# ROLE OF NEEDLE SUSPENSIONS

*Elizabeth Takacs and Philippe E. Zimmern*

Female urinary incontinence (UI) and pelvic organ prolapse (POP) are ubiquitous to the aging female population. A woman has an 11.1% lifetime risk of requiring a single surgery for POP, and one-third of those women will require a repeat procedure.<sup>1</sup> A review of data from the National Hospital Discharge Summary in 1997 and 1998 concluded that 226,000 surgeries for POP<sup>2</sup> and 135,000 for UI<sup>3</sup> were performed, compared with 169,000 total knee replacements and 307,000 cholecystectomies. Twenty-one percent of patients undergo concomitant procedures for POP and UI.<sup>1,2</sup> Both conditions have afflicted women for centuries, but during the past 50 years understanding of the pathophysiology and development of treatment options have progressed.

The bladder neck needle suspension was initially described by Pereyra in 1959<sup>4</sup> for treatment of urethral hypermobility; he initiated the concept of passing a ligature carrier through the retropubic space to transfer sutures placed to suspend or secure the anterior vaginal wall tissue. Today, the role of needle suspensions is decreasing; many practitioners are abandoning the procedure because of its reported low success rate and expansion of the use of the more “minimally invasive” sling procedures.<sup>5,6</sup> One of the most significant advantages of modern-day needle suspensions is the ability to correct urethral hypermobility associated with a cystocele in patients with or without stress urinary incontinence (SUI) by providing support to the urethra, bladder neck, and bladder as a unit without the use of foreign materials.

This chapter briefly reviews the history and evolution of the needle suspensions and looks more in depth at current variations, including indications, technique, complications, and long-term results of the four-corner colposuspension, the anterior vaginal wall suspension, the in situ vaginal wall sling, and the “goalpost” technique. We conclude by debating briefly the pros and cons of using native tissue for these repairs.

## HISTORICAL REVIEW OF NEEDLE SUSPENSIONS (1949-1989)

Retropubic bladder neck suspensions were initially described in 1949 by Marshall, Marchetti, and Krantz<sup>7</sup>; the Burch procedure was described in 1961.<sup>8</sup> The goal of these procedures was to fix the bladder neck into a high retropubic position, while returning the urethra to an abdominal position, thus allowing equal transmission of pressures to the bladder and bladder neck/proximal urethral regions. In 1959, Pereyra described “a simplified surgical procedure” to accomplish the same goal (support of the urethra and bladder neck) through a transvaginal approach with a resulting decrease in morbidity.<sup>4</sup>

Pereyra’s original procedure described the passage of a trocar needle via a small transverse suprapubic incision blindly through the retropubic space, lateral to the bladder neck, exiting through the anterior vaginal wall. The trocar was passed a total of four

times, two times on each side. Pereyra used stainless steel wire; he recognized that the wires were apt to cut through the tissues but served as a temporary support mechanism until scarring and fibrous tissue developed to create a more permanent support. In 1967, Pereyra and Lebherz reported improved urinary continence results when the Pereyra procedure was combined with a Kelly plication.<sup>9</sup> Together, the procedures corrected the anatomic defects that “neither procedure alone could remedy.” In his initial description, Pereyra emphasized the need to avoid tension on the sutures, recognizing already that it is scar formation that brings long-term support and good results.

In 1973, Stamey described the endoscopic vesical neck suspension.<sup>10</sup> Similar conceptually to the Pereyra procedure, this technique recommended the use of cystoscopy to observe the needle passage near the bladder neck and introduced a series of specially designed needles for passage of the sutures. A Dacron pledget was used to buttress the periurethral tissues and decrease suture pull-through. The double-pronged ligature carrier was introduced in 1978 by Cobb and Ragde to decrease the number of passages and ensure a consistent fascial bridge.<sup>11</sup>

The Raz bladder neck suspension or modified Pereyra procedure was described in 1981.<sup>12</sup> The key differences were using an inverted U-shaped incision vaginally, to allow dissection lateral to the urethra and bladder neck, entering the retropubic space to allow for adequate mobilization of the bladder and urethra, passing the ligature carrier under fingertip guidance to avoid bladder injury, and placing the anchoring sutures through the full-thickness vaginal wall (excluding epithelium) in addition to the pubocervical fascia (Fig. 32-1). The suspension sutures were secured more laterally in the vaginal wall to decrease the risk of damage or obstruction of the urethra.<sup>13</sup> Because incontinence can occur after an isolated Kelly plication, Raz further modified the Raz bladder neck suspension to concomitantly correct a cystocele and to decrease postoperative incontinence, a procedure known as the “four-corner bladder neck suspension,” which is examined in detail later.

In 1987, Gittes and Loughlin proposed a no-incision technique that could be performed under local anesthesia in an outpatient setting.<sup>14</sup> Because the sutures were placed through the full-thickness vaginal mucosa in a helical fashion at the bladder neck level and tied suprapubically under tension, it was believed that the sutures would pull through the vaginal mucosa and form an “autologous pledget” of scar tissue along their retracting path.

The short-term results of all these procedures were very promising, with success rates for subjective cure greater than 90%. As time passed and long-term data became available, it became apparent that it was difficult to reproduce the success of the initial surgeon (Table 32-1).

The morbidity of the needle suspensions was limited and included bleeding from the retropubic space and periurethral

**Figure 32-1** Modified Pereyra or Raz bladder neck suspension. **A**, Helical suspension suture placed at the level of the bladder neck provides a narrow anchor point. **B**, Demonstration of the single-prong ligature carrier passed through the retropubic space under fingertip guidance to transfer suspension suture suprapubically. 1989	Raz	Vaginal wall sling	Use of in situ vaginal wall as sling
1989	Raz, Klutke	Four-corner bladder neck suspension	Concomitant correction of urethral hypermobility and cystocele
1997	Dmochowski, Zimmern	Modified four-corner suspension	Broader anterior vaginal wall anchor for each of the four sutures, leading to the anterior vaginal wall suspension/plate concept

tissues; bladder injury, especially after a prior retropubic anti-incontinence procedure; suture entry into the bladder detected by cystoscopy; failure due to suture pull-through of the anchoring tissues; and rare reports of ilioinguinal nerve entrapment. Urinary retention and the development of de novo urge incontinence were very infrequent.<sup>23</sup>

Based on this overview of the various needle suspensions from 1959 to the late 1980s, it is clear that each new technique improved the preceding one by adding some important modifications that are still in use today (Table 32-2). Avoiding the periurethral tissue, fingertip guidance of the trocar through the retropubic space, and use of cystoscopy are some of the critical steps learned from several decades of vaginal needle suspension procedures.

### CONTEMPORARY APPROACHES (1989-2005)

In 1997, the American Urological Association (AUA) Guideline Panel grouped all needle suspensions into one category. Compared to the Burch or the pubovaginal sling procedure, the results at 4 years were globally inferior, but the series were short and had very inhomogeneous methods of reporting and follow-up.<sup>24</sup> More recently, the Cochrane database reviewed the role of needle suspensions for SUI and concluded that, although they were more likely to fail than open retropubic suspensions, the evidence was limited; no conclusions could be drawn when compared to the suburethral sling.<sup>25</sup> Nonetheless, reports still emerge periodically on series from all over the world using the vaginal wall as the support mechanism. Therefore, we review in the following sections four procedures aimed at restoring the support of the anterior vaginal plate, either in its entirety (Four-Corner Bladder Neck Suspension and anterior vaginal wall suspension), beneath the urethra/bladder neck area (vaginal wall sling), or with support of the bladder neck and concomitant anterior colporrhaphy (goalpost technique); we then discuss several other series using similar or slightly modified techniques.

#### Four-Corner Bladder Neck Suspension (FCBNS)

The FCBNS,<sup>26</sup> initially described by Raz in 1989, was a progression from the original Raz bladder neck suspension and attempted to correct a minimal to moderate cystocele and urethral

hypermobility without performing a Kelly plication. Although the Kelly plication and/or anterior colporrhaphy was the standard treatment to repair cystoceles, there was a significant rate of postoperative SUI and cystocele recurrence. For the treatment of SUI, the Kelly plication had a cure rate of 63% to 92% at 1 year and 37% to 54% at 5 years of follow-up.<sup>27,28</sup> Recent randomized studies have also revealed a success rate of 30% to 71% at 1 year for correction of prolapse stage I through IV with this approach.<sup>29-31</sup> The idea of combined correction of a cystocele and urethral hypermobility was a turning point in addressing the vaginal wall as a single unit and not as separate components.

Briefly, the procedure involves creation of an inverted U-shaped anterior vaginal wall incision with the apex midway between the urethral meatus and the bladder neck.<sup>26</sup> The pubocervical fascia is exposed, and the retropubic space is entered and developed laterally. Two pairs of helical nonabsorbable sutures are placed, one pair proximally incorporating the vaginal wall (excluding epithelium), the cardinal ligament, and pubocervical fascia; and the second pair located distally at the level of the bladder neck but avoiding the periurethral tissue (Fig. 32-2). The sutures are transferred suprapubically with a double-pronged Raz ligature carrier. Cystoscopy is performed to confirm no injury to the bladder or ureters and no suture entry. The sutures are then tied to themselves and to the corresponding sutures on the contralateral side, care being taken to avoid tension.

As for many other procedures, the long-term follow-up has not been as promising as the initial short-term reports. Suture pull-through has been a significant criticism. Kilcarslan and colleagues, with a follow-up of 3.8 years, reported a cure rate of 74%; cure was defined as absence of complaints and no evidence of leakage during urodynamic studies.<sup>32</sup> With a mean of 37 months' follow-up and using a standing cystography as an outcome measure, Dmochowski and associates reported a 53% success rate defined as no incontinence and an 83% success rate defined as 0 to 1 incontinent episodes per week.<sup>33</sup> Recurrent cystocele was found in 57%, and 8/33 (24%) of women with their uterus in situ developed symptomatic uterine prolapse postoperatively. Constatini and coworkers reported a success rate of 85% with a mean of 62 months' follow-up.<sup>34</sup> However, in their study, patients underwent concomitant vaginal wall sling if the Valsalva leak point pressure (VLPP) was less than 60 cm H<sub>2</sub>O and the FCBNS was performed for correction of POP with or without

**Figure 32-2** Four-corner bladder neck suspension. Placement of two pairs of nonabsorbable sutures incorporating full-thickness vaginal wall minus the epithelium, one pair at the level of the bladder neck and the other at the top of the cystocele. (Adapted from Hadley HR, Zimmern PE, Staskin DR, Raz S: Transvaginal needle bladder neck suspension. *Urol Clin North Am* 12:291-303, 1985.)

incontinence. For correction of cystocele, 12 of 37 patients with grade 3 cystocele preoperatively failed based on physical examination postoperatively; de novo hysterocele was noted in 4 of 37 patients (10%).

### Anterior Vaginal Wall Suspension

The ideal patient for the anterior vaginal wall suspension<sup>35</sup> is a woman who experiences SUI due to urethral hypermobility and has a Baden-Walker grade 1 to 3 cystocele, but no midline defect on physical examination. Cystoceles can be graded not only clinically but also radiographically. On a voiding cystourethrogram with lateral images, a grade 1 cystocele is defined as 0-2 cm of descent below the inferior margin of the pubic symphysis; grade 2 as 2 to 5 cm of descent; and grade 3 as >5 cm of descent.<sup>36</sup> In women with this lateral detachment, the anterior vaginal wall suspension reestablishes support and prevents the downward mobility of the anterior vaginal wall during straining efforts. This procedure is not intended to correct intrinsic sphincter deficiency. A unique aspect of the anterior vaginal wall suspension is its versatility to correct a cystocele at the time of a sling procedure or urethrolysis.

Conceptually, it is similar to the FCBNS in viewing the bladder, bladder neck, and urethra as a single unit, but the suspension sutures are placed not solely at “four corners” but over the entire

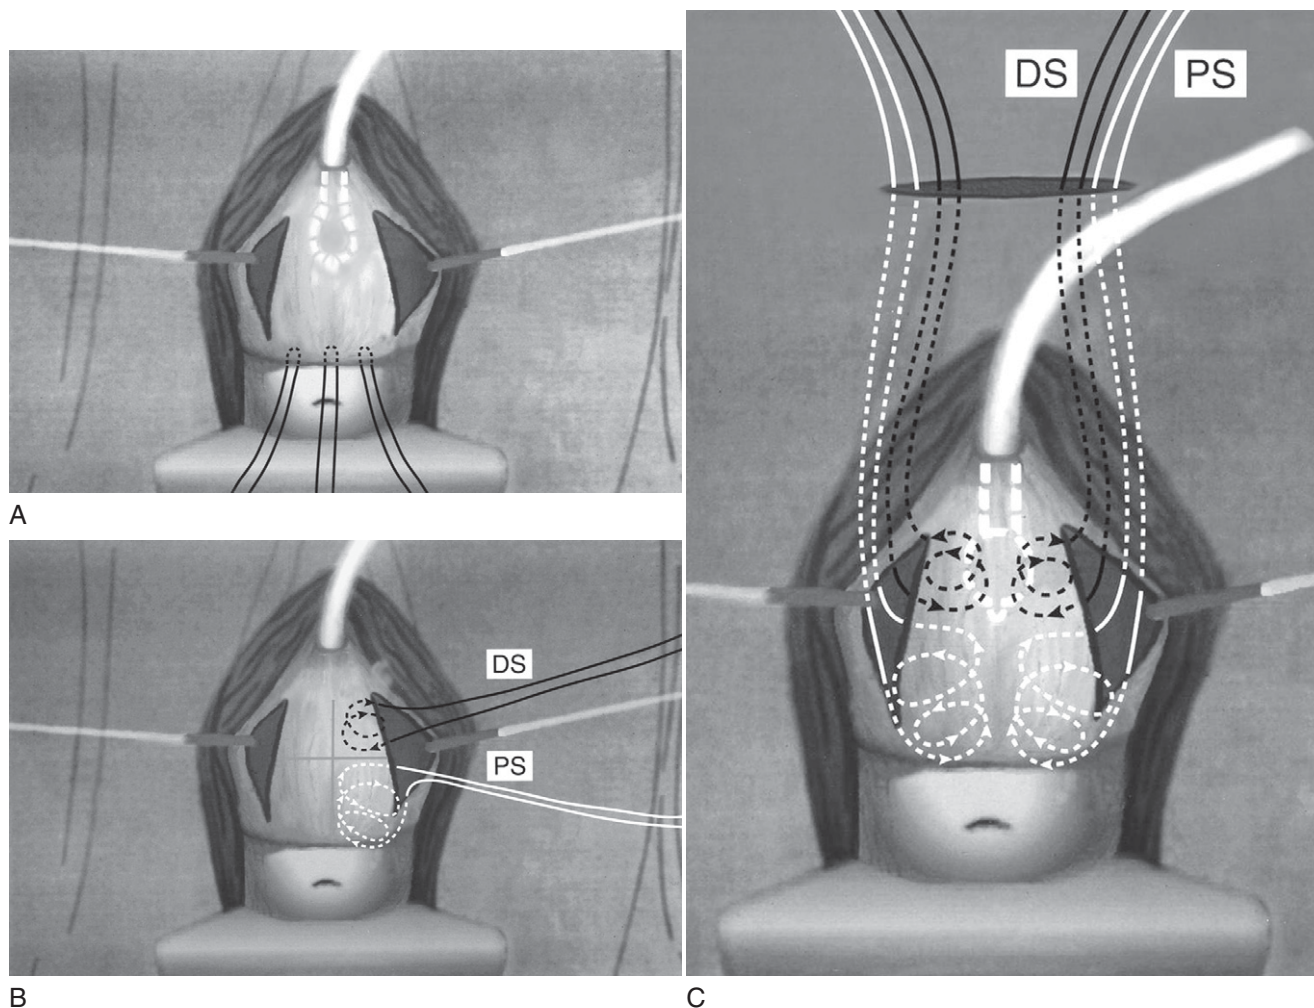

**Figure 32-3** Modified four-corner bladder neck suspension. The helical narrow suspension suture is changed to a broad-based suture placement to reduce suture pull-through.

length of the vaginal plate, from the bladder neck to the vaginal apex. It is believed that sutures placed broadly allow for greater distribution of pressure, thus decreasing the risk of suture pull-through (Fig. 32-3). This technical change was adopted after studies in a rabbit model done by Bruskwitz and colleagues demonstrated that the cross-sectional area serving as anchor determines the force required for tissue pull-through. These authors reported that suture loops cut through tissue at lower forces and act as a cutting string.<sup>37</sup>

A second important technical difference is the ability to excise redundant vaginal tissue laterally at the site of the primary defect. This maneuver narrows the potential space for lateral cystocele recurrence and recreates the natural lateral sulci present in the vagina. This technical modification resonates with the “pinch test” and “tuck procedure” described by Petros and Ulmsten.<sup>38,39</sup>

After the bladder neck is identified (balloon of Foley catheter) and marked with an ink pen, three marking sutures are placed at the vaginal apex: one in the midline, and then one approximately 1.5 cm lateral to the midline on each side (Figs. 32-4A and 32-5A). An incision is made from approximately 1.5 cm lateral to the bladder neck to the apical marking sutures. This incision is performed on both sides of the vagina, creating a trapezoid-shaped vaginal plate in the center with a width of approximately 3 cm and a length of 4 to 8 cm. A marking pen is used to divide this in situ vaginal wall plate into four equal quadrants (see Figs. 32-4B and 32-5B). A separate no. 1 polypropylene suture is used for each of the four suspension sutures, one suture in each quadrant. The suture is placed in a helical fashion, incorporating large

**Figure 32-4** Anterior vaginal wall suspension. **A**, Initial setup. Bilateral incisions are created extending from the bladder neck to the vaginal cervix or cuff, with apical marking stitches placed to define the vaginal plate, approximately 3 cm wide and 4 to 8 cm long. **B**, Placement of the suspension sutures. Sutures are helically placed over the entire length of the vaginal plate and approaching the midline. One suture is placed in each of the four quadrants. **C**, Final appearance. Suspension sutures have been placed bilaterally and passed through the retropubic space. Before closure of the vaginal incisions, cystoscopy is performed to confirm no suture entry in the bladder. DS, distal suture; PS, proximal suture. (Adapted from Vasavada SP, Appell RA, Sand PK, Raz S (eds): *Female Urology, Urogynecology, and Voiding Dysfunction*. New York: Marcel Dekker, 2005.)

