynamic type of incontinence in women older than 75 years, especially those in institutions, and it is commonly a component of the overactive bladder syndrome.<sup>50-52</sup> Urge incontinence can be caused by a variety of lower genitourinary and neurologic disorders. Older incontinent individuals with urge incontinence are more likely than their older, continent counterparts to be white, have arthritis, be using oral estrogen therapy, have insulin-treated diabetes, have depression, be older (within a 70- to 79-year-old cohort), and have poor lower extremity physical performance.<sup>49</sup> It is most often associated with detrusor motor instability or detrusor hyperreflexia. Some patients have a poorly compliant bladder without involuntary contractions (due to radiation or interstitial cystitis, both of which are unusual conditions in older women). Other patients have symptoms of urge incontinence but do not exhibit detrusor motor instability on urodynamic testing. This is usually called *sensory instability* or *hypersensitive bladder*; it is likely that some of these patients have detrusor motor instability in everyday life that is not documented at the time of the urodynamic study. However, some patients with neurologic disorders have detrusor hyperreflexia on urodynamic testing but may not have urgency and are incontinent without any warning symptoms (i.e., unconscious incontinence). These patients are generally treated as if they have urge incontinence if they can empty the bladder and do not have other correctable genitourinary pathology (discussed later). A subgroup of very elderly incontinent patients with detrusor hyperreflexia has been described who also have impaired bladder contractility; they empty less than a third of the bladder volume with involuntary contractions on urodynamic testing.<sup>51-53</sup> The implications of this urodynamic finding for the pathophysiology and treatment of incontinence in the elderly are unclear and are being investigated.

Urinary retention with overflow incontinence is relatively unusual among older women and can result from anatomic or neurogenic outflow obstruction, a hypotonic or acontractile bladder, or both (Box 94-1). Several types of drugs can also contribute to this type of incontinence (see Table 94-2).

Stress, urge, and overflow incontinence can occur in combination. About one third of older women with stress incontinence

#### Box 94-1 Causes of Urinary Retention in Elderly Women

- Bladder outlet obstruction
  - Mechanical compression
    - Gynecologic malignancy
    - Uterine fibroids
    - Ovarian cyst
    - Fecal impaction
    - Fibrosis of bladder outlet (uncommon) secondary to chronic inflammation
  - Urethral obstruction
    - Stricture
    - Prolapse and urethral distortion
  - Hypotonic bladder
    - Peripheral neuropathy
      - Diabetes
      - Alcoholism
    - Mechanical interruption of motor innervation
      - Tumor
      - Herniated disk
      - Trauma
    - Overdistention injuries
  - Detrusor-sphincter dyssynergy
  - Drug-induced retention (see Table 94-2)

also have symptoms of urge incontinence and detrusor instability. Similarly, about one third of women with urge incontinence also have symptoms or signs of stress incontinence.<sup>46-48,54</sup> These mixed types of incontinence can have important therapeutic implications, especially in decisions about surgery for stress incontinence.

Functional incontinence results when an elderly person is unable or unwilling to reach a toilet on time. Distinguishing this type of incontinence from other types of persistent incontinence is critical to appropriate management. Factors that cause functional incontinence (e.g., inaccessible toilets, psychological disorders) can exacerbate other types of persistent incontinence.

### Box 94-2 Diagnostic Evaluation of Urinary Incontinence in Older Women

#### All Patients

- Focused history
- Targeted physical examination
- Urinalysis
- Postvoid residual determination

#### Selected Patients

- Simple urodynamic test
- Complex urodynamic tests
  - Dual-channel cystometrogram
  - Pressure-flow study
  - Urethral pressure profilometry
  - Sphincter electromyography
  - Video urodynamic evaluation
- Laboratory studies
  - Urine culture
  - Renal function tests
  - Blood glucose
  - Serum calcium
  - Urine cytology
- Radiologic studies
  - Renal ultrasound
  - Voiding cystourethrography
- Urologic or gynecologic evaluation
  - Cystourethroscopy

Patients with incontinence that appears to be predominantly related to functional factors may also have abnormalities of the lower genitourinary tract such as detrusor hyperreflexia. In some patients, it can be very difficult to determine whether the functional factors or the genitourinary factors predominate without a trial of specific types of treatment. It is therefore appropriate to consider functional incontinence as a diagnosis of exclusion among older patients. Cognitive impairment or impaired mobility should not preclude a trial of specific treatment for incontinence when indicated.

#### Evaluation

In patients with a sudden onset of incontinence (especially one associated with an acute medical condition and hospitalization), the possible causes (see Table 94-5) can be determined by a brief history, physical examination, and basic laboratory studies (e.g., urinalysis, culture, serum glucose or calcium level).

Box 94-2 lists the basic components of the evaluation of persistent urinary incontinence. All patients should have a focused history, targeted physical examination, urinalysis, and a determination of postvoid residual urine volumes. The history should focus on the characteristics of the incontinence, current medical problems and medications, and the impact of incontinence on the patient and caregivers. Bladder records or voiding diaries are often helpful. Physical examination should focus on abdominal, rectal, and genital examinations and on evaluation of lumbosacral innervation. During the history and physical examination, special attention should be paid to factors such as mobility, mental status, medications, and accessibility of toilets that may be causing incontinence or interacting with urologic and neuro-

logic disorders to make the condition worse. A clean urine sample should be collected for urinalysis to exclude glucosuria, pyuria, bacteriuria, and hematuria. Persistent sterile microscopic hematuria (>5 red blood cells/high-power field) is an indication for further evaluation to exclude a tumor or other urinary tract abnormality.

A series of simple tests of lower urinary tract function can be carried out in a clinic, hospital, nursing home, or even at home. They include observation of voiding, a pad test for stress incontinence, and simple cystometry.<sup>55</sup> These tests are not necessary for all patients (discussed later). Like other diagnostic tests, they should be performed only if the results will change the patient's management. When they are performed, they must be carried out and interpreted carefully in light of other information from the history and physical examination. Bladder capacity and stability as determined by simple cystometry are highly correlated with results of formal multichannel cystometrograms.<sup>56</sup> Simple cystometry may be unnecessary to make a reasonable treatment plan in many elderly patients, such as those who have sterile urine and no atrophic vaginitis, meet none of the criteria given in Table 94-6, and who reliably give a history of stress incontinence without irritative or obstructive voiding symptoms, leak with stress maneuvers, and can empty the bladder completely (they can be treated for stress-type incontinence) or who reliably give a history of urge incontinence without symptoms of stress incontinence or voiding difficulty and can empty the bladder completely (they can be treated for urge-type incontinence). These tests are not essential for patients who are going to be treated initially with behavioral therapy alone, which can be used for stress, urge, mixed, and functional incontinence. The criteria for referral for further evaluation given in Table 94-6 have been shown to be reasonably sensitive but not very specific for identifying patients who require further evaluation for appropriate treatment.<sup>50</sup>

#### Management

Several therapeutic modalities are used in managing incontinent older women. Special attention should be paid to the management of acute forms of incontinence, which are most common in elderly patients in acute care hospitals. These forms of incontinence are often transient if managed appropriately; however, inappropriate management may lead to a permanent problem. The most common treatment for incontinent elderly patients in acute care hospitals is indwelling catheterization. In some instances, this therapy is justified by the necessity for accurate measurement of urine output during the acute phase of an illness. In many instances, however, it is unnecessary and poses a substantial and unwarranted risk of catheter-induced infection. Although it may be more difficult and time consuming for caregivers, making toilets and toilet substitutes accessible combined with some form of scheduled toileting is probably a more appropriate approach to the treatment of patients who do not require indwelling catheters. Launderable or disposable and highly absorbent bed pads and undergarments may also be helpful in managing these patients. These products may be more costly than catheters but probably result in less morbidity and therefore lower overall cost in the long run. Specially designed incontinence undergarments and pads can be very helpful for many nonhospitalized patients but must be used appropriately. They are being marketed on television and are readily available in retail stores. Although they can be effective, several caveats should be

**Table 94-6 Criteria for Referral of Elderly Incontinent Women for Urologic, Gynecologic, or Urodynamic Evaluation**

Criteria	Definition	Rationale
<b>History</b>		
Recent history of lower urinary tract or pelvic surgery or irradiation	Surgery or irradiation involving the pelvic area or lower urinary tract within the past 6 months	A structural abnormality related to the recent procedure should be sought.
Relapse or rapid recurrence of a symptomatic urinary tract infection	Onset of dysuria, new or worse irritative voiding symptoms, fever, suprapubic or flank pain associated with growth of more than 100,000 colony-forming units of a urinary pathogen; symptoms and bacteriuria that return within 4 weeks of treatment	A structural abnormality or pathologic condition in the urinary tract predisposing to infection should be excluded.
<b>Physical examination</b>		
Marked pelvic prolapse	Pronounced uterine descent to or through the introitus; prominent cystocele that descends the entire height of the vaginal vault with coughing during speculum examination	Anatomic abnormality may underlie the pathophysiology of the incontinence and may require surgical repair.
Severe stress incontinence*	Prominent, bothersome stress incontinence that has failed to respond to adequate trials of nonsurgical therapy	Bladder neck suspension procedures are generally well tolerated and successful in properly selected elderly women who have stress incontinence that responds poorly to more conservative measures.
Severe hesitancy, straining, or interrupted urinary stream	Straining to begin voiding and a dribbling or intermittent stream when the patient's bladder feels full	Signs suggest obstruction or poor bladder contractility.
<b>Postvoid residual</b>		
Difficulty in passing a 14-Fr straight catheter	Catheter passage impossible or requires considerable force or a larger or more rigid catheter	Anatomic blockage of the urethra or bladder neck may exist.
Postvoid residual volume >200 mL <sup>†</sup>	Volume of urine remaining in the bladder within 5 to 10 minutes after the patient voids spontaneously in as normal a fashion as possible	Anatomic or neurogenic obstruction or poor bladder contractility may exist.
<b>Urinalysis</b>		
Hematuria (sterile)	More than five red blood cells/high-power field on microscopic examination in the absence of infection	A pathologic condition in the urinary tract should be excluded.
Failure to respond to nonsurgical management	After behavioral or drug therapy, or both, incontinence persists and the patient desires further evaluation and treatment.	A formal urodynamic evaluation may help to better define and reproduce the symptoms associated with the patient's incontinence and target treatment more effectively.

\*If medical conditions preclude surgery or the patient is adamantly opposed to considering surgical intervention, the patient should not be referred.

<sup>†</sup>Some patients with lesser degrees of urinary retention may require evaluation, depending on other findings.

mentioned. Garments and pads are a nonspecific treatment. They should not be used as a first response to incontinence or before some type of diagnostic evaluation is done. Many patients are curable if treated with specific therapies, and some have potentially serious factors underlying their incontinence that must be diagnosed and treated. Pants and pads can interfere with attempts at certain types of behaviorally oriented therapies (discussed later).

Supportive measures are critical in managing all forms of incontinence and should be used in conjunction with other more specific treatment modalities. A positive attitude, education, environmental manipulations, appropriate use of toilet substitutes, avoidance of iatrogenic contributions to incontinence,

modifications of diuretic and fluid intake patterns, and good skin care are all important.

To a large extent the optimal treatment of persistent incontinence depends on identifying the types of incontinence that exists. Table 94-7 outlines the primary treatments used for the basic types of persistent incontinence found among older incontinent women. Each treatment modality is briefly discussed in the following sections.

### Drug Treatment

The efficacy of drug treatment has not been as well studied in the elderly as in younger populations,<sup>56,58</sup> but for many patients, especially those with urge or stress incontinence, drug treatment

**Table 94-7 Primary Treatments for Different Types of Urinary Incontinence in Elderly Women**

Type of Incontinence	Primary Treatment
Stress	Pelvic muscle (Kegel) exercises $\alpha$ -Adrenergic agonists Estrogen Biofeedback, bladder training
Urge	Surgical intervention Bladder relaxants Estrogen topically (if vaginal atrophy is present) Behavioral intervention (e.g., bladder training, biofeedback) Surgical removal of pathologic lesions
Overflow*	Surgical removal of obstruction Intermittent catheterization (if practical) Indwelling catheterization
Functional	Behavioral therapies (e.g., prompted voiding, habit training) Environmental manipulations Incontinence undergarments and pads External collection devices Bladder relaxants (selected patients) <sup>†</sup> Indwelling catheters (selected patients) <sup>‡</sup>

\*Overflow incontinence is no longer a recommended term (since 2002) by the International Continence Society, which favors the terminology of *acute or chronic retention of urine*.<sup>57</sup>

<sup>†</sup>Many patients with functional incontinence also have detrusor hyperreflexia, and some may benefit from bladder relaxant drug therapy.

<sup>‡</sup>See Box 94-3.

may be very effective. Drug treatment can be prescribed in conjunction with one or more of the behavioral interventions discussed in the following section. Head-to-head comparisons of drug and behavioral therapy have shown that both are efficacious for treatment of urinary incontinence,<sup>59</sup> and in practice, they often complement each other. Treatment decisions should be made on an individual basis and depend in a large part on the characteristics and preferences of the patient and the physician.

For urge incontinence, drugs with anticholinergic and bladder smooth muscle-relaxing properties are used. All of them may cause bothersome systemic anticholinergic side effects, especially dry mouth, in the elderly, and they can precipitate urinary retention in some patients. The advantages of extended-release preparations (e.g., tolterodine LA, oxybutynin XL, oxybutynin transdermal) and newer drugs (e.g., trospium, darifenacin, solifenacin) for overactive bladder over older, cheaper, immediate-release oxybutynin are more favorable side effect profiles (but no more efficacy). In animal models, these agents demonstrate more selectivity for the bladder than for the salivary glands, but some insist that the tolerability and effectiveness of agents are related to their antimuscarinic activity. Although use of immediate-release oxybutynin in older patients who are tolerant of side effects is possible, consensus guidelines recommend against immediate-release oxybutynin.<sup>60</sup> One newer agent, tolterodine, has been shown to have a slight decrease in efficacy and no decline in tolerability.<sup>61</sup>

The potential for severe anticholinergic side effects is much more likely in older adults than in younger adults. Patients with Alzheimer's disease must be followed for the development of drug-induced delirium. Patients with cognitive impairment may be taking cholinesterase-inhibitor agents (i.e., medications for dementia that offer small gains in cognition and slower rates of cognitive decline). The potential interaction can be clinically evident at times; patients may have a worsening of their cognition with bladder relaxants (i.e., anticholinergic effect)<sup>13</sup> or may have a worsening in their continence with acetylcholinesterase inhibitors (i.e., procholinergic effects). Research has shown that receptor targeting or properties that prevent a drug from crossing the blood-brain barrier may be important considerations in whether a medication will have effects on cognition. One study using darifenacin demonstrated in 129 nondemented patients that active drug did not have any significantly greater effect on cognition compared with placebo.<sup>62</sup> Drugs specifically indicated for use in urinary incontinence or overactive bladder likely offer some advantage over other drugs with more pronounced systemic anticholinergic side effects.<sup>63</sup> Several studies suggest that cognitive and physical functional impairments are associated with poor responses to bladder-relaxant drug therapy.<sup>64-66</sup> The results of these studies should not preclude a treatment trial in this patient population. Some patients may respond, especially in conjunction with scheduled toileting or prompted voiding. The goal of treatment in these patients may not be to cure the incontinence but to reduce its severity and prevent discomfort and complications.

For stress incontinence, drug treatment involves a combination of an  $\alpha$ -adrenergic agonist, duloxetine<sup>67</sup> (approved in Europe but not in the United States for treatment of stress incontinence), a selective serotonin reuptake inhibitor (SSRI) medication used in the treatment of depression, or topically applied estrogen, or both. Drug treatment is appropriate for motivated patients who have mild to moderate degrees of stress incontinence, do not have a major anatomic abnormality (e.g., large cystocele), and do not have any contraindications to these drugs. Although there are few published data on duloxetine in older patients, its inclusion here is merited because of the dearth of other medications for the treatment of stress urinary incontinence. Duloxetine generally enhances urine storage by facilitating the vesical sympathetic reflex pathway and inhibiting the parasympathetic voiding pathway. Duloxetine has been shown to increase significantly bladder capacity and sphincter tone without interfering with the normal voiding cycle. Duloxetine has also been evaluated for depression and lower urinary tract disease.<sup>67</sup>

$\alpha$ -Agonist medications that may be given for stress urinary incontinence have an effect on hypertension. The most commonly used over-the-counter medication previously used for stress urinary incontinence was phenylpropanolamine, which was removed from the market in 2000 because it was shown in women to be highly associated with intracranial hemorrhage when used as a dietary aid, which leaves pseudoephedrine as the over-the-counter agent. Pseudoephedrine may exacerbate hypertension and contribute to insomnia in some older patients. These patients may also respond to behavioral treatments (discussed later), and some data suggest that the two treatment modalities are roughly equivalent, with about three fourths of patients reporting improvement.<sup>68</sup> A combination of these modalities can be a reasonable approach for some patients.

Estrogen alone is not as effective as it is in combination with an  $\alpha$ -agonist for stress incontinence. Estrogen is also used

chronically or intermittently (i.e., 1- to 2-month courses) for the treatment of overactive bladder symptoms and urge incontinence in women with atrophic vaginitis and urethritis.

Given that lack of estrogen results in conditions that make urinary incontinence more likely, several studies have examined estrogen as a preventive agent or therapy for urinary incontinence. In a large study of more than 20,000 women, oral estrogens (0.625 mg of conjugated equine estrogen, with and without progesterone) were shown to increase the risk of developing urinary incontinence at 1 year. Among women who were incontinent, estrogen treatment worsened the frequency of urinary incontinence.<sup>1</sup> Despite the pessimism about using oral estrogens, there may still be a role for topical estrogen. Its administration has been shown to yield significant improvements in colposcopic findings, statistically significant increases in mean maximum urethral pressure and mean urethral closure pressure, and improvements in the abdominal pressure transmission ratio to the proximal urethra. The continence outcomes are less well understood.<sup>69</sup> It is not possible to infer that because low estrogen levels are associated with physiologic changes, hormone replacement will reverse these changes, restore function, or reduce symptoms.

Drug treatment for chronic overflow incontinence using a cholinergic agonist or an  $\alpha$ -adrenergic antagonist is usually not effective, although anecdotal reports suggest  $\alpha$ -blockers may be useful in some female patients. Bethanechol may be helpful when given for a brief period subcutaneously in patients with persistent

bladder contractility problems after an overdistention injury, but it is generally not effective when given orally over the long term.<sup>70</sup>

Symptomatically and urodynamically, many elderly women have a combination of urge and stress incontinence. In theory, a combination of estrogen and imipramine may be appropriate for these patients because imipramine has both anticholinergic and  $\alpha$ -adrenergic effects. When urge incontinence is the predominant symptom, a combination of estrogen and oxybutynin would be appropriate. Behavioral interventions are also a reasonable approach to women with mixed incontinence.

### Behavioral Interventions

Many types of behavioral procedures have been described for the management of urge and stress urinary incontinence.<sup>71,72</sup> The nosology of these procedures has been somewhat confusing, and in much of the literature, the term *bladder training* is used to encompass a wide variety of techniques. It is important to distinguish between procedures that are patient dependent (i.e., require adequate function and motivation of the patient), in which the goal is to restore a normal pattern of voiding and continence, and procedures that are caregiver dependent and can be used for functionally disabled patients, in which the goal is to keep the patient and environment dry (Table 94-8).

Pelvic muscle (Kegel) exercises consist of repetitive contractions of the pelvic floor muscles. This procedure is taught by having the patient interrupt voiding. This technique should be

**Table 94-8 Behavioral Interventions for Urinary Incontinence in Elderly Women**

Procedure	Definition	Types of Incontinence	Comments
<b>Patient dependent</b>			
Pelvic muscle (Kegel) exercises	Repetitive contraction of pelvic floor muscles	Stress Stress and urge	Requires adequate function and motivation
Biofeedback	Use of bladder, rectal, or vaginal pressure recordings to train patients to contract pelvic floor muscles and relax bladder		Requires equipment and trained personnel
Bladder training	Use of educational components of biofeedback, bladder records, pelvic muscle, and other behavioral exercises	Stress and urge	Requires trained therapist, adequate cognitive and physical function, and patient motivation
Bladder retraining	Progressive lengthening or shortening of intervoiding interval, with adjunctive techniques* Intermittent catheterization used in patients recovering from overdistention injuries with persistent retention	Acute (e.g., postcatheterization with urge or overflow, poststroke)	Goal is to restore normal pattern of voiding and continence; requires adequate cognitive and physical function and patient motivation
<b>Caregiver dependent</b>			
Scheduled toileting	Fixed toileting schedule	Urge and functional	Goal is to prevent wetting episodes
Prompted voiding	Regular opportunities to toilet with behavioral reinforcement		Can be used in patients with impaired cognitive or physical functioning
Habit training	Toileting based on established individual pattern with behavioral reinforcement		Requires staff or caregiver availability and patient motivation

\*Techniques to trigger voiding (e.g., running water, stroking thigh, suprapubic tapping), completely emptying the bladder (e.g., bending forward, suprapubic pressure), and alterations of fluid or diuretic intake patterns may be helpful for some patients.

used only to identify the proper muscles, and patients should be discouraged from doing this repeatedly because of the potential risk of teaching patients dysfunctional voiding habits. To get a sense of the muscles used, the patient is asked to squeeze the examiner's fingers during a vaginal examination (without doing a Valsalva maneuver, which is the opposite of the intended effect). One exercise consists of a several-second squeeze and a several-second relaxation. Once learned, the exercises should be practiced many times throughout the day (usually 75 exercises per day, broken down into three sessions of 25 exercises each), and they should be used in everyday life during situations (e.g., coughing, running water) in a variety of positions (e.g., sitting, standing, lying down) that can precipitate incontinence. Pelvic muscle exercises may be taught in conjunction with biofeedback procedures and can be especially helpful for women who bear down (i.e., increasing intra-abdominal pressure) when they attempt to contract the pelvic floor muscles. Vaginal cones (weights) may be useful adjuncts to pelvic muscle exercises in some patients.

Biofeedback procedures involve the use of bladder, rectal, or vaginal pressure or electrical activity recordings to train patients to contract the pelvic floor muscles and relax the bladder. Studies have shown that these techniques can be very effective for managing stress and urge incontinence, even in the elderly.<sup>73</sup> The use of biofeedback techniques may be limited by requirements for equipment and trained personnel; some of these techniques are relatively invasive and require the use of bladder or rectal catheters, or both. Some newer biofeedback techniques use surface electrodes and are less invasive. Electrical stimulation vaginally or rectally has also been used in the management of stress and urge incontinence. Research suggests that excellent results can be achieved in some older women in treating stress and urge incontinence without the use of electrical stimulation or computer-assisted biofeedback.<sup>74,75</sup> In contrast to medication therapy, the degree of continence achieved with pelvic muscle exercises is not as highly correlated with an increase in bladder capacity.<sup>76</sup>

Other forms of patient-dependent training procedures include various forms of bladder training and bladder retraining. Bladder training procedures involve the educational components taught during biofeedback but not the use of biofeedback equipment. Patients are taught how to do pelvic muscle exercises, provided strategies for managing urgency, and instructed to regularly use bladder records. These techniques are highly effective in selected community-dwelling patients, especially women.<sup>77</sup> Investigators have attempted to identify baseline characteristics that predict clinical success with behavioral techniques. It is probably more important to discuss factors that *do not* predict worse outcomes: greater age, greater parity, lower levels of education, and previous surgery (the latter two may actually predict greater success).<sup>78</sup>

The goal of caregiver-dependent behavioral interventions, such as prompted voiding and habit training, is to prevent incontinence episodes rather than restore the normal pattern of voiding and complete continence. These procedures have been shown to be effective in reducing incontinence in selected nursing home residents. In its simplest form, scheduled toileting involves toileting the patient at regular intervals, usually every 2 hours during the day and every 4 hours during the evening and night. Habit training involves a schedule of toilettings or prompted voidings that is modified according to the patient's pattern of continent voids and incontinence episodes as demonstrated by a monitoring record. Positive reinforcement is offered for continent voids

and neutral reinforcement when incontinence occurs. Adjunctive techniques to prompt voiding (e.g., running tap water, stroking the inner thigh, suprapubic tapping) and to help empty the bladder completely (e.g., bending forward after completion of voiding) may be helpful for some patients. Prompted voiding has been the best studied of these procedures. It is a simple behavioral procedure that combines several of the elements mentioned earlier.<sup>79</sup> The success of these procedures is largely dependent on the knowledge and motivation of the caregivers implementing them, rather than on the physical functional and mental status of the incontinent patient. These techniques are not feasible in home settings without available caregivers. For these types of procedures to be feasible and cost-effective in the nursing home setting, the amount of time generally spent by the nursing staff in changing patients after incontinence episodes should not be exceeded by the time and effort needed to implement such training procedures. Targeting these procedures to selected patients, such as those with less frequent voiding and larger bladder capacities or voided volumes, may enhance their cost-effectiveness.<sup>79</sup> Quality assurance methods, based on principles of statistical quality control used in industry, have been shown to be helpful in maintaining the effectiveness of prompted voiding in nursing homes.<sup>80</sup>

### Surgery

Surgical interventions are described in detail in other chapters in this textbook. Surgery should be considered for elderly women with stress incontinence that continues to be bothersome after attempts at nonsurgical treatment have been made and in women with a significant degree of pelvic prolapse or intrinsic urethral dysfunction. As with many other surgical procedures, patient selection and the experience of the surgeon are critical to success. Several case series have demonstrated that with proper patient selection, even elderly adults can successfully undergo surgery, but the number of overall incontinence procedures in older women remains low. All women being considered for surgical therapy should have a thorough evaluation, including urodynamic tests, before undergoing the procedure. Women with mixed stress incontinence and detrusor motor instability may also benefit from surgery, especially if the clinical history and urodynamic findings suggest that stress incontinence is the predominant problem. Modified techniques of bladder neck suspension can be done with minimal risk and are highly successful in achieving continence, even in the elderly. Urinary retention can occur after surgery, but it is usually transient and can be managed by intermittent catheterization. Injection of bulking agents appears to be effective in older women, and age does not appear to correlate with outcomes.<sup>81</sup> This procedure may be especially helpful for frail older women who have stress or mixed incontinence that has not responded to behavioral or drug therapy.

### Catheters and Catheter Care

Three basic types of catheters and catheterization procedures are used for the management of urinary incontinence: external catheters, intermittent straight catheterization, and chronic indwelling catheterization. An external catheter for use in women is commercially available, but its safety and effectiveness have not been well documented in the elderly. Intermittent catheterization can help in the management of patients with urinary retention and overflow incontinence. The procedure can be carried out by the patient or a caregiver, and it involves straight catheterization two to four times daily, depending on residual urine volume. In

**Box 94-3 Indications for and Principles of Chronic Indwelling Catheter Use****Indications**

1. Urinary retention that
  - Is causing persistent overflow incontinence, symptomatic infections, or renal dysfunction
  - Cannot be corrected surgically or medically
  - Cannot be managed practically with intermittent catheterization
2. Skin wounds, pressure sores, or irritations that are being contaminated by incontinent urine
3. Care of terminally ill or severely impaired patients for whom bed and clothing changes are uncomfortable or disruptive
4. Preference of patient or caregiver when patient has failed to respond to more specific treatments

**Catheter Care**

1. Maintain sterile, closed, gravity drainage system; change the catheter every 4 to 8 weeks.
2. Avoid breaking the closed system.
3. Use clean techniques in emptying and changing the drainage system; wash hands between patients in institutionalized settings.
4. Secure the catheter to the upper thigh or lower abdomen to avoid perineal contamination and urethral irritation due to movement of the catheter.