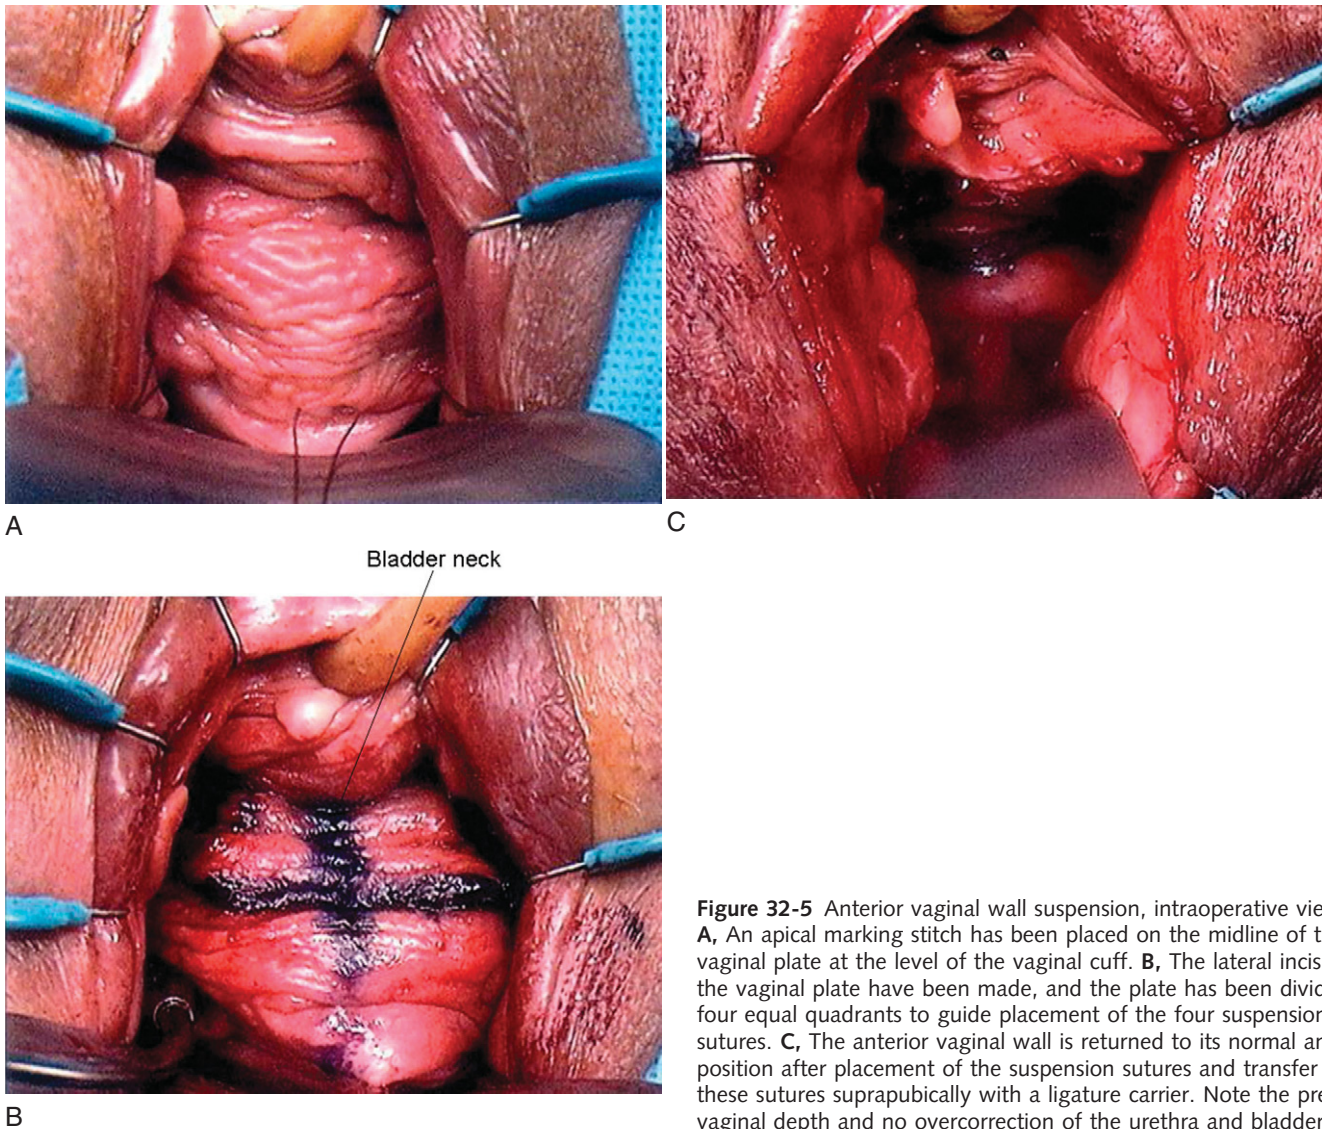

segments of vaginal mucosa (minus epithelium) while remaining parallel to the vaginal plate (see Fig. 32-4B). At the proximal portion of the plate, the suture should incorporate the cardinal ligament at the time of hysterectomy or scar at the vaginal cuff.

Once the suspension sutures have been placed, a short suprapubic incision is made one fingerbreadth above the pubic bone to access the tendinous portion of the rectus fascia at its insertion on the pubis. Next, the endopelvic fascia is perforated with blunt and/or sharp dissection, and the retropubic space is easily entered. A double-pronged ligature carrier is passed under fingertip guidance down into the vaginal incision. The two ends of each suture are placed through the eyes of the carrier, which is then withdrawn suprapubically (see Fig. 32-4C). Indigo carmine IV is administered, and a cystoscopy is performed to confirm no bladder or ureteral injury. After the vaginal incisions are closed, the suspension sutures are tied individually with minimal tension, and this is followed by closure of the suprapubic incision (see Fig. 32-5C).

Short and mid-term results for the procedure have been promising. At a mean of 25 months' follow-up, based on

questionnaire data, 77% of patients reported that they were cured or improved from their incontinence, and the rate of de novo urge incontinence was reported to be 8%.<sup>40</sup> In an objective study based on voiding cystourethrogram appearance, the lateral height of the cystoceles decreased in a statistically significant fashion postoperatively (Fig. 32-6).<sup>41</sup> Long-term results with 5- to 10-year follow-up will soon be available. From a sexual function perspective, approximately 8% to 13% of middle-aged and elderly women experience dyspareunia.<sup>42,43</sup> Lemack and Zimmern examined the rate of dyspareunia in women undergoing anterior vaginal wall suspension alone or with concomitant posterior repair. Overall, there was no difference between the two groups: 4/22 (18%) of sexually active women reported intercourse as being painful postoperatively, compared with 6/21 (28%) of sexually active patients preoperatively. From these data, it was concluded that the anterior vaginal wall suspension procedure does not adversely affect sexual function.<sup>44</sup>

Cosson and associates, in 2001, described a technique similar to the anterior vaginal wall suspension. In this approach, an in

**Figure 32-5** Anterior vaginal wall suspension, intraoperative views. **A**, An apical marking stitch has been placed on the midline of the vaginal plate at the level of the vaginal cuff. **B**, The lateral incisions of the vaginal plate have been made, and the plate has been divided into four equal quadrants to guide placement of the four suspension sutures. **C**, The anterior vaginal wall is returned to its normal anatomic position after placement of the suspension sutures and transfer of these sutures suprapubically with a ligature carrier. Note the preserved vaginal depth and no overcorrection of the urethra and bladder base.

situ vaginal patch approximately 4 cm wide and 6 to 8 cm long is created and suspended to the arcus tendineus with three pairs of sutures. The suspended in situ patch is then buried under the anterior colporrhaphy flaps (Fig. 32-7). This approach was performed in 47 patients with grade 3 cystocele, 38% of whom had concomitant UI. A 93% cure rate was achieved for cystocele correction at 16.4 months' follow-up; no result of continence status was reported.<sup>45</sup>

### Vaginal Wall Sling

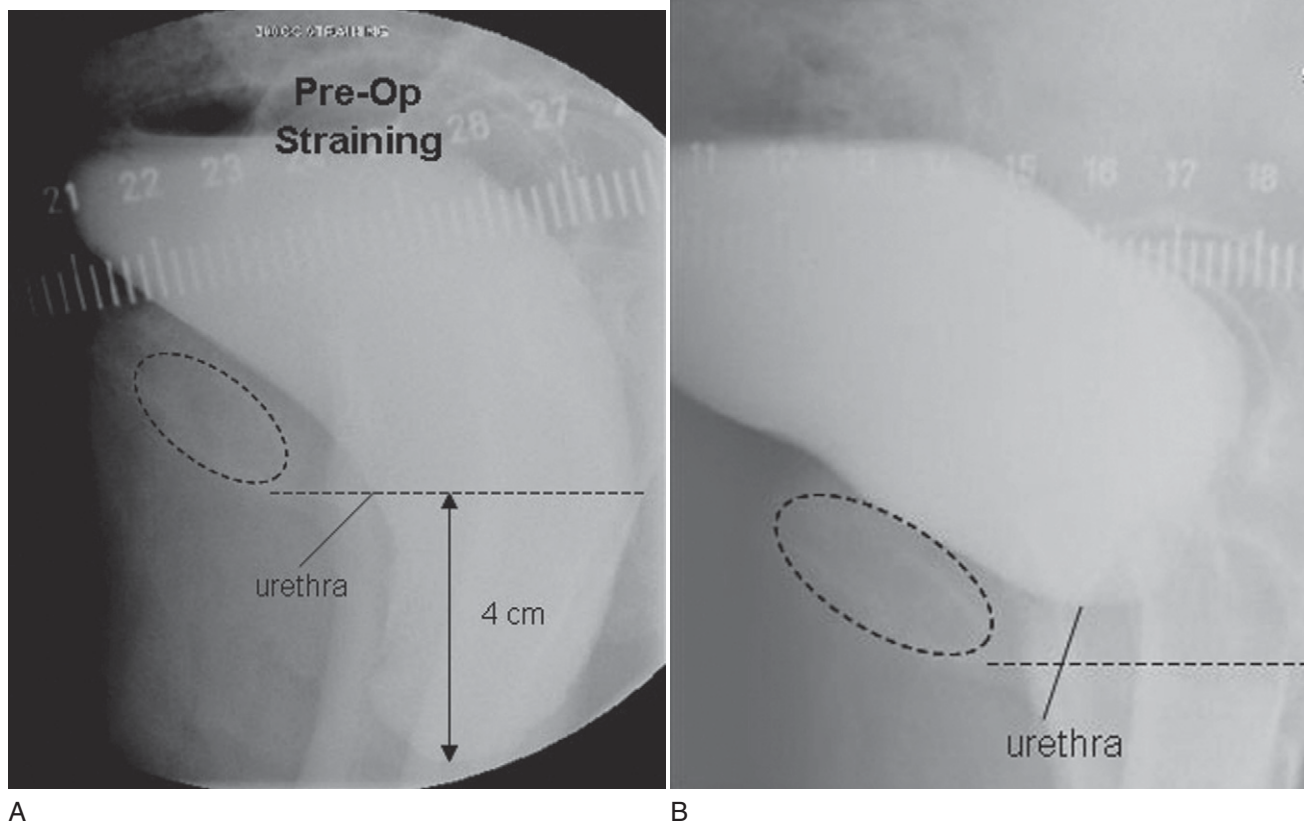

In 1989, Raz also introduced the vaginal wall sling,<sup>46</sup> more to increase outlet resistance than to restore the anatomic support of the urethra. The tension on the vaginal tissue not only increased urethral resistance but created a backboard for improved pressure transmission.

A block A incision is made with the apex just proximal to the urethral meatus and the base extending several centimeters proximal to the bladder neck (Fig. 32-8A). Lateral dissection is performed to mobilize the urethra, but the midline tissue is

left intact. A transverse incision is made across the flap at the area of the bladder neck. Proximally, the anterior vaginal wall is further dissected free to raise a vaginal flap. Polypropylene helical sutures are placed in the four corners of the distal vaginal island beneath the urethra. The sutures are transferred by a double-pronged ligature carrier into a previously made small suprapubic incision (see Fig. 32-8B). Cystoscopy is performed to ensure no injury to the bladder or ureters. Next, the proximal vaginal flap is advanced over the "in situ" sling, and the vaginal wall is closed. The suprapubic sutures are then tied and the incisions are closed.

Appell reported modifications of the vaginal wall sling using retropubic or suprapubic bone anchors for suspension, a horizontal mattress suture placed along the lateral edge, and preservation of the endopelvic fascia.<sup>47</sup> Based on these modifications, Goldman and colleagues reported, at 19 months' follow-up, a 79.5% success rate.<sup>48</sup> Mubiayi and associates reported experience with an in situ vaginal sling using a running (nonhelical) suture incorporating the entire lateral edge of the sling.<sup>49</sup> With a mean of 25.1 months' follow-up of the first 75 patients, a 70% rate of

**Figure 32-6** Standing cystourethrogram demonstrates the height of a cystocele with straining at maximum bladder capacity on a lateral view. **A**, Preoperatively, a grade 2 cystocele is present. **B**, Six months after an anterior vaginal wall suspension, there is no inferior descent below the level of the pubic symphysis on voiding cystourethrogram.<sup>36</sup>

**Figure 32-7** Cosson and associates described modification to the anterior vaginal wall suspension. This schematic diagram represents the 4 × 8 cm in situ vaginal patch suspended to the arcus tendineus. The vaginal patch is then covered by anterior colporrhaphy flaps. (Adapted from Cosson M, Collinet P, Ocelli B, et al: Cure de cystocele par plastron vaginal. *Progres en Urologie* 11:340, 2001.)

cure or improvement was achieved. In patients with ISD the rate was 80%. Twenty percent developed de novo urgency or dysuria.