5. Avoid frequent and vigorous cleaning of the catheter entry site; washing with soapy water once each day is sufficient.
6. Do not irrigate routinely.
7. If bypassing occurs in the absence of obstruction, consider the possibility of a bladder spasm, which can be treated with a bladder relaxant.
8. If catheter obstruction occurs frequently, increase the patient's fluid intake and acidify the urine if possible.
9. Do not routinely use prophylactic or suppressive urinary antiseptics or antimicrobials.
10. Do not perform routine surveillance cultures to guide management of individual patients because all chronically catheterized patients have bacteriuria (which is often polymicrobial), and the organisms change frequently.
11. Do not treat infection unless the patient develops symptoms; symptoms may be nonspecific, and other possible sources of infection should be carefully excluded before attributing symptoms to the urinary tract.
12. If a patient develops frequent symptomatic urinary tract infections, a genitourinary evaluation should be considered to rule out pathology such as stones, periurethral or prostatic abscesses, or chronic pyelonephritis.

the home, the catheter should be kept clean (but not necessarily sterile). Studies conducted largely among younger paraplegics have shown that this technique is practical and reduces the risk of symptomatic infection compared with chronic catheterization.

Self-intermittent catheterization has been shown to be feasible for elderly women outpatients who are functional and are willing and able to catheterize themselves.<sup>82</sup> However, studies carried out in young paraplegics and elderly female outpatients cannot automatically be extrapolated to frail elderly women or the institutionalized population. The technique may be useful in certain patients in acute care hospitals or nursing homes, such as those who have undergone bladder neck suspension, or in certain situations, such as after removal of an indwelling catheter in a bladder-retraining protocol. Nursing home residents, however, may be difficult to catheterize, and the anatomic abnormalities commonly found in elderly patients' lower urinary tracts may increase the risk of infection because of repeated straight catheterizations.

Use of this technique in an institutional setting (which may have an abundance of organisms that are relatively resistant to many commonly used antimicrobial agents) may yield an unacceptable risk of nosocomial infections, and the use of sterile catheter trays for these procedures would be very expensive. It therefore may be extremely difficult to implement such a program in a typical nursing home setting.

Chronic indwelling catheterization is overused in some settings, and when used for periods of up to 10 years, it has been shown to increase the incidence of a number of other complications, including chronic bacteriuria, bladder stones, periurethral abscesses, and even bladder cancer. Elderly female nursing home residents managed by this technique are at relatively high risk for developing symptomatic infections.<sup>83</sup> Given these risks, it seems appropriate to recommend limiting the use of chronic indwelling catheters to certain specific situations and to follow sound principles of catheter care when using indwelling catheterization to attempt to minimize complications (Box 94-3).

# URODYNAMICS EVALUATION IN THE ELDERLY

*Pat O'Donnell*

Urodynamic studies are the most comprehensive objective clinical measures of bladder and urethra function available for the clinical evaluation of elderly women with urinary incontinence or any other voiding dysfunction. Although urodynamic studies have many limitations, the clinical information derived from these studies is invaluable for making reasonable long-term management decisions in the treatment of urinary incontinence in older women. Comprehensive urodynamic studies are accepted well by older women, and discomfort or complications related to the studies do not preclude performing studies, even in frail elderly women.

Elderly incontinent women represent a group of patients who derive the most clinical benefit from urodynamic studies because of the complexity of voiding dysfunctions in this patient population and the impact that these voiding dysfunctions have on the quality of life in older women. Although the consequences of urinary incontinence in younger women are debilitating and life changing, it is primarily the elderly women who are placed in nursing homes because of it. Urodynamic studies represent a diagnostic evaluation available that has the potential to change the outcome of long-term incontinence therapy in older women. Successful treatment of voiding dysfunctions in older women has a profound impact on the quality of life of these patients, which emphasizes the importance of the diagnostic clinical information from urodynamic studies. Urodynamic studies provide the clinician with a basic understanding of the pathophysiology of the complex condition of incontinence in older women.

The clinical value of urodynamic studies in elderly women reflects the magnitude of the problem of incontinence in this patient population. The incidence of incontinence is higher among older women than younger women. The personal impact of urinary incontinence on quality of life is so powerful that it can potentially take an older woman away from her home in a community-dwelling environment to the chronic-care environment of a nursing home. The life-changing consequences of incontinence are so great that aggressive evaluation should be considered as an initial part of management of these older patients.

Changes in the bladder and urethral function, along with the changes in physical and mental function, that are associated with aging significantly complicate the diagnosis and management of incontinence in older women. Although voiding dysfunctions in this group represent a survival risk related to complications such as urinary tract infections or hip fractures associated with nocturia and urge urinary incontinence, the most common reasons to consider initial comprehensive urodynamic studies in elderly women are the quality-of-life concerns of the patient about activities that matter most in her daily life. These are the activities she needs to do each day to care for herself and the activities that she enjoys and that make life worthwhile. The long-term choices about evaluation and management are personal decisions by the individual patient that are based on the information provided to

her by the physician, the recommendations made to her by the physician, and how she chooses to use that information to live the rest of her life the best way possible. The diagnostic information provided by urodynamic studies is necessary for the physician to counsel the patient about the many decisions that she must make over time regarding the long-term management of her bladder symptoms.

The mental functional status and physical functional status of an elderly individual determine to some extent to how she can participate in the choices about evaluation and therapy. The choices may be different if an elderly woman is in a community-dwelling, assisted-living, or chronic-care environment. The availability of family support is important in decisions about urodynamic studies and long-term management of urinary incontinence. If family members and the patient understand the value of urodynamic studies in clinical management decisions, the patient can commit to maximum personal participation in the procedure. The commitment by the patient and her family to the choice that she makes about comprehensive evaluation and long-term therapy is an essential component of the quality of the urodynamic studies and the clinical value of the information provided by the studies for the physician.

Occasionally, family members of older women may have unrealistic expectations about treatment outcomes. The patient also may have treatment expectations that are not realistic. This situation is even more difficult for the physician when the family or the patient does not have a commitment to working through complications of therapy or treatment failure. In these circumstances, the urodynamic studies can be very helpful in providing objective information about the complexity of the clinical problem that can be communicated to the patient and her family. Urodynamic studies provide objective clinical information that allows realistic expectations about therapy and provide a basis for a personal commitment to therapy that needs to be made by the patient and her family.

Urodynamic studies help the physician advise an older woman about her condition, explain the treatment choices that are reasonable, and help her to understand the possible treatment outcomes so that her expectations are realistic and she can become an active participant with the physician in the long-term management process. Because of the complexity of incontinence in older women, the partnership between the physician and the patient in the long-term management of urinary incontinence is an extremely important relationship. Complex urodynamic studies that are well performed have a positive impact on the relationship between the physician and the elderly patient. As a result, the physician is better able to recommend a practical approach to therapy, and the patient can become a confident partner in a process that is usually a long-term relationship. Urinary incontinence in older women rarely has a single therapeutic modality that results in complete resolution of bladder problems. Instead, voiding dysfunctions in older women usually require long-term

treatment with a therapeutic goal of decreasing the severity of symptoms over time. Therapeutic choices and periodic changes in treatment need to be based on the best urodynamic studies available. Repeating the urodynamic studies during long-term management of older women can be valuable to the physician in altering the course of therapy.

### URODYNAMICS LABORATORY

A laboratory for urodynamic evaluation of incontinence in elderly women needs to have the highest diagnostic capabilities possible and to be a very comfortable and congenial experience for the patient. The ambience of a urodynamics laboratory for older women is one of the most important aspects of the evaluation. Because the performance of the measurements alters the very functions that are being measured, the environment needs to feel as much like home to the patient as possible to minimize the measurement effect on the study results. A comfortable environment can make it possible for an older woman to be an active participant in the studies, and it enables the study results to provide the best possible information about her bladder and urethral function relative to symptoms experienced during her daily life.

Another important aspect of the urodynamics laboratory is the relationship between the urodynamicist and the patient. Scheduling extra time in the laboratory before the studies is helpful in developing a personal relationship that is nurturing and congenial to minimize any feelings of fear and anxiety that the older patient may experience during the studies. Older women are often more difficult to engage in active participation in the studies than younger women. Because the complexity of bladder dysfunctions and functional impairment is greater in older women compared with younger women, the studies are considerably more difficult to perform and usually require more time to complete.

When performing urodynamic studies in older women, the urodynamicist sometimes may feel like a flight attendant who says, "In the event of a sudden loss in cabin pressure, place the oxygen mask over your nose and mouth and breathe normally." It is not likely that anyone would breathe normally under those conditions. Although it is necessary to recognize the artificial conditions of the urodynamics laboratory, the goal is to create an environment and testing experience that allows the measured behavior of the bladder in elderly women to be as normal as possible. It is one of the primary objectives during testing of older women to minimize the measurement effects of the urodynamic studies on normal bladder and urethral function.

Comprehensive urodynamic studies in older women are not like an electrocardiogram of the bladder in the way the studies are performed and interpreted. Much of the information required for interpretation of urodynamic studies is recorded by the urodynamicist as the studies are being done by describing events and sensations experienced by the older patient. The training and experience of the urodynamicist is an integral part of the diagnostic capabilities of the urodynamics laboratory.

The symptoms experienced by the older woman are less predictive of urodynamic findings than those in younger women.<sup>1</sup> The voiding history and physical examination do not provide enough clinical information to make decisions about treatment in older women without the additional information provided by urodynamic studies. However, the urodynamicist needs to know

the clinical history and the observations made on physical examination to perform the best studies possible for the patient. Because urodynamic studies are more difficult to perform in older women and the results are so important in clinical management decisions for these patients, measurements often need to be repeated during the initial testing procedure to ensure that the clinical information provided is as complete and accurate as possible.

It is a goal of the urodynamicist to duplicate the clinical symptoms described by the patient in the urodynamics laboratory. However, the symptoms experienced during the daily life of an older woman often do not occur during the urodynamic studies. In the elderly population, another approach to evaluation may be necessary. If the clinician can identify the symptoms experienced by the patient during her daily activities as completely and thoroughly as possible, the urodynamic studies can be used to better understand why she experiences those symptoms and what can be done to treat the symptoms based on the information provided by the studies.

The diagnostic capabilities of the urodynamic testing equipment are frequently a concern of the physician. Physicians do not want to be limited in their diagnostic capabilities by the limitations of the equipment in the urodynamics laboratory. Although midlevel equipment from most manufacturers can provide the basic information needed for most patients, higher-level equipment is preferred for elderly women because of the complexity of the clinical problems. However, the most expensive equipment does not ensure high-quality studies. The ambience of the laboratory and the skill of the urodynamicist are as important as the capabilities of the equipment. Because elderly women usually have more complex voiding dysfunctions than younger women, the higher-level equipment is often required to meet the performance needs of the clinician in testing these patients.

Urodynamic studies are objective measurements that require a significant knowledge of lower urinary tract function and clinical experience for interpretation. Similar knowledge and experience are required to clinically use the urodynamic studies to make reasonable recommendations for treatment in older women. Each study or test can provide only a fraction of the clinical data, and to see the complete clinical picture and make treatment decisions, especially for older patients, the physician needs comprehensive urodynamic studies.

Urodynamic studies of older women are needed when considering pharmacologic, behavioral, or surgical therapy. It is much easier to change medications or combine pharmacologic therapy with behavioral therapy than it is to revise an operation. However, any long-term treatment needs to be based on the most complete clinical information available. Without urodynamic studies, the clinician is voluntarily relinquishing the most comprehensive objective measurements of bladder and urethral function that are available. Without urodynamic studies in this population, the opportunity of providing the most appropriate initial treatment is significantly decreased, even when nonsurgical therapy is recommended. An ineffective trial of pharmacologic therapy without urodynamic studies is rarely harmful in the long term, but the cost to the elderly woman is time and money at a moment in her life when she often feels she has little of either.

### NONINVASIVE URINARY FLOW STUDIES

Noninvasive urinary flow studies are relatively easy to perform in younger women but can be difficult to perform in older women

for many reasons. Older patients with urinary incontinence often have an impaired ability to inhibit involuntary detrusor contractions and an impaired ability to voluntarily initiate a bladder contraction.<sup>2</sup> The older woman is usually instructed to arrive at the urodynamics laboratory with her bladder as full as possible so that the noninvasive urinary flow study can be done. She might have “had to go” just before coming to the urodynamics laboratory, or she might have had an “accident” just before arrival. She may be unable to voluntarily void even though she has not voided for hours. Catheterization of the bladder in an elderly woman who is unable to void often demonstrates a relatively large amount of urine in the bladder. The volume of urine obtained in this case is not a postvoid residual urine volume because the patient was unable to void. It is common for older women with urinary incontinence to be unable to prevent or initiate a bladder contraction. In contrast, young women can usually voluntarily void at almost any time.

It is helpful to have a urinary flow unit in the office so that measurement of urinary flow rate can be done many times for older women to determine as closely as possible the urinary flow characteristics of the patient. An ultrasound postvoid residual volume measurement unit in the office allows the assessment to be done with each office visit to obtain multiple determinations. Ultrasound bladder volume measurements have been shown to have a high correlation with catheterized volume measurements in elderly patients.<sup>3</sup> Although the measurement of the postvoid residual urine volume is a simple method to evaluate bladder emptying in elderly patients, it is not possible to predict the type of bladder dysfunction that the patient has without additional studies.<sup>4</sup>

### Urethral Pressure Profile

The maximum urethral pressure and urethral length decrease in continent women with increasing age.<sup>5</sup> Clinical evaluation of urethral function in older women is one of the most important aspects of assessment of lower urinary tract function. However, urethral function remains one of the most elusive measurements of lower urinary tract function. Urethral dysfunction of some type is usually a component of urinary incontinence in older women. The urethral pressure profile (UPP) measurements in women significantly correlate with incontinence episodes and absorbent pad use.<sup>6</sup> Although the UPP measurements have a significant correlation with incontinence severity, the UPP is a measurement of resting urethral pressure and not a direct measurement of continence. This distinction is important when using the UPP measurement in clinical decisions.

Assessment of urethral sphincter dysfunction may require a composite of historic, urodynamic, anatomic, and clinical severity criteria.<sup>7</sup> The composite of intrinsic sphincter deficiency has been suggested to include a maximum urethral closure pressure less than or equal to 20 cm/H<sub>2</sub>O, a Valsalva leak point pressure of less than or equal to 50 cm/H<sub>2</sub>O, and a stress urethral axis less than or equal to 20.<sup>7</sup>

The concept that intrinsic functional properties of the urethra exist that contribute to the integrity of the urethral continence mechanism resulted from many years of clinical work by McGuire and others.<sup>8,9</sup> During the 1970s, McGuire and Lytton<sup>8</sup> observed that women who had failed previous incontinence procedures had poor urethral function indicated by low urethral pressure. McGuire and colleagues<sup>9</sup> subsequently categorized women who have poor urethral function as having type III incontinence. Type

III incontinence refers to a poorly closed proximal sphincter identified by video urodynamics and leak point pressure measurement. Intrinsic sphincter deficiency refers to a low-pressure urethra identified using UPP measurements recorded in the mid-urethral high-pressure zone. The UPP and abdominal leak point pressure (ALPP) assessments are performed differently and identify different characteristics of urethral function. Although the low-pressure urethra and the type III urethra identify different aspects of urethral function, the clinical objective of both studies is to recognize women who have severely compromised urethral function. Because clinical evaluation of urethral function in older women is important in the management of incontinence, the UPP and ALPP measurements can be used to better characterize urethral dysfunction. Although the UPP has many limitations, the measurements can contribute to the information obtained from ALPP assessment if the UPP is used appropriately. Elderly women who have intrinsic sphincter deficiency based on the UPP should be clinically identified and counseled about treatment because of the higher risk for failure of any therapeutic approach in this group.<sup>10,11</sup>

The maximum urethral closure pressure and the Valsalva leak point pressure are significantly decreased with increasing severity of the incontinence grade.<sup>13</sup> Some studies have suggested a statistically significant relationship between the UPP and ALPP.<sup>12-15</sup> From a clinical management perspective, the UPP and ALPP are different measurements of urethral function that can be useful in combination, but they are not comparable measurements.

UPP measurements are usually performed using micro tip transducers. Although many techniques have been used, the microtip transducer remains the clinical standard for UPP measurements. A dual-channel microtip catheter is preferred. It has a microtip transducer located at the tip of the catheter for bladder pressure measurement and a microtip transducer located approximately 5 cm proximally for measurement of urethral pressure. The subtraction of intravesical pressure from urethral pressure produces the urethral closure pressure profile.<sup>16</sup> The dual-channel microtip transducer allows the urodynamicist to perform stress UPP measurements. An electronic catheter puller is used to ensure a constant rate as the catheter passes through the urethra. Because of measurement variations in the UPP, many measurements are done to determine the maximum resting urethral pressure. The UPP measurement in older women is usually performed in the supine position because of measurement artifact that occurs in the standing position.

A stress UPP is a measure of the difference between the intravesical pressure and intraurethral pressure during stress maneuvers such as coughing. A stress pressure profile is performed in the same way as a resting UPP with additional instructions for the patient to cough during the urethral pressure measurement. Usually, the patient is instructed to cough approximately six or more consecutive times as the UPP catheter is pulled through the functional urethra at a rate of approximately 1 mm per second. The pressure transmission ratios of a stress pressure profile measurement have been found to be sufficiently reproducible to be useful in characterizing stress sphincteric function.<sup>17</sup>

During coughing, an increase in urethral pressure occurs that is usually greater in magnitude than the increase in abdominal pressure, which indicates that active and passive compensatory pressure mechanisms are involved in continence. Denervation of the urethra, hypermobility of the urethra, and intrinsic dysfunction of the urethra are some of the reasons that the normal compensatory pressure mechanisms fail. A negative pressure

gradient between the urethra and bladder during coughing indicates that the pressure compensatory mechanisms of the urethra are not functioning normally. Urethral function studies in healthy women compared with women having genuine stress incontinence show that the active closure mechanisms at the bladder neck and mid-urethra are significantly weakened in women with genuine stress incontinence, and the results do not support the concept that impaired passive pressure transmission to the urethra is an important pathophysiologic factor in genuine stress incontinence.<sup>18</sup> A dynamic active closure mechanism has been demonstrated at the bladder neck in addition to the dynamic closure mechanism that is located in the middleurethra.<sup>18</sup> Increases in urethral closure pressure during coughing probably occur because the urethra is compressed against a hammock supportive layer, rather than the urethra being truly intra-abdominal.<sup>19</sup> These observations do not support the concept of passive abdominal pressure transmission to an intra-abdominal urethra as the mechanism of urethral continence.

Pelvic organ prolapse can produce obstructive symptoms and prevent or reduce urinary leakage.<sup>20</sup> The resting urethral pressure is often higher than expected in women who have a cystocele. The resting UPP measurement is usually done initially without cystocele reduction. Repeat urethral pressure measurements are done after cystocele reduction. Results of the Scopettes (Birchwood Laboratories, Eden Prairie, MN) reduction technique to reduce prolapse revealed a 56% incidence of low-pressure urethra and stress urinary incontinence in 83% of patients with grade 4 vaginal prolapse.<sup>21</sup> A statistically significant relationship exists between urethral incompetence and hypermobility of the urethra.<sup>22</sup> If a significant decrease in resting urethral pressure occurs with reduction of the cystocele, surgical reduction of the cystocele can be expected to produce an even greater decrease in resting urethral pressure.

The effect of a cystocele on the UPP can indicate relatively good urethral function even though the actual urethral function after surgical repair of the cystocele may be significantly compromised. The change in urethral pressure with cystocele reduction in the laboratory setting can be helpful for indicating changes in urethral function after surgical repair of the cystocele. However, in some older women, surgical reduction of a cystocele can result in a profound decrease in urethral function compared with preoperative manual reduction of the cystocele in the urodynamics laboratory.

### Abdominal Leak Point Pressures

An ALPP is a measure of the lowest total bladder pressure at a known volume at which leakage occurs during prompted increases in abdominal pressure.<sup>23</sup> The total bladder pressure is equal to the sum of the detrusor pressure and the abdominal pressure measured in the bladder. If the bladder compliance is normal, the abdominal pressure is usually approximately the same as the total bladder pressure at a low intravesical volume in the absence of a detrusor contraction.

A simplified office technique for measuring ALPP in older women can be done during filling cystometry. The patient is placed in a semi-erect position, and bladder filling is stopped at 200 mL. The patient is instructed to strain progressively to the maximum abdominal pressure possible or until leaking occurs. The external urethral meatus is visually observed. When leaking is observed, the intravesical pressure is recorded. If leaking does not occur, the patient is instructed to cough progressively to a

maximum coughing pressure. The point at which leaking occurs with coughing is recorded. If leaking does not occur, the maximum abdominal pressure measured is recorded, and the absence of leaking is documented. At this point, filling cystometry is continued. This technique is particularly suited to office-based urodynamic studies in older women. The ALPP measured using this technique may have measurement error causing a higher ALPP value because the patient is not in a full standing position.<sup>12</sup> It is more difficult to identify leaking using a visual technique compared with a fluoroscopic technique.

If fluoroscopy is available, the measurement can be done in the semi-erect position or the standing position using the smallest catheter that is practical. A 5-Fr, double-lumen catheter can be used. One lumen is used to fill the bladder, and the other lumen is used to measure intravesical pressure. A 3-Fr microtip catheter can be used to measure ALPP fluoroscopically, but it is expensive and requires filling of the bladder with a separate catheter, which may not be practical for most urodynamics laboratories. A 20% iodinated contrast medium typically is used, although a 60% contrast medium can be used when better visualization of the urethra is required as in obese patients. An anteroposterior view of the urethra is often used, although a lateral view may provide better visualization of the bladder neck and mid-urethral continence mechanisms. When a lateral view is used, positioning the patient about 10 degrees off a line perpendicular to the x-ray table places the femoral heads out of alignment and allows a better radiographic view of the urethra. In this position, the urethra is usually centered between each femur, which makes leaking much easier to visualize.

The measurement of ALPP in elderly women is an essential urethral function study. During the urodynamic studies, older women occasionally are unable physically to generate an abdominal pressure of 60 cm H<sub>2</sub>O, which is needed to identify type III incontinence if no leaking is seen. Some frail elderly women may have low abdominal pressures during most daily activities.

Because women who have stress incontinence usually leak in the standing position, it is preferable to measure the ALPP in the standing position. Some older women may have difficulty standing and performing straining maneuvers at the same time. Although a semi-erect position is a compromise in the measurement technique, it is often a more feasible position to perform the ALPP measurement for older women.

A cystocele can cause an error in the ALPP measurement, resulting in a higher abdominal pressure required for leaking. The ALPP can be measured with cystocele reduction using Scopettes, vaginal gauze packing, or a vaginal speculum.<sup>24</sup> It is sometimes difficult to reduce the cystocele in older women enough in the urodynamics laboratory to be confident that the ALPP measurement accurately indicates urethral function. Women who demonstrate stress incontinence with the vaginal prolapse reduced and the urethra supported normally should be suspected of having type III incontinence.<sup>25</sup> Placement of a pessary to reduce vaginal vault prolapse can obstruct the urethra and result in a measurement error.

The clinical objective of ALPP measurement in older women is to determine the functional status of the urethra so that a reasonable clinical management recommendation can be made. Many older women have very complicated combinations of urethral dysfunction, bladder dysfunction, and vaginal prolapse. Vaginal vault prolapse can significantly complicate the measurement of urethral function. The ALPP is an essential piece of the clinical puzzle, and without the leak point pressure measure-

ments, clinical evaluation of urethral function in older women is not complete.

### Cystometrogram

The cystometrogram is a measure of the response of the bladder to being filled.<sup>26</sup> Cystometry is the method by which the pressure-volume relationship of the bladder is measured.<sup>16</sup> A medium filling rate typically is used when obtaining a cystometrogram in elderly women. A medium fill rate ranges from 10 to 100 mL per minute, which is a relatively wide range for older women. A lower filling rate in the medium filling range is preferred in older women to better evaluate the response of the bladder to filling. A filling rate of 30 mL per minute is usually satisfactory for older women. A slow filling rate of 10 mL per minute requires a long time to fill the bladder if the capacity is normal. Repeat filling of the bladder using a slow filling rate is a consideration for women who have severe detrusor instability or a very small bladder capacity.

A common filling technique uses a small (5 to 7 Fr), double-lumen urethral catheter attached to a perfusion pump, and water or saline is the infusion medium. A 5-Fr urethral catheter is preferred because of the small size, although the small lumen may decrease the pump flow rate during filling. A larger urethral catheter (e.g., 6 Fr) has been shown to decrease the maximum urinary flow rate during pressure flow studies in women.<sup>27</sup> The 5-Fr, double-lumen catheter allows filling cystometry and pressure flow studies to be done consecutively using the same catheter, which is an advantage for older women.

A rectal catheter is a common method for measurement of abdominal pressure in older women. The intravesical catheter is a much more reliable initial measure of intra-abdominal pressure than the rectal catheter measurement. For this reason, the rectal catheter recording is adjusted to equal the bladder pressure recordings during resting and straining maneuvers at baseline before filling. Using a cough and strain maneuver, the rectal catheter recording usually can be adjusted to almost exactly match the bladder pressure recording at baseline. When the rectal pressure channel and the bladder pressure channel are reading as close to the same as possible during straining maneuvers, bladder filling is begun. During filling, small fluctuations in abdominal pressure can be seen that result from respiration, which assures the urodynamicist that both channels are working properly. Occasionally, a rectal contraction may cause the differential pressure measurement to have a negative value, which usually can be disregarded. Spontaneous rectal contractions usually disappear as the study progresses.<sup>28</sup> Rectal contractions of some type occur in approximately 29% of patients having urodynamic studies, regardless of age.<sup>29</sup> Persistent rectal contractions are a relatively uncommon event while obtaining the cystometrogram in older women.

Bladder sensation during filling cystometry can be difficult to evaluate in older women because of the subjective nature of the measurement. The relationship of bladder sensation to bladder activity needs to be recorded, and identifying bladder sensation requires the patient to understand the importance of communicating awareness of bladder sensation to the urodynamicist.

Unstable detrusor contractions may occur during the filling phase of cystometry in older women. The pressure resulting from involuntary detrusor contractions, the duration of the contractions, and the number of contractions during filling varies considerably among patients. When an involuntary detrusor

contraction occurs during filling, involuntary loss of urine usually occurs. A sensation of urinary urgency may precede an involuntary detrusor contraction, or the sensation of urgency may occur during the contraction. However, older women who have a history of urge urinary incontinence may not exhibit unstable detrusor contractions during filling.

Elderly women who have had a previous stroke with residual neurologic deficits may exhibit detrusor hyperreflexia during filling cystometry. Suprapontine lesions in elderly patients can result in involuntary detrusor contractions during filling cystometry with associated electromyographic activity that has the appearance of detrusor sphincter dyssynergia. Involuntary loss of urine has occurred during phases of electromyographic relaxation in older patients who were studied using telemetry (Fig. 95-1).<sup>30</sup>

When continuous involuntary detrusor contractions occur during filling cystometry, the problem in some patients can be obtaining any further useful information from the studies. At that point, measurement of pressure flow studies during voluntary voiding would be useful, although measurements requiring voluntary voiding may not be possible. Further filling of the bladder should be discontinued during continuous involuntary contractions. After the bladder has stabilized, a slow filling rate of 10 mL per minute can sometimes allow filling to a volume adequate for voluntary voiding. Older women who cannot inhibit bladder contractions often have an inability to voluntarily initiate a bladder contraction. Sometimes, it is impossible to obtain a pressure flow study in older women who have continuous involuntary detrusor contractions, regardless of the techniques used for filling the bladder to a higher capacity. Same-session repeat cystometry and pressure flow studies have shown an increase in volume for the first desire to void and normal desire to void, whereas the maximum cystometric capacity remained unchanged in healthy women.<sup>31</sup> However, for some older women who have a small capacity or detrusor instability, changing to a slow filling rate can increase the maximum cystometric capacity.

If detrusor activity during filling cystometry remains stable, the first or normal desire to void is recorded, a strong desire to void is recorded, and the maximum cystometric capacity is recorded. At the maximum cystometric capacity, the passive bladder pressure is measured to determine compliance. Compliance is a measure of the change in volume per unit of change in pressure, and it is expressed in milliliters per centimeter of water.<sup>16</sup> From a clinical management perspective, compliance is a measurement of the ability of the bladder to stretch without increasing pressure inside the bladder. A normal bladder can be filled to the maximum cystometric capacity with minimal change in the passive pressure within the bladder. In a study to determine the relationship of detrusor instability with changes in compliance in 270 women, 75% of the patients showed a compliance of greater than 130 mL/cm, 95% showed a compliance greater than 40 mL/cm, and women having compliance less than 40 mL/cm had a 16 times greater incidence of detrusor instability.<sup>32</sup>

Low bladder compliance can be a serious problem in older women who have had radiation therapy or previous pelvic surgery.<sup>33</sup> Older women with abnormal bladder compliance often present with severe stress urinary incontinence. Although a significant abnormality in bladder compliance is relatively uncommon in older women, it is extremely important to recognize it. A sling procedure in an elderly woman with stress incontinence and low bladder compliance can result in increased bladder outlet resistance and passive bladder pressures of more than

**Figure 95-1** This 90-year-old woman has no known neurologic disease. She has detrusor instability with a high-pressure contraction and increased electromyographic activity. There is a delay in the onset of involuntary urine loss. The highest peak of electromyographic activity correlated with decreased the urinary flow, which was caused by outlet obstruction that resulted in an increase in detrusor pressure. The increased detrusor pressure appeared to overcome the opposing electromyographic activity, resulting in a sustained decline in electromyographic activity and an increase in urine flow that decreased bladder outlet resistance and decreased bladder pressure because of the outflow of urine. This pattern was previously observed during telemetric monitoring of incontinent elderly men.<sup>30</sup>

40 cm H<sub>2</sub>O, which can cause hydronephrosis and deterioration of renal function.

### Voiding Pressure Flow Studies

Voiding pressure flow studies are useful for assessing older women. However, the clinical importance of pressure flow studies is not often emphasized in the management of older women. Voiding pressure flow studies identify three fundamental voiding states<sup>34</sup>:

1. Low detrusor pressure and high urinary flow rate (unobstructed)
2. High detrusor pressure and low urinary flow rate (obstructed)
3. Low detrusor pressure with low urinary low rate (poor detrusor contractility)

Older women present with problems ranging from mixed incontinence with vault prolapse to recurrent urinary tract infections with incomplete bladder emptying. Although these are not precise categories, most older women with incontinence can be

classified by the results of pressure flow studies. These categories often are associated with similar symptoms but represent different clinical entities, and the approach to management usually is different for the three pressure flow categories.

Older women who have had previous incontinence surgery usually present with complex combinations of lower urinary problems. For example, it is common for older women who have had a urethral suspension procedure to experience symptoms of mixed incontinence and symptoms of bladder outlet obstruction. Some degree of vaginal vault prolapse is a common physical finding in women with these symptoms. Only pressure flow studies can differentiate high detrusor pressure with a low urinary flow rate from low detrusor pressure with a low flow rate.

Minimally invasive surgical procedures for the treatment of stress incontinence in women have reduced the morbidity of incontinence surgery enough that operative procedures often are offered to elderly women. Successful surgical treatment is available to many older women who would not have been advised to consider a surgical option in the past. However, older women with urinary incontinence are a complicated group of patients,

especially when surgical options are being considered, because the results of surgery in older women can be disappointing.

Older women often have very poor urethral function (ALPP less than 60 cm H<sub>2</sub>O) with minimal urethral mobility. Although a pubovaginal sling placed without tension usually results in continence for women with good urethral function, a compressive sling is required to achieve continence in women with very poor urethral function. Pressure flow studies are important in the preoperative evaluation of bladder function in older women with urinary incontinence and poor urethral function because urinary retention can be a complication of a compressive sling procedure.

The advent of minimally invasive surgery for urinary incontinence in older women has resulted in clinical diagnoses after surgical procedures in this population that were uncommon in the past. Pressure flow studies are invaluable in elucidating the pathophysiology of these unique clinical problems that occur after minimally invasive incontinence surgery in elderly women. When persistent voiding symptoms occur in these patients, comprehensive urodynamic studies performed preoperatively are invaluable for comparison with postoperative studies. The pressure flow studies are among the most valuable studies for clinical evaluation and formulating management strategies for these complicated clinical problems. Persistent voiding symptoms after minimally invasive surgical procedures in older women should be evaluated with comprehensive urodynamics studies.

Bladder outlet obstruction in older women may occur after minimally invasive procedures for treatment of stress urinary incontinence, and pressure flow studies are the most important studies in the postoperative evaluation of these patients. The measurement parameters for bladder outlet obstruction in older

women after incontinence surgery have not been well defined. Voiding dysfunctions in elderly women after incontinence surgery need prompt urodynamic evaluation to plan long-term management. If bladder outlet obstruction is identified, a significant delay in urethrolysis after a sling procedure is associated with persistent bladder symptoms after urethrolysis,<sup>35</sup> which suggests that changes in bladder activity after prolonged obstruction may not be reversible. De novo urge incontinence after minimally invasive sling procedures in older women needs to be evaluated with pressure flow studies to be sure that the overactive bladder symptoms are not caused by bladder outlet obstruction.

The urethra has a different role in maintaining continence from that of the bladder. However, when considering the dynamics of voiding, the bladder and urethra appear to behave as a functional unit. Abnormalities of urethral function can affect bladder function, and abnormalities of bladder function can affect urethral function. Pressure flow studies are a measure of the dynamic functional unit of the bladder and urethra. Pressure flow studies are reproducible and provide consistent urodynamic measurements in women.<sup>36</sup>

Aging significantly alters the function of the urethra and the bladder. Elderly women who experience symptoms of stress urinary incontinence may have urinary flow rates that are considerably lower than would be expected based on the measured bladder pressure, even when the bladder pressure is low (Fig. 95-2). In these older women, it appears that the intrinsic urethral closing properties and the intrinsic urethral opening properties are deficient. The aging urethra seems to lose some of the dynamic properties that maintain continence and those required for normal voiding.

**Figure 95-2** This elderly woman has severe symptoms of stress incontinence. The physical examination shows minimal hypermobility, no cystocele, and atrophic vaginitis. Her bladder is stable during filling. The urinary flow rate is low relative to the detrusor pressure. It appears as if the urethra has compromised dynamic properties related to voiding and continence.

**Figure 95-3** This older woman has symptoms of mixed urinary incontinence. Her bladder is stable during filling. She has bladder outlet obstruction that appears to be caused by a cystocele.

Voiding pressure flow studies allow the clinician to identify the dynamic relationships within the voiding functional unit of the bladder and urethra in elderly women. These studies are essential for any management decision, especially if a surgical procedure that could alter the functional dynamic relationship between the urethra and bladder is being considered.

Bladder outlet obstruction is the association of a low urinary flow rate with a detrusor contraction of sufficient magnitude, duration, and speed to empty the bladder.<sup>34</sup> This is an important definition because it requires the clinician to examine the pressure flow studies to assess the voiding dynamics of the patient. However, well-established parameters for voiding pressure flow studies in elderly women are not available. Bladder outlet obstruction can occur in women who have a cystocele (Fig. 95-3), and a low urinary flow rate may result from low detrusor pressure (Fig. 95-4).

### Voiding Pressure Flow Techniques

A 5- to 7-Fr, double-lumen catheter is placed into the bladder for measurement of bladder pressure and infusion of fluid into the bladder. A balloon catheter is placed into the rectum for measurement of intra-abdominal pressure. Except in elderly women with severe physical or mental impairment, the pressure flow studies can be performed without significant discomfort or difficulty. Even though older women may have the neurologic capacity to voluntarily initiate voiding, that ability is often significantly impaired, and the patient may be unable to voluntarily initiate voiding in the urodynamics laboratory. Turning on a faucet in the room to allow the patient to hear the sound of running water can sometimes assist the patient to voluntarily initiate voiding. When an elderly woman is unable to voluntarily void for a study, it does not mean that she has an acontractile bladder.

The measurement of voiding pressure flow studies should be done during voluntary voiding. Elderly people who experience urge urinary incontinence usually void voluntarily most of the time.<sup>2,37</sup> It may be possible to obtain a voluntary voiding pressure flow study by using a lower filling rate and allowing the patient a longer time to initiate voiding. Every effort should be made to obtain voluntary voiding pressure flow studies because the information has immense clinical value.

The urodynamicist sometimes instructs the patient to voluntarily void as an involuntary detrusor contraction is in progress. This should not be considered a true voluntary voiding pressure flow study. Although it may be the best measurement that can be obtained under the circumstances, the information should be used carefully, and the limitations of the study should be recognized when making clinical decisions about management.

Involuntary detrusor contractions in elderly patients do not appear to be normal bladder contractions that are uninhibited.<sup>2</sup> Involuntary detrusor contractions in elderly people appear to be abnormal bladder contractions. In elderly patients with urinary incontinence due to detrusor hyperreflexia, cystometric measures of contractility vary considerably on repeating the study on the same occasion.<sup>38</sup> Voiding pressure flow studies measured during an involuntary detrusor contraction therefore provide limited clinical information about the dynamics of normal voiding in that individual. Because the goal of treatment in elderly women is improvement of quality of life, the clinical objective is to incorporate the information obtained from urodynamic studies into reasonable, practical, and feasible clinical management decisions.

### Electromyography

Measurement of the sphincteric electromyography in elderly women is important clinically, but the measurement can be

**Figure 95-4** This elderly woman has symptoms of mixed incontinence. She has a low urinary flow rate because of poor bladder function.

technically difficult to perform. Although it is of immense clinical value to identify abnormal electromyographic activity, it is useful for the clinician to know that the sphincteric electromyographic activity during voiding is normal in elderly patients. For example, older patients may have central nervous diseases that result in an electromyographic appearance of detrusor sphincter dyssynergia.<sup>30</sup> Older women who have had long-standing urge urinary incontinence caused by involuntary detrusor contractions may have a highly developed voluntary sphincteric contraction in response to the sensation of urinary urgency that has the appearance of detrusor sphincter dyssynergia. Although it may not be possible to differentiate these entities without neurourologic testing, both can be treated with biofeedback.

Routine electromyographic measurement in elderly women is relatively uncomplicated after the technique has been developed and established for a particular urodynamics laboratory. The signal source is usually the external anal sphincter. Because the amplitude and frequency of electromyographic activity is usually lower in older women compared with younger women, the external anal sphincter is considered the best location for the signal source. Intravaginal surface electrodes and intraurethral surface electrodes are less reliable for electromyographic measurement<sup>39</sup> and rarely provide an adequate signal for clinical evaluation in older women. Well-placed surface electrodes are preferred in elderly patients.<sup>40</sup> Although needle electrodes are considered superior to surface electrodes in patients who may have neurologic disease, surface electrodes are more practical and desirable

for electromyographic studies in older women. Because needle electrodes easily become dislodged during the study, many attempts to replace a needle electrode are very uncomfortable for older women.

Preparation of the skin and correct placement of surface electrodes are important to ensure an adequate signal is obtained.<sup>41</sup> After the surface electrodes have been placed and the electromyographic activity is being monitored by the urodynamicist, the patient is instructed to perform a mild cough. If the electromyographic electrodes are properly placed, a mild cough will result in a sharp increase in electromyographic activity and an immediate return to baseline. With the bladder empty at rest, the gain on the electromyographic amplifier can be adjusted in response to a mild cough by the patient. Increasing the gain on the electromyographic amplifier is often required because of the low baseline electromyographic activity in this patient population. If the electronic gain on the amplifier becomes too high, a mild cough will produce a full-scale response on the electromyographic display. As the gain is increased, baseline electrical activity increases, which is usually caused by background electrical activity rather than the baseline sphincteric electromyographic activity. This baseline electromyographic artifact is usually caused by 60-cycle interference from the electrical power source. Interference from external electrical power sources is a much greater problem in these studies of older women because the electromyographic activity of the muscles measured is usually lower than in younger women, and it requires a higher electromyographic amplifier gain.

# USE OF BOWEL IN LOWER URINARY TRACT RECONSTRUCTION IN WOMEN

*Christoph Wiesner and Joachim W. Thüroff*

The use of small and large bowel for bladder augmentation or substitution has been reported by surgeons since the first experimental report by Tizzoni and Foggi in 1888.<sup>1</sup> Bladder enlargement by augmentation enterocystoplasty is predominantly offered to women with neuropathic and non-neuropathic bladder dysfunction who have not responded to pharmacologic regimens. Female patients in whom complete removal of bladder and urethra is mandatory because of urologic or gynecologic malignancies and those who have a bladder problem and irreparable loss of the functional urethra are candidates for urinary diversion. The underlying disease and the patient's preference must be considered when deciding on the type of urinary reconstruction or diversion, such as bladder augmentation or orthotopic bladder substitution to the trigone or bladder neck, orthotopic bladder substitution to the urethra, continent cutaneous urinary diversion, or continent anal urinary diversion.

Preoperative preparation in all female patients includes ultrasound of the upper urinary tract, evaluation of the renal function to judge the renal reserve to compensate for reabsorption of acids from an intestinal reservoir (i.e., renal isotope clearance >50% of the age-specific norm, serum creatinine level <2.0 mg/dL), and a colonic contrast study or colonoscopy to exclude bowel pathology when large bowel segments are used. In patients with a history of previous irradiation encompassing the bowel segments required to construct the planned reservoir, previous resection of longer segments of ileum, or chronic inflammatory bowel disease (e.g., Crohn's disease, ulcerative colitis), the urinary diversion must be tailored according to the bowel pathology. Postoperative care comprises follow-up of acid-base balance, renal ultrasound, and pouchoscopy starting from the fifth postoperative year.

### HISTORY OF AUGMENTATION ENTEROCYSTOPLASTY AND ORTHOTOPIC BLADDER SUBSTITUTION

Augmentation enterocystoplasty is considered the last resort of functional bladder reconstruction before urinary diversion is required. Females with benign diseases such as intractable idiopathic or neurogenic detrusor overactivity incontinence, low-compliance bladder from irradiation, or interstitial cystitis may benefit from enlarging the organ with bowel segments or removing the diseased bladder tissue and substituting it with bowel segments.<sup>2-6</sup>

The cup-patch technique for bladder augmentation was first reported by Goodwin and colleagues for small bowel<sup>7</sup> (Fig. 96-1)

and for large bowel<sup>8</sup> in 1959. A 20- to 25-cm ileal segment serving as the cup is opened at its antimesenteric border before it is formed to a U-shaped patch, folded over, and sutured to the bladder dome. When supratrigonal cystectomy is required (i.e., in interstitial cystitis or detrusor hyperreflexia), the resection line runs just above the trigone, leaving the ureteral orifices in place for preservation of the natural anti-reflux mechanism and avoiding potential complications of ureteral reimplantation into bowel.

Bladder substitution to the bladder neck may become necessary in female patients with interstitial cystitis because of inflammation of the remnant trigone and when preexisting ureteral reflux or obstruction is apparent. Bladder augmentation or substitution can be performed with different bowel segments, such as ileum only,<sup>9</sup> ileum combined with cecum,<sup>10</sup> or sigmoid colon only.<sup>11</sup> An additional sling procedure or colposuspension may be required when coexisting stress incontinence is apparent.<sup>6</sup>

Flood and coworkers<sup>6</sup> reported the long-term outcomes of 106 patients, including 82 women, who underwent augmentation enterocystoplasty. Preoperatively, all patients had reduced bladder compliance or detrusor overactivity caused by different underlying benign diseases. The overall success rate was 95% for all patients. Postoperative bladder capacity increased significantly from 108 to 438 mL. Urodynamic evaluation revealed stress incontinence in 15 patients (14%). Six of these patients had occasional leakage and did not require further treatment, and five were successfully treated by a sling procedure or collagen injection.

Complete relief of clinical symptoms of bladder pain and frequency was reported for 73% to 100% of patients in several series when enterocystoplasty was performed for intractable forms of interstitial cystitis.<sup>2-4</sup> Between 66% and 86% of female patients were able to void spontaneously; the remainder had to empty their bladders by intermittent self-catheterization.

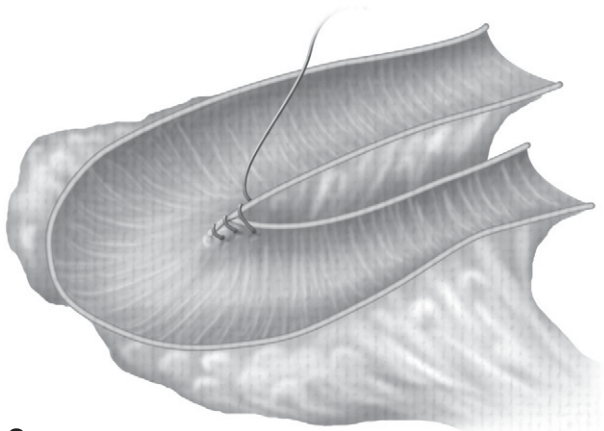

Linn and associates<sup>12</sup> reported the clinical outcomes of 23 patients, including 22 women and 1 man, who underwent subtrigonal ( $n = 17$ ) or supratrigonal ( $n = 6$ ) cystectomy and orthotopic bladder substitution with the ileocecal pouch (i.e., Mainz pouch I) for interstitial cystitis. Postoperative bladder capacity was significantly increased, and urinary frequency was significantly decreased in all patients. Complete relief of clinical symptoms was achieved in 82% of the patients with subtrigonal cystectomy and in 100% of the patients with supratrigonal cystectomy. All patients who underwent supratrigonal cystectomy were able to void spontaneously, whereas 41% of the patients in whom the trigone was resected had to empty their bladder by intermittent self-catheterization.

### ORTHOTOPIC BLADDER SUBSTITUTION

The first radical cystectomy in combination with an orthotopic bladder substitution for treatment of bladder cancer in a woman was reported by Tscholl in 1987,<sup>13</sup> but before 1990, orthotopic urinary diversion was mostly limited to male patients when radical cystoprostatectomy was performed.<sup>14</sup> Removal of the urethra was considered mandatory in female patients with bladder cancer to provide an adequate surgical margin. It was considered impossible to achieve urinary continence with the remaining short female urethra. Studies of cystectomy specimens that were removed for bladder cancer and a better anatomic understanding of the continence mechanism made it likely that urinary diversion to the urethra could be applied to selected female patients.<sup>15-17</sup>

Intraoperative frozen section analysis of the distal urethral margin is mandatory to exclude tumor involvement when ortho-

topic diversion is planned for bladder cancer or gynecologic malignancies. Preoperatively, competence of the external rhabdosphincter must be proved to ensure postoperative continence and to allow spontaneous voiding through the urethra. The choice of the reservoir depends on the surgeon's preference when orthotopic bladder substitution in the female patient can be performed by using any segments of the gastrointestinal tract for constructing the reservoir.

### Ileal Bladder Substitutes

In 1987, Ghoneim and colleagues<sup>18</sup> described the urethral Kock pouch, which used 45 to 50 cm of the distal ileum.<sup>18</sup> The proximal third of ileum is preserved for the reflux-preventing valve. The reservoir is created by the distal two thirds of bowel, which is opened along its antimesenteric border before folding it into a U-shape and performing a side-to-side anastomosis of the adjacent

margins with a single layer of running suture. A nipple valve is created by isoperistaltic ileal intussusception and fixed by three or four rows of metal staples. Its position is secured by interrupted seromuscular sutures at the base of the nipple valve. The intestinal plate is folded over and closed by a single layer of running suture. The reservoir is rotated such that the posterior aspect is brought anteriorly and positioned into the pelvis with the apex facing toward the urethral stump, where the pouch is opened and anastomosed to the urethra by interrupted sutures. Ureterointestinal reimplantation is performed by end-to-side anastomosis of the ureters to the afferent limb of the nipple valve.

The T-pouch ileal neobladder was established in 1998 as a modification of the urethral Kock pouch diversion (Fig. 96-2).<sup>19</sup> The afferent segment is created by an 8- to 10-cm segment of the proximal ileum. Its distal portion of 3 to 4 cm is tapered and tunneled into a serosa-lined tunnel, which is created at the midline anastomosis of the back wall of the pouch.

The ileal neobladder was established in 1987 by using a 60- to 70-cm ileal segment and leaving the distal portion of the terminal ileum and Bauhin's valve intact (Fig. 96-3).<sup>20</sup> The ileum is folded in a W-shaped manner and opened at its antimesenteric border except over a 5-cm segment, where the incision is made close to the anterior mesentery to create a posterior flap, which serves as the new bladder neck and to which the urethra is anastomosed. The reservoir is accomplished by side-to-side anastomosis of the posterior walls before the anterior wall is folded over and closed. Anti-refluxive ureteral reimplantation was initially favored using the LeDuc technique of creating a mucosal sulcus<sup>21</sup> or by using the Abol-Enein technique of serosa-lined extramural tunnels.<sup>22</sup> Since 1996, the technique of ureterointestinal implantation is predominantly performed by a refluxive ileoureteral end-to-side anastomosis into two 3- to 5-cm chimneys of ileum serving as afferent segments.<sup>23</sup>

Studer's ileal neobladder was established in 1985 by using 60 to 65 cm of terminal ileum and leaving the proximal 25 cm intact for creation of an isoperistaltic afferent limb (Fig. 96-4).<sup>24</sup> The distal 40 cm of ileum is folded into a U-shape and opened antimesenterically before the medial borders of the U are anastomosed to each other by a single layer of running suture. The ureterointestinal anastomoses are performed by direct end-to-side anastomosis to the proximal portion of the afferent limb. The reservoir is finalized by folding the bottom of the U over the proximal end. Before complete closure, an incision is placed into the most dependent part of the reservoir for the ileourethral anastomosis.

### Ileocecal Bladder Substitute: Orthotopic Mainz Pouch

For creation of the orthotopic ileocecal reservoir (i.e., orthotopic Mainz pouch), a 10- to 15-cm segment of cecum in continuity with 20 to 30 cm of terminal ileum is isolated. The bowel is opened along its antimesenteric border. The opposing margins of the bowel are anastomosed to each other by a single row of running suture to create the posterior pouch wall. Originally, the ureters are implanted through a submucosal tunnel into the ascending colon to prevent reflux. Urethroidintestinal anastomosis is performed by an incision at the base of the cecum. The reservoir is closed by side-to-side running sutures. In 2003, El-Mekresh and coworkers<sup>25</sup> reported a modified technique of ureterointestinal reimplantation into the terminal ileum with the ileocecal valve serving as an anti-reflux-mechanism by using an end-to-

end anastomosis (Wallace) for the left ureter and end-to-side anastomosis (Nesbit) for the right ureter with the afferent ileal limb (Fig. 96-5).

Clinical studies that included long-term follow-up predominantly reported outcomes for male patients who underwent orthotopic bladder substitution. However, some reports are available on the outcomes of female patients with a specific focus on voiding patterns.

The rates of ileal neobladder-related early and late complications in a large series of 363 male patients were reported to be 15.4% and 23.4%, respectively.<sup>26</sup> Early pouch-related complications included urinary leakage (7.7%), pyelonephritis (7.4%), and early obstruction of the ureteroileal anastomosis (3.0%). Late complications were associated with the ileoureteral anastomosis and upper urinary tract, including stenosis (9.3%), acute pyelonephritis (6.3%), and reflux (3.3%). Ileourethral anastomotic strictures were seen in 2.2%, 96.1% of the patients were able to void spontaneously, and daytime continence was achieved in 95%.

Ghoneim and associates<sup>27</sup> reported the clinical outcomes of 185 male patients treated with the urethral Kock pouch diversion. Deterioration of the upper urinary tract occurred in 13.7% of the renal units, with 9% due to reflux and 4.7% due to anastomotic strictures. Calculus formation was recognized in 18%, and urethral anastomotic strictures were encountered in 5.1%. Daytime and nighttime continence rates were 92% and 73%, respectively.