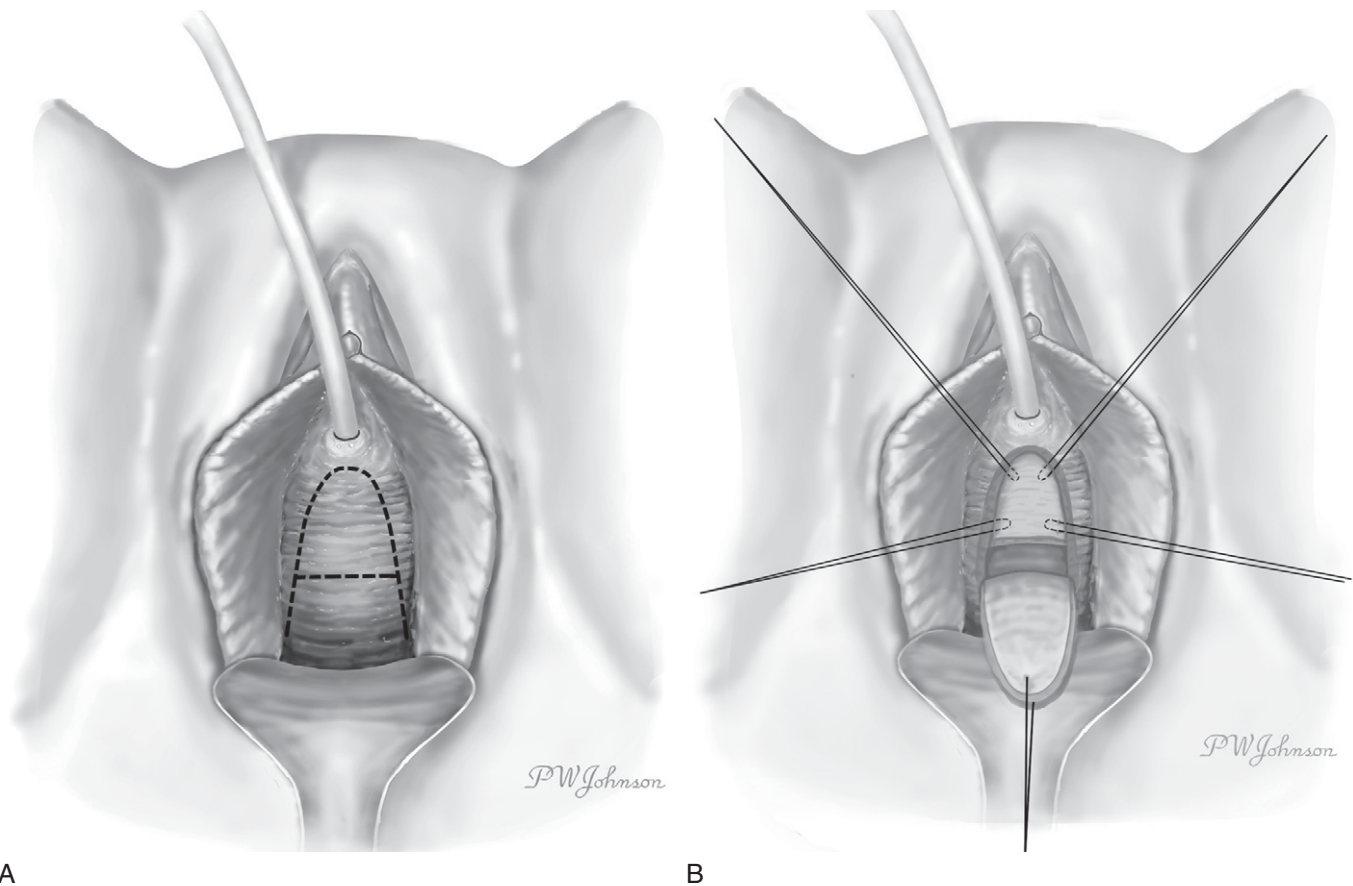

Mikhail and coworkers reported success with several modifications, including a running helical stitch incorporating the entire length of the lateral edge of the sling, bone anchors,

denuding of the vaginal patch, and closure over the sling longitudinally rather than by flap advancement.<sup>50</sup> In this study, 53 women with SUI and no ISD underwent a vaginal wall sling with the modifications described, and 31 underwent a concomitant prolapse procedure. Forty-four patients (83%) with a minimum of 5 years of follow-up were reported as being symptomatically dry and without pads; 5.6% reported de novo urgency, and there were no cases of de novo dyspareunia. Serels and colleagues examined the success of combining in situ sling with cystocele repair.<sup>51</sup> Eighteen patients with grade 2 or grade 3 cystocele and SUI with no evidence of ISD on urodynamic studies (VLPP >50 cm H<sub>2</sub>O) were evaluated with 6 to 48 months of follow-up. Sixteen patients (89%) were dry postoperatively, 3 (17%) developed de novo urgency, and no patients had recurrence of their prolapse.

The vaginal wall sling appears to afford a mid-term success rate comparable to that of the fascial pubovaginal sling.<sup>52</sup> Two studies, that of Mikhail and colleagues<sup>50</sup> with a minimum follow-up of more than 5 years and that of Kilicarlsan and associates<sup>32</sup> with a mean follow-up of 4 years, reported dry rates of 83% and 97%, respectively. However, neither study included patients with ISD based on urodynamic criteria.

Raz cautioned against performing the procedure in sexually active women with a short vagina due to the risk of shortening,

**Figure 32-8** Vaginal wall sling. **A**, A “Block A” incision is outlined on the anterior vaginal wall. **B**, Four suspension sutures have been placed with a narrow base anchor. Proximally, a vaginal wall flap has been created and will be advanced over the in situ vaginal sling patch at the end of the procedure. (Adapted from Raz S, Little NA, Juma S. Female Urology. In Walsh PC, Gittes RF, Perlmutter AD, Stamey TA: *Compbell’s Urology*, 6<sup>th</sup> ed., chap. 75, pp. 2782-2806; 1992. Philadelphia: WB Saunders.)

In older women with significant atrophic vaginitis, adequate tissue strength may be lacking. Additionally, women with significant scarring of the anterior vaginal wall may not be good candidates. In regard to dyspareunia, Mikhail and coworkers, using a longitudinal closure over the flap, reported no de novo dyspareunia in 49 of 51 sexually active patients.<sup>50</sup> Angulo and associates reported a modification using a longitudinal flap placed transversely to avoid the potential of foreshortening the vagina. No sexually active patient had complaints of dyspareunia 6 months postoperatively.<sup>53</sup>

With the technique of the vaginal wall sling, buried epithelium creates a potential for the development of inclusion cysts in the area of the sling. Mubiayi and colleagues reported a 5% (4/75) rate of vaginal mucocele.<sup>49</sup> In the English literature, there have been two further case reports.<sup>54,55</sup>

### Goalpost Technique

Raz described his four-defect repair of grade 4 cystocele, a procedure known as the goalpost technique. He used a vaginal wall sling to support the bladder neck and urethra with concomitant reduction of the cystocele by reapproximation of the perivesical fascia and the cardinal ligaments over the midline (Fig. 32-9). Safir and associates reported a 92% (103/112) success rate for cystocele correction and, in patients with preoperative SUI, a cure rate (dry or improved) of 90% (44/49).<sup>57</sup> Leboeuf and

colleagues reported a modified procedure wherein Pelvicol mesh was interposed between the reapproximated perivesical fascia and the vaginal wall closure. In this study, 24 patients had the standard four-defect repair, and 19 had Pelvicol interposition. Overall, there was a 93% cure rate of the cystocele. Only 3 of 43 patients had a recurrence, all within the Pelvicol group. For SUI, 22/24 (91.6%) had resolution of their symptoms.<sup>58</sup>

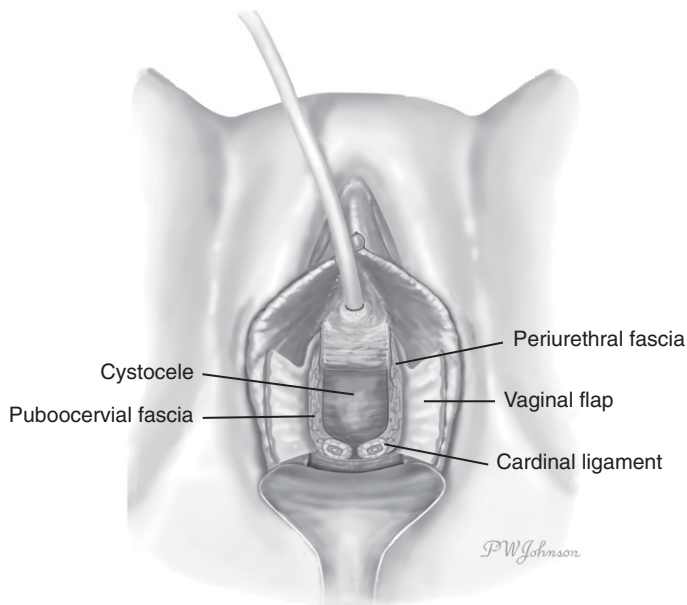

### DEBATE: A FUTURE FOR NEEDLE SUSPENSIONS?

*[T]he Burch colpo-suspension was better in controlling stress incontinence but it led to an unacceptable high rate of prolapse recurrence. The anterior colporrhaphy was more effective in restoring vaginal anatomy but it was accompanied by an unacceptable low cure rate of stress incontinence. Neither of the two operations is recommended for women who are suffering from a combination of stress incontinence and advanced cystocele.*<sup>59</sup>

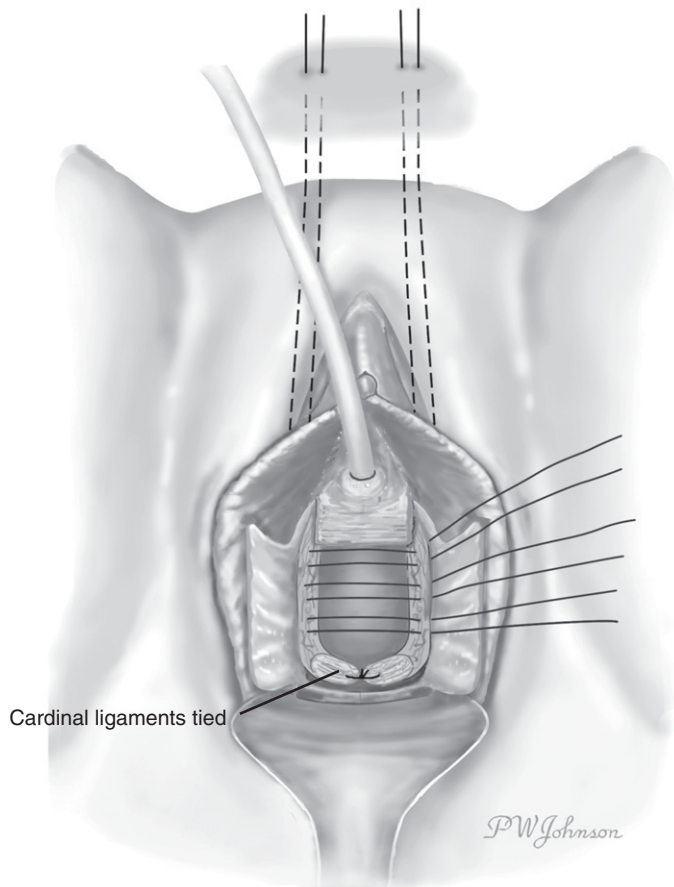

As time has progressed, it has become apparent that prolapse and urethral hypermobility are not independent events. The vagina is a dynamic organ, and redistribution of forces may result in herniation in other parts of the vagina. Therefore prolapse disease can be viewed as a global vaginal phenomenon.<sup>60</sup> In recent

**Figure 32-9** Goalpost technique. **A**, Goalpost incision is outlined. The arms extend from the mid-urethra to 1 cm proximal to the bladder neck. The transverse crossbar connects the arms. The post extends from the crossbar (which is 1 cm proximal to the bladder neck and extends to the vaginal cuff). **B**, The vaginal mucosa is dissected off the underlying structures. The mucosa between the arms of the goalpost remains in situ to serve as the vaginal wall sling. **C**, Final appearance, with vaginal wall sling sutures passed through the retropubic space. Sutures are placed transversely to reapproximate the perivesical fascia for correction of the cystocele.

statistics, 18% to 41% of patients undergoing procedures for POP received concomitant anti-incontinence procedures.<sup>2,3</sup>

The paradigm has shifted with regard to the needle suspension procedures. Pereyra first conceptualized needle suspension for the correction of urethral hypermobility and treatment of incontinence; we now have needle suspension procedures that can concomitantly correct cystoceles and SUI secondary to urethral hypermobility. One of the greatest assets of current needle suspension procedures has been the use of native tissue to provide broad support to the anterior vaginal wall as a single unit. Unlike the anterior colporrhaphy, the anterior vaginal wall suspension and the vaginal wall sling do not rely on weakened muscular or fascial attachments but use the actual vaginal mucosa beneath the bladder neck and bladder base to provide the support mechanism. Careful review of more recent literature indicates that experienced vaginal surgeons can attain a good success rate

in the correction of cystocele and urethral hypermobility with one simple procedure and with minimal perioperative risks (Table 32-3).

The concept of using a foreign tissue to reinforce the strength of a defective tissue was first applied in general surgery. However, the use of foreign materials such as synthetics, allografts, and xenografts has both real and theoretical beneficial and adverse implications. In the area of vaginal reconstruction and treatment of SUI, surgeons began using foreign materials for midurethral slings a decade ago, and, with increasing practice, this experience has now been extended to reinforce the vaginal mucosa in cystocele repairs and other vaginal compartments.

One can argue for the advantages and disadvantages of every material regarding safety, durability, and effectiveness (Table 32-4). This is beyond the scope of this chapter, but it is fair to state that, for the transvaginal repair of SUI with

**Table 32-4 Advantages and Disadvantages of Use of Native Tissue in Anterior Vaginal Wall Reconstruction**

Topic	Advantages	Disadvantages
Goal	FCBNS and AVWS: Anterior vaginal wall support VWS: Sling effect	Does not correct ISD Does not provide support to the upper anterior vaginal wall
Technique	Low cost Simple and versatile Short OR time No change in vaginal length	Basic training in vaginal surgery
Recovery	Minimal discomfort and narcotic use	Longer convalescence recommended than for midurethral sling
Safety	Low morbidity (bladder injury, transfusion) Low rate of de novo urge incontinence and rare voiding dysfunction	
Results	Effective for anatomic correction of urethral hypermobility and cystocele	No long term data (>5 years) Concern in young patients

AVWS, anterior vaginal wall suspension; FCBNS, four-corner bladder neck suspension; ISD, intrinsic sphincter deficiency; VWS, vaginal wall sling.

concomitant cystocele, an ideal mesh material has not yet been identified. In the case of synthetics, additional issues currently debated are related to surgical technique, how and where to anchor the mesh material, mesh shrinkage, changes in sexual function, and challenges posed by removal of the mesh material if erosion, infection, or pain forces a reoperation.<sup>63-67</sup>

As with any surgical procedure, there will always be failures. Failure of a procedure can be attributed to technical factors, tissue factors, and, perhaps most importantly, patient selection. We now understand the process of detachment of the anterior vaginal wall from its lateral pelvic support resulting in SUI and a lateral defect cystocele, possibly progressing to a more advanced stage with a central defect,<sup>68,69</sup> and we better understand the intrinsic “flaws” of many of the early needle suspension procedures. Today, we realize that repetitive stitch placement in the same plane will create a point of weakness resulting in suture pull-through, that tension on the tissues leading to overcorrection should be avoided, and that broad-based plates are better than narrow flaps. We also better understand that satisfactory results depend on retropubic scar formation induced by the dissection of the retropubic space (as in a Burch procedure) and has little to do with the variable atrophic appearance of the vaginal tissue. We have also recognized that all patients with SUI are not equal; there is an important subgroup that has ISD. In this group of patients, stabilization of the anterior vaginal wall to eliminate urethral hypermobility is unlikely to correct their incontinence.

It is well known that we lack good scientific data to compare the outcomes of different surgical procedures and that the definition of success is not uniform across studies. The Cochrane report exemplified this in its statement: “[B]ladder neck needle

suspension surgery is probably not as good as open abdominal retropubic suspension. . . . However, the reliability of the evidence was limited by poor quality and small trials. . . . There was not enough information to comment on comparisons with suburethral sling operations.”<sup>25</sup> These observations spurred interest for several randomized control trials on incontinence and prolapse repair,<sup>21-23,70</sup> including multicenter study sponsored by the National Institutes of Health to compare the Burch procedure versus rectus fascia sling in women with stress-predominant incontinence.<sup>71</sup>

## CONCLUSION

Despite the shortfalls of the literature, it appears that the current role of the needle suspension procedures is their applicability to patients with anterior vaginal wall mobility resulting in cystocele and/or SUI. The safety, simplicity, and minimal morbidity of these procedures need to be weighed against the long-term concern of using native tissue for repair. Recently, the trend has been to enhance the traditional anterior colporrhaphy with the interposition of a variety of mesh materials, but very little is known about the results and complications of these newer materials. Both the Cochrane and International Consultation on Incontinence (ICI) groups reviewing existing data cautioned that these materials should be used only in the context of well-designed randomized controlled trials on properly consented patients.<sup>72</sup> Ongoing studies on the biomechanical properties of the human anterior vaginal wall may shed light on the changes of the vaginal wall with aging and help in designing an ideal biocompatible material suited to an individual patient.<sup>73</sup>

# VAGINAL WALL SLING

Rodney A. Appell

There are a plethora of surgical procedures for the treatment of female stress urinary incontinence (SUI). More than 200 procedures currently exist, and the list is still growing. Sincere attempts to overcome imperfect results and to avoid complications, as well as pressures from industry and patients, have all taken part in this evolution, or perhaps revolution, with innovative, creative attempts over the last decade aimed at performing less invasive surgery for SUI, to decrease morbidity, hospital stay, postoperative discomfort, and perhaps even the cost of surgery. There are nonlaparoscopic procedures available for SUI that are minimally invasive and share many of these qualities just described; in the carefully chosen patient, they provide a reasonable surgical option for the treatment of SUI. This chapter reviews the surgical techniques and results of vaginal wall slings.