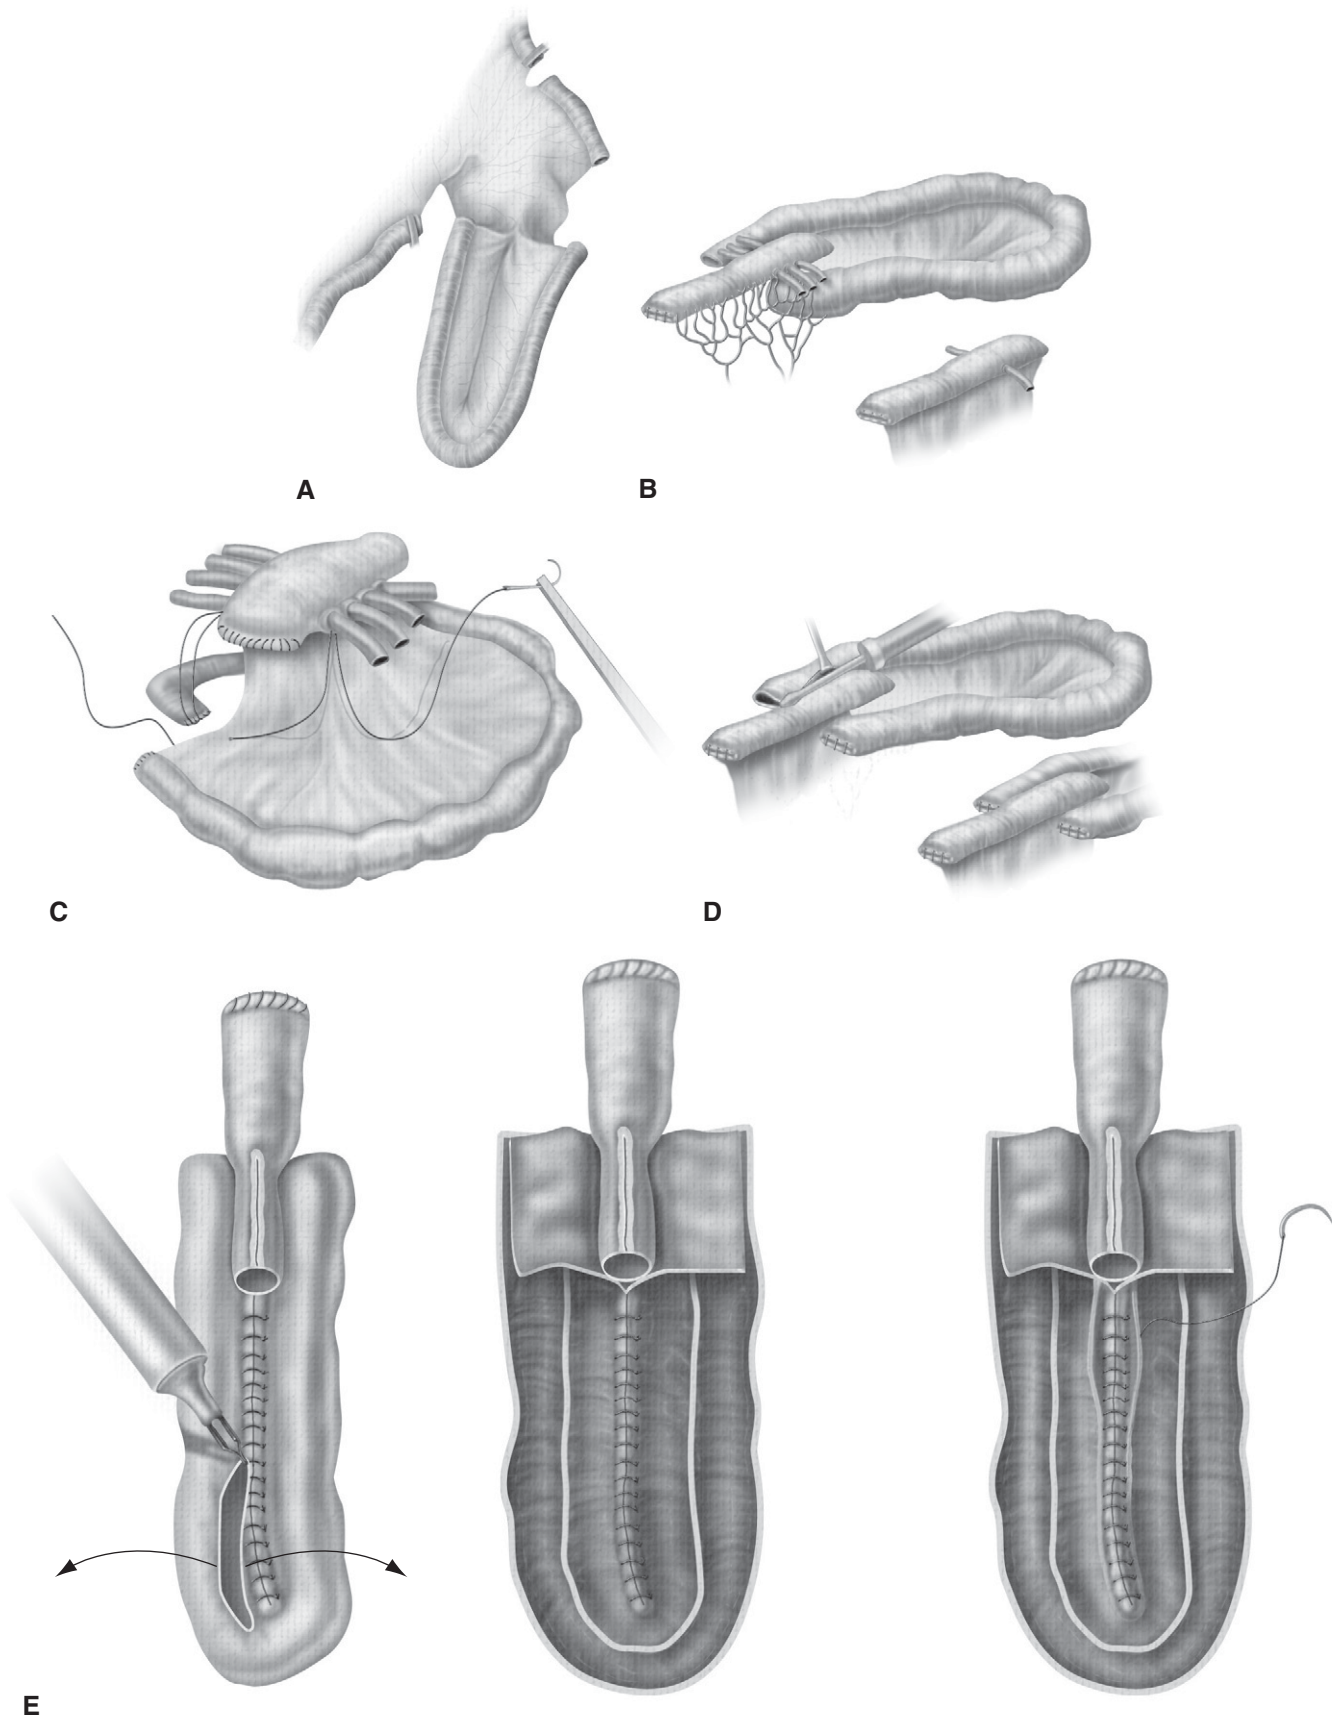

Perimenis and colleagues<sup>13</sup> evaluated the long-term outcomes of male patients treated with Studer's ileal neobladder with an afferent tubular segment. Nine (3.5%) of 254 renal units were treated for ureterointestinal anastomotic strictures. At the latest follow-up, renal parenchyma was normal in 246 units (97%), and serum creatinine levels remained unchanged compared with preoperative values in all patients. Daytime continence rates were 94% and 91% at 5 and 10 years, respectively, whereas nighttime continence rates were 72% and 60%, respectively. Residual urine volumes greater than 100 mL were recognized in 8% and were associated with urethroidintestinal anastomotic strictures or protrusion of the intestinal mucosa into the urethra.

Cancrini and coworkers<sup>28</sup> reported their 2-year experiences of orthotopic urinary diversion by Studer's ileal neobladder in seven female patients.<sup>28</sup> The rate of urinary continence was 100% during the day and 71% at night. Urodynamic studies 12 months postoperatively revealed a good neobladder capacity of 320 mL and no evidence of stress incontinence or significant levels of residual urine.

Stenzl and associates<sup>29</sup> performed radical cystectomy with nerve-sparing dissection of the bladder neck and proximal urethra by leaving the lateral vaginal walls and the tissue next to the bladder neck intact. The technique was based on their previous studies of anatomic and histologic studies of the urethra in female cadavers. Daytime and nighttime continence was achieved within 6 months in all patients, and the residual urine volume was between 0 and 150 mL.

Ali-El-Dein and colleagues<sup>30</sup> reported the clinical outcomes of 136 female patients who underwent radical non-nerve-sparing cystectomy and orthotopic bladder substitution by ileal neobladders ( $n = 120$ ) or hemi-Kock pouch reservoirs ( $n = 16$ ).<sup>30</sup> Early pouch-related complications included development of vaginal fistulas in four patients, who were treated by open surgical revision. Calculi developed in seven patients, who were treated endoscopically. One hundred patients were evaluable by urodynamic

F

**Figure 96-5, cont'd** **F**, The opposing margins of the bowel are anastomosed to each other by a single row of running suture to close the pouch. Before it is rotated (*arrow*) in a manner that the afferent ileal segment is located in an upper right position. **G**, The ureters are reimplanted using an end-to-end anastomosis (Wallace) for the left ureter and end-to-side anastomosis (Nesbit) for the right ureter. A buttonhole is made at the caudal portion of the reservoir and anastomosed to the urethra.

studies. The rate of daytime continence was 95%, and that of nighttime continence was 86%. Of the female patients, 12% were incontinent during the night. Total incontinence occurred in 2%. Stress incontinence was documented by urodynamic studies in 3%, and it was related to negative urethral pressure transmission. Chronic urinary retention was seen in 16% of female patients. The lateral pouch–urethra angle, which was evaluated by voiding radiography, was between 90 and 160 degrees before and during voiding in females without voiding difficulties. Voiding radiography showed a smaller pouch–urethra angle of 61 to 103 degrees and concomitant posterior herniation of the anterior vaginal wall or pouchocele formation in female patients with significant postvoiding urinary retention. Treatment of voiding dysfunction included conversion into a continent cutaneous diversion in two women with total incontinence, pharmacotherapy with imipramine when nocturnal incontinence was diagnosed, clean intermittent self-catheterization in cases of chronic urinary retention, and pouch revision with correction of the posterior angle for significant overflow incontinence with pouchocele. The investigators conclude that chronic urinary retention in female patients with orthotopic urinary diversion is caused by a mechanical problem, not neurogenic factors. They concluded from their investigations that an autonomic nerve-sparing procedure, which compromises on the radicality of cystectomy, is not necessary for a satisfactory functional outcome.

Another study evaluated the long-term outcomes of 18 female patients with urethral substitution by the ileal neobladder.<sup>31</sup> Pouch-related complications occurred in two, including one with urethroileal stenosis and one with ureteroileal stenosis. Seventy percent of the patients were hypercontinent and emptied their neobladder by clean intermittent self-catheterization because of significant residual urine or complete voiding incompetence. A difference in voiding pattern was not observed when comparing resection lines located at the proximal urethra and at the bladder neck.

Volkmer and colleagues<sup>32</sup> investigated the impact of urinary diversion by orthotopic ileal neobladder on sexuality in 29 female patients (8 with benign and 21 with malignant diseases) by questionnaires. Influencing factors were age (<60 years), benign disease, partnership at surgery, and current partnership. Sexuality was not influenced by the necessity of pouch catheterization, urinary stress incontinence, and hormonal therapy. The study authors concluded that orthotopic urinary diversion did not influence female sexuality postoperatively.

### CONTINENT CUTANEOUS DIVERSION

A catheterizable cutaneous stoma represents an alternative continent urinary diversion that provides an intact body image. It can be offered to patients who experience radical cystectomy, including urethrectomy. Benign indications include irreparable loss of the sphincteric urethra and severe cases of interstitial cystitis. Careful patient selection for motivation, compliance, and manual dexterity to perform a self-catheterization is necessary to ensure success of the continent diversion in the long term. Exclusion criteria are inadequate manual dexterity, reduced intellectual capacity, or decreased motivation to perform self-catheterization.

Continent cutaneous urinary diversion is achieved by creation of a urinary reservoir, which is to be emptied by intermittent

self-catheterization; preservation of the upper urinary tract; and provision of continence by a specific outlet. Several surgical techniques use different bowel segments and different mechanisms to provide continence.

### Kock Pouch

Kock developed the first continent ileal reservoir using 60 to 70 cm of ileum for pouch formation and construction of two nipple valves (Fig. 96-6).<sup>33</sup> At the proximal and distal ends of the ileum, which is excluded from intestinal continuity for pouch formation, 10- to 12-cm of bowel segments are left intact for creation of the afferent and efferent nipple valves. The remaining 40 cm of ileum is incised antimesenterically, sutured side to side in a U-shape, folded over, and closed to create a spherical pouch. For the final position, the reservoir is rotated such that the posterior aspect is brought anteriorly. Staple fixation of the intussusception nipple to itself and to the wall of the reservoir is crucial to secure the afferent anti-reflux-valve and the efferent continence valve and to prevent nipple gliding or eversion. The ureters are implanted end to side into the afferent ileal limb.

Overall complication rates between 32% and 53% are reported in the literature.<sup>34-40</sup> Early pouch-related complications at a rate of up to 25% include pouch rupture, pouch sepsis, pouch abscess, and pinhole fistula at the efferent segment.<sup>34</sup> Late complications are mostly associated with dysfunction of the efferent segment, including stoma incontinence (17% to 23%), nipple prolapse or nipple gliding (7% to 10%), stoma stenosis (0% to 10%), and calculus formation (8% to 15%). Complications of the afferent segment are less common and mostly related to strictures of the ureteral-intestinal anastomosis (2% to 5%), ureteral reflux (2% to 13%), and afferent nipple stones (5.2%).<sup>40</sup> Continence rates vary between 78% and 94%.

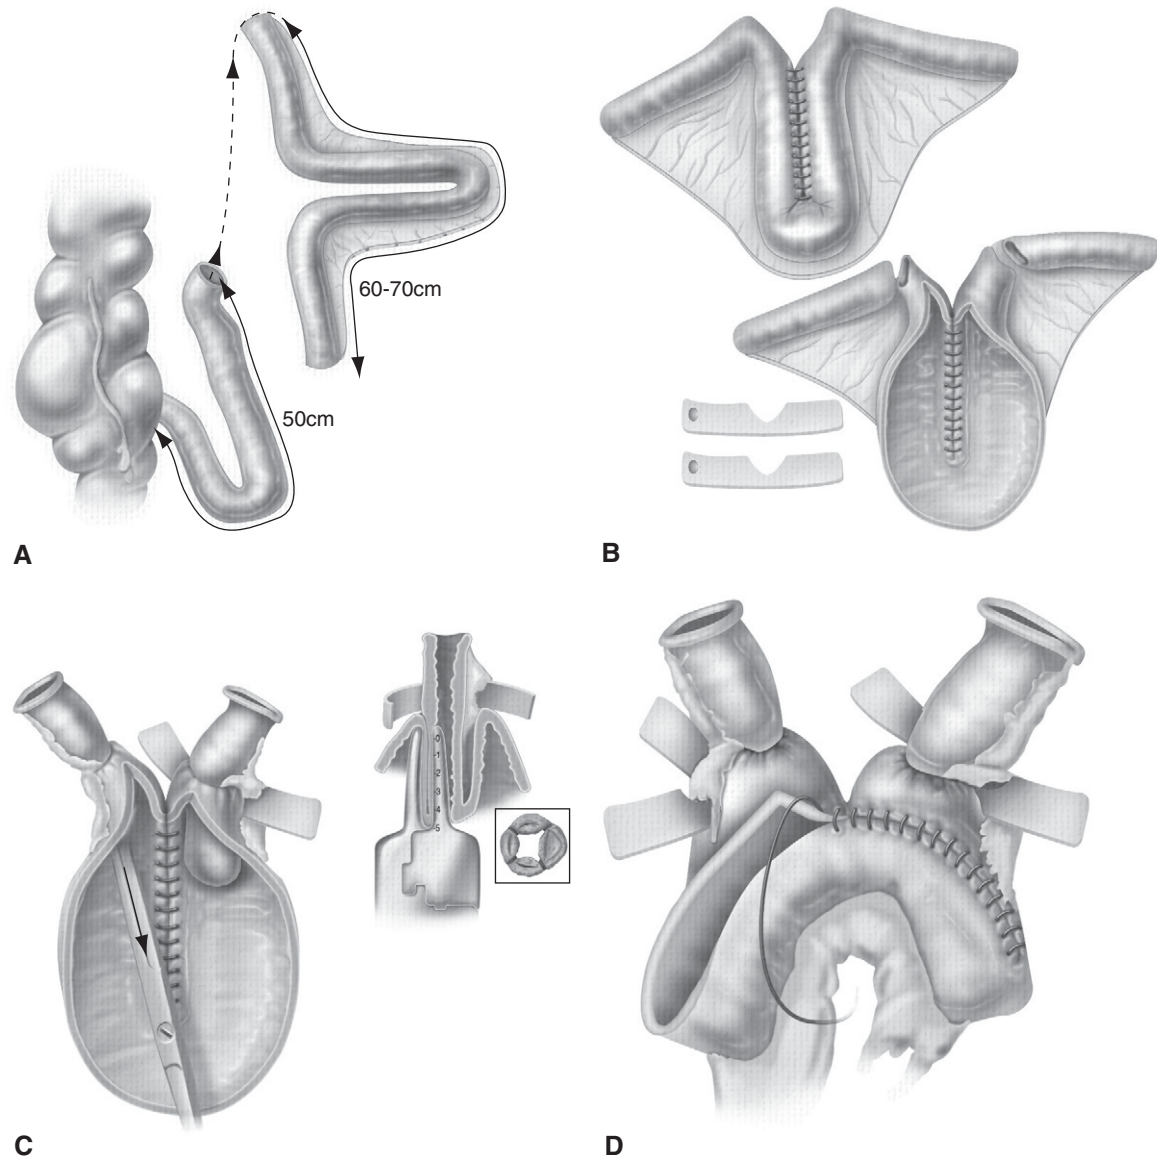

### ILEOCECAL POUCH: MAINZ POUCH I

The Mainz pouch I procedure was established in 1983. It uses 10 to 15 cm of cecum and ascending colon and two terminal ileal segments of equal length for reservoir construction (Fig. 96-7).<sup>10</sup> The surgical procedure comprises antimesenteric incision of ileum, cecum, and ascending colon and side-to-side anastomosis of the ascending colon with the terminal ileal loop and of the latter with the proximal ileal loop. The anterior wall of the pouch is closed by a single row of running sutures.

Both ureters are implanted in an anti-refluxive manner into the large bowel using the submucosal tunnel technique described by Goodwin.<sup>41</sup> The Abol-Enein technique was introduced for preoperatively dilated ureters.<sup>22</sup> The technique entails fashioning two serosa-lined, extramural tunnels. The buttonhole technique implies oblique, end-to-side, refluxive ureteral implantation.<sup>42</sup>

Originally, the continent outlet was created using 12 to 15 cm of terminal ileum, which is left intact and is intussuscepted isoperistaltically over a length of about 5 cm through the ileocecal valve and stapled to itself, the ileocecal valve, and the wall of the pouch (Fig. 96-8A to C). Since 1990, the submucosally embedded, in situ appendix is used for construction of the continent outlet when possible (see Fig. 96-8D and E).<sup>43</sup> The submucosal tunnel is created by seromuscular incision of the free tenia. The seromuscularis layer is closed over the embedded appendix. Seromuscular and full-thickness bowel-flap tubes were described in

**Figure 96-6** Kock pouch cutaneous diversion. **A**, A 60- to 70-cm segment of ileum is isolated approximately 50 cm above the ileocecal valve. The bowel is positioned in a U-shape. **B**, The ileum is incised along its antimesenteric border and sutured in a side-to-side manner into a U-shape. **C**, The nipple valves are fixated by ileal intussusception with three rows of staples. The afferent valve serves as anti-reflux mechanism to ureteral implantation, the efferent valve as continent outlet. **D**, Closure of the reservoir is performed by 2 inverting running sutures. (Modified from Kock NG, Nilson AE, Nilsson LO, et al: Urinary diversion via a continent ileal reservoir: Clinical results in 12 patients. *J Urol* 128:469-475, 1982.)

1995 as alternative procedures for patients in whom the appendix was not available (Fig. 96-9).<sup>44</sup>

Most reported complications are related to the continent outlet. Calculus formation is more often reported for the stapled intussuscepted ileal nipple valve (3% to 5.5%).<sup>45,46</sup> Major complications such as nipple necrosis, nipple prolapse, and nipple gliding are seen in 3.8% to 6.6% of patients.<sup>45,46</sup> Complications of the appendix stoma include necrosis of the appendix in 2.1% to 2.5% and stoma stenosis in 14.6% to 21% of patients.<sup>45-48</sup> Continence rates are between 98% and 100%.<sup>45,46,48</sup> Anti-refluxive ureteral implantation through the submucosal tunnel technique is associated with a 5.7% ureteral obstruction rate for preoperatively nondilated ureters and a 16% obstruction rate for preoperatively dilated systems at long-term follow-up.<sup>49</sup> When direct ureterointestinal implantation was performed in 30 patients (i.e.,

10 patients with direct ureteral reimplantation and 20 patients with primary direct ureteral implantation), no deterioration of kidney function and no evidence of obstruction were seen at a median follow-up of 50.7 months.<sup>42</sup> Reflux occurred in one renal unit, without necessity for reintervention.

### Transverse Colonic Pouch: Mainz Pouch III

The transverse colonic pouch (i.e., Mainz pouch III or the transverse ascending or transverse descending pouch) was created for continent urinary diversion in patients who had prior pelvic irradiation (Fig. 96-10).<sup>50</sup> About 20 cm of transverse colon and ascending or descending colon are used. The outlet is created by a full-thickness colonic tube of about 8 cm, 6 cm of which are embedded into a submucosal tunnel. The ureteral implantation

**Figure 96-7** Cutaneous ileocecal pouch (MZ-pouch I). A 10- to 15-cm segment of cecum and ascending colon and two terminal ileal segments of equal length are used for reservoir construction. The ileum, cecum, and ascending colon are incised antimesenterically. The posterior wall of the pouch is done by anastomosis of the ascending colon with the terminal ileal loop, and the latter with the proximal ileal loop by a single row of running sutures. The anterior wall of the pouch is also closed by a single row of running sutures. (Modified from Hohenfellner R: *Ausgewählte Urologische OP-Techniken*, 2. Auflage Stuttgart, New York, Thieme Verlag, 1997).

follows the Goodwin technique or the serosa-lined extramural tunnel technique. Eighteen percent of complications of the transverse colonic pouch (i.e., Mainz III) are related to the efferent colonic outlet, with stoma incontinence occurring in 5% and stoma stenosis developing in 14%.<sup>50</sup>

#### Indiana Pouch

The Indiana pouch was developed 1984 as a modification of the Gilchrist procedure (Fig. 96-11).<sup>51</sup> An 8- to 10-cm segment of terminal ileum and 25- to 30-cm of cecum and ascending colon are isolated, and the large bowel is opened along the antimesen-

teric border. The distal end of the opened colon is folded down to the apex of the incision. The reservoir is closed with a single layer of sutures. For a reservoir constructed by mechanical stapling, a 2- to 3-cm incision at the antimesenteric border of the cecum opposite the ileocecal valve is performed. The distal end of the colonic segment is folded down to the cecal incision, fixed by holding sutures, cut open, and stapled between the holding sutures using the GIA stapler with absorbable staples until complete detubularization of the colonic segment is achieved. The edges of the opposing colonic segments are closed by absorbable TA55 staples. Originally, ureteral implantation was performed in an anti-refluxive manner through a submucosal tunnel. Currently, an end-to-side direct anastomosis is employed. The efferent segment is constructed by tapering the terminal ileum, allowing easy passage of an 18-Fr catheter. A modification encompasses embedding the tapered ileal segment into a submucosal tunnel.<sup>52</sup>

Complication rates range between 10.8% and 52.0%.<sup>53-55</sup> Pouch-related complications are pouch rupture (2.5% to 3.2%) and calculus formation (3.7% to 10.5%). Complications of the efferent segment are stoma stenosis (3.7% to 15.2%) and stoma incontinence (1.2% to 28.2%). Obstruction of the ureteral anastomosis is reported in up to 7.2%. Preoperative radiotherapy negatively influences the postoperative outcome.<sup>56</sup> Ureteral obstruction was seen in 15% of patients with preoperative irradiation, compared with 4% without preoperative irradiation. Stoma incontinence developed in 4% of patients, all whom had undergone preoperative radiotherapy.

#### Right Colonic Reservoir with a Stapled Ileal Outlet

Davidsson and colleagues<sup>57</sup> reported a right colonic reservoir with a stapled ileal (Lundiana) outlet in 1992. The reservoir is created by a 30-cm, right colonic segment and a 10-cm segment of the terminal ileum serving as the outlet. The colonic segment is opened along the anterior tenia down to the level of the ileocecal valve. The incision is extended transversely to the base of the valve.

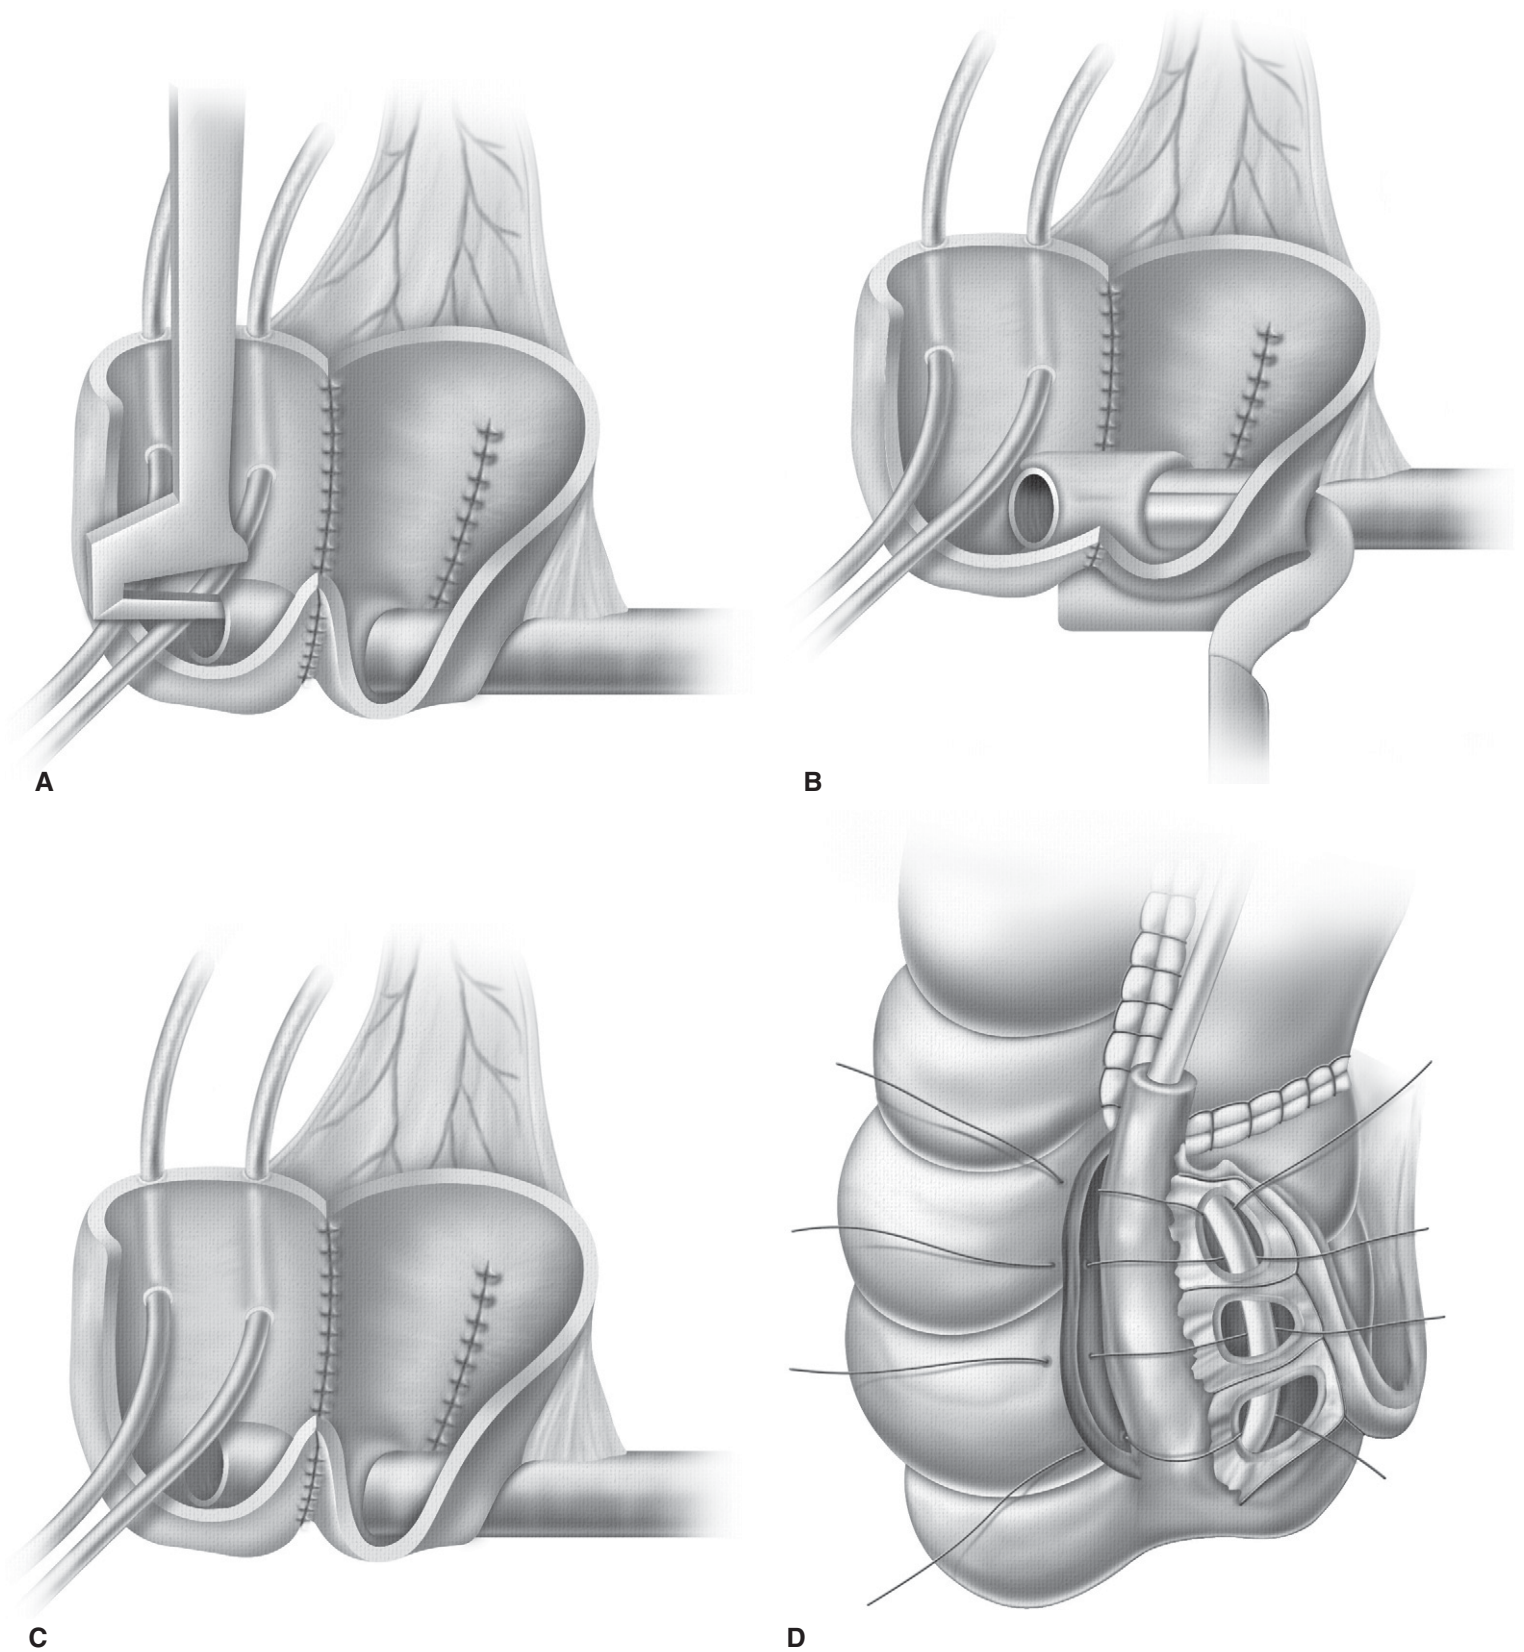

The edges of the cecal wall incision are grasped together with the ileocecal valve using a Babcock clamp. The ileal segment is tapered over a 10-Fr catheter with a TA55 stapler in a position that allows the edges of the cecal wall and part of the ileocecal valve to be incorporated. The staple line closes the cecum, tapers the valve on the catheter, and tethers the narrowed ileocecal valve to the cecal wall. The ureters are implanted in an anti-refluxive manner following the LeDuc technique of creating a mucosal sulcus or the technique of making a submucosal tunnel before the reservoir is closed.

At a mean follow-up of 58 months, clinical outcome was investigated in 99 patients, who received a right colonic reservoir with the Lundiana outlet.<sup>58</sup> Early pouch-related complications included partial pouch necrosis (1%), pouchovaginal fistula (1%), ureteral implantation stenosis (1%), and acute pyelonephritis (2%). Late pouch-related complications were diagnosed in 25% of the patients, including calculus formation (10%), stomal stenosis (7%), ureteral implantation stenosis (5%), acute pyelonephritis (4%), and perforation of the pouch (3%).

#### Florida Pouch

In 1987, Lockhart<sup>59</sup> described an alternative colonic reservoir (i.e., Florida pouch) that included the cecum, ascending colon,

**Figure 96-8** Intussuscepted ileal nipple and appendix stoma. **A** to **C**, The intussuscepted ileal nipple is created by using 12- to 15-cm of terminal ileum, which is left intact and is intussuscepted isoperistaltically over a length of about 5 cm through the ileocecal valve and stapled to itself, the ileocecal valve, and the wall of the pouch. **D**, The submucosally embedded in situ appendix is created by seromuscular incision of the free tenia.

E

**Figure 96-8, cont'd E.** The seromuscular layer is closed over the embedded appendix. (Modified from Hohenfellner R: *Ausgewählte Urologische OP-Techniken*, 2. Auflage Stuttgart, New York, Thieme Verlag, 1997).

one third of the right transverse colon, and 10 to 12 cm of the terminal ileum for the outlet. The colon is folded in a U-shape, fully detubularized, and closed by a locking running suture. Ureteral implantation was originally performed using the LeDuc anti-refluxive ureteroileal implantation (described earlier)<sup>21</sup> or by the Goodwin technique (described earlier).<sup>41</sup> It was later modified to a direct anastomosis of the ureters to the colon, avoiding an anti-refluxive implantation.<sup>60</sup> The terminal ileum is used as the efferent segment. The ileum is left attached to the reservoir and plicated with two parallel rows of sutures placed longitudinally into the ileum and ileocecal valve.

Complication rates for ureter implantation were evaluated for the ureteral implantation technique (tunneled by LeDuc or Goodwin or nontunneled end-to-side anastomosis).<sup>60,61</sup> Ureteral obstruction occurred in 13.3% with tunneled implantation and in 4.9% with end-to-side implantation of the ureters, but the rate of refluxing units was higher in the latter group (7.0% versus 3.3%). Complications of the efferent segment were stoma incontinence in 3.0% to 6.7% and stoma stenosis in 4.0% to 10.0%.<sup>21</sup> Pouch stones were seen in 3.0% to 5.4% of patients.<sup>38,62</sup>

#### Ureterosigmoidostomy and Rectosigmoid Pouch: Mainz Pouch II

Intestinal urinary diversion by ureterosigmoidostomy was introduced by Simon in 1852<sup>63</sup> and was followed by numerous modifications of the anti-refluxive ureterointestinal anastomosis.<sup>64-66</sup>

The rectosigmoid pouch (i.e., Mainz pouch II) was established in 1990 (Fig. 96-12).<sup>67</sup> It provides a low-pressure reservoir and decreases the risk for the upper urinary tract. The rectosigmoid functions as a urinary reservoir, and the anal sphincter functions as a continence mechanism. The procedure can be offered to female patients who require radical cystectomy including the urethra and to those with benign or malignant conditions who have irreparable loss of the sphincteric urethra. It provides continence without a stoma and the need for intermittent self-catheterization.<sup>67-69</sup> Women with an incompetent anal sphincter and dilatation of the upper urinary tract are not candidates for this procedure. A volume of 250 mL of saline should comfortably be accommodated for 2 hours in a preoperative test. Additional evaluation of the anal sphincter competence by anal pressure profilometry is recommended.

For construction of the rectosigmoid pouch, about 20 to 25 cm bowel are opened antimesenterically down to the peritoneal reflection of the rectum and folded to an inverted U-shape. The posterior wall of the pouch is created by side-to-side anastomosis of the medial margins of the inverted U. Non-refluxing uretero-intestinal anastomosis is performed through a 4-cm submucosal tunnel. Alternatively, ureterointestinal reimplantation can be performed by a serosa-lined extramural tunnel, especially with preoperatively dilated ureters<sup>22</sup> or by LeDuc's implantation technique.<sup>21</sup> Before closure, the back wall of the pouch is fixed to the promontory to avoid displacement of the pouch and ureteral kinking. Closure is achieved by side-to-side anastomosis of the lateral margins of the inverted U.

Early complications occurring within 3 months after the surgery are reported in up to 10% of patients.<sup>67,68,70</sup> Complications include mechanical or paralytic ileus, suture leakage, and dislocation of ureteric stents with development of urinoma, peritonitis, or urinary fistulas. Late complications comprise pyelonephritis in up to 6% of patients, ureteric implantation stenosis in 1% to 7%, metabolic acidosis in up to 70%, and development of secondary tumors in up to 22%.<sup>67,68,70,71</sup> Continence rates range between 95% and 100%.<sup>68</sup>

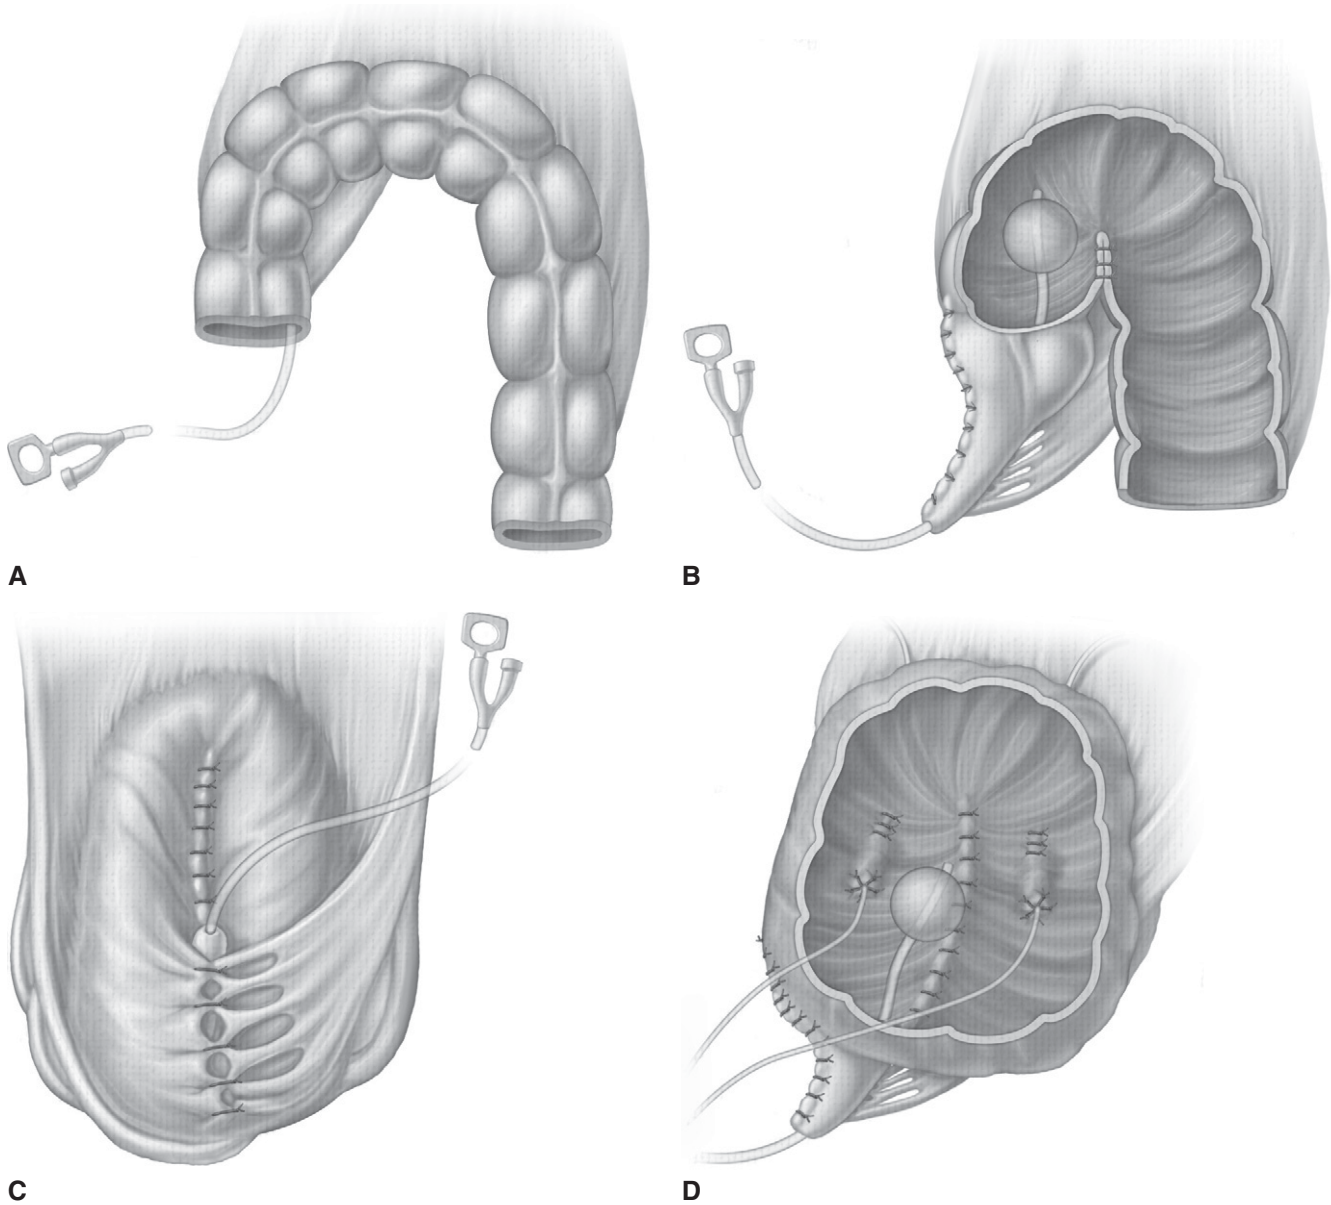

Volkmer and coworkers<sup>72</sup> reported four pregnancies in three women after ureterosigmoidostomy. During pregnancy, monthly urologic examinations included renal ultrasound and resistance index; levels of serum electrolytes, urea, and creatinine; and blood gas analysis. Antibiotics and sodium-potassium-hydrogen citrate were administered prophylactically in all pregnant women. Delivery was achieved by cesarean section in three (one with preeclampsia at week 36) and vaginally in one.

#### CONCLUSIONS

A variety of surgical techniques and their modifications offer a broad spectrum of possible solutions to female patients when reconstruction of the lower urinary tract by bowel segments becomes necessary. Augmentation enterocystoplasty and orthotopic substitution to the trigone or bladder neck is reserved for women with benign diseases, such as low-capacity or low-compliance bladders caused by neurogenic and non-neurogenic diseases or chronic inflammation that is refractory to conservative treatment regimens. Women in whom radical cystectomy becomes necessary because of a malignant disease require total bladder substitution. Surgical techniques of ureterosigmoidostomy or rectosigmoid pouch diversion provide continence through the anal sphincter. These techniques can be offered to

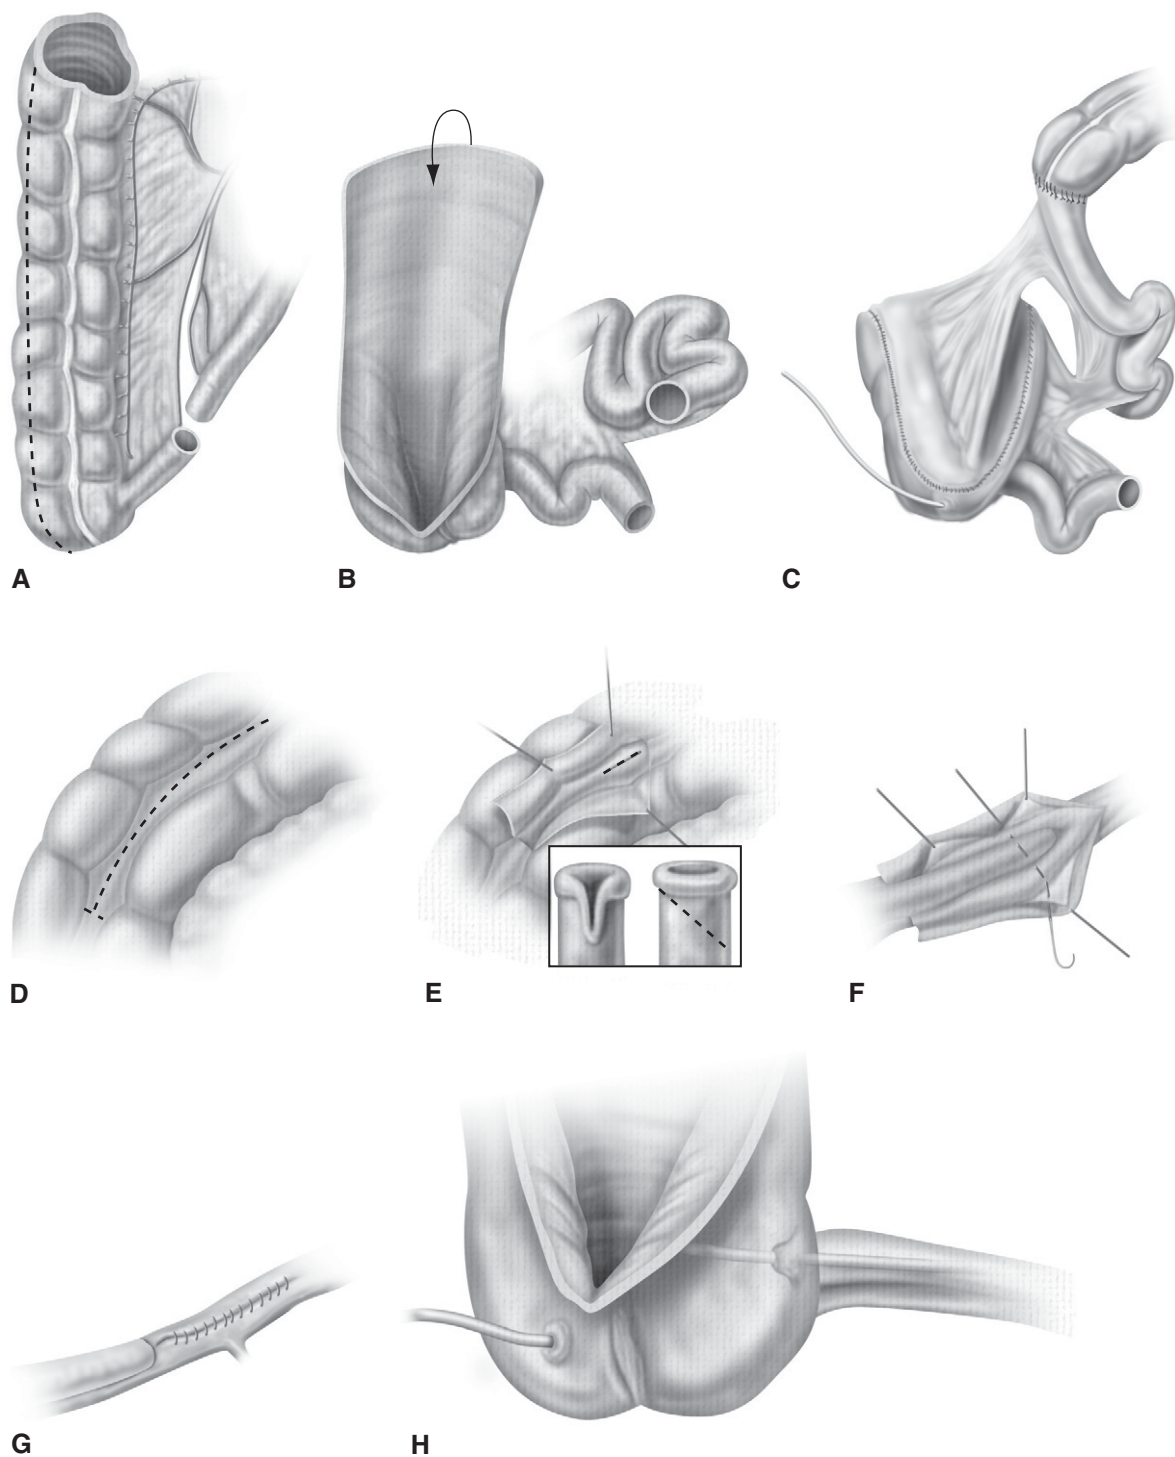

**Figure 96-9** Full-thickness bowel flap. **A** and **B**, The full-thickness bowel flap tube is created by an inverted-U-shaped incision along the tenia libera of the cecum and tubularized. **C**, The tube is embedded into a submucosal tunnel at the tenia omentalis. **D**, The tunnel is finished by closing the lateral margins of the seromuscularis. (Modified from Hohenfellner R: *Ausgewählte Urologische OP-Techniken*, 2. Auflage Stuttgart, New York, Thieme Verlag, 1997).

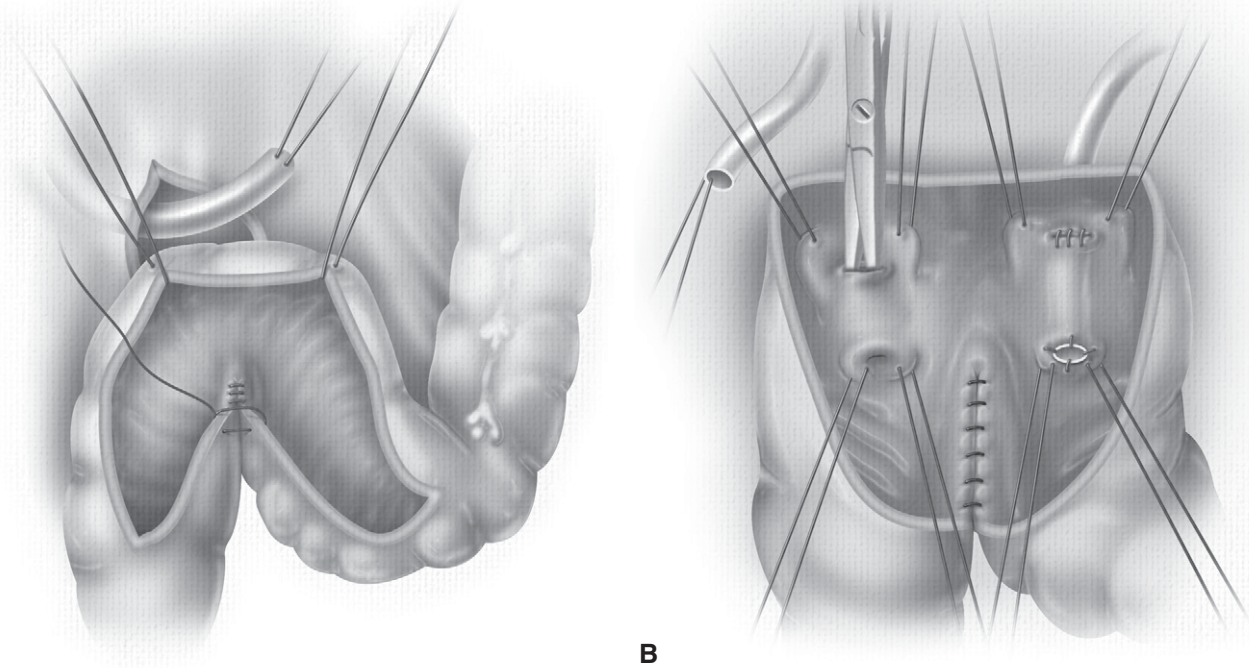

**Figure 96-10** Transverse colonic pouch diversion (Mainz pouch III). **A**, A 20-cm segment of transverse colon and ascending or descending colon are isolated. **B**, The outlet is created by a full-thickness colonic tube of about 8 cm. **C**, The colonic tube is embedded into a submucosal tunnel. **D**, The ureters are implanted by the Goodwin technique (shown) or by an extramural serosal tunnel. (Modified from Leissner J, Black P, Fisch M, et al: Colon pouch (Mainz pouch III) for continent urinary diversion after pelvic irradiation. *Urology* 56:798-802, 2000).

**Figure 96-11** Indiana pouch. **A**, A 8- to 10-cm segment of terminal ileum and 25- to 30-cm of cecum and ascending colon are used for construction of the Indiana pouch, and they are opened along the antimesenteric border. **B** and **C**, The aboral end of the opened colon is folded down (*arrow*) to the apex of the incision and closed with a single layer of sutures. **D**, Ureteral implantation is performed through a T-shaped incision of the colonic tenia, leaving the mucosa intact. **E**, The ureteral orifice is established after mucosal incision. **F** and **G**, The spatulated ureter is anastomosed to the bowel mucosa by single sutures, and the seromuscularis is closed over it. **H**, The efferent segment is established by tapering the terminal ileum using absorbable GIA staples, leaving a caliber of ileum for passage of an 18-Fr catheter. The outlet is imbricated by sutures at the junction of ileum and cecum. (Modified from Rowland RG: Present experience with the Indiana pouch. *World J Urol* 14:92-98, 1996.)

**Figure 96-12 A**, Sigma rectum pouch (Mainz pouch II). A 20- to 25-cm segment of bowel is chosen and opened antimesenterically down to the peritoneal reflection of the rectum and folded to an inverted U-shape. **B**, The posterior wall of the pouch is created by side-to-side anastomosis of the medial margins of the inverted U. Non-refluxing ureterointestinal anastomosis is performed through a 4-cm submucosal tunnel. (Modified from Fisch M, Wammack R, Hohenfellner R: The sigma-rectum pouch [Mainz pouch II]. In Hohenfellner R, Wammack R [eds]: *Continent Urinary Diversion*. Edinburgh, Churchill Livingstone, 1992, pp 165-166.)

patients with irreparable loss of the functional urethra or if urethrectomy is required in radical tumor surgery.