Surgical procedures in this category are really modifications of transvaginal suspensions that were designed to support the proximal urethra and bladder neck into a high retropubic position transvaginally, presumably in a less invasive way than with retropubic suspensions. A midline or inverted U-shaped incision was created at the anterior vaginal wall. The periurethral ligaments and, in some procedures, the deep part of the vaginal epithelium were included in a helical suture. The suture was then transferred, using a long needle passer, to a small suprapubic incision. This step was then repeated on the contralateral side. Tying the sutures in the suprapubic area resulted in suspension of the bladder neck and the proximal urethra into a high retropubic position. Variations on these themes included modifications by Pereyra in 1959,<sup>1</sup> Stamey in 1973<sup>2</sup> and 1981,<sup>3</sup> and Gittes in 1987.<sup>4</sup> These variations differed in the shape of the vaginal incision (midline, T-shaped, inverted U), the way the needle was passed (direct finger guidance or blindly), the anchoring tissue, and the use of cystoscopy (to rule out injury or to confirm suture placement). As a group, these procedures have been less efficacious than retropubic suspensions or sling procedures. They carry a success rate of 67% with 4 or more years of follow-up.<sup>5</sup> A possible explanation for their lesser efficacy may include pull-through of the sutures through the supporting anchoring structures and eventual failure of the supporting mechanism at the level of the bladder neck and proximal urethra. Future applications for these procedures seem to be limited unless they can be used in conjunction with the “sling concept.”

### MINIMALLY INVASIVE SLING PROCEDURES

Sling procedures have been used for almost a century in efforts to correct SUI and are constantly evolving. In recent years, several observations have helped direct innovations. In the past, SUI was separated into urethral hypermobility (type I and II) and intrinsic sphincter deficiency or ISD (type III). Now it is believed that, if SUI is present, there must be some component of sphincteric

deficiency. Sling procedures were originally designed for the treatment of the ISD type of urinary SUI and for recurrent SUI when prior surgical treatments had failed. Now, however, sling procedures are used also in the treatment of primary SUI.

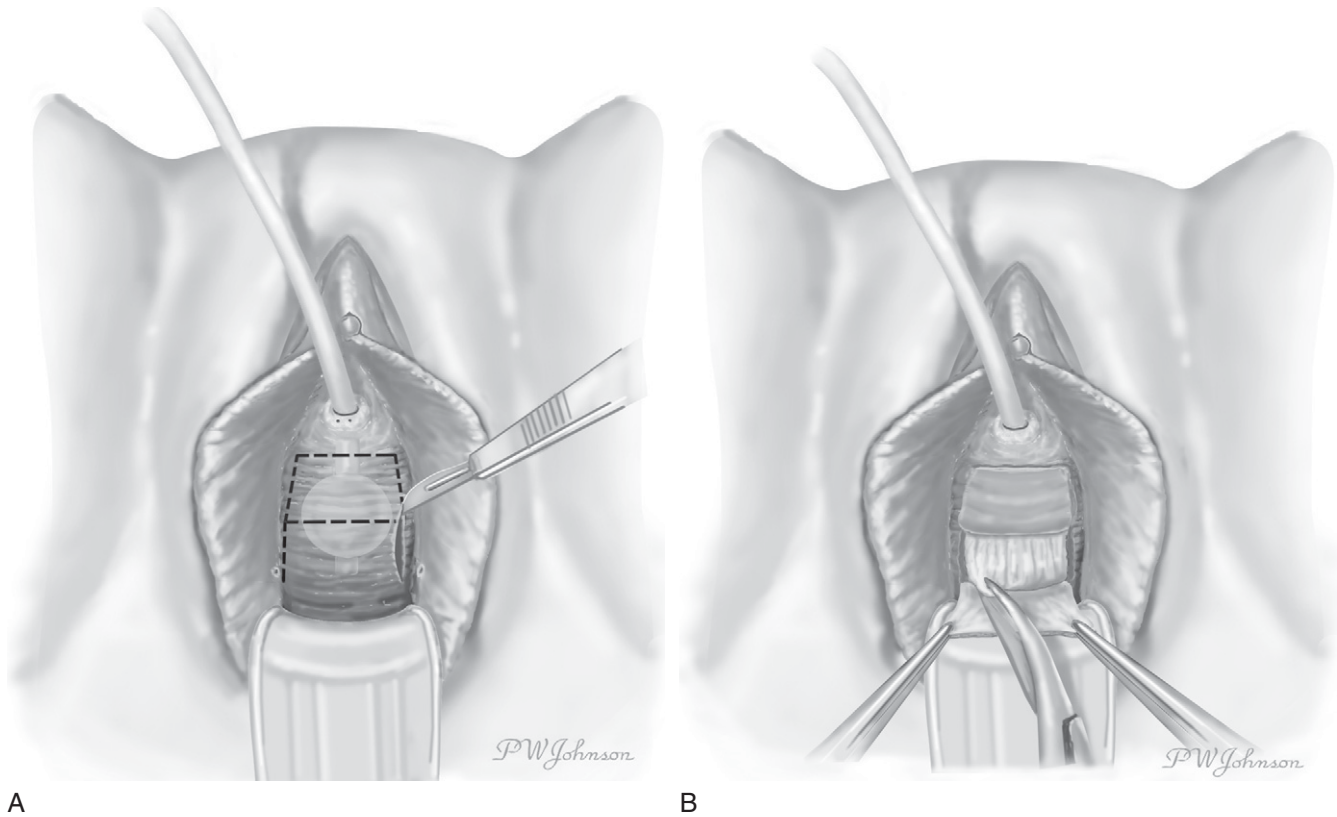

If a sling procedure is chosen, there are many technical options available for placement and choice of sling material: in situ vaginal wall, free vaginal wall graft, synthetic material, cadaveric fascia lata, autologous rectus fascia, and autologous fascia lata. Despite the success of synthetic slings placed at the mid-urethra, there are many patients and surgeons for whom the placement of a foreign body through the vagina is not acceptable. For such patients, and especially for those with abdominal (Valsalva) leak point pressure (VLLP) greater than 50 cm H<sub>2</sub>O, an acceptable alternative is an in situ vaginal wall sling.<sup>6</sup> Through the use of the vaginal wall, the time and morbidity of the sling procedure can be decreased, and the use of any foreign material is avoided. Furthermore, regardless of the sling material, preservation of the endopelvic fascia may help to prevent recurrent paravaginal defects may decrease the operative morbidity by reducing the surgical dissection and adverse side effects such as detrusor instability. The sling should then be fixed in position and tied without tension.

### PREOPERATIVE ASSESSMENT

Every patient undergoes a careful pelvic examination, measurement of postvoid residual volume, and a supine stress test. Patients with mixed incontinence or an elevated postvoid residual volume always undergo urodynamic testing. Patients with pure SUI, on the other hand, should have urodynamic testing with determination of VLLP to help determine whether the type of sling material to be used is in question. Cystoscopy can be reserved preoperatively for the patient with complaints of significant urgency. Any pelvic organ prolapse noted on physical examination should be addressed at the time of the proposed incontinence surgery.

### METHOD: IN SITU VAGINAL WALL SLING WITH PRESERVATION OF THE ENDOPELVIC FASCIA

An incision is created in the anterior vaginal wall in the shape of an “A.” The island of the “A” is used as the in situ sling. The proximal end of the island is at the bladder neck, and the distal end is at the mid-urethra. The anterior vaginal wall tissue lateral to the in situ sling is mobilized to the inferior pubic rami just to the level of the endopelvic fascia. The legs of the “A” are then further dissected so as to create a flap to cover the in situ sling (Fig. 33-1).

**Figure 33-1** A, Incision line for formation of the in situ sling. B, Dissection of vaginal flap for ultimate closure.

A suprapubic incision is then made, and a heavy, nonabsorbable suture is fixed into position. Classically, the fixation may take place in one of three ways. The suture can be anchored using bone anchors into both pubic tubercles, or it can be anchored by taking a no. 6 free Mayo needle and driving it through the fascial leaf overlying the insertion of the rectus fascia behind the pubic bone or into the pubic bone itself.<sup>7,8</sup> One end of the suture is then passed from the suprapubic site into the vaginal lumen via the lateral sling incision, using a 15- or 30-degree Stamey-type needle. The suture is then loaded onto the no. 6 free Mayo needle and placed through the in situ sling as well as the pubocervical fascia, using a horizontal mattress or U-stitch suture. The Stamey-type needle delivers the suture back to the suprapubic wound (Figs. 32-2 and 33-3). Cystoscopy is then performed with a 70-degree lens to evaluate for efflux of urine from the ureteral orifices and bladder perforation.

The vaginal wall is closed with a running locking 2-0 polyglycolic acid suture. At this point, the catheter and vaginal retractors are removed (Fig. 33-4). A wink sign (i.e., a tugging up of the bladder neck when pressure is applied to pull on the sling sutures) is noticed, and the sutures are tied over a clamp or Hegar dilator that is approximately 5 to 7 mm in diameter or over the forefinger of the surgical assistant. The catheter is replaced, and gentle traction is applied to the bladder neck to allow the suprapubic knots to lie correctly. A vaginal pack with estrogen cream is then applied.

The use of transvaginal bone anchors and vaginal wall to correct SUI has also been reported.<sup>9,10</sup> In these studies, two vaginal wall screws on either side of the urethra were placed through the

**Figure 33-2** Stabilization of bladder neck: placement of vaginal sutures.

**Figure 33-3** Stabilization of bladder neck: transfer of sutures to suprapubic site.

**Figure 33-4** Closure of vaginal incision.

vaginal wall itself, for a total of four bone anchors. The bone anchors were driven into the pubic bone on either side of the symphysis. They were placed approximately 2 cm from the urethra, and each pair of ipsilateral sutures was approximately 1 to 2 cm apart. On each side, one of the sutures was passed through its defect created in the vaginal wall to the ipsilateral suture vaginal wall defect, a distance of approximately 1 to 2 cm. The ipsilateral sutures were then tied to each other, and the knot was buried in the vaginal wall.

## RESULTS

The Cleveland Clinic Foundation reported on a series of patients using the in situ sling technique.<sup>11</sup> In this series, 20 patients with a mean age of 55 years were monitored for a mean of 26 months (range, 24 to 29 months). Follow-up consisted of a questionnaire and physical examination with provocative pad test. Ninety-five percent of the patients were cured. One patient had recurrent SUI. Three patients had a delay in voiding until 3 weeks after the procedure. There were two patients with de novo instability in whom the problem resolved within 2 months. Raz and colleagues<sup>12</sup> had previously reported success in 77% of patients, and in a follow-up study 4 years later, Juma and associates<sup>13</sup> reported a success rate of 94.4% in a series of 65 patients. Kaplan and colleagues<sup>14</sup> performed a comparison of rectus fascia and vaginal wall slings. The satisfaction and success rates were similar, and the group that underwent the vaginal wall sling had a shorter operative time and shorter hospital stay.

The procedure has few complications reported to date. The disadvantages are thought to be the fact that the vaginal tissue used is weak<sup>6</sup> and that there may be a risk of epithelial inclusion cyst formation.<sup>15</sup>

The group from Israel has published results on their transvaginal bone anchoring techniques.<sup>9,10</sup> The most recently published study evaluated 61 patients with a mean follow-up of at least 12 months (range, 12 to 30 months). In this study, the cure rate was reported as 82%.<sup>9</sup> An earlier study of 50 patients with a 12-month mean follow-up showed a cure rate of 82% and a mean operative time of 28 minutes.<sup>10</sup> There were no instances of urinary retention or osteitis pubis noted. However, three patients did report transient dyspareunia, and three patients were found to have suture material in their bladder which required removal. There was no mention of preprocedure urgency or of de novo urgency or urge incontinence.

## POSTOPERATIVE MANAGEMENT

All patients stay in the hospital for up to 23 hours. The vaginal packing and catheter are then removed before the patient is discharged.

## COMMENT

The pubovaginal sling, when used in conjunction with preservation of the endopelvic fascia, can cure SUI. It is known that entry into the retropubic space may increase the risk of bleeding, neurovascular damage, and injury to adjacent structures.<sup>15-18</sup> In a study by Kohle and colleagues,<sup>19</sup> there was a greater incidence of recurrent cystocele formation and paravaginal defects after Raz

needle suspension procedures that involved detachment of the endopelvic fascia from its insertion on the arcus tendineus.

The in situ sling, in the carefully chosen patient, is an excellent way to correct SUI. The currently available data seem to support the use of bone fixation with preservation of the endopelvic fascia without a need to enter the space of Retzius, although there is a

lack of comparative studies to confirm this statement. However, it is clear that this technique can reduce morbidity and provide a more stable point of fixation for the sling. The procedure provides an appropriate alternative sling for those patients and/or physicians who reject the idea of foreign body slings through the vagina.

# FREE VAGINAL WALL SLING

*Dmitry U. Pushkar*

Pubovaginal sling procedures are the main surgical operations used to correct stress urinary incontinence (SUI). These procedures provide for a tape insertion underneath the urethra or bladder neck. The American Urological Association guidelines panel studied the long-term efficacy of all anti-incontinence procedures and found that pubovaginal slings were among the most versatile and successful.<sup>1-14</sup>

Until the end of the 1990s in most cases autologous tissues were used to create a tape. However, by the late 1990s specialists began to make use of synthetic materials, mainly in the form of Prolene tapes.<sup>9,13</sup>

This chapter covers several aspects of the free vaginal wall sling procedure. At the same time, it touches on the technical particularities of the full-thickness, nonisolated vaginal wall flap, based on the bladder neck area. This procedure was first described in 1996 by the French group from Nice.<sup>11</sup> The patient is placed in the lithotomy position with access to the suprapubic area, and an 18-Fr Foley catheter is inserted. After the vaginal cavity is exposed a U-shaped incision is made to create a rectangular flap based superiorly in the bladder neck (Fig. 34-1). During vaginal dissection, it is preferable to create a thin flap to preserve perivesical tissue for cystocele repair. After flap mobilization, the cystocele is repaired with a running double-layer 3-0 monofilament polyglyconate suture (Fig. 34-2). The rectangular vaginal flap is then rolled to form a tube and secured at each end with two 2-0 polypropylene sutures. Before being rolled, the vaginal flap must be de-epithelialized with a scalpel to prevent postoperative cyst formation. Then, the vaginal tube is positioned in the bladder neck and sutured to periurethral tissues or suspended subcutaneously with two 2-0 polypropylene sutures (Fig. 34-3). Cystoscopy is performed to rule out urethral or bladder perforation and confirm bladder neck suspension. Posterior colporrhaphy is performed, and a povidone-iodine-impregnated vaginal gauze is inserted; it is removed the following day. Normally, the Foley catheter is withdrawn after 48 hours.

It is still questionable whether the vaginal wall sling procedure should remain in the surgical armamentarium. We believe that this textbook would not be complete without coverage of this procedure.

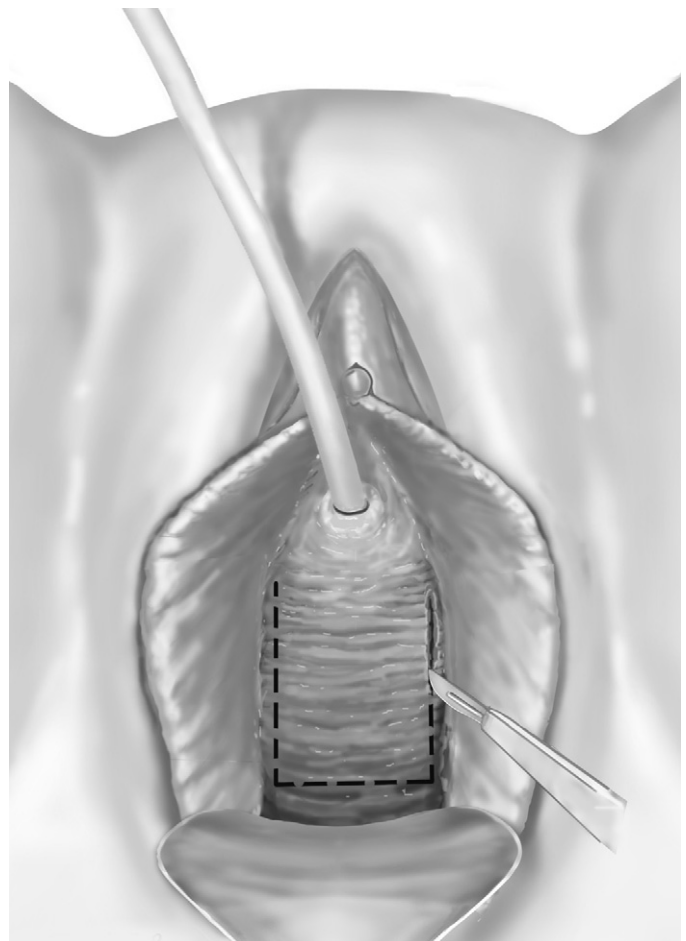

The desire to make use of autologous vaginal tissue for the treatment of SUI first surfaced at the beginning of the 20th century. This was motivated by patients experiencing a combination of incontinence and cystocele, which provided for the enlargement of the vaginal wall, with subsequent preparation of a viable vaginal flap. Previously, full-size flaps had been employed, which led to a high rate of morbidity.

The application of monofilament polypropylene materials, such as Prolene sutures, allowed for further minimization of the procedures, with shorter flap creation. These sutures were used for a wide variety of suspensions. The flap itself had to meet several requirements. The primary requirement was that the flap

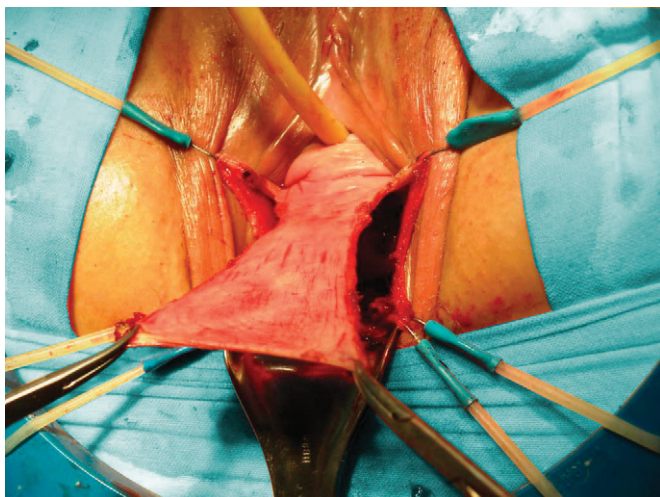

must be long enough to support the bladder neck, and it must be viable, providing for full thickness of the vaginal wall.

It remains to be asked whether the classification of type 1, 2, or 3 SUI is still useful. Sling procedures were in the past reserved for correction of ISD. Today, it has been shown that most female patients with SUI have some kind of ISD. In our department, we have edged away from a standard classification of SUI and now pay particular attention to the anatomy of the patient. We believe that SUI associated with either cystocele, rectocele, or pelvic floor dysfunction clearly calls for a change in accepted “textbook” treatment planning.

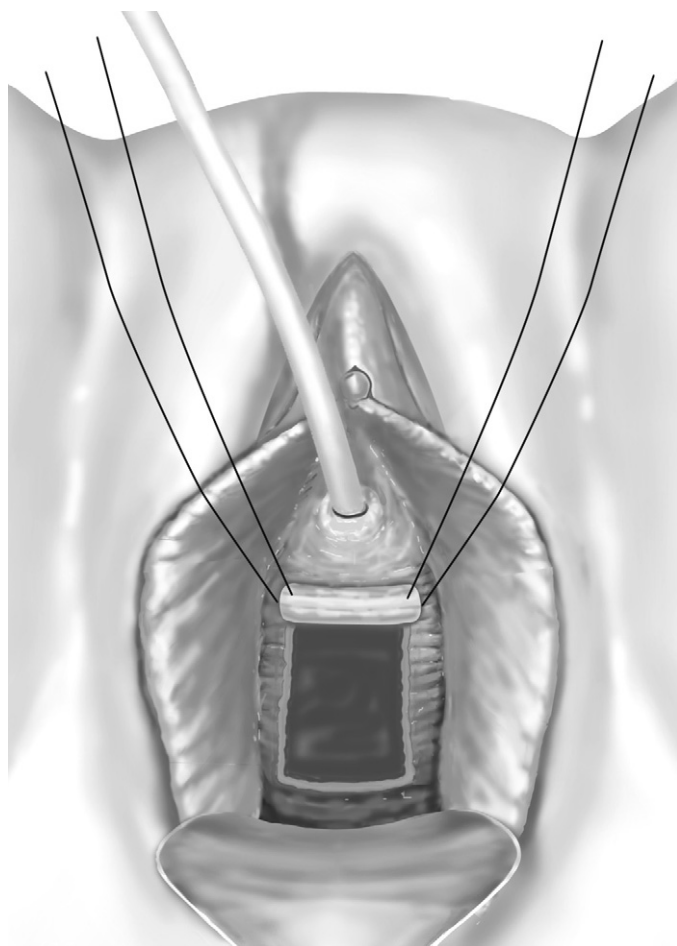

Why do patients choose free vaginal wall sling procedures? What are the long-term functional results of these procedures? What is the purpose of the patient-doctor conversation, and

**Figure 34-1** A U-shaped incision is performed to create a rectangular vaginal flap based on the bladder neck area.

**Figure 34-2** A full-thickness rectangular flap based on the bladder neck area is created from the anterior vaginal wall. This flap may be kept and used as a fixed flap based on the bladder neck suspended by two 1-0 Prolene sutures in the suprapubic area. Cystocele is repaired. This flap may also be isolated if a free vaginal wall sling by isolated flap is preferred.

**Figure 34-3** A vaginal flap is rolled to form a tube and is secured at each end with two 1-0 Prolene sutures, with subsequent passage and attachment of these sutures suprapubically.

should we convince our patients to proceed with this type of surgery? Should the free vaginal wall procedure remain in the surgical armamentarium? Finally, should we make any comparison with synthetic tapes or other tension-free vaginal tape (TVT)-like procedures?

#### RATIONALE

The free vaginal wall procedure may have the following applications:

1. Mild to moderate SUI in elderly patients with cystocele
2. Patients unwilling to use any synthetic materials
3. Young patients with mild SUI, who are rarely scheduled for surgery. There is a lack of long-term follow-up of synthetic materials. These patients may develop recurrence in the distant future, which can dictate the use of synthetic materials such as TVT.
4. Patient desire to have a minimal operation with use of autologous tissue and no abdominal scar.

#### PREOPERATIVE CONSIDERATIONS

Preoperative considerations currently include the following requirements:

1. Mild to moderate SUI
2. Symptoms confirmed by signs is always preferable, which means demonstrable involuntary urine loss during physical examination while coughing or sneezing
3. No signs of vaginal atrophy
4. No signs of detrusor instability—cystometry must be performed if detrusor instability is suspected
5. Cystocele provides enlarged vaginal wall to create viable flap; surgeon may decide whether flap can be created from posterior part if rectocele is present
6. Urinary tract infection excluded
7. Cystoscopy, which is routinely performed in our department
8. Ultrasound examination, also a usual part of preoperative assessment
9. Informed consent and strong will of the patient to undergo surgery

#### SURGICAL TECHNIQUE

We believe that several flap sizes may be used. The choice depends on the surgeon's experience and preference. For example, if the surgeon has substantial experience in using full-size slings, he or she may opt for a longer vaginal wall flap. If the patient's anatomy does not allow for the creation of such a long flap, the operation may nonetheless still be performed. Our patient experience has shown an average flap size of 1.5 to 3.5 cm. An isolated vaginal flap may be formed from either the anterior or the posterior vaginal wall. Rectocele facilitates a vaginal flap formation from the posterior part of the vaginal wall (Fig. 34-4). After the flap has been prepared, the next step of the procedure is cystocele repair, using conventional techniques with several layers of absorbable sutures. Because a lack of vaginal mucosa may occur after the flap formation, care must be taken to restore the

**Figure 34-4** Isolated flaps may be formed from either the anterior (**A**) or the posterior (**B**) vaginal wall.

cystocele well, in order to provide a tension-free closure of the vaginal wall. Normally, we use Monocryl 3/0, providing several layers of sutures. Recently, we have tried to avoid extensive mobilization of the perivesical tissues.

On each corner of the flap, four Prolene 1-0 sutures are attached and the flap is placed in an antibiotic solution (Fig. 34-5). The flap will be positioned in such a way that the vaginal mucosa is exposed. We have now decided to lengthen the vaginal incision, in order to locate the vaginal flap around the mid-urethra (Fig. 34-6). This allows us to avoid the creation of perivesical tunnels. Previously, we used Pereyra ligature carriers to pass Prolene sutures from the vagina to the suprapubic area. Now, we opt for a different approach, which provides for passage of the suture from the vagina to the suprapubic area with the use of special vaginal needles, called tunnelers (Fig. 34-7).

In cases where the flap is taken from the posterior vaginal wall, rectocele repair should be performed. If there is no cystocele or rectocele, the flap should always be taken from the anterior vaginal wall and positioned in the midurethral area.

Cystoscopy must be performed on all patients to exclude bladder perforation. A 70-degree cystoscopic lens should be used. We do not inject indigo carmine intravenously. If a bladder

perforation should occur, we extract the suture and insert it again in a more lateral position. In such cases, we leave a Foley catheter in place for 72 hours. Otherwise, in normal cases, the Foley catheter is removed on the morning after surgery. Vaginal closure with either running or interrupted absorbable sutures is a final step of the procedure (Fig. 34-8). Vaginal packing is routinely used after this procedure and is removed the next day.

Antibiotic therapy is administered to all patients intraoperatively and during the course of the three following days.

The average hospital stay for patients experiencing noncomplicated cases is 2.1 days. For those patients who have undergone simultaneous rectocele or cystocele repair, 4.2 days is the average stay.

## RESULTS

Free vaginal wall sling procedures have been performed in our department since 1989. A total of 189 patients, with a mean age of 67.3 years (range, 31 to 87 years) have undergone free vaginal wall sling procedures. The mean operative time was 43.1 minutes. The vast majority of patients had flaps taken from the anterior

A

B

**Figure 34-5** A, An isolated full-thickness vaginal wall flap is formed. B, The four 1-0 Prolene sutures are attached on each corner of the flap.

vaginal wall. We were able to conduct follow-up studies of 109 (57.7%) of these patients after a mean of 9.7 years. Other patients were unavailable for follow-up.

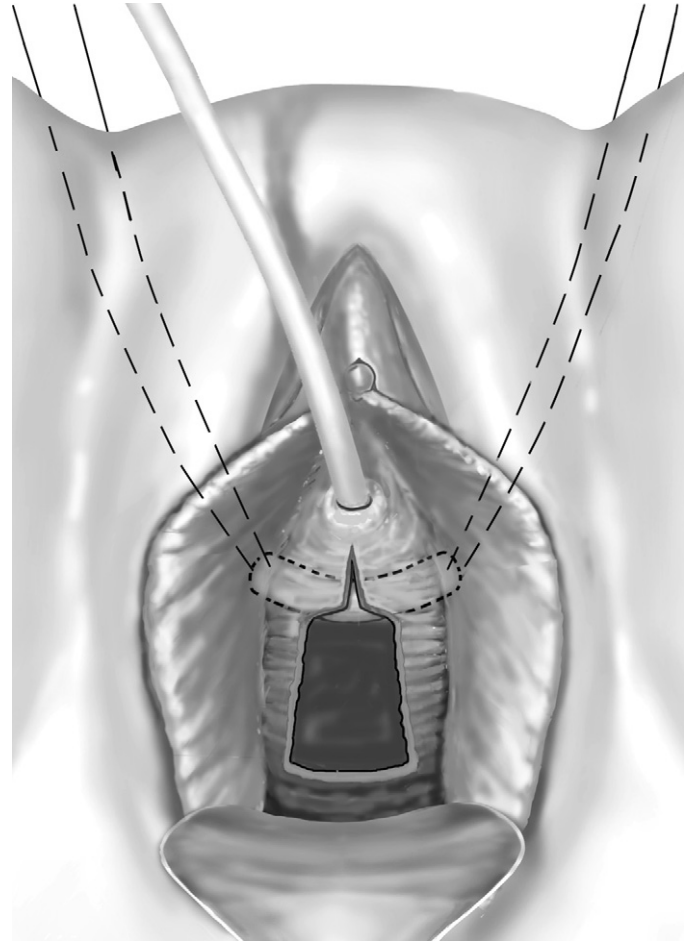

Eighty-six percent of the patients undergoing free vaginal wall sling procedures showed good results after a 6-month follow-up (i.e., no signs of SUI or other voiding disorders). Sixty-seven (61.5%) of the 109 patients showed good results after a mean of 9.7 years with no anatomic problems. Retrospectively, it was observed that those patients with mild to moderate SUI showed better results. There was no correlation between grade of cystocele and continence restoration. Patients applying to us during the follow-up with recurrent SUI after 1999 underwent TVT procedures. When performing TVT procedures on these patients, we did not observe any technical difficulties.

#### SURGICAL TIPS AND TRICKS AND POSSIBLE INTRAOPERATIVE COMPLICATIONS

A careful vaginal examination, once the surgical procedure has started and the patient is under anesthesia (we use spinal anesthesia for most patients), helps to determine the flap location and create a final surgical plan.

In most cases, we employ a hydropreparation of the vaginal wall, which facilitates flap creation.

Careful mobilization of the perivesical tissues toward the pelvic wall permits a proper repair of the cystocele and minimizes tension on the vaginal wall during vaginal closure. Usually, it should not be a problem to close the vaginal wall during the final step of the procedure if the tissues were properly mobilized.

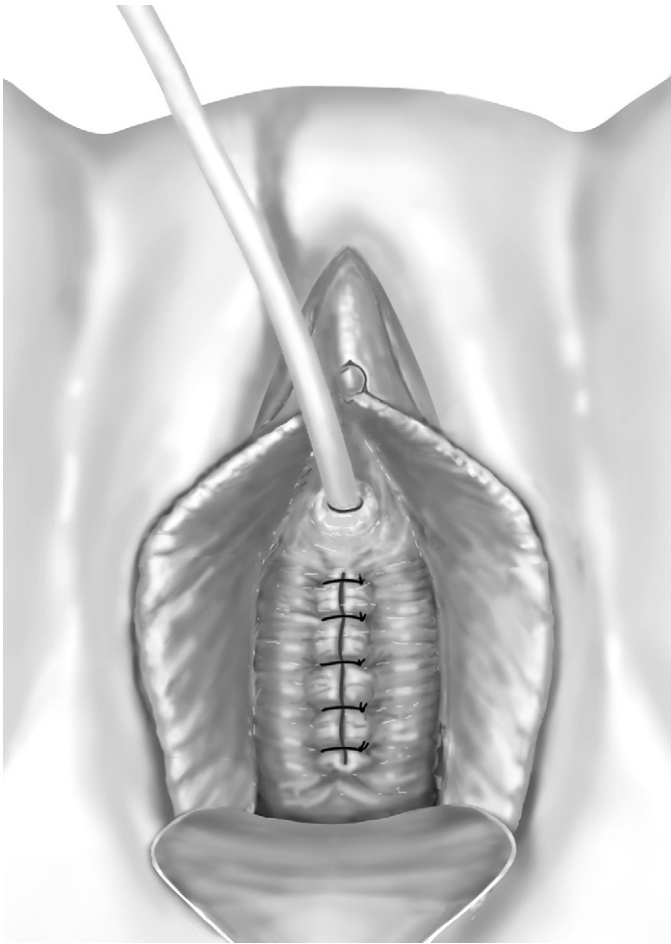

**Figure 34-6** The vaginal incision is lengthened to locate the vaginal flap around the mid-urethra. A vaginal flap is secured by two 1-0 Prolene sutures with subsequent attachment of these sutures suprapubically.

**Figure 34-7** The main surgical instruments and suture material used to perform a vaginal wall sling procedure. It should be noticed that either Pereyra ligature carrier or a vaginal tunneler with handles may be used for Prolene suture passage. A Metzenbaum dissecting scissors is used to mobilize perivesical tissues and to create a periurethral space. Russ. modell forceps are helpful to facilitate tissue traction.

**Figure 34-8** A vaginal wall closure is the final step of the procedure.

Nowadays, both a vaginal and suprapubic needle passage may be used, because several tunnelers have been introduced on the market.<sup>13</sup> Pereyra ligature carriers are the standard applicator used to pass sutures from the vaginal to suprapubic area, tying them over the rectus fascia. Passing needles from the vagina suprapubically can facilitate the procedure, avoiding extra mobilization of the periurethral areas and preserving the bladder neck.

Bleeding from the perivesical venous systems can be massive. It stops once the vaginal wall restoration has been completed. We usually employ mattress sutures to provide additional hemostasis.

Bladder perforation is a rare complication and should be discovered once a cystoscopy is performed. If a needle should be found penetrating inside the bladder, one must reinsert the needle, with a prolonged Foley placement for an additional 48 hours.

In rare cases, if a newly created flap appears to be nonviable, the surgeon should consider a new operative plan. In such cases, we normally use a different tissue for the flap (i.e., the patient's skin taken from the abdominal wall). Notwithstanding that this is a rare condition, the patient must be aware beforehand that this is a possible outcome of the procedure and that the treatment plan might have to be changed if the vaginal tissue is not viable enough.<sup>11</sup>

A vaginal hysterectomy may be easily performed, if necessary, before flap creation. In this case, the flap is created in the same fashion.

#### EARLY POSTOPERATIVE COMPLICATIONS (0 TO 48 HOURS)

Early postoperative complications may include inability to void, pain, SUI, and hematoma formation.

We differentiate inability to void after surgery from typical bladder outlet obstruction, which has been described after several sling procedures. We believe that anatomic changes are the main cause for bladder outlet obstruction. In our experience, 11 patients (5.8%) demonstrated an inability to void after the procedure, which was resolved after a simple catheterization.

Pain in the suprapubic or groin area is rarely noted, and it usually disappears after secondary medical treatment with nonsteroidal anti-inflammatory medications. Two patients in our series experienced severe pain, which lasted more than 3 months.