Continent cutaneous diversion with a catheterizable cutaneous stoma is a practicable and safe alternative when diversion or orthotopic urinary diversion to the urethra is not feasible or desired. To ensure success of continent cutaneous diversion, careful patient selection is required for motivation, compliance, and the manual dexterity necessary to perform self-catheterization. Orthotopic bladder substitution to the urethra is simple to perform and can be offered to selected female

patients. Intraoperatively, frozen sections of the distal urethral stump and surrounding tissues are sampled to ensure complete tumor excision. Sparing the autonomic nerves is questioned because of the possibility of compromising the radicality of tumor excision. Patients should be educated about postoperative functional problems, including incontinence and chronic urinary retention requiring clean, intermittent self-catheterization. Intermittent self-catheterization should be practiced preoperatively to ensure acceptance and compliance with the maneuver after surgery.

# TRANSVAGINAL CLOSURE OF THE BLADDER NECK IN THE TREATMENT OF URINARY INCONTINENCE

*R. Duane Cespedes*

The treatment of urinary complications in the female patient with advanced neurologic disease is a challenging problem. Unlike their male counterparts, reliable urinary collection devices do not exist, limiting the available options. Most of these patients are treated with a long-term indwelling Foley catheter, which frequently causes severe complications, including a small and contracted bladder, recurrent infections, bladder stones, and a destroyed urethra. The long-term indwelling catheter and Foley balloon may produce urethral erosion and bladder neck pressure necrosis, resulting in spontaneous urethral expulsion with bladder spasms. In many cases, after the problems of detrusor compliance and bladder storage have been addressed, the patient is left with a fixed, open, and severely damaged urethra. Many options have been proposed for treatment of the destroyed urethra, including transvaginal closure, transabdominal closure, combined transvaginal and transabdominal approaches, a tight pubovaginal sling, or an artificial urinary sphincter. For milder cases with a partially intact urethra, a sling procedure can adequately close the bladder neck of most incontinent patients, but for the more severe cases, a bladder neck closure and suprapubic diversion are often necessary. Bladder neck closure methods remain the therapy of last resort, but they must occasionally be used because not all patients can be successfully managed with minimally invasive therapies.

### HISTORICAL PERSPECTIVE

For urethras that are not totally destroyed, a pubovaginal sling has been used successfully to close the urethra. Chancellor and associates<sup>1</sup> used a combined “tight” autologous pubovaginal sling and enterocystoplasty in 10 female patients with urethras destroyed by long-term Foley use. At 24 months, the investigators reported excellent results with minimal incontinence or other complications. They remarked that at least 1 cm of normal urethra was required for proper functioning of the sling and that the sling must be pulled tighter than normal. Mesh may not be applicable in this circumstance because the sling is purposely pulled very tight, possibly leading to a catastrophic erosion. Overall, this method is appealing because it reduces the fistula risk, allows a relief valve if the suprapubic diversion becomes obstructed, and allows alternative catheter access if needed.

There are few published reports on the techniques and outcomes of transvaginal bladder neck closure in female patients. Reid and colleagues<sup>2</sup> described five female patients (three procedures were performed transabdominally, and two were performed transvaginally) with an overall 80% cure rate. Fenely<sup>3</sup>

reported 24 female patients with neurologic disease who underwent transvaginal bladder neck closure and suprapubic tube placement. A vesicovaginal fistula developed in four patients, resulting in persistent incontinence. Zimmern and colleagues<sup>4</sup> described six female patients with closure of the bladder neck. At 21 months of follow-up, no fistulas or cases of incontinence had occurred. In 1994, Levy and associates<sup>5</sup> reported a 40% success rate using a transvaginal bladder neck closure. They subsequently modified their approach by using a combined transvaginal-transabdominal approach and reported a 100% success rate at a mean of 16 months’ follow-up for their subsequent 10 patients. Shpall and Ginsberg<sup>6</sup> reported 39 patients who underwent a combined transabdominal bladder neck closure and continent cutaneous diversion. At a mean of 37 months, six patients (15%) had developed fistulas, and four patients were successfully repaired.

As illustrated by this historical perspective, the risk of complications, specifically a vesicovaginal fistula, is real, and they are difficult to repair. A bladder neck closure is much different from simple closure of the bladder wall, and the risk of a fistula should not be underestimated. Several principles should be understood before performing a bladder neck closure. The bladder neck is usually hyperactive in patients with neurologic disease because most of them have detrusor hyperreflexia, and every voiding reflex includes active opening of the bladder neck. Active opening and closing of the bladder neck therefore forcibly attempts to destroy the bladder neck closure. To reduce this risk, postoperative suppression of the voiding reflex using prolonged, continuous catheter drainage (3 weeks) and liberal use of anticholinergics is imperative.

For a fistula to form, leakage must occur. The repair must be watertight from the beginning, and this requires a precise mucosal closure using a running suture, with multiple additional layers above it to reinforce the strength of the repair. The urethral mucosa sutures lines and the vaginal epithelial suture lines should not overlap the bladder neck closure. For added protection, a drain should be placed through an abdominal incision.

### INDICATIONS FOR THE PROCEDURE

A transvaginal bladder neck closure is an uncommon surgical procedure. The main indication is for patients with a neurogenic bladder who have a urethra destroyed by prolonged Foley catheter drainage. The usual clinical scenario is a progressive increase in leakage around the catheter, necessitating progressively larger catheters and more fluid in the Foley balloon. This eventually results in a wide, patulous, and severely damaged urethra.

Management of these patients often requires transvaginal closure of the bladder neck and simultaneous urinary diversion using a continent catheterizable augmentation, incontinent ileovesicostomy, or suprapubic catheter.

Other possible indications for a bladder neck closure include a urethra destroyed by disease or injury, such as a urethral diverticulum, recurrent urethrovaginal fistula after surgical procedures, and severe urethral trauma.

### PREOPERATIVE EVALUATION

Pelvic examination of the urethra usually reveals an enlarged, shortened, patulous urethra with overt visualization of the bladder neck or bladder itself in severe cases. Cystoscopy is performed to confirm the absence of other pathology in the bladder, such as foreign bodies, stones, cancer, or diverticula, which may accompany long-term Foley catheter drainage. Evaluation of the upper urinary tracts is indicated to assess for stones, hydronephrosis, or ureteral obstruction.

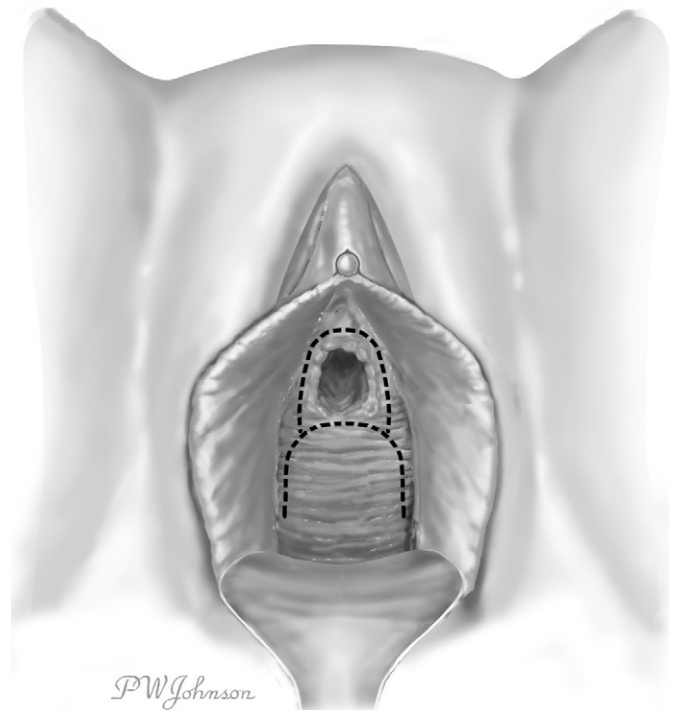

The choices for urinary diversion must be comprehensively discussed with the patient and family. If a continent diversion will be performed in conjunction with bladder neck closure, the patient must demonstrate sufficient manual dexterity to perform self-catheterization. If the patient has a reliable caregiver, this may be sufficient, although this does introduce additional risk for complications because a high-pressure system may develop if catheterizations are delayed.

In many cases, an incontinent ileovesicostomy to the skin ("chimney") is the safest long-term option because it reliably creates a low-pressure system and largely avoids the inflammatory and infectious complications of an indwelling catheter. This method also provides an easy, inexpensive, and reliable bag-on-stoma situation for caregivers. Two different methods for performing an incontinent ileovesicostomy diversion have been described.<sup>7,8</sup> When performing a diversion that entails opening of the bladder, it is preferable in some situations to close the bladder neck transabdominally. Khoury and colleagues<sup>9</sup> have reported an effective method of transabdominal closure.

Suprapubic catheter drainage is perhaps the most commonly used diversion because it is initially the least invasive, but it is not without complications. Although a suprapubic tube minimizes the urethral complications and allows the use of larger catheters, the problems with bladder inflammation, infection, bladder fibrosis, stone formation, and upper tract deterioration can still occur. In many cases, a suprapubic tube is used temporarily until the definitive diversion can be performed. Suprapubic tube placement is facilitated by using a transurethral Lowsley retractor to tent up the anterior bladder wall to the rectus and subsequently pull the Foley down into the bladder.<sup>10</sup> The urine should be routinely cultured and broad-spectrum antibiotics, matched to the culture, used before surgery.

### SURGICAL TECHNIQUE

The patient is placed in the dorsal lithotomy position and then prepared and draped to allow access to the lower abdomen and vagina. If a suprapubic tube will be used postoperatively, a large (20- to 24-Fr) tube is placed first using a Lowsley retractor to elevate the bladder to the anterior abdominal wall. Normal saline is injected into the vaginal wall to develop a subepithelial plane

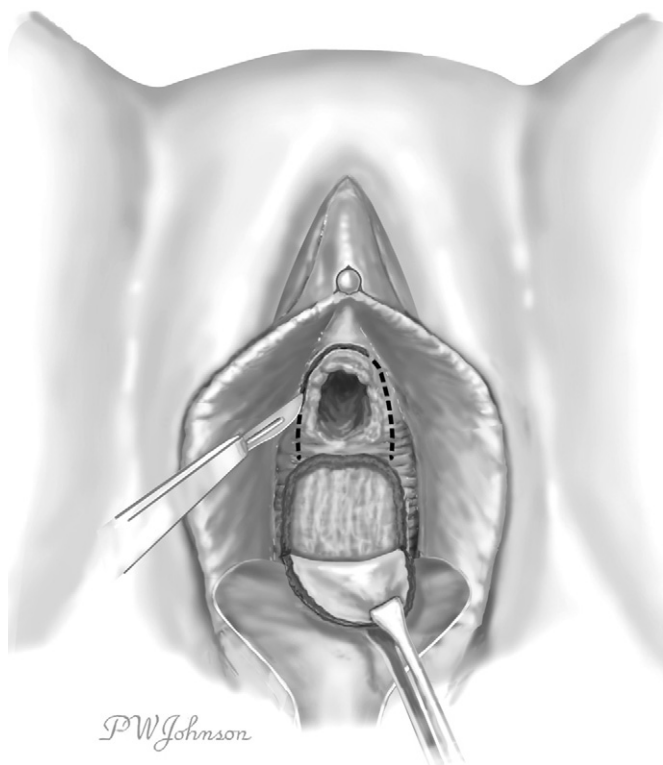

**Figure 97-1** After injection of normal saline into the anterior vaginal wall, an incision is made around the urethral opening to create the vaginal wall flap.

around the urethra and to develop a mucosal flap for coverage. A circumscribing incision is made around the urethral opening, and an inverted-U-shaped incision is made in the anterior vaginal wall below the urethra (Fig. 97-1). The vaginal flap is created by sharp dissection in the anterior vaginal wall, separating the epithelium from the underlying fascia. The dissection is carried laterally and superiorly around the open bladder neck (Fig. 97-2). The dissection is continued deeper around the bladder neck, freeing the bladder from its attachments to the symphysis pubis and lateral pelvic side wall. This invariably requires entering the retropubic space by detaching the urethropelvic ligaments on either side of the bladder neck and the pubourethral ligaments superior to the urethra. If the urethra is more than about 1 cm long, the distal portion should be resected to ensure that it can be folded in without leaving any exposed mucosa. Indigo carmine is injected to ensure identification of the ureteral orifices to prevent injury during bladder neck closure.

The bladder neck is closed in three layers. The first two layers are vertically closed, and the third layer is closed horizontally. The mucosal layer is precisely closed with a running 3-0 polyglycolic acid suture to ensure a watertight closure. If any tension exists on this or a subsequent suture line, further dissection is required to ensure that it is tension free. The muscular layer is then closed over the mucosa with a running 2-0 polyglycolic acid suture, incorporating the urethral muscle and distal bladder neck region (Fig. 97-3). The bladder neck and anterior bladder wall should be closed horizontally (to prevent overlapping suture lines) over the previous layers using interrupted 1-0 polyglycolic acid sutures. At this point, the bladder neck closure should be elevated somewhat back into the retropubic space behind the pubic symphysis (Fig. 97-4). A Martius flap may be placed at this time to advance another layer over the repair, although it is rarely

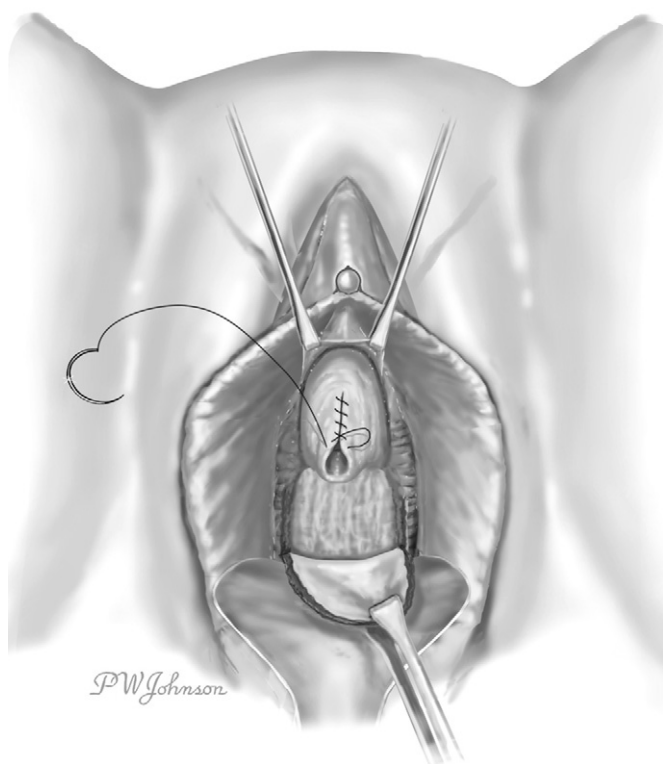

**Figure 97-2** The urethral meatus is dissected free, and the vaginal wall flap is created.

**Figure 97-4** The final muscular layer is closed in a horizontal fashion and rotated superiorly behind the pubis.

**Figure 97-3** The bladder neck wall musculature is vertically closed in a running fashion after the mucosal layer has a watertight closure.

needed unless the patient has poor tissue or has been irradiated.<sup>11</sup> A retropubic drain is usually placed and advanced out through a suprapubic incision. The vaginal wall flap is advanced over the entire bladder neck closure, ensuring that it covers the original urethral opening (Fig. 97-5).

#### POSTOPERATIVE CARE AND COMPLICATIONS

A vaginal pack is placed in the vagina for tamponade purposes and to place pressure on the tissue layers to facilitate adhesion between them. I usually leave the pack in place for 24 hours. The drain is removed when drainage is less than 50 mL per day. The suprapubic tube is carefully secured and irrigated routinely until all hematuria subsides. Antibiotics are used postoperatively for 2 weeks during the healing period. After 3 weeks, a cystogram is performed to ensure the bladder neck is completely closed.

The most significant complication of transvaginal bladder neck closure is postoperative vesicovaginal fistula. This may occur early or late in the healing period. Several steps can be taken to prevent the development of fistulas: using several watertight closure layers; positioning the bladder neck high in the retropubic space; minimizing suture overlap; avoidance of postoperative bladder spasms with anticholinergics; using a drain such that inadvertent urine leakage does not fistulize to the vagina; use of a Martius flap for irradiated or poor tissue; and ensuring low-pressure drainage during the healing process. If a fistula does form despite these measures, a secondary repair may be performed after the inflammation has subsided, which is

**Figure 97-5** The vaginal epithelium is advanced over the entire defect and closed with a running suture.

approximately 3 months. In some cases, a pedicled graft may be required to bring good tissue into the area, or an abdominal approach can be used to allow an omental interposition flap to cover the repair.

### CONCLUSIONS

Bladder neck closure is an uncommon procedure and is typically used in patients with urethras destroyed by long-term Foley usage. A successful closure can be performed by using the principles of watertight, non-overlapping suture lines and by ensuring low-pressure drainage during healing. There are many choices for urinary diversion, and these should be discussed with the patient, keeping the long-term goals in mind.

# TISSUE ENGINEERING FOR RECONSTRUCTION OF THE URINARY TRACT AND TREATMENT OF STRESS URINARY INCONTINENCE

*Daniel Eberli and Anthony Atala*

Urinary incontinence is associated with impairment of quality of life, social isolation, and depressive symptoms.<sup>1</sup> A conservative estimate is that urinary incontinence affects approximately 20% of women. However, the prevalence may be as high as 50% among older women, with a peak at 47 years old.<sup>2-4</sup> In the United States the estimated annual direct cost of caring for patients with urinary incontinence is more than \$16 billion.<sup>5</sup>

In general, treatment plans are usually directed toward the specific type of urinary incontinence, and the treatment option with the lowest risk for adverse complications is usually offered. Lifestyle intervention, pelvic floor muscle training, vaginal devices (i.e., pessaries), and pharmacologic treatments are usually considered before surgical intervention.<sup>1</sup>

Surgical options include endoscopic injection of bulking agents, colposuspension (e.g., Burch procedure), sling operations, traditional transvaginal needle suspension, and tension-free vaginal tape. However, many of the current surgical treatment options only offer short-term relief of urinary incontinence, and the overall success of these therapies is limited by the complications, including infection, graft erosion, bladder and bowel perforation, prolonged catheterization, and vascular injury.<sup>2</sup> The shortcomings of current therapies have led to the application of regenerative medicine and tissue engineering to the field of urinary incontinence.

Regenerative medicine encompasses various areas of technology, such as tissue engineering, stem cells, and cloning. Tissue engineering, one of the major components of regenerative medicine, follows the principles of cell transplantation, materials science, and engineering toward the development of biologic substitutes that can restore and maintain normal function. Tissue engineering strategies generally fall into two categories: the use of acellular matrices, which depend on the body's natural ability to regenerate for proper orientation and direction of new tissue growth, and the use of matrices with cells. Acellular tissue matrices are usually prepared by manufacturing artificial scaffolds or by removing cellular components from tissues by mechanical and chemical manipulation to produce collagen-rich matrices.<sup>6-9</sup> These matrices tend to slowly degrade on implantation and are generally replaced by the extracellular matrix (ECM) proteins that are secreted by the ingrowing cells. Cells can also be used for therapy by injection alone or with carriers such as hydrogels.

When cells are used for tissue engineering, a small piece of donor tissue is dissociated into individual cells. These cells are

implanted directly into the host or are expanded in culture, attached to a support matrix, and then reimplanted into the host after expansion. The source of donor tissue can be heterologous, allogeneic, or autologous (Table 98-1). Ideally, structural and functional tissue replacement will occur with minimal complications. The preferred cells to use are autologous cells. For this method, a biopsy of tissue is obtained from the host, the cells are dissociated and expanded in culture, and the expanded cells are implanted into the same host.<sup>9-12</sup> The use of autologous cells, although it may cause an inflammatory response, avoids rejection, and the deleterious side effects of immunosuppressive medications can be avoided.

Most strategies for tissue engineering depend on a sample of autologous cells from the diseased organ of the host. However, for many patients with extensive end-stage organ failure, a tissue biopsy may not yield enough normal cells for expansion and transplantation. In other instances, primary autologous human cells cannot be expanded from a particular organ, such as the pancreas. In these situations, stem cells are envisioned as being an alternative source of cells from which the desired tissue can be derived. Stem cells can be derived from discarded human embryos (i.e., human embryonic stem cells), from fetal tissue, or from adult sources (e.g., bone marrow, fat, skin). Therapeutic cloning has also played a role in the development of the field of regenerative medicine. Therapeutic cloning, which has also been called nuclear transplantation and nuclear transfer, involves the introduction of a nucleus from a donor cell into an enucleated oocyte to generate an embryo with a genetic makeup identical to that of the donor. Stem cells can be derived from this source, which may have the potential to be used therapeutically.

Major advances have been achieved within the past decade. Regenerative medicine may extend the treatment options for urinary incontinence. However, like every new field, regenerative medicine and tissue engineering are expensive. Several of the

**Table 98-1 Origin of Tissue**

Source of Donor Tissue	Definition
Autologous	Same individual
Homologous (allogeneic)	Same species, different individual
Heterologous	Different species (bovine)

clinical trials involving bioengineered products have been placed on hold because of the costs involved with the specific technology. With a bioengineered product, costs are usually high because of the biologic nature of the therapies involved. As with any therapy, the costs allowed by the medical health care system for a specific technology must be limited. The costs of bioengineered products must be lowered for them to have an impact clinically. This issue is being addressed for many tissue-engineered technologies. As the technologies advance over time and the volume of the application is considered, costs will naturally decrease.

### NATIVE CELLS

One of the limitations of applying cell-based regenerative medicine techniques to organ replacement has been the inherent difficulty of growing specific cell types in large quantities. By studying the privileged sites for committed precursor cells in specific organs and by exploring the conditions that promote differentiation, researchers may be able to overcome the obstacles that limit cell expansion *in vitro*. For example, urothelial cells have been grown in an institutional setting in the past, but only with limited expansion. Several protocols developed over the past 2 decades identified the undifferentiated cells and kept them undifferentiated during their growth phase.<sup>13-16</sup> Using these methods of cell culture, it is possible to expand a urothelial strain from a single specimen that initially covered a surface area of 1 cm<sup>2</sup> to one covering a surface area of 4202 m<sup>2</sup> (the equivalent of one football field) within 8 weeks.<sup>13</sup>

These studies indicated that it should be possible to collect autologous bladder cells from human patients, expand them in culture, and return them to the donor in sufficient quantities for reconstructive purposes.<sup>13,15-20</sup> Major advances have been achieved within the past decade on the possible expansion of a variety of primary human cells, with specific techniques that make the use of autologous cells possible for clinical application.

### ANGIOGENIC FACTORS

The engineering of large organs requires a vascular network of arteries, veins, and capillaries to deliver nutrients to each cell. One possible method of vascularization is the use of gene delivery of angiogenic agents such as vascular endothelial growth factor (VEGF) with the implantation of vascular endothelial cells to enhance neovascularization of engineered tissues. Skeletal myoblasts from adult mice were cultured and transfected with an adenovirus encoding VEGF, and these cells were combined with human vascular endothelial cells.<sup>21</sup> The mixtures of cells were injected subcutaneously in nude mice, and the engineered tissues were retrieved up to 8 weeks after implantation. The transfected cells formed muscle with neovascularization, as determined by histology and immunohistochemical probing, with maintenance of their muscle volume, whereas engineered muscle of nontransfected cells had a significantly smaller mass of cells, with loss of muscle volume over time, less neovascularization, and no surviving endothelial cells. These results indicate that a combination of VEGF and endothelial cells may be useful for inducing neovascularization and volume preservation in engineered tissue. The use of angiogenic factors may support cell-based therapy in patients with postirradiation incontinence or patients with large fibrotic degeneration of the urinary sphincter.

### BIOMATERIALS

For cell-based tissue engineering, the expanded cells are seeded onto a scaffold synthesized with the appropriate biomaterial. In tissue engineering, biomaterials replicate the biologic and mechanical function of the native ECM found in tissues in the body by serving as an artificial ECM. Biomaterials provide a three-dimensional space for the cells to form into new tissues with appropriate structure and function, and they allow the delivery of cells and appropriate bioactive factors (e.g., cell-adhesion peptides, growth factors) to desired sites in the body.<sup>22</sup> Because most mammalian cell types are anchorage dependent and will die if no cell-adhesion substrate is available, biomaterials provide a cell-adhesion substrate that can deliver cells to specific sites in the body with high loading efficiency. Biomaterials can provide mechanical support against *in vivo* forces such that the predefined three-dimensional structure is maintained during tissue development. Bioactive signaling agents, such as cell-adhesion peptides and growth factors, can be loaded along with cells to help regulate cellular function.

The ideal biomaterial should be biodegradable and bioresorbable to support the replacement of normal tissue without inflammation. Incompatible materials are destined for an inflammatory or foreign body response that eventually leads to rejection and necrosis. Degradation products, if produced, should be removed from the body by means of metabolic pathways at a rate that keeps the concentration of these degradation products in the tissues at a tolerable level.<sup>23</sup> The biomaterial should also provide an environment in which appropriate regulation of cell behavior (i.e., adhesion, proliferation, migration, and differentiation) can occur such that functional tissue can form. Cell behavior in the newly formed tissue is regulated by many interactions of the cells with their microenvironment, including interactions with cell-adhesion ligands<sup>24</sup> and with soluble growth factors.<sup>25</sup>

Biomaterials provide temporary mechanical support while the cells undergo spatial tissue reorganization. The properly chosen biomaterial should allow the engineered tissue to maintain sufficient mechanical integrity to support itself in early development, and in late development, it should have begun degradation so that it does not hinder further tissue growth.<sup>22</sup> Three classes of biomaterials have been used for engineering tissues (Table 98-2): naturally derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa, small intestinal submucosa), and synthetic polymers such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA). These classes of biomaterials have been tested in terms of their biocompatibility.<sup>26,27</sup> Naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition. However, synthetic polymers can be produced on a large scale with controlled properties of strength, degradation rate, and microstructure.