Immediate recurrence of SUI after the procedure has not been noted.

Perivesical hematoma formation is a rare complication if a Pereyra ligature carrier is used. Two patients in our series developed large hematomas with associated fever, which required percutaneous drain placement. In the case of smaller hematomas, careful follow-up is important. Abdominal ultrasound postoperatively is used for the residual volume assessment, facilitating hematoma evaluation.

#### LONG-TERM POSTOPERATIVE COMPLICATIONS AND OPERATIVE RESULTS

Long-term follow-up data were obtained from 109 (57.7%) of 189 patients who underwent free vaginal wall sling procedures. The mean follow-up time was 9.7 years. For various reasons, the remainder of patients were not available for subsequent evaluation.

We did not observe any de novo voiding dysfunctions at 3 or 6 months after the procedure. After 6 months, de novo detrusor instability was observed in 6% of the patients, which is slightly lower than after other procedures.

We began to analyze results 6 months after completion of the individual procedures. Good results included no sign of SUI and no voiding dysfunctions. Those patients who were well acquainted with the operative procedure and involved in the decision-making process had better functional results, with faster voiding restoration. Good results were noted in 86% of the patients 6 months after the procedure.

Currently, we do not have regular annual data, and therefore we may report only that 67/109 patients (61.5%) had good results with no signs of incontinence or anatomic abnormalities.

Retrospectively, it should be noted that earlier recurrences of SUI occurred in patients with severe SUI symptoms, whereas patients with mild to moderate SUI had better results, with later or no recurrences of SUI. It should also be emphasized that no correlation between SUI recurrence and the degree of cystocele was found.

Patients with SUI recurrence who applied to us after 1999 underwent TVT procedures. We did not experience any technical

difficulties doing TVT procedures on patients who had previously had vaginal wall sling operations.

## CONCLUSIONS

The use of autologous tissues in SUI surgery in female patients should remain in the surgical armamentarium for specialists dealing with patients suffering from SUI. Currently, this procedure should be reserved for patients who choose autologous tissues instead of synthetics for their treatment. At the same time, cystocele provides extra tissue for the flap creation—mainly for elderly patients with mild to moderate SUI .

It should be emphasized that patients with mild to moderate SUI and cystocele showed better results, with no sign of involuntary loss of urine or new voiding dysfunctions.

The success rate of 61.5% for such a procedure, although lower than that of the TVT procedure, has a longer follow-up study period.<sup>15</sup> The TVT procedure can still be easily performed in case of recurrence of SUI after the vaginal wall sling.

The vaginal wall sling leads to a lower rate of complications, which in any case are easier to manage. This should be emphasized in patient-doctor consultations.

Abdominal ultrasound is an easy tool to evaluate patients postoperatively for hematoma formation. Hematomas may be managed conservatively. New voiding dysfunctions occurred in 6% of the patients and were mainly of a transitory nature.

# COLPOCYSTOURETHROPEXY

*Emil A. Tanagho*

Genuine stress urinary incontinence (SUI) is a specific entity directly related to an anatomic abnormality that results in impaired efficiency of the urethral sphincteric mechanism, allowing loss of urine with increased intra-abdominal pressure. Owing to recent advances in urodynamic studies and the appreciation of the pathophysiology of true SUI, the treatment of this problem has become better understood; consequently, the purpose of surgical repair and the means of achieving it can be clearly defined.

### SURGICAL PRINCIPLES

In pure SUI, the sphincteric mechanism, with its striated somatic component and its smooth sphincteric element, is essentially normal. It is loss of the normal anatomic position or normal anatomic support, or both, that weakens the functional efficiency of this sphincteric unit. Accordingly, restoration of normal position and support of the vesicourethral segment usually reestablishes normal sphincteric function.

From this basic principle, it is clear that a suprapubic approach is both more effective than an anterior vaginal repair and longer lasting in terms of restoring the position and support of the sphincteric unit. Trying to push the urethrovesical junction into

a normal retropubic position from below is obviously less sound than achieving the same result from above. The latter is the logical approach for placing the urethra and the urethrovesical segment in a secure, well-supported, normal anatomic position.

Preoperative demonstration of the presence of the anatomic abnormality is essential to the evaluation of the patient, because, in the absence of any anatomic variance, there is no reason for a surgical repair primarily intended to restore normal anatomy and support.

A lateral cystogram obtained with a radiopaque, soft red Robinson catheter permits visualization of the vesicourethral segment and its anatomic relationships. Two exposures with the patient in the absolute lateral position, first relaxed and then with maximum straining (Figs. 35-1 and 35-2), will demonstrate the extent of mobility and thus the effectiveness of the support to the vesicourethral segment. This study permits evaluation of both the normal resting position and the extent of mobility. If the resting position is abnormal (lower than normal), if the mobility of the vesicourethral segment is excessive (Fig. 35-3), or if both conditions are present, the lateral cystogram will confirm the anatomic basis for the existing and clinically established fact of SUI. It must be emphasized that this cystographic study does not permit the diagnosis of SUI but demonstrates the presence of the basic anatomic abnormality responsible for genuine SUI.

**Figure 35-1** Cystogram (two views) shows the relationship between the vesicourethral segment and the pubic bone in the relaxed state. The perpendicular line from the vesicourethral point over the long axis of the pubic bone meets the pubic bone opposite its lower third.

**Figure 35-2** Lateral cystogram shows the patient in the relaxed state (*left*), then straining (*right*). Note the extent of mobility of the vesicourethral segment in relation to any bony point. Normally, movement is less than 1.5 cm in any direction.

**Figure 35-3** Lateral cystourethrograms of a patient with urinary stress incontinence, in the relaxed position (**A**) and with straining (**B**). Note the excessive drop of the vesicourethral segment and an increase in intra-abdominal pressure associated with straining. This is the classic anatomic abnormality of urinary stress incontinence.

Surgical repair should attempt to restore normal position and support without compression or obstruction. SUI is encountered frequently in multiparous women after middle age as a result of pelvic floor weakness, which might have begun earlier in life but has progressed and become manifest. As mentioned earlier, the intrinsic sphincteric mechanism is essentially normal. However, because of the laxity of the pelvic floor and the weakness of the

normal mechanism of support to the vesicourethral segment, the latter tends to lie abnormally low and exhibits excessive mobility with increased intra-abdominal pressure (see Fig. 35-3) or with assumption of the upright position. The intrinsic sphincteric mechanism can be restored to normal function once this anatomic abnormality is corrected, without any need to plicate, constrict, or otherwise directly interfere with the sphincteric unit itself.

It is imperative to avoid the creation of any obstruction or damage to the delicate intrinsic sphincteric muscular element. If this principle is adhered to, the sphincter will regain and maintain its effectiveness, and the repair will be permanent. In my opinion, the suprapubic approach is the best way to achieve this goal.

### SURGICAL TECHNIQUE

The patient is supine, with the lower limbs stretched and supported in a slightly abducted position. The footpiece of the operating table is dropped down to permit easy access to the vagina, which is properly prepared and draped into the sterile field. A 22- or 24-Fr 5-mL Foley catheter is passed and kept in the sterile field.

The retropubic space is exposed through a suprapubic transverse or midline incision. In making this incision, one should stay close to the back of the pubic bone, dropping the anterior bladder wall, the urethra (easily palpated with the Foley catheter in place), and the anterior vaginal wall downward. This step is easy in patients who have had no previous surgical intervention in this area but is otherwise extremely difficult, and it is of critical importance. In the latter situation, adhesions are usually dense, and the anterior bladder wall frequently is found displaced downward and adherent to the back of the pubic bone. Unless the anterior bladder wall is freed and pulled upward, it will not be possible to expose the urethra and the urethrovesical junction.

### Virginal Cases

Once the retropubic space is entered and the urethra is dropped downward with the anterior vaginal wall, no dissection should be done in the midline over the urethra. Whatever amount of tissue is covering it should be left undisturbed. In this way, the delicate musculature of the urethra is protected from any possibility of surgical trauma. Attention should be directed to the anterior vaginal wall on each side of the urethra—again, easily identified with the catheter in it. Most of the overlying fat should be dissected and cleared away to permit future firm adherence to any tissue brought into contact with it. This area is extremely vascular because it has a rich, thin-walled venous plexus which should be avoided as much as possible. As this region is cleared, the vesicourethral junction becomes more apparent. This step can be facilitated by palpating the Foley balloon or, even better, by partially distending the bladder and defining the rounded lower margin of the anterior bladder wall as it meets the anterior vaginal wall. No dissection should be done at the vesicourethral junction itself, because at that point all the detrusor muscle fibers are moving downward to encircle the urethra, and every effort should be made to protect them from trauma. More laterally, however, the inferior margin of the bladder is identified and mobilized upward. The extent of this mobilization depends on the extent of downward displacement, and on occasion very little is needed. Placing fingers in the vagina facilitates this dissection and also is essential to determine the extent of the needed mobilization and freeing of the anterior vaginal wall.

### Repeat Cases

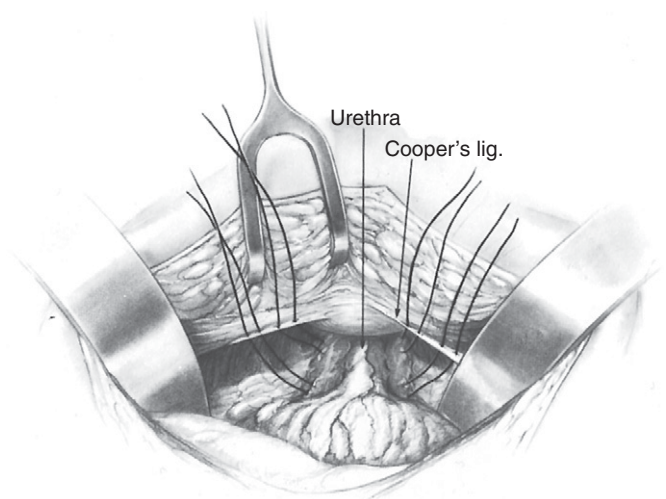

The dissection in repeat cases is most difficult, particularly if three or four previous attempts at repair have failed. Neverthe-

less, it is in such circumstances that the dissection must be impeccable if good results are to be achieved. Unless the urethrovaginal wall is adequately exposed, all adhesions are severed, and the lower margin of the bladder, together with the vesicourethral junction, is permitted to slide upward, proper positioning and support will not be obtained. Utmost care must be taken not to lacerate or damage the urethral or vesical musculature. If identification of the lower margin of the bladder is difficult, one should open the bladder and, with a finger inside the cavity, define its limits for easier dissection and mobilization.

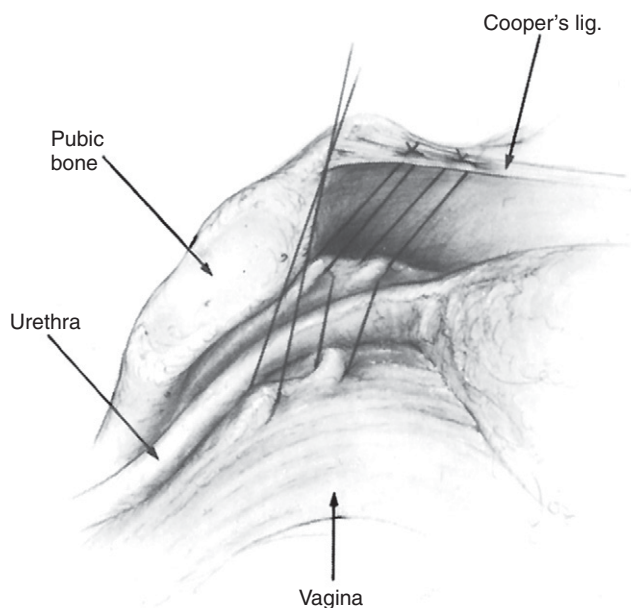

### Sutures

Once mobilization is completed and judged adequate (as determined by inserting two fingers in the vagina and lifting the anterior vaginal wall upward and forward, thus revealing adequate mobility and bringing the vesicourethral segment to a normal position), it is time to place the sutures. I prefer absorbable suture material and use no. 1 Maxon or Vicryl on an atraumatic tapered needle. Positioning of sutures is a most important step in the procedure, second only to proper mobilization. The sutures should be placed as far laterally in the anterior vaginal wall as is technically possible. I apply two sutures on each side. The distal suture is placed first, opposite the mid-urethra. The proximal suture is the most essential and is placed just below the reflection of the anterior bladder wall at the level of the vesicourethral junction, yet far laterally from it (Fig. 35-4).

In placing these sutures, one should take a good bite in the vaginal wall parallel to the urethra, taking full thickness but sparing the mucosa and being guided by the vaginal finger at the appropriate selected sites. A double-bite or figure-eight suture is preferable. All four sutures are placed in the vagina and left with their needles attached before being placed anteriorly. As noted previously, this area is extremely vascular, and visible vessels should be avoided if at all possible. If excessive bleeding occurs, it can be controlled by under-running with figure-of-eight

**Figure 35-4** Placement of the sutures in the anterior vaginal wall. They are placed lateral to the vesicourethral segment, and there are two on each side. The lower ones are opposite the midurethral segment, and the upper ones are exactly at the level of the vesicourethral junction. Sutures are then passed through Cooper's ligament. (Adapted from Tanagho EA: Colpocystourethropexy: The way we do it. *J Urol* 116:751, 1976.)

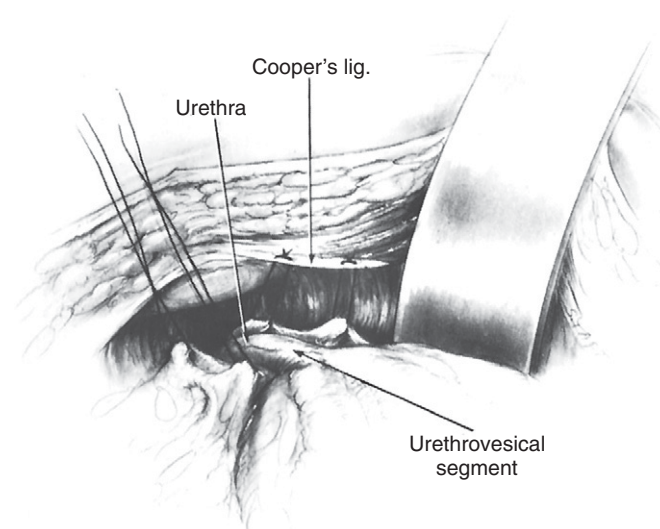

**Figure 35-5** Lateral view of the sutures as placed in Figure 35-4 with one side tied. Note that the vaginal wall did not meet Cooper's ligament and that there is free suture between the two. (Adapted from Tanagho EA: Colpocystourethropey: The way we do it. *J Urol* 116:751, 1976.)

sutures. Less severe bleeding usually stops once these fixation sutures are finally tied.

The vaginal sutures are then attached to Cooper's ligament. They are not placed in the midline of the symphysis but are pulled straight upward to Cooper's ligament. With the needle that was left attached to the vaginal suture, a deep bite is taken in the ligament. A Mayo needle is threaded to the free end of the vaginal suture and passed superficially in Cooper's ligament. When this suture is tied, it is tied around the main thickness of the ligament. The distal two sutures are placed first, followed by the two proximal sutures, which are placed in the same ligament but slightly lateral (Fig. 35-5). Once all the sutures are placed, with the operator's fingers in the vagina lifting it upward and forward, the assistant ties the distal sutures and then the proximal ones. In tying the sutures, one does not have to be concerned about whether the vaginal wall site of the suture meets Cooper's ligament, and one should not overdo the tension on the vaginal wall. The suture is approximated as close as the supporting fingers in the vagina feel it to be safe. There should be no tension on the sutures beyond that governed by the fingers lifting the vaginal wall. Free suture material between the two points is of no disadvantage (Fig. 35-6). After the two sutures are tied, the vaginal fingers will appreciate immediately how much the vaginal wall is lifted upward and forward, carrying with it the vesicourethral segment. However, the latter is still free in the retropubic space. One should be able to insert two fingers easily between the pubic bone and the urethra. The urethra is in no way compressed against the bone. Its continuing fixation and support are dependent on fibrosis and scarring of opposed tissues rather than on the suture material's holding it in place. Absorbable sutures are meant to last only long enough for tissue fixation to take place.

Closed drainage of the retropubic space lateral to the sutures is established, and the wound is closed. The catheter is then changed to a 16-Fr 5-mL Foley and left indwelling for 5 days. The patient is restricted to bed for about the same period.

**Figure 35-6** Same as Figure 35-5 except at a different projection; this view shows the vesicourethral segment well supported by the vaginal wall behind it. Note that the urethra is free in the retropubic space without being compressed against the pubic bone.

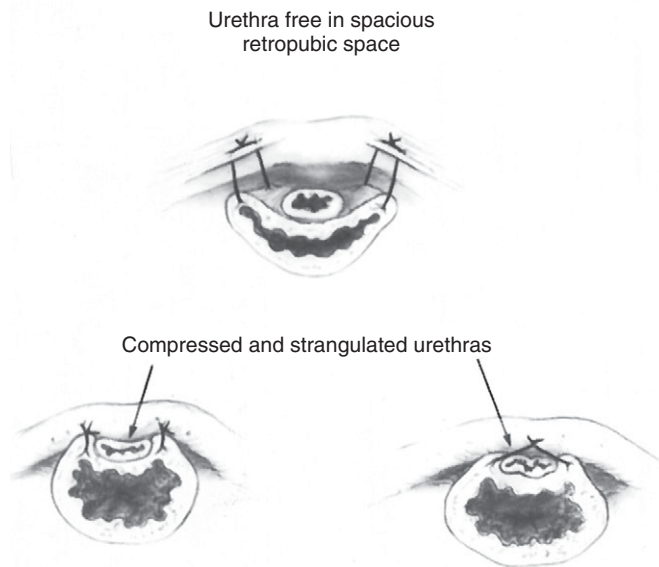

Voiding after removal of the catheter is usually free, without problems of urinary retention or residual urine. If for any unexpected reason the patient has to strain to void, the catheter is replaced for a few more days. This replacement is rarely necessary and has been used only in cases of atonic bladder that did not demonstrate any detrusor activity in the preoperative physiologic studies. Postoperative activity is restricted for 3 to 4 months and is then gradually built up to the normal individual level.

## PRECAUTIONS

The following precautions should be kept in mind:

1. Make every effort to avoid direct dissection of the delicate urethral sphincteric muscular element throughout the entire length of the urethra as well as close to the vesicourethral junction.
2. Avoid by any means creating any compression or obstruction of the urethra while placing the sutures (Fig. 35-7).
3. Keep in mind that healing and permanent support will be achieved by the adherence and fibrosis that occurs and not by the sutures placed at the time of surgery. Accordingly, absorbable suture material is usually advised. Nonabsorbable suture, no matter how far from the bladder, not infrequently finds its way toward the lumen of the urinary tract.

The preexisting funneling of the internal meatus and vesiculation of the proximal urethral segment are a result of the downward and posterior sagging of the vesical neck as well as its poor support. This need not be corrected surgically, because the vesical neck will regain tonus and normal configuration once the normal support and position are restored. The posterior urethrovesical angle is not in itself a critical factor in maintaining continence or losing it. It is usually corrected spontaneously with the proper suspension and support of the vesicourethral segment, so no special effort should be made to create a posterior angle. At the end of the procedure, the retropubic space should be relatively free, and there should be an adequate space for the urethra

**Figure 35-7** Effect of the suspension in the technique described in the text. Top drawing shows the urethra free in a widely opened retropubic space; drawings below show other techniques, in which the urethra can be compressed and strangulated between the bone and the vaginal wall. (Adapted from Tanagho EA: Colpocystourethropey: The way we do it. *J Urol* 116:751, 1976.)

to move without being compressed against the pubic bone. There is no need to fix the anterior bladder wall itself; once the entire vesicourethral segment is supported in a normal position, the rest of the bladder will follow suit. Pulling the anterior bladder wall close to the bladder neck (toward the anterior abdominal wall) will probably defeat the free mobility and ability of the muscular tonus to occlude the internal meatus and keep it open.

## CONCLUSIONS

The technique described here has been uniformly successful, and highly so in repeat cases, regardless of the number of previous failures, as long as the urodynamic studies showed an element of active sphincteric musculature. Physiologic studies have confirmed the fact that the only failures were those in which severe intrinsic damage had been inflicted previously on the sphincteric mechanism by surgical repairs that had traumatized and scarred the urethral musculature. The extent of the damage is usually dependent on the techniques used initially. Excessive scarring and fibrosis create a rigid drain pipe that, whatever amount of support or elevation is provided, will never function as an active sphincter unit. There is no remedy possible in these cases except creation of obstruction by compression or slings. What was learned from these cases led to adoption of the technique described, by which one can avoid any close dissection toward the vesicourethral segment, thus sparing its delicate musculature from any surgical damage. From experience, I believe that adherence to these principles will result in the highest rate of success and the longest-lasting repairs.

# AUTOLOGOUS FASCIAL SLINGS

Edward J. McGuire and Linda Ng

### HISTORICAL BACKGROUND

Slings are relatively old procedures; they have in use sporadically since the turn of the last century.<sup>1</sup> Since the 1960s, slings have been used mainly to treat recurrent stress urinary incontinence (SUI) after one or more failed operative procedures and in reconstructive surgery on the urethra.<sup>2-4</sup> These applications of the sling technique developed because operative failure was common for traditional SUI procedures. Anterior repairs failed at least 50% of the time, a rate which led to adoption of the retropubic suspension as the standard operation for SUI. Although retropubic operations had better outcomes than anterior repairs, they also had high late failure rates.<sup>5</sup>

Autologous fascial slings used to treat incontinence that persists or develops after a prior retropubic or needle suspension operative procedure have relatively good outcomes.<sup>6</sup> Because good results were obtained in these cases and in other complex urethral reconstructive procedures performed with autologous slings, surgeons began using slings as a primary procedure for most patients with SUI. The introduction of slings made from synthetic materials was based on the realization that a sling provided superior support for the urethra. Early experience with synthetic slings was not good, but recent changes in materials used for slings have led to vastly improved results and dramatic decreases in the complications related to synthetic materials.

Uncomplicated primary SUI associated with urethral mobility can be very successfully treated with synthetic slings.<sup>7-9</sup> Some authors have suggested that synthetic material slings can be used for severe intrinsic sphincter deficiency (ISD) and even for neuropathic urethral dysfunction.<sup>10,11</sup> On the other hand, autologous fascial slings have an excellent record in reconstructive urethral surgery and in neuropathic urethral dysfunction, in which proximal urethral failure leads to severe incontinence.<sup>12-14</sup> In these cases, compression of the urethra by the sling is a requirement to reestablish urethral continence function. Synthetic materials do not allow much tension to be applied, because they tend to erode into the urethra if used in that manner. There are data suggesting that patients with ISD, defined by videourodynamics, do not do as well with synthetic material slings.<sup>15</sup>

### SPECIFIC INDICATIONS FOR AUTOLOGOUS PUBOVAGINAL SLINGS

#### Neuropathic Urethral Dysfunction

Neuropathic conditions are not always associated with urethral dysfunction, but specific neural conditions are associated with total absence, or loss of, proximal urethral function and severe SUI.<sup>16-18</sup> Prototypical proximal urethral failure occurs in myelodysplasia affecting the lumbosacral area; in sacral agenesis; after injury to the T12-L1 spinal cord segments, where the sympathetic

nerve supply to the urethra originates; and after peripheral pelvic neural injury, for example that sustained during extirpative surgery on the rectum or uterus. It can also occur in patients with pelvic fracture. All of these urethral conditions are associated with a neural lesion which almost always also produces decentralization of the bladder. The bladder is thus *areflexic*, but it is not *flaccid* by any means. The decentralized bladder reacts to volume increments, although the pressure developed is controlled by the magnitude of the outlet resistance associated with residual urethral closing function. That is, in an untreated situation, the bladder gains pressure related to incremental volume until the urethra leaks. Although the bladder can develop dangerously high pressures if the distal sphincter urethral resistance is high, proximal urethral function from the bladder outlet to the distal sphincter mechanism is simply lost. There is no function, reflex or static, in the proximal urethra. The urethra is open and stays that way (Fig. 36-1). This condition is associated with very low abdominal pressure-driven leakage from the urethra (Fig. 36-2). Leakage occurs with movement, transfers, coughing and straining, and the upright position.

Patients with proximal urethral and bladder decentralization after pelvic surgery preserve partial reflex and full volitional function of the distal sphincter. Partial preservation of reflex activity of the distal sphincter refers to the fact that sphincteric activity

**Figure 36-1** Upright cystourethrogram taken during a videourodynamics study from an 18-year-old male patient with a T12-L1 spinal cord injury. The patient has severe stress incontinence despite excellent bladder storage function and frequent intermittent catheterization. The patient is straining at the time of the exposure. Note the open proximal urethra and the leakage with stress at a total vesical pressure of 34 cm H<sub>2</sub>O.

**Figure 36-2** Upright cystourethrogram taken during a videourodynamic study from an 18-year-old female patient with a lumbosacral myelomeningocele. The proximal urethra is open and nonfunctional, and the Valsalva leak point pressure is 52 cm H<sub>2</sub>O. The image was taken at the onset of leakage associated with straining.

is no longer linked to detrusor behavior. There is no neural network to support that activity. Thus, relatively fixed urethral resistance is offered by the distal sphincter to detrusor pressure generated by incremental bladder volume. The latter is the result of constant urine production. Distal urethral closure does not mean that the urethra is stress competent, and severe SUI in men and women is the rule in these cases. Nevertheless, the distal sphincter closing function does require a certain detrusor pressure to induce leakage, and that can be a problem. This same situation occurs in the other causes of neuropathic urethral dysfunction, such as myelodysplasia and T12 spinal cord injury, although distal sphincter function is less well preserved in these cases.

A concrete risk of upper tract damage is related to the detrusor pressure at leakage.<sup>18</sup> Although any urethral resistance results in changes in detrusor storage behavior, this is dangerous if the outlet resistance approaches 40 cm H<sub>2</sub>O. That degree of outlet resistance leads to high ambient storage pressures that overwhelm ureteral peristaltic function. One example of this are the problems that developed in children with myelodysplasia treated with

**Figure 36-3** Videourodynamic study from a 34-year-old woman after a complicated urethral diverticulectomy. Leakage is gross and continuous. The urethra functions so poorly that there is no hold up of contrast in the urethra at all, only continuous leakage. There is an urethrovaginal fistula as well. The Valsalva leak point pressure is not measurable and is close to 0.

a bladder neck artificial sphincter. The device effectively raised both the detrusor and abdominal leak point pressure and was associated with upper tract deterioration.<sup>19</sup> Similar problems were associated with the Kropp urethral reimplantation procedure in children with myelodysplasia.<sup>20</sup>

The problem here is to gain closure of the proximal urethra without increasing the detrusor leak point pressure. Slings—either the standard posterior vector force sling, the fascial urethral wrap, or the crossover sling—increase the Valsalva leak point pressure substantially but change the detrusor leak point pressure either very slightly or not at all.<sup>4</sup> Therefore, these are safe procedures.

### Acquired Urethral Incompetence

Severe loss of proximal urethra function can occur after erosion of synthetic slings into the urethra, after urethral diverticulectomy, or in association with other types of urethral trauma, including surgery (Figs. 36-3 and 36-4). Acquired loss of proximal urethral function is associated with a very low abdominal leak point pressure but usually with little or no urethral mobility on an upright videourodynamic study. Erosion into the urethra after placement of synthetic slings or of donor fascia slings suspended with bone anchors can be associated with urethrovaginal fistulas that are difficult to recognize in the face of severe constant urethral urinary loss.

Very severe urethral dysfunction is also associated with chronic indwelling catheters, especially in patients with neurogenic conditions, in whom complete loss of closing function often occurs. In addition, complete or partial urethral erosion is associated with chronic catheterization (Fig. 36-5). These conditions are not effectively treated by synthetic material slings. Anterior urethral

**Figure 36-4** Image taken during a video study from a 42-year-old woman with severe continuous incontinence after a bone anchor cadaveric sling. There is continuous low-pressure leakage. The urethra is poorly functional, but the major problem is a high fistula involving the bladder neck and proximal urethra. The Valsalva leak point pressure cannot be accurately determined.

**Figure 36-5** Image taken during a videourodynamics study from a 72-year-old woman with a spinal cord injury treated for incontinence with a Foley catheter. There is no urethral function at all. The Valsalva leak point pressure is essentially 0.

erosion almost always destroys the bladder neck, in which case no sling procedure will be effective (Fig. 36-6).

Radiation therapy for cervical and other uterine malignancy can be associated with the late development of loss of reflex bladder function and severe ISD. Often, bladder compliance is very poor, and the urethra is fixed and immobile but poorly functioning. If bladder dysfunction can be controlled with the combination of an anticholinergic medication, a tricyclic antidepressant, and an  $\alpha$ -adrenergic blocking agent (for their effects on compliance) and the patient accepts intermittent catheterization, then a sling can be done to gain urethral competence. If the low-compliance bladder is not controlled before the sling procedure, the increase in urethral resistance associated with the sling leads only to more leakage at a higher detrusor pressure—not a good situation. In some cases, bladder function after prolonged catheter usage or late after radiation therapy is so poor that an augmentation cystoplasty must be done at the same time as the sling (Fig. 36-7).

Pelvic fractures can seriously disturb urethral support and function. Wide diastasis of the symphysis, associated with violent

**Figure 36-6** Upright video image from a 52-year-old woman with a neurogenic bladder treated for 5 years with a Foley catheter. There is no urethral function, and the posterior urethra is eroded into the vagina. The Valsalva leak point pressure is 0.

**Figure 36-7** Video image taken at 50 mL bladder volume from a 73-year-old woman with continuous incontinence. She had cobalt 60 irradiation for carcinoma of the cervix in the late 1960s. There is very low bladder compliance and very gross leakage. Most of the leakage is related to the bladder dysfunction, but that was determined only after the low-compliance bladder was treated.

pelvic trauma, disrupts the levator muscle attachments to the arcus and bony pelvis and thus the support of the vagina, urethra, and bladder (Fig. 36-8). Very severe SUI is often present in association with a lack of urethral and bladder support. Autologous fascial slings can work here, but the challenge is to find some solid tissue on which to anchor the sling, because the lower abdominal muscle and fascia often are poorly functional, widely separated, or simply gone in the suprapubic area.

Severe SUI that develops immediately after labor and delivery is often associated with profound loss of proximal urethral function (Fig. 36-9). This condition does not resolve with time. Abdominal leak point pressures are very low, and the urethra may or may not be mobile. Crossover slings work in these cases (see later discussion), but, if the urethra is very mobile, a standard posterior vector force sling may be a better option. Crossover slings provide good compression but are less effective at urethral support than a standard sling.

Severe SUI can follow cystectomy and orthotopic neobladder construction. No urethral function, as demonstrated on a videourodynamics study, is often compounded by poor reservoir storage function in the short term. Often, the severe, constant incontinence is treated by catheter drainage which exacerbates

**Figure 36-8** Very poor urethral function and gross leakage associated with a pelvic fracture. The urethra is not very mobile, but there is gross leakage at very low pressures.

**Figure 36-9** Low-pressure leakage with straining during a videourodynamics study. The Valsalva leak point pressure is 34 cm H<sub>2</sub>O. The patient is 27 years old and developed stress incontinence after a difficult labor and delivery. The incontinence did not improve with time.

the reservoir storage problem even after a continent urethra is reestablished with a crossover sling (Fig. 36-10).

Erosion of any kind of sling into the urethra mandates total removal. After that procedure, severe SUI is almost always present (Fig. 36-11). There may also be an urethrovaginal fistula. These

**Figure 36-10** **A**, Upright cystogram made during a video study from a 63-year-old woman with severe incontinence after a cystectomy and neobladder construction. She had continuous incontinence despite placement of a suprapubic catheter to achieve better drainage. Reservoir storage behavior is poor, with sustained pressures in excess of 60 cm H<sub>2</sub>O, but there is very little functional urethra, and there is severe stress incontinence as well. **B**, After removal of the suprapubic tube, medical therapy to achieve better reservoir storage function, and a sling procedure, there is no stress incontinence, and reservoir function continues to improve. The patient does intermittent catheterization and is troubled now only by nocturnal incontinence. At the time of this exposure, the total vesical pressure with straining was 124 cm H<sub>2</sub>O.

are complex reconstructive cases, and a crossover sling, in conjunction with closure of the fistula and reinforced with a Martius flap, is required to correct the problem.

#### **More Common Expressions of Stress Incontinence**

SUI associated with little or no urethral mobility and a low Valsalva leak point pressure is an indication for a sling of some kind (Fig. 36-12). We typically use autologous fascia for this condition, but other natural materials work just as well.

Recurrent or persistent SUI after a prior retropubic operation or sling procedure, where the urethra is well supported but leaks at a low pressure, is a relative indication for an autologous fascial sling, because compression of the urethra is usually required to regain continence. It may be advantageous in those cases in which a prior sling procedure has been done to use a crossover sling. These slings provide compression with fewer tendencies to cause retention. A midline approach to the retropubic space can be used to avoid the scarring related to prior surgery lateral to the urethra. This is a different situation than that encountered after a Burch-type retropubic suspension, in which there is scar-

ring and fixation of the bladder to the symphysis. An approach to the retropubic space lateral to each rectus muscle is the best route to avoid scarring associated with the prior procedure. Bone anchor fascial or donor dermal slings create a dense band along the posterior surface of the symphysis, usually well lateral to the midline, so that a midline approach between the rectus muscles is generally the best route.