**Table 98-2 Classes of Biomaterials**

Class	Example
Naturally Derived Materials	Collagen and Alginate
Acellular tissue matrices	Bladder submucosa or small intestinal submucosa
Synthetic polymers	Polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA)

### Naturally Derived Materials

Collagen is the most abundant and ubiquitous structural protein in the body, and it can be readily purified from animal and human tissues with an enzyme treatment and salt or acid extraction.<sup>28</sup> Collagen implants degrade through a sequential attack by lysosomal enzymes. The *in vivo* resorption rate can be regulated by controlling the density of the implant and the extent of intermolecular cross-linking. The lower the density, the greater the interstitial space and the larger the pores for cell infiltration, leading to a higher rate of implant degradation. Collagen contains cell-adhesion domain sequences (e.g., RGD) that may assist to retain the phenotype and activity of many types of cells, including fibroblasts<sup>29</sup> and chondrocytes.<sup>30</sup>

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell-delivery vehicle<sup>31</sup> and a cell-immobilization matrix<sup>32</sup> because of its gentle gelling properties in the presence of divalent ions such as calcium. Alginate is relatively biocompatible, and it is approved by the U.S. Food and Drug Administration (FDA) for human use as material to dress wounds. Alginate is a family of copolymers of D-mannuronate and L-guluronate. The physical and mechanical properties of alginate gel are strongly correlated with the proportion and length of polyguluronate block in the alginate chains.<sup>31</sup>

### Acellular Tissue Matrices

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues. The matrices are often prepared by mechanical and chemical manipulation of a segment of tissue.<sup>6-9</sup> The matrices slowly degrade on implantation, and they are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrowing cells.

### Synthetic Polymers

Polyesters of naturally occurring  $\alpha$ -hydroxy acids, including PGA, PLA, and PLGA, are widely used in tissue engineering. These polymers have gained FDA approval for human use in a variety of applications, including sutures.<sup>33</sup> The ester bonds in these polymers are hydrolytically labile, and the polymers degrade by nonenzymatic hydrolysis. The degradation products of PGA, PLA, and PLGA are nontoxic natural metabolites and are eventually eliminated from the body in the form of carbon dioxide and water.<sup>33</sup> The degradation rate of these polymers can be tailored from several weeks to several years by altering crystallinity, initial molecular weight, and the copolymer ratio of lactic to glycolic acid. Because these polymers are thermoplastics, they can be easily formed into a three-dimensional scaffold with a desired microstructure, gross shape, and dimension by various methods, including molding, extrusion,<sup>34</sup> solvent casting,<sup>35</sup> phase-separation techniques, and gas-foaming techniques.<sup>36</sup> Many applications in tissue engineering require a scaffold with high porosity and ratio of surface area to volume. Other biodegradable synthetic polymers, including poly-anhydrides and poly-ortho-esters, can be used to fabricate scaffolds for tissue engineering with controlled properties.<sup>37</sup>

## TISSUE ENGINEERING OF SPECIFIC STRUCTURES

Investigators around the world, including those at our institution, have been working toward the development of several cell

types and tissues and organs for clinical application. In the following sections, we describe the engineering of tissues that may have an impact on the reconstructive strategies for urinary incontinence.

### Urethra

The urethra consists of layers of longitudinal and circular smooth muscle. Weakening of the urethral muscle wall by compression damage during delivery or trauma can result in incontinence.<sup>2</sup> Various biomaterials without cells, such as PGA and acellular collagen-based matrices from small intestine and bladder, have been used in animal models for the regeneration of urethral tissue.<sup>6,38-42</sup> Some of these biomaterials, such as acellular collagen matrices derived from bladder submucosa, have also been seeded with autologous cells for urethral reconstruction. Our institution has been able to replace tubularized urethral segments with cell-seeded collagen matrices.

Acellular collagen matrices derived from bladder submucosa by our institution have been used experimentally and clinically. In animal studies, segments of the urethra were resected and replaced with acellular matrix grafts in an onlay fashion. Histologic examination showed complete epithelialization and progressive vessel and muscle infiltration, and the animals were able to void through the neo-urethras.<sup>6</sup> These results were confirmed in a clinical study of patients with hypospadias and urethral stricture disease.<sup>43</sup> Decellularized cadaveric bladder submucosa was used as an onlay matrix for urethral repair in patients with stricture disease and hypospadias. Patent, functional neo-urethras were confirmed in these patients, with up to 7 years of follow-up. The use of an off-the-shelf matrix appears to be beneficial for patients with abnormal urethral conditions, and it obviates the need for obtaining autologous grafts, decreasing operative time and eliminating donor site morbidity.

These techniques are not applicable for tubularized urethral repairs. The collagen matrices are able to replace urethral segments only when used in an onlay fashion. However, if a tubularized repair is needed, the collagen matrices should be seeded with autologous cells to avoid the risk of stricture formation and poor tissue development.<sup>44,45</sup> Tubularized collagen matrices seeded with autologous cells can be used successfully for urethra replacement.

### Bladder

Gastrointestinal or colon segments are commonly used as tissues for bladder replacement or repair. However, both tissues are designed to absorb specific solutes, whereas bladder tissue functions as a barrier to prevent resorption of waste products. Because of the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted using alternative materials and tissues for bladder replacement or repair.

The success of cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long-term survival, differentiation, and growth. Urothelial and muscle cells can be expanded *in vitro*, seeded onto polymer scaffolds, and allowed to attach and form sheets of cells.<sup>46</sup> These principles were applied in the creation of tissue-engineered bladders in an animal model that required a subtotal cystectomy with subsequent replacement with a tissue-engineered organ in beagle dogs.<sup>47</sup> Urothelial and muscle cells were separately expanded from an autologous

bladder biopsy and seeded onto a bladder-shaped biodegradable polymer scaffold. The results from this study showed that it is possible to tissue engineer bladders that are anatomically and functionally normal. Clinical trials for the application of this technology are being conducted.

### Vagina

Several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. According to the hammock hypothesis, the vagina provides a firm backdrop for the urethra to rest against when the intra-abdominal pressure increases, preventing urinary leakage.

Vaginal reconstruction has been challenging because of the paucity of available native tissue. The feasibility of engineering vaginal tissue *in vivo* has been investigated.<sup>48</sup> Vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. These cells were seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into nude mice for up to 6 weeks. Immunocytochemical, histologic, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed similar functional properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, patent vaginal structures were confirmed in the tissue-engineered specimens, whereas the non-cell-seeded structures were stenotic.<sup>49</sup>

### Uterus

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy and intersex disorders may not have sufficient uterine tissue for future reproduction. We investigated the possibility of engineering functional uterine tissue using autologous cells.<sup>50</sup> Autologous rabbit uterine smooth muscle and epithelial cells were harvested and then grown and expanded in culture. These cells were seeded onto preconfigured uterine-shaped biodegradable polymer scaffolds, which were used for subtotal uterine tissue replacement in the corresponding autologous animals. On retrieval 6 months after implantation, histological, immunocytochemical, and Western blot analyses confirmed the presence of normal uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of normal uterine tissue. Breeding studies using these engineered uteri are being performed.

### Additional Treatment Options

#### *Bulking Agents*

Injectable bulking agents can be endoscopically placed in the treatment of urinary stress incontinence. The advantages in treating urinary incontinence with this minimally invasive approach include the simplicity of a quick outpatient procedure and the low morbidity associated with it. Several investigators are seeking alternative implant materials that would be safe for human use.<sup>51</sup>

The ideal substance for the endoscopic treatment of incontinence should be injectable, nonantigenic, nonmigratory, volume

stable, and safe for human use. Toward this goal, long-term studies were conducted to determine the effect of injectable chondrocytes *in vivo*.<sup>52</sup> It was initially determined that alginate, a liquid solution of gluronic and mannuronic acid, embedded with chondrocytes could serve as a synthetic substrate for the injectable delivery and maintenance of cartilage architecture *in vivo*. Alginate undergoes hydrolytic biodegradation, and its degradation time can be varied depending on the concentration of each of the polysaccharides. The use of autologous cartilage for the treatment of stress urinary incontinence in humans would satisfy all the requirements for an ideal injectable substance.

Chondrocytes derived from an ear biopsy can be readily grown and expanded in culture. Neocartilage formation can be achieved *in vitro* and *in vivo* using chondrocytes cultured on synthetic biodegradable polymers. In these experiments, the cartilage matrix replaced the alginate as the polysaccharide polymer underwent biodegradation. This system was adapted for the treatment of vesicoureteral reflux in a porcine model.<sup>53</sup>

Patients with urinary incontinence were treated endoscopically with injected chondrocytes at three different medical centers. Phase I trials showed an approximate success rate of 80% at follow-up 3 and 12 months postoperatively.<sup>54</sup> These studies showed that chondrocytes can be easily harvested and combined with alginate *in vitro*, the suspension can be easily injected cystoscopically, and the elastic cartilage tissue formed is able to correct urinary stress incontinence.

#### *Restoration of Functional Urinary Sphincter Muscle*

The pelvic diaphragm prevents urinary incontinence by providing resting urethral tone by means of slow-twitch fibers and rapid refractory contraction by means of fast-twitch fibers if the abdominal pressure rises. The external striated urethral sphincter is mostly responsible for preventing stress urinary incontinence. The use of injectable cultured myoblasts (*i.e.*, muscle precursor cells) for the treatment of stress urinary incontinence has been investigated, and it has the potential to become the first treatment to restore sphincter muscle function.<sup>55,56</sup> Labeled myoblasts were directly injected into the proximal urethra and lateral bladder walls of nude mice with a microsyringe in an open surgical procedure. Tissue harvested up to 35 days after injection contained the labeled myoblasts and had evidence of differentiation of the labeled myoblasts into regenerative myofibers. The study authors reported that a significant portion of the injected myoblast population persisted *in vivo*. Myoblasts were further investigated using sciatic nerve–transected rats, which showed a significant improvement of the fast-twitch muscle contraction amplitude 2 weeks after myoblast injection.<sup>57</sup> The study authors report a minimal inflammation response with a low number of CD4-activated lymphocytes at the injection site, confirming the immunologic acceptance of the autologous cells. A subsequent study showed a significant improvement in leak point pressure when the sciatic nerve–transected rats were treated with myoblast injections.<sup>58</sup>

The fact that myoblasts (Fig. 98-1) can be labeled, survive after injection, and begin the process of myogenic differentiation further supports the feasibility of using cultured cells of muscular origin as an injectable bioimplant. The use of injectable muscle precursor cells has also been investigated for use in the treatment of urinary incontinence due to irreversible urethral sphincter injury or maldevelopment. Muscle precursor cells are the quiescent satellite cells found in each myofiber that proliferate to form myoblasts and eventually form myotubes and new muscle tissue.

**Figure 98-1** Characterization of the muscle precursor cells (i.e., satellite cells) obtained using the myofiber explant culture technique. **A**, Aspect of a single myofiber of the flexor brevis muscle immediately after isolation. **B**, After 2 days in culture, satellite cells are detached from the native myofibers. **C**, Immunofluorescence staining showed that the activated satellite cells emerging from the myofibers were desmin positive (red, Texas red stain). The nuclei are counterstained (blue) with 4',6-diamidino-2-phenylindole (DAPI). **D**, On day 7, satellite cells had proliferated around the native myofibers (arrows) and started to fuse into myotubes. **E**, On day 15, mature myotubes expressing  $\alpha$ -actinin-2 were present. **F**, The muscle precursor cells expressing  $\beta$ -galactosidase formed myotubes (blue) with the X-Gal staining on day 15 (magnification  $\times 100$ ). (Courtesy of Anthony Atala, MD, Wake Forest Institute for Regenerative Medicine, Winston Salem, NC.)

Intrinsic muscle precursor cells have previously been shown to play an active role in the regeneration of injured striated urethral sphincter.<sup>59</sup> In a subsequent study, autologous muscle precursor cells were injected into a rat model of urethral sphincter injury, and replacement of mature myotubes and restoration of functional motor units were confirmed in the regenerating sphincteric muscle tissue (Fig. 98-2).<sup>60</sup> The urethral sphincter contraction force was measured 5 and 30 days after injection and showed a significant improvement for the group with the muscle precursor cell injection (Fig. 98-3). This is the first demonstration of the replacement of sphincter muscle tissue and its innervation by the injection of muscle precursor cells. The innervation is crucial for muscle contraction, for activation of the satellite cells,<sup>61</sup> and for the maturation of the regenerated myotubes.<sup>62</sup>

Preclinical trials for the application of this technology are being conducted in large animals. Sphincter-derived muscle cells have been used for the treatment of urinary incontinence in a pig model.<sup>63</sup> The damaged sphincter was visualized by transurethral ultrasound, and the muscle precursor cells and fibroblasts were injected into the damaged zone. Our institution is performing a preclinical study in dogs. Animals that received a muscle precursor cell injection after damage to the sphincter showed a significant improvement in leak point and sphincter pressure compared with controls.

In summary, these results are promising, and the first clinical trials are within reach. Muscle precursor cells may be a minimally invasive solution for urinary incontinence in patients with irreversible urinary sphincter muscle insufficiency.

**Figure 98-2** Muscle formation after injection of muscle precursor cells (MPCs). Aspect of the urethral sphincter stained with X-Gal solution on day 5 (A) and day 30 (B) after autograft of  $\beta$ -galactosidase-expressing MPCs. On day 5, numerous  $\beta$ -galactosidase-expressing cells were found in the injured side. On day 30, they had migrated toward each boundary of the injured side and had formed myotubes. (Courtesy of Anthony Atala, MD, Wake Forest Institute for Regenerative Medicine, Winston Salem, NC.)

**Figure 98-3** Comparison of urethral sphincter contraction force within each group at different times. The urine leak point pressure was measured with (p2) and without (p1) electrical stimulation of the striated urethral sphincter. The graph shows the difference (p2 – p1 in cm H<sub>2</sub>O), reflecting the maximal bladder pressure that the urethral sphincter can sustain. Significant differences between normal and injured sphincters were seen at all times ( $P = .0001$ ) and between injured groups with and without injection of muscle precursor cells on day 30 ( $P = .0028$ ). The difference between the two injured groups was not significant on day 5 ( $P = .3817$ ). (Courtesy of Anthony Atala, MD, Wake Forest Institute for Regenerative Medicine, Winston Salem, NC.)

#### ALTERNATE CELL SOURCES: STEM CELLS AND NUCLEAR TRANSFER

Human embryonic stem cells exhibit two remarkable properties: the ability to proliferate in an undifferentiated but pluripotent state (i.e., self-renewal) and the ability to differentiate into many specialized cell types.<sup>64</sup> They can be isolated by immunosurgery

from the inner cell mass of the embryo during the blastocyst stage (5 days after fertilization), and they are usually grown on feeder layers consisting of mouse embryonic fibroblasts or human feeder cells.<sup>65</sup> Later reports showed that these cells could be grown without the use of a feeder layer,<sup>66</sup> thereby avoiding exposure of the human cells to mouse viruses and proteins. These cells have demonstrated longevity in culture by maintaining their undifferentiated state for at least 80 passages when grown using current protocols.<sup>67,68</sup>

Human embryonic stem cells have been shown to differentiate into cells from all three embryonic germ layers in vitro. Skin and neurons have been formed, indicating ectodermal differentiation.<sup>69-72</sup> Blood, cardiac cells, cartilage, endothelial cells, and muscle have been formed, indicating mesodermal differentiation.<sup>73-75</sup> Pancreatic cells have been formed, indicating endodermal differentiation.<sup>76</sup> As further evidence of their pluripotency, embryonic stem cells can form embryoid bodies, which are cell aggregations that contain all three embryonic germ layers while in culture, and they can form teratomas in vivo.<sup>77</sup>

Although there has been tremendous interest in the field of nuclear cloning since the birth of Dolly in 1997, the first successful nuclear transfer was reported more than 50 years ago by Briggs and King.<sup>78</sup> Cloned frogs, which were the first vertebrates derived from nuclear transfer, were subsequently reported by Gurdon in 1962,<sup>79</sup> but the nuclei were derived from nonadult sources. Since 2000, tremendous advances in nuclear cloning technology have been reported, indicating the relative immaturity of the field. Dolly was not the first cloned mammal to be produced from adult cells; live lambs were produced in 1996 using nuclear transfer and differentiated epithelial cells derived from embryonic discs.<sup>80</sup> The significance of Dolly was that she was the first mammal to be derived from an adult somatic cell using nuclear transfer.<sup>81</sup> Since then, animals from several species, including cattle,<sup>82</sup> goats,<sup>83,84</sup> mice,<sup>85</sup> and pigs,<sup>86-89</sup> have been grown using nuclear transfer technology.

Two types of nuclear cloning—reproductive cloning and therapeutic cloning—have been described, and a better understanding of the differences between the two types may help to

alleviate some of the controversy that surrounds these technologies,<sup>90,91</sup> Banned in most countries for human applications, *reproductive cloning* is used to generate an embryo that has genetic material identical to that of its cell source. This embryo can be implanted into a uterus to give rise to an infant that is a clone of the donor. *Therapeutic cloning* is used to generate early-stage embryos that are explanted in culture to produce embryonic stem cell lines whose genetic material is identical to that of its source. These autologous stem cells have the potential to become almost any type of cell in the adult body and are therefore useful in tissue and organ replacement applications.<sup>92</sup> Therapeutic cloning, which has also been called somatic cell nuclear transfer, may provide an alternative source of transplantable cells.

According to data from the Centers for Disease Control and Prevention (CDC), an estimated 3000 Americans die every day of diseases that could have been treated with stem cell–derived tissues.<sup>93</sup> With current allogeneic tissue transplantation protocols, rejection is a frequent complication because of immunologic incompatibility, and immunosuppressive drugs are usually administered to treat or prevent graft-versus-host disease.<sup>92</sup> The use of transplantable tissue and organs derived from therapeutic cloning may enable avoidance of immune responses that typically are associated with transplantation of non-autologous tissues.<sup>94</sup>

Although promising, somatic cell nuclear transfer technology has certain limitations that require further improvements before therapeutic cloning can be applied widely in replacement therapy. The efficiency of the overall cloning process is low. Most embryos derived from animal cloning do not survive after implantation.<sup>95–97</sup> In practical terms, many nuclear transfers must be performed to produce one live offspring for animal cloning applications. The potential for cloned embryos to grow into live offspring is between 0.5% to 18% for sheep, pigs, and mice.<sup>98</sup> However, greater success (80%) has been reported in cattle,<sup>99</sup> which in part may reflect the availability of advanced bovine supporting technologies, such as *in vitro* embryo production and embryo transfer, which have been developed for this species for agricultural purposes. To improve cloning efficiency, further improvements are required in the many complex steps of nuclear transfer, such as enucleation and reconstruction, activation of oocytes, and cell cycle synchronization between donor cells and recipient oocytes.<sup>100</sup>

Common abnormalities have been found in newborn clones, including enlarged size with an enlarged placenta (i.e., large-offspring syndrome),<sup>101</sup> respiratory distress, and defects of the kidney, liver, heart, and brain.<sup>102</sup> They are also affected by obesity<sup>103</sup> and premature death.<sup>104</sup> These problems may be related to the epigenetics of the cloned cells, which involve reversible modifications of the DNA or chromatin, whereas the original DNA (genetic) sequences remain intact. Faulty epigenetic reprogramming in clones, in which the DNA methylation patterns, histone modifications, and overall chromatin structure of the somatic nuclei are not being reprogrammed to an embryonic pattern of expression, may explain these abnormalities.<sup>97</sup> Reactivation of key embryonic genes at the blastocyst stage is usually not present in embryos cloned from somatic cells, whereas embryos cloned from embryos consistently express early embryonic genes.<sup>105,106</sup> Proper epigenetic reprogramming to an embryonic state may help to improve the cloning efficiency and reduce the incidence of abnormal cloned cells.

Nuclear transfer has the potential to be used for functional reconstruction of the urinary sphincter, especially when muscle

biopsies are not suitable or will not yield a sufficient amount of precursor cells. Decline of tissue regenerative potential is a hallmark of ageing, and several studies have shown the decline in muscle precursor cells with age.<sup>107,108</sup> Because most patients with stress urinary incontinence are elderly women, nuclear transfer may offer a tool to overcome the donor problem.

We applied the principles of tissue engineering and therapeutic cloning in an effort to produce genetically identical skeletal muscle tissue in a large animal model, the cow (*Bos taurus*).<sup>109</sup> Bovine skin fibroblasts from adult Holstein steers were obtained by ear notch, and single donor cells were isolated and microinjected into the perivitelline space of donor enucleated oocytes (i.e., nuclear transfer). The resulting blastocysts were implanted into progesterin-synchronized recipients to allow further *in vivo* growth. After 12 weeks, cloned cells were harvested, expanded *in vitro*, and seeded onto biodegradable scaffolds. The constructs, which consisted of the cloned muscle cells and the scaffolds, were then implanted into the subcutaneous space of the same steer from which the cells were cloned to allow tissue growth, and they were retrieved 12 weeks after implantation. The cloned skeletal explants showed spatially orientated tissue bundles with elongated multinuclear muscle fibers. The skeletal muscle was further identified by immunohistochemistry staining that was positive for sarcomeric tropomyosin and by Western blot using antibodies against desmin and myosin. Histologic analysis found extensive vascularization and little inflammation.

Because previous studies have shown that bovine clones harbor the oocyte mitochondrial DNA,<sup>110–112</sup> the donor egg's mitochondrial DNA (mtDNA) was thought to be a potential source of immunologic incompatibility. Differences in mtDNA-encoded proteins expressed by cloned cells may stimulate a T-cell response specific for mtDNA-encoded minor histocompatibility antigens when the cloned cells are implanted back into the original nuclear donor.<sup>113</sup> We used nucleotide sequencing of the mtDNA genomes of the clone and fibroblast nuclear donor to identify potential antigens in the muscle constructs. Only two amino acid substitutions distinguished the clone and the nuclear donor, and as a result, a maximum of two minor histocompatibility antigens could be defined. Given the lack of knowledge regarding peptide-binding motifs for bovine major histocompatibility complex class I molecules, there is no reliable method to predict the impact of these amino acid substitutions on bovine histocompatibility.

Oocyte-derived mtDNA was thought to be a potential source of immunologic incompatibility in the cloned renal cells. Maternally transmitted minor histocompatibility antigens in mice have been shown to stimulate skin allograft rejection *in vivo* and cytotoxic T-lymphocyte expansion *in vitro*<sup>113</sup> that could prevent the use of these cloned constructs in patients with chronic rejection of major histocompatibility matched human renal transplants.<sup>114,115</sup> We tested for a possible T-cell response to the cloned skeletal muscle using delayed-type hypersensitivity testing *in vivo* and Elispot analysis of interferon- $\gamma$ -secreting T cells *in vitro*. Both analyses revealed that the cloned muscle cells showed no evidence of a T-cell response, suggesting that rejection will not necessarily occur in the presence of oocyte-derived mtDNA. This finding may represent a step forward in overcoming the histocompatibility problem of stem cell therapy.<sup>116</sup>

These studies demonstrated that cells derived from nuclear transfer can be successfully harvested, expanded in culture, and

transplanted *in vivo* with the use of biodegradable scaffolds on which the single suspended cells can organize into tissue structures that are genetically identical to that of the host. These studies were the first demonstration of the use of therapeutic cloning for regeneration of tissues *in vivo*.

## CONCLUSIONS

Regenerative medicine techniques are being employed experimentally for virtually every type of tissue and organ in the human

body. Because regenerative medicine incorporates the fields of tissue engineering, cell biology, nuclear transfer, and materials science, personnel who have mastered the techniques of cell harvest, culture, expansion, transplantation, and polymer design are essential for the successful application of these technologies. Various tissues are at different stages of development, with some already being used clinically, a few in preclinical trials, and some in the discovery stage. Recent progress suggests that engineered tissues may have expanded clinical applicability in the future and may represent a viable therapeutic option for those who require tissue replacement or repair.

# VAGINOPLASTY—CONSTRUCTION OF NEOVAGINA

Malcolm A. Lesavoy

Reconstruction of the female perineum is indicated for congenital absence of the vagina, lymphedema, vaginal defects, previous ablative surgery for various perineal malignancies, relief of pain after radiation therapy, and repair of labial hypertrophy. Vaginal reconstruction has become a standard procedure performed by plastic surgeons, gynecologists, and urologists. The most common indication for vaginal reconstruction is congenital absence of the vagina.

In general, the results of vaginal reconstruction are satisfactory. However, problems may include inadequate genital wound coverage because of foreshortened graft or flap harvest, fecal contamination if preoperative bowel preparation has not been adequate, adjacent urethral injuries during dissection of the new vaginal pocket, and difficult immobilization of the patient in the postoperative period.

Counseller<sup>1</sup> reported that congenital absence of the vagina occurs in approximately 1 of every 4000 births and that these abnormalities usually coexist with uterus and urinary tract abnormalities. Usually, the ovaries are not affected, and the secondary sex characteristics develop normally. Embryologically, because the cervix and vagina initially form a solid unit, the lack of cavitation and cell death needed to form a vagina is the reason for vaginal agenesis.<sup>1</sup> However, the hormonal factors that stimulate cavitation are unknown.

Patients with labial hypertrophy undergo labioplasty for functional, aesthetic, and social reasons. Hypertrophy of the labia minor or labia majora may be congenital or acquired. Patients with this condition may experience inflammation, poor hygiene, and self-consciousness during sexual activity and when wearing tight pants. Reduction of the labia minora or labia majora is a relatively minor outpatient procedure that yields satisfactory results for many patients.

## VAGINAL RECONSTRUCTION

### History

In 1573, a student of Vesalius, Realdus Columbus, first reported vaginal agenesis, and it was not until 1872 that Heppner described vaginal reconstruction using the labia.<sup>2</sup> However, the landmark report for vaginal reconstruction is credited to Abbe in 1898.<sup>3</sup> In one patient, Abbe described dissecting a canal and lining it with split-thickness skin grafts.

These skin grafts were placed over a rubber stent packed with gauze. After 10 days, the stent was removed, and the skin grafts were completely vascularized. The patient was asked to wear a vaginal conformer postoperatively, and evidently, intercourse was possible. However, Abbe's report was lost for almost 40 years, until McIndoe<sup>4</sup> popularized the Abbe technique by lining the new

vaginal canal with partial-thickness skin grafts. McIndoe reported an impressive array of 63 repairs,<sup>5</sup> and in 1948, Counseller reported 70.<sup>1</sup> Other methods of vaginal reconstruction have been attempted, but most have had undesirable effects, especially when segments of the gastrointestinal tract have been used for lining the new vaginal canal. In 1953, Conway and Stark<sup>6</sup> described use of the rectum; earlier, Sneguireff,<sup>7</sup> Popow,<sup>8</sup> and Schubert<sup>9</sup> had described the same thing. In 1904, Baldwin<sup>10</sup> even described using a loop of ileum. However, obvious difficulties with bowel transposition such as necrosis, infection, and abscess formation occurred. If the procedure was successful, the secretions arising from the bowel lining were mostly inappropriate and unwanted. The added morbidity of an intra-abdominal procedure, various bowel anastomoses, the possibility of vascular compromise, and undesired mucosal secretions account for the lack of popularity of these procedures.

The Frank procedure, a nonoperative technique, has been successful in some instances of incomplete vaginal atresia. In 1927, Frank and Geist<sup>11</sup> demonstrated the use of intermittent pressure at the perineal dimple between the anus and the urethra in the normal location of the vagina. This pressure is applied until the patient feels mild discomfort by a series of graduated obturators in the form of increasing sizes of test tubes. The pressure is relieved and then reapplied. The skin is inwardly stretched in the same way that a skin expander works with an outward force. This process continues for weeks until the largest dilator can be introduced within the neovagina and worn comfortably. This procedure requires a very compliant and persistent patient and an anatomy that is consistent with incomplete vaginal agenesis. The skin lining the new vagina is cutaneous squamous epithelium, and it must be lubricated externally to allow intercourse.

## Surgical Techniques

### Abbe-McIndoe Procedure

Over the years, the Abbe-McIndoe procedure evolved to become the easiest and most successful method of vaginal reconstruction, avoiding the risks and disadvantages of laparotomy (Figs. 99-1 and 99-2). The procedure must be performed under general or spinal anesthesia. A Y-shaped incision is made along the median raphe between the urethra and the anus. A catheter is placed in the urethra, and dissection is carried cephaloposteriorly. This dissection can be done relatively bluntly, and safety is ensured by keeping a gloved finger in the rectum for tactile ease of dissection. The Y incision allows three cutaneous flaps to be enfolded into the vaginal canal so that circumferential scar contraction can be avoided. The depth of dissection should be somewhat exaggerated and is in the range of 10 to 14 cm in the adult. The surgeon

**Figure 99-1** Congenital vaginal aplasia with an enlarged urethral meatus below the clitoris. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: *Female Urology*, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

must overcorrect somewhat because of the expected subsequent contraction (Fig. 99-3).

After the vaginal canal has been bluntly dissected, a partial-thickness skin graft is harvested from the buttock-hip area. The surgeon must keep in mind the subsequent scar that will ensue from this partial-thickness skin graft and therefore should avoid harvesting the graft from an area low on the thigh. The skin graft can be taken with any type of dermatome, and two or three sheets of skin may be needed to achieve a total dimension of approximately 14 × 7 cm.

Several techniques have been developed to apply the skin graft to the vaginal canal. Historically, candle wax, carved balsa wood, gauze packing, syringe casing, dental wax, and hard plastic conformers have been used. The Heyer-Schulte Company has produced a soft, pliable, and expandable vaginal conformer that works very well. This stent has a central semirigid foam core and a surrounding silicone envelope that can be expanded with air or saline (Fig. 99-4). There is a central drain site through the core of the stent. After the graft has been harvested, the vaginal stent should be inflated with air and lubricated with mineral oil.

The skin graft sheets are sutured to each other and placed over the stent with the raw dermal sides out (Fig. 99-5). The epidermal side of the skin is adjacent to the stent. Subsequently, hemostasis is checked in the neovaginal canal, and the stent and overlying skin grafts are eased into the canal (Fig. 99-6). It may be necessary to deflate the vaginal stent while slowly rotating and pushing the stent and skin graft into the vaginal canal, but after the stent is

**Figure 99-2** Sutures holding the labia majora. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: *Female Urology*, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

seated to the depth of the dissection, it should again be inflated to spread out the skin graft, ensure direct apposition to the raw walls, and provide an excellent bolster for the ensuing neovascularization of the skin graft.

The flaps from the Y incision are sutured to the superficial ends of the skin graft in a tacking fashion with absorbable sutures. Fluff gauze is then packed around the perineum under compression, and the labia majora are sutured to each other to ensure that the stent does not slide out of the canal.

Postoperatively, the patient remains in bed for a minimum of 5 days and is medically constipated (a lower bowel preparation is required preoperatively). On the fifth or sixth postoperative day, the patient is sedated in bed, and the labial sutures are removed. The skin graft can then be checked by aspirating the outer lumen of the Heyer-Schulte vaginal stent and deflating it, gently removing the stent, and leaving the skin graft intact within the vaginal vault. If there is any difficulty with this maneuver, mineral oil can be injected between the stent and the skin graft using a soft rubber catheter. This lubricates the interface between the stent and the skin graft so that disruption and shearing of the skin graft are avoided when the stent is removed. The perineum can be cleansed, and the stent can be washed and replaced immediately. Subsequently, a perineal binder can be applied, and the

**Figure 99-3** Catheter in the urethra and dissection of the neovaginal canal. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

**Figure 99-4** Heyer-Schulte inflatable vaginal stent. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

patient can be allowed to ambulate; the constipating medicine is then discontinued.

The vaginal stent is checked every other day, and the patient is usually discharged on the seventh or eighth postoperative day. The patient should be fully aware of the mechanics of the stent so that she can remove, wash, and reintroduce the stent daily while at home.

After vaginal reconstruction, a conformer must be worn for a minimum of 6 months postoperatively. If this is not done, contraction of the vaginal vault will ensue. After 3 or 4 months, as

**Figure 99-5** Split-thickness skin graft sutured around the vaginal stent, with the epithelial side inward next to the stent and the raw side out. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

**Figure 99-6** Vaginal stent with the skin graft invaginated into the neovaginal canal. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

the skin graft matures, vaginal intercourse should be encouraged. This procedure should not be done unless intercourse is anticipated. Intercourse provides an excellent obturator and conformer. After 6 months, the conformer can be eliminated during the day but should be worn at night. If the patient is active

**Figure 99-7** A photograph taken 3 months postoperatively shows the normal-looking vulva and the size of the speculum that can be inserted into the vagina. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: *Female Urology*, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

sexually and has intercourse two to three times per week, the conformer can be eliminated. However, if there is a time when intercourse is not anticipated for weeks or months, the conformer should be worn at night (Figs. 99-7 to 99-10). Because the skin grafts do not have the same properties as normal vaginal mucosa and do not have secretory abilities, most patients require the application of lubricants before intercourse.<sup>30,31</sup>

#### Full-Thickness Skin Grafts

Full-thickness skin grafts are important for certain types of vaginal reconstruction, such as for vaginal aplasia, vaginal stenosis, intersex conditions, and iatrogenic disease. One advantage of these grafts is that they allow reconstruction at an earlier age (any time after puberty), providing psychological reassurance as the child develops that she is normal. They also reduce postoperative stenting time and minimize vaginal stenosis by decreasing postoperative vaginal contraction. They improve the cosmesis of the donor site, and a full-thickness skin graft grows with the body proportionately.<sup>12,13</sup> Inguinal donor sites are used for full-thickness skin grafts, and the donor site closure occurs primarily.

#### Flaps

##### Vulvobulbocavernosus Myocutaneous Flap

The vulvobulbocavernosus myocutaneous flap was described by Knapstein and colleagues<sup>14</sup> in 1990. This flap is based on the skin fat and underlying vulvobulbocavernosus erectile muscle tissue, and it is useful because of the low axis of the flap. It is not easily used for transfer into the upper pelvis, but it is best for reconstruction of the vagina after a pelvic exenteration that removes the perineal body and the anus (i.e., a lower pelvic defect). This

**Figure 99-8** Discrepancy in the skin graft color of the neovagina. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: *Female Urology*, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

**Figure 99-9** Depth of the neovagina as seen through the plastic speculum. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: *Female Urology*, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

**Figure 99-10** Donor site on the right buttock. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

is a relatively new procedure and should be considered for patients with anterior or total exenteration with low rectal anastomosis.

The vulvobulbocavernosus myocutaneous flap usually is not large enough to form a complete vaginal canal. The anterior edges of the flap are sewn together to form the anterior margins of the newly formed vaginal cylinder. Its disadvantage is the retention of vulvar hair, which results in vaginal discharge and a strong odor. The blood and nerve supply comes from the pudendals.<sup>15</sup>

### Gracilis Myocutaneous Flaps

The gracilis muscle is the most common flap used after pelvic exenteration for vaginal reconstruction.<sup>16,17</sup> After pelvic exenteration, an abdominoperineal resection, or vaginal irradiation (Fig. 99-11), the patient is usually left with a large vaginal defect. Use of a gracilis island myocutaneous flap can enhance vaginal reconstruction. It also provides adequate vaginal length and is an expendable muscle for the most part.

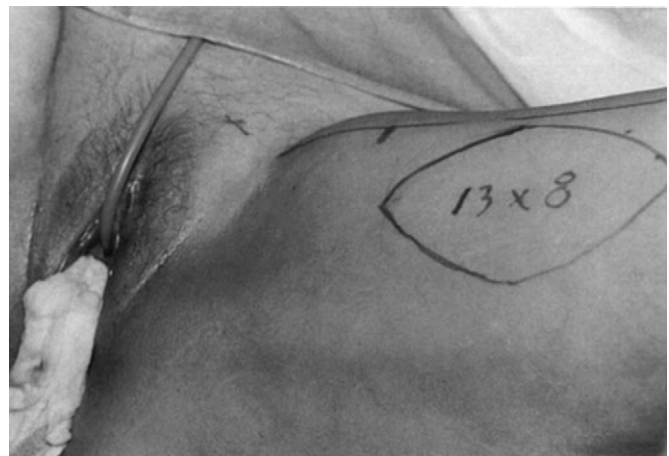

The gracilis myocutaneous flap provides sufficient bulk to fill the empty pelvic space and simultaneously brings its own blood supply, leading to a softness and pliability not achievable with skin graft techniques. The disadvantage of the gracilis may include a loss of approximately 10% to 20% of the flap due to vascular compromise of the flap resulting from potential tension of its small-caliber vascular pedicle when transposed into the pelvic defect. Residual scarring on the legs is commonly a source of minor complaints.<sup>18-20</sup>

The principle of employing muscle with its overlying skin, vascularized by the muscular perforators, has been well documented in the plastic and reconstructive surgical literature by Owens (1955),<sup>21</sup> Bakamjian (1963),<sup>22</sup> Hueston and McConchie (1968),<sup>23</sup> and McCraw and colleagues (1976).<sup>24</sup> McCraw and associates were the first to describe the principle of the skin island over the muscle unit, and this principle is applicable to vaginal reconstruction. McCraw's paper on vaginal reconstruction was one of the landmark works in the plastic surgery literature, and the findings revived the use of myocutaneous flaps.

The operation begins with the patient in the lithotomy position (Fig. 99-12). Unilateral or bilateral island gracilis

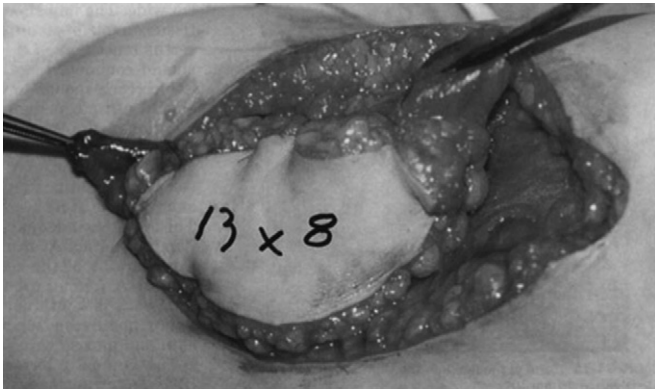

**Figure 99-11** A patient with radiation vaginitis had severe pain, drainage, fibrosis, and contraction. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

**Figure 99-12** After excision of radiation-damaged tissue and a pack in the vaginal vault, a 13 × 8 cm gracilis myocutaneous island flap is outlined on the left medial thigh. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

myocutaneous flaps are harvested (Fig. 99-13) based on their superior neurovascular pedicles (Fig. 99-14). The flap can then be tunneled (Fig. 99-15) under intact perineal skin (Fig. 99-16) and invaginated into the neovaginal canal. A conformer is not needed, and the donor sites are closed in a linear fashion with primary approximation along the medial thigh area (see Fig. 99-15).

**Figure 99-13** The gracilis muscle and island skin flap are isolated. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

**Figure 99-14** The undersurface of the gracilis myocutaneous island flap and its neurovascular bundle. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

A unilateral gracilis myocutaneous flap may be used for radiation contracture and pain of the vaginal vault (see Figs. 99-11 to 99-17). Sensibility of the skin of the gracilis myocutaneous island is maintained through the sensory branches of the obturator nerve as described by Lesavoy and colleagues.<sup>25</sup> However, sensitivity of the transposed skin is not the same as that of a normal vagina. Sensitivity to pressure is excellent, but tactile sensitivity is diminished.<sup>26</sup> Sexual sensitivity is mostly cerebral.

#### Rectus Abdominis Myocutaneous Flap

Because of its success in breast reconstruction, the rectus abdominis myocutaneous flap can also be used for vaginal reconstruction. Its primary arterial blood supply is the inferior epigastric vessels. Two island flaps can be harvested: the horizontally oriented lower abdominal myocutaneous flap<sup>27</sup> or the vertically oriented upper abdominal myocutaneous flap.<sup>28</sup> The transverse and vertical rectus abdominis myocutaneous flaps, because of the extended length of their vascular pedicles, allow a high arc of rotation. The axis is determined by the vascular supply, and the flap is transferred intra-abdominally through the posterior rectus

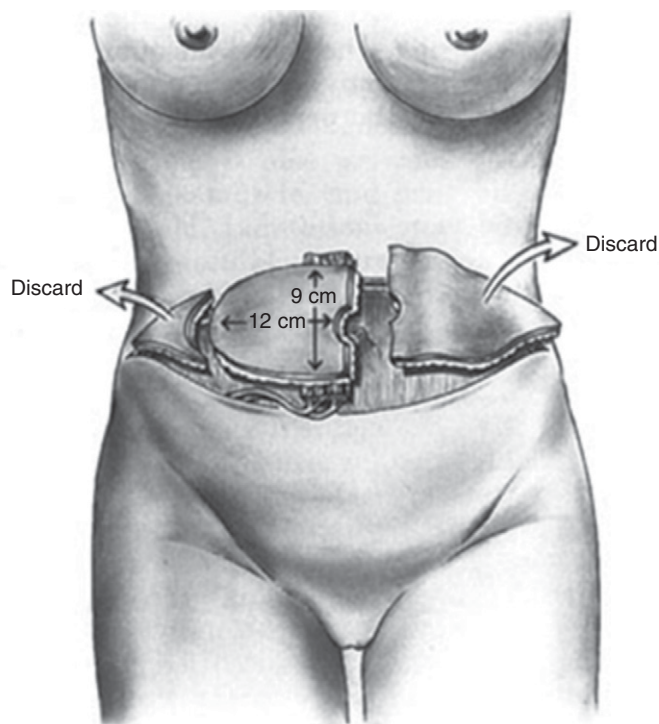

**Figure 99-15** The flap is set into the vaginal defect. The donor site is closed primarily.

**Figure 99-16** The myocutaneous island flap is transferred to subcutaneously to be inset. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

**Figure 99-17** Harvesting of right rectus abdominis myocutaneous flap for vaginal reconstruction.

sheath. This need for laparotomy is a negative aspect of this procedure. A vertically oriented flap may be preferred when it is necessary to maintain an intact lower abdominal rectus muscle for exit sites of stomas on the contralateral side.

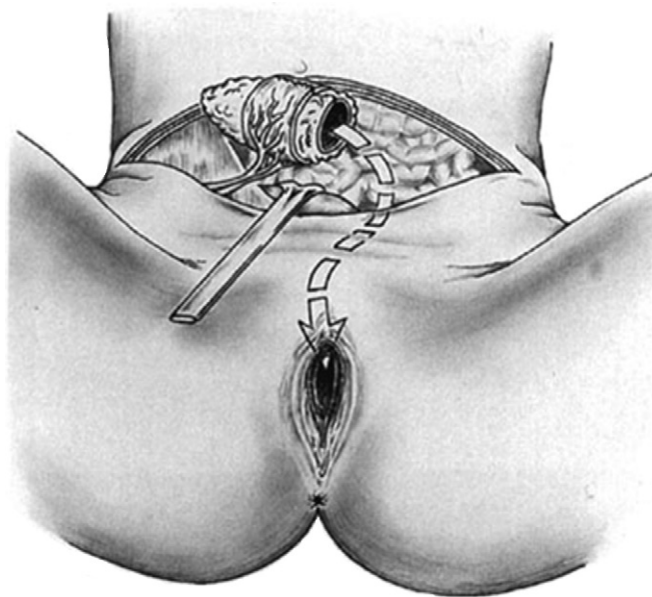

Among the many advantages of this flap are a very reliable blood supply<sup>19</sup> and the ability to resurface a defect with a single flap. This flap also provides ease of mobilization without tension and is associated with a low incidence of vascular compromise.<sup>18,29</sup> In a series of 22 patients, there was little tissue loss and an acceptable donor site,<sup>28</sup> and return to sexual activity was possible for 80% of patients.<sup>28</sup>

After completion of the exenteration procedure, attention is directed toward harvesting the myocutaneous flap from the abdomen. Centered just to the left or right of the umbilicus, a transverse rectus abdominal myocutaneous (TRAM) flap is harvested measuring approximately 9 cm long by 12 cm wide. The flap should include skin, subcutaneous tissue, a strip of anterior rectus sheath, and the rectus muscle itself (see Fig. 99-17). The initial incision should commence at the lateral apex of the TRAM (which corresponds to the anterior axillary line) and should extend medially to include all of the abovementioned flap components. The rectus muscle is identified and carefully dissected laterally to the region of the deep inferior epigastric perforating vessels, with identification of the inferior epigastric vascular pedicle at its origin on the external iliac vessels. This ensures adequate flap mobilization when the flap is isolated. At this point, the superior and inferior margins of the rectus muscle are divided (Fig. 99-18). A vaginal tube is formed from the flap by means of continuous and interrupted sutures to approximate the superior and inferior margins of skin and muscle with the raw side out (Fig. 99-19).

The manually formed vaginal cone is then mobilized and transferred through the posterior rectus sheath after a laparot-

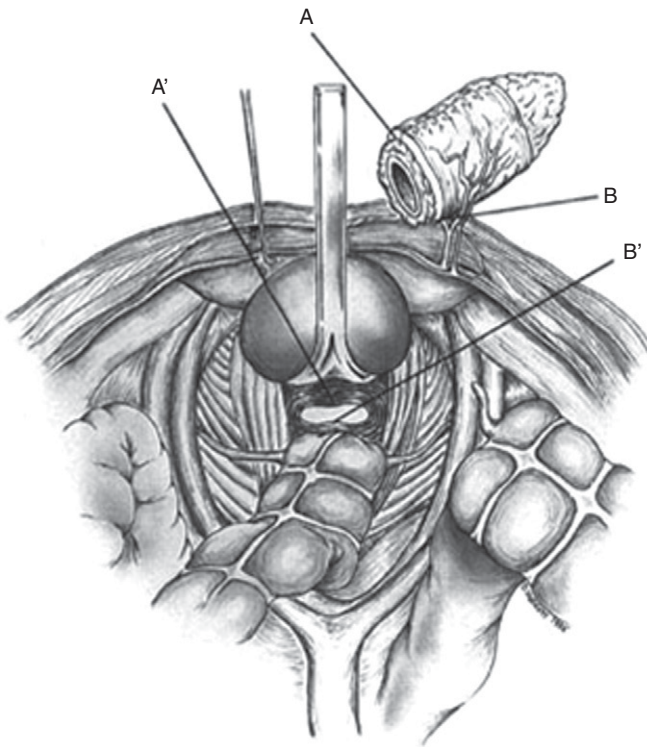

**Figure 99-18** The flap is mobilized and formed into a tube. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

**Figure 99-19** The mobilized myocutaneous flap is sutured together to form a blind tube of sufficient length and diameter to serve as a functional vagina. It is then transferred through the posterior rectus sheath to reach the vaginal defect. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

omy incision is made through the peritoneum at the origin of the deep inferior epigastric vessels into the pelvis to reach the vaginal defect (Fig. 99-20). The lateral-most portion of the flap becomes the apex of the vagina. Care must be taken when placing the flap to ensure that no tension is placed on the vascular pedicle. The neovagina is then attached to the introitus with interrupted

**Figure 99-20** View after a laparotomy incision is made through the peritoneum at the origin of the deep inferior epigastric vessels into the pelvis to reach the vaginal defect. (From Lesavoy MA, Carter EJ: Vaginal reconstruction. In Raz S [ed]: Female Urology, 2nd ed. Philadelphia, WB Saunders, 1996, pp 605-616.)

sutures (Fig. 99-21).<sup>15,18</sup> An estrogen cream is spread on the mold, which is placed in the vagina and sutured in place.<sup>18</sup> On day 5, the mold is removed, and a vaginal dilator is worn three times per week for 3 months in conjunction with the application of estrogen cream.<sup>18</sup>

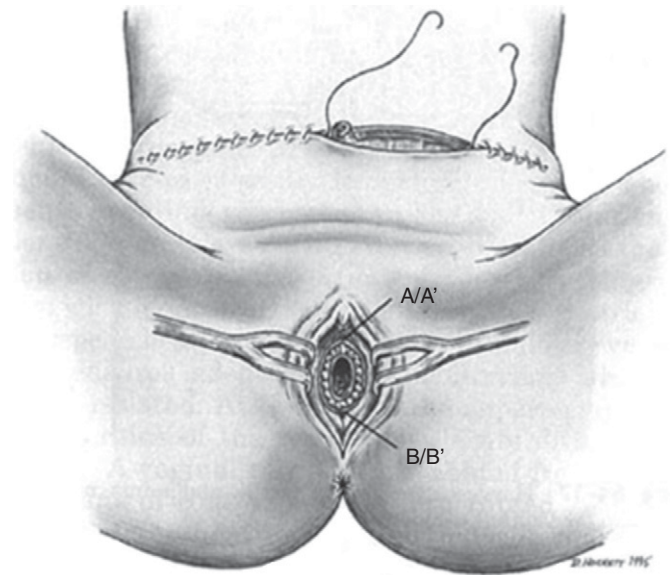

The initial procedure is concluded with primary closure of the fascial defect with interrupted or continuous permanent sutures. The closure of subcutaneous tissue after a horizontal (TRAM) harvest is best achieved with the patient in a 30-degree, semi-Fowler position to assist with approximation. A subcutaneous drain is placed beneath the mobilized skin flaps and is externalized through a separate incision.

It is advisable postoperatively to maintain strict bed rest for 48 hours. The hips are flexed 30 degrees to decrease abdominal wall fascial tension at the repair site. The vertical rectus abdominis myocutaneous (VRAM) flap has all the advantages of the TRAM flap, but it leaves a single para-midline scar at closure rather than the additional horizontal lateral scar.

### Intestinal Flaps

Other methods of vaginal reconstruction, such as flaps of small intestine, ascending colon, sigmoid colon, and sigmoid and lower rectum, are briefly described because they have been used with various degrees of success for vaginal reconstruction. The patient requires hospitalization 2 days before the operation to allow time to prepare and sterilize the bowel adequately.

With the patient in the lithotomy position, a vaginal tract is dissected from the perineum into the peritoneum, and the tract is widened laterally. When hemostasis is satisfactory, the vaginal

**Figure 99-21** The myocutaneous flap is transposed into the pelvis and sutured to the perineal (introital) incision.

tract is packed and the abdomen opened. The sigmoid usually is mobile enough to allow a satisfactory vascular pedicle to be developed. With proper planning, an adequate length of intestine (12 to 15 cm) can be isolated, an oblique end-to-end anastomosis is performed, and the bowel segment is drawn through the vaginal tract. The patient is returned to a lithotomy position. The end of the bowel is incised on an angle to gain additional room, and it is then attached to the introitus.

Advantages of the intestinal neovagina include the absence of a need for frequent dilatation or stent wearing. However, the disadvantages include excessive mucus formation, especially when the small intestine is used, and a mortality rate between 1% and 2%.<sup>12</sup>

### Summary of Vaginal Reconstruction

Vaginal reconstruction can be an uncomplicated and straightforward procedure when attention to detail is maintained.<sup>30,31</sup> The Abbe-McIndoe procedure of lining the neovaginal canal with split-thickness skin grafts has become the standard. Use of the inflatable Heyer-Schulte vaginal stent provides comfort for the patient and ease for the surgeon in maintaining skin graft approximation.

For large vaginal and perineal defects, myocutaneous flaps such as the gracilis island flap have been extremely useful for correction of radiation-damaged tissue to the perineum and for the reconstruction of large ablative defects. Minimal morbidity and scarring ensue because the donor site can be closed primarily.

The gracilis has sufficient bulk to fill the pelvis, decreasing the incidence of herniation or obstruction. It also provides vaginal length, is an expendable muscle, and generally is out of the irradiated field. Limitations may be its 10% to 20% incidence of vascular compromise due to the vessel's small caliber, which results in tension as the flap is moved into the pelvic defect.

The TRAM flap is used to form a functional vagina. Its advantage over the gracilis is its variable vascular pedicle caliber and

length. Its reliable blood supply and potentially long vascular pedicle provide flap versatility, with a resulting low incidence of vascular compromise. This flap augments the surgical options available for pelvic and vaginal reconstruction.

An absolute contraindication to rectus harvest is a history of vascular disruption of the inferior epigastric vessels. Obesity may be a relative contraindication because the thick subcutaneous tissue prohibits flap flexibility and mobilization into the pelvic space.

There is a wide range of procedures from which to choose for the correction of congenital absence of the vagina. Unfortunately, no consensus has been reached about which is best. Each patient must be evaluated on an individual basis.

For the success of all types of vaginal reconstruction, a compliant patient is a necessity. The patient must wear a vaginal obturator for a minimum of 3 to 6 months postoperatively and is encouraged to use intercourse as an obturator. Vaginal reconstruction can be a gratifying procedure that enhances the functional and emotional well-being of these patients. Reconstruction can be successful in patients with congenital or ablative vaginal absence, and it can be a functional and emotional advantage for

all concerned. Attention to detail and support are necessary for all patients.

#### LABIAL REDUCTION: LABIOPLASTY

Congenital, traumatic, or neoplastic deformities can affect the labia minora and labia majora in some women. Congenital or traumatic hypertrophy of the labia minora has been an increasing concern to some women, and the defect can be relatively easily corrected. The labia minora that protrude beyond the confines of the labia majora can be functionally and aesthetically unsatisfactory, and some women may experience irritation from clothing during athletic exercise, cosmetic or functional interference with sexual intercourse, and embarrassment and self-consciousness with tight undergarments.<sup>32,33</sup>

Surgical indications for reduction of the labia minora are for patient satisfaction with functional and aesthetic characteristics. The surgical procedure for reduction of the labia minora is relatively straightforward and can be performed on an outpatient basis.<sup>34,35</sup>

A

B

**Figure 99-22** A, Preoperative view of a large and patulous labia minora exhibiting symptoms of irritation from sports, clothing, and aggressive sexual activity. B, Intraoperative retraction of the labia minora.

**Figure 99-22, cont'd** **C**, Immediate postoperative indications of asymmetric resection and closure of labia minora. **D**, Postoperative result.

The surgical contour should be explicitly discussed with the patient before surgery, and the excision should avoid eversion of mucosal surfaces so that the superficial squamous epithelium is turned inward. In this way, the scars are inconspicuous, and mucosal irritation from eversion does not occur. Infiltration with local anesthetic and epinephrine can reduce postoperative pain, intraoperative bleeding, and postoperative bruising, but it should be done in conjunction with general anesthesia. The protuberant

area is excised, and the remaining edge is sutured with absorbable material (Figs. 99-22 to 99-25).

Surgical reduction of the labia minora often improves the physical comfort and psychological aspects of hypertrophy. If the hypertrophied labia interfered emotionally and physically with intercourse, the sexual satisfaction of these patients will be improved. Patients undergoing labia minora reduction usually are pleased with the aesthetic and functional results.