In primary SUI conditions associated with urethral hypermobility and urethral mobility, autologous fascia can be used, but other materials work very well and may be less troublesome in terms of retention and pain. Sling patients usually are discharged on the first postoperative day, but most patients receiving synthetic slings are discharged on the day of surgery; most of the latter group will not require intermittent catheterization, whereas most autologous sling patients will.

The primary advantages of autologous fascia are nonreactivity, a lack of influence of growth on sling function when used in adolescents and children, and tissue tolerance for considerable applied tension. Spontaneous erosion of autologous fascia slings has been described but is rare.<sup>21</sup> In my experience, this occurs only in association with traumatic catheterization in which the

**Figure 36-11** Severe stress incontinence after a prior sling-type procedure. The Valsalva leak point pressure is 54 cm H<sub>2</sub>O. The proximal urethra is open at rest. This image was made during straining.

**Figure 36-12** Valsalva leak point pressure from a 45-year-old woman 1 year after a cadaveric sling procedure. There is gross leakage at a vesical pressure of 13 cm H<sub>2</sub>O during straining. There is a small urethrovaginal fistula as well.

catheter tip actually penetrates the urethra, exposing the sling. A short period of catheter drainage assures healing without sling resection or removal.

### OPERATIVE PROCEDURE

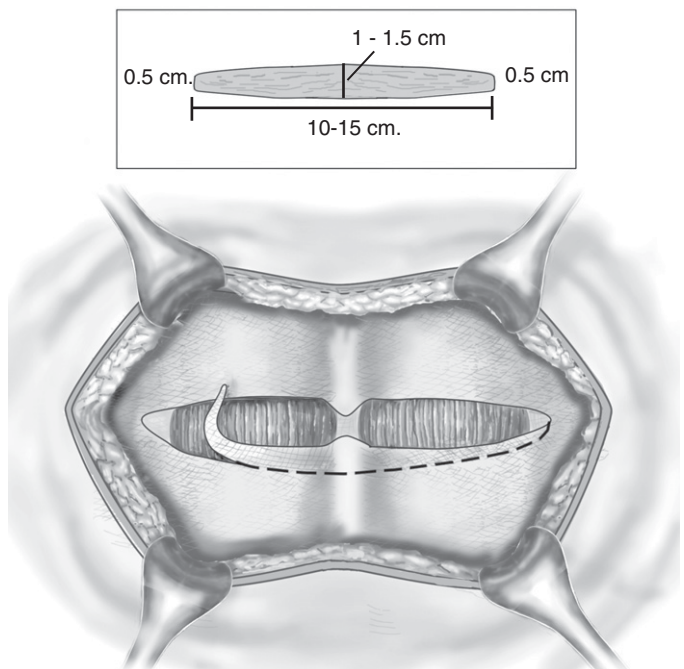

Preoperative antibiotic prophylaxis is started 1 hour before the patient enters the operating room. The nursing staff teaches the patient self-catheterization well before the procedure. The choice of anesthetic is usually left to the patient and the anesthesia staff. Either spinal or general anesthesia with an endotracheal tube or a laryngeal mask is satisfactory. The procedure takes about 35 minutes unless there are problems. Problems include obesity, prior surgery on the bladder or urethra, pelvic fracture, neobladder construction, and fistula formation, among other things.

### Positioning

We use Yellowfin stirrups and place the patient in lithotomy position. For the primary part of the operation, we lower the stirrups to provide better access to the retropubic space.

### Suprapubic Approach

A transverse suprapubic incision is made just above the symphysis. The dissection is carried to the rectus fascia, which is opened. The fascia is mobilized off the rectus muscles, and the sling is taken from the inferior leaf of rectus fascia (Fig. 36-13). The sling measures 6 to 9 cm long; about 1.5 cm wide in the center; and about 0.7 cm wide at either end. The sling is oversutured at each

**Figure 36-13** The sling is harvested from the lower leaf of the fascial incision. The fascial incision runs to the lateral border of the recti muscles. (Adapted from Hurt WG [ed]: *Urogynecologic Surgery*. New York: Raven Press, 1992.)

**Figure 36-14** Entering the retropubic space from below. The scissors are kept flat and parallel with the perineum. (Adapted from Hurt WG [ed]: *Urogynecologic Surgery*. New York: Raven Press, 1992.)

end with 1-0 polyglactin suture material. Several bites are taken, and the sutures are tied down, but the ends are left full length. The sling is placed in saline solution.

Depending on the circumstances, one of two approaches to the retropubic space is used. If there has been prior surgery in the midline area of the retropubic space (e.g., a Burch urethropexy, one of the needle suspensions), a lateral approach is used. Just lateral to the insertion of the rectus muscle on the symphysis, the transverses abdominis fascia is opened sharply, and blunt, gentle, finger dissection used to develop the retropubic space down to the endopelvic fascia on either side of the urethra. This can be difficult but usually is not. If our procedure follows a synthetic sling, a cadaveric fascial sling, or other type of sling procedure in which retropubic bone anchors have been used, an approach between the rectus muscles is safer and stays away from the scarring and other problems related to the prior operations. The rectus muscles are gently separated, and the bladder is pushed gently posteriorly off the symphysis right down to the urethra.

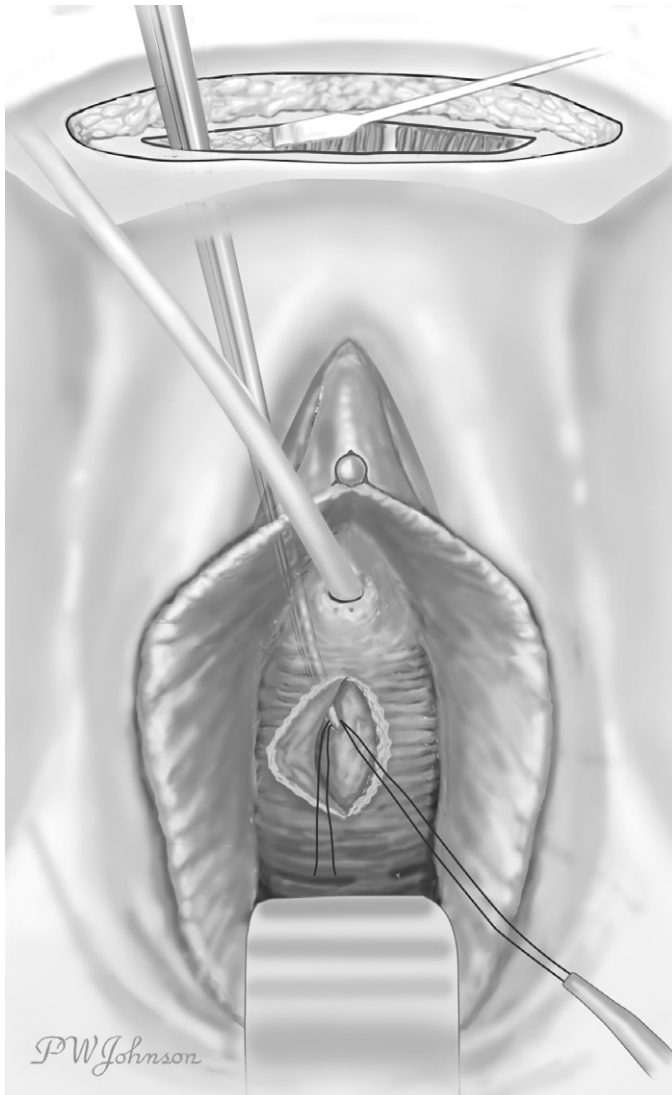

At this point, the abdominal wound is covered, the legs are flexed more at the hip, and a vaginal retractor is placed. A 16-Fr Foley catheter is used to aid the dissection and keep the bladder empty. An inverted U-shaped vaginal incision is made, and the

**Figure 36-15** Passing the clamp down the tunnel. (Adapted from Hurt WG [ed]: *Urogynecologic Surgery*. New York: Raven Press, 1992.)

vagina is carefully dissected off the periurethral fascia. The periurethral fascia should not be entered, because doing so causes brisk bleeding. The dissection is continued until the upper two thirds of the urethra is visible. Starting in the superior corner of the U incision, an entry plane is made with dissecting scissors lateral to the urethra into the retropubic space (Fig. 36-14). This requires only very gentle dissection. The entry point through the tissue lateral to the urethra into the free retropubic space is kept small. Under bimanual control, an instrument (a Crawford clamp, a Bard Ligature Carrier, or the like) is passed from above down into the vagina (Fig. 36-15). It is most important to keep the instrument tip on the symphysis during passage.

The sling sutures are then grasped and passed up into the abdomen (Fig. 36-16). After the tension of the sling is checked, the sling sutures are passed through the lower fascial leaf and tied (Fig. 36-17). If passage from above is difficult or the operator senses that the bladder is in the path of the instrument, then passage from the vagina upward into the suprapubic incision is safer. Under vision, the instrument is placed in the dissection

**Figure 36-16** Grasping the sling sutures before passing them up into the abdomen. (Adapted from Hurt WG [ed]: *Urogynecologic Surgery*. New York: Raven Press, 1992.)

plane lateral to the urethra and advanced to the endopelvic fascia and held there. The vaginal retractor must be removed at this point, so that the proper angle of the instrument can be achieved. The instrument should be in a periosteal plane on the posterior surface of the symphysis at all times. The angle upward is steep to achieve this plane, and the vaginal retractor is always in the way. The technique is a little cumbersome, in that the sling has to be pulled down from above after the first passage and then loaded on the instrument for transfer to the contralateral side,

**Figure 36-17** Checking the tension of the sling. The sling sutures are passed through the lower fascial leaf and tied. The fascial incision should be closed before the knot is tied. (Adapted from Hurt WG [ed]: *Urogynecologic Surgery*. New York: Raven Press, 1992.)

but in cases where there is no free retropubic space, it is safe. We use this technique, for example, when doing slings in women with incontinence related to urethral dysfunction after cystectomy and neobladder construction in whom there is no free retropubic space at all in any plane lateral or medial.

# USE OF CADAVERIC FASCIA FOR PUBOVAGINAL SLINGS

*Neil D. Sherman and George D. Webster*

The pubovaginal sling (PVS) is a popular and successful treatment for female stress urinary incontinence whether due to urethral hypermobility or intrinsic sphincter deficiency. There are many variations for this procedure, and techniques have changed since it was first introduced in 1907<sup>1</sup> and then later resurrected by McGuire and Lytton.<sup>2</sup> Over the last two decades, there have been many modifications in technique, and even the supposed underlying principle of function has changed. Historically, the mechanism by which the PVS was thought to work was to provide support and prevent urethral descent during increases in intra-abdominal pressure and to provide a backstop against which urethral compression would occur. The “new era” slings, positioned at the mid-urethra, are suggested to function by providing a point of support about which distortional “obstruction” occurs during stress.

Other variables aside, the debate about the most appropriate material for sling construction remains heated. There are proponents for each of the various alternatives, which include autologous, allograft, xenograft, and synthetic materials. Although current literature emphasizes the minimally invasive approach using synthetic materials, it is important that surgeons performing this procedure be versed in other options, because the individual patient may have an indication or contraindication for use of any one of these materials.

The ideal graft material would be durable, inexpensive, and readily available; could be obtained without the need for harvesting with its associated morbidity; and would not be susceptible to infection, immune reaction/rejection, or erosion. Unfortunately, no material meets all of these criteria. Historically, the autologous PVS was fashioned from the fascia lata or, less commonly, from the abdominal wall fascia, and it is with these that other nonautologous alternatives should be compared.

This chapter concentrates on the use of one of these alternatives, the human cadaveric (allograft) fascia.

### PATIENT SELECTION

The specific criteria for those patients who are candidates for PVS placement are well described elsewhere in the text. Essentially, all patients undergo a thorough urogynecologic history and physical examination before any form of surgical intervention. We require a positive stress test during physical examination or demonstration of stress incontinence during urodynamic study, in addition to the patient’s history, before acknowledging the existence of stress urinary incontinence. We also use a 3-day bladder diary, a 24-hour pad weight study, and videourodynamic evaluation before proceeding with surgery. If pelvic organ prolapse is present, we routinely repair it simultaneously.

### GRAFT SELECTION

Of the various factors that may influence the selection of graft material it is probably true to say that the major influence comes from physician philosophy and patient preference, each of which may be uninformed.

### Cadaveric Fascia

The successful use of cadaveric fascia has been described in the orthopedic and ophthalmologic literature for many years,<sup>3,4</sup> and the use of allograft fascia for PVS surgery was first reported in 1994.<sup>5</sup> Currently in the United States, more than 90,000 soft tissue allografts are used annually.<sup>6</sup> These tissues are harvested, processed, preserved, and distributed by certified tissue banks that comply with the policies of the American Association of Tissue Banks.

The benefits of allograft fascia over autologous fascia include shorter operative time and hospital stay, lower morbidity, and less postoperative pain.<sup>7-10</sup> Potentially, the cadaveric fascia might also be superior to the patient’s own fascia, because the latter may be collagen deficient, which may be a cause for the original support deficiency. It has been reported that the theoretical mechanism of action of the allograft fascia is to serve as a scaffold for the in-growth of host tissues, ultimately leading to replacement of the allograft collagen with host collagen.<sup>11</sup> However, in many cases in our experience with exploration years after the original surgery, these grafts usually have maintained their integrity and show little evidence of “incorporation” by the host.

### PROCESSING OF FASCIA

The preparation of cadaveric fascia is a multistep process. It begins with the medical and social screening of a potential donor, using information provided by the potential donor’s family and physician. Next comes testing of the potential donor’s blood with tests approved by the U.S. Food and Drug Administration (FDA) to rule out AIDS, hepatitis B and C, human immunodeficiency virus (HIV) types 1 and 2, and syphilis.<sup>12</sup>

After completion of the screening step, the fascia is harvested with aseptic technique and processed to remove all cells and DNA, thus further decreasing the risk of disease transmission while maintaining the native collagen/protein framework. Ideally, the fascia should be harvested from within 2 cm of the iliotibial band, because only this location has the integrity for graft strength and durability. Processing and decellularization techniques vary, but all maintain a common theme that requires incubation in

70% isopropyl alcohol or other bactericidal and antiviral solutions to remove any viruses.

The tissue is then dehydrated via deep-freezing (lyophilization) or with organic solvents. The fascia may then undergo gamma irradiation. Radiation dosage is not standardized, and it is suggested that doses greater than 25,000 Gy (2.5 Mrads) may increase tissue weakening.<sup>13</sup>

Despite these preparation techniques, intact genetic material has still been found in final allografts.<sup>14,15</sup> Whether this isolated DNA has the ability to replicate or to transmit infectious material remains to be seen. Explanations for failure of disease transmission include an unclear mode of pathogen transmission, an unidentified pathogen, and a window of time before a donor seroconverts with positive antibody (e.g., HIV testing).<sup>14</sup> Of course, the donors may simply have been free of transmissible disease.

Fitzgerald and colleagues showed that allografts retain donor antigens after processing but that ultimately host antigens replace donor antigens after implantation.<sup>16</sup> Because donors and recipients are not cross-matched, and graft rejection does not appear to be a problem, the identification of donor antigens in a graft is of questionable clinical significance.

### Effect of Preparation on Fascia Strength

Tissue banks differ in the method used for graft preparation, and researchers have attempted to determine which process is associated with improved outcomes. However, outcomes are influenced by many other patient variables that are rarely included when these analyses are considered. Not surprisingly, therefore, the results have been conflicting. Sutaria and Staskin compared freeze-dried, freeze-dried/gamma-irradiated, and solvent-dehydrated/gamma-irradiated fascias and found no statistical differences in maximum load and thickness-adjusted maximum load.<sup>17</sup> However, Lemer and coworkers found that freeze-dried allograft had inferior mechanical properties compared with autologous fascia or solvent-dehydrated fascia.<sup>18</sup> Hinton and associates compared solvent-dehydrated/gamma-irradiated fascia with freeze-dried/nonirradiated fascia and found a higher stiffness, higher maximum load to failure, and higher maximum load per unit width of graft with the former.<sup>19</sup>

The cause of the potential differences in various fascia preparations is unclear and also is of questionable significance. A possible explanation for the difference between freeze-dried and solvent-dried fascia is that ice crystal formation during the freeze-drying process may weaken the collagen structure in the fascia.<sup>18</sup> Of note, the forces generated in studies measuring fascial strength are usually much greater than the physiologic forces created at the bladder neck and proximal urethra. This raises the issue that *ex vivo* strength is not the only variable necessary for success with an allograft fascia PVS. Lin and colleagues attempted to confirm this suspicion, showing that, with the patient in a horizontal and mild tilt position, the tension placed on the sling was far less than that necessary to break the fascia.<sup>20</sup> Finally, but most importantly, the variability of fascial thickness is not addressed in any of these studies.

### Risk of Disease Transmission

The prevention of disease transmission focuses on the areas of screening and sterilization. Since 1985, when the American Association of Tissue Banks began requiring the screening of prospec-

tive donors and testing of tissue for viruses, there have been no documented cases of HIV transmission.<sup>21</sup> Other extensive reviews have not identified a single case of disease originating from transplanted allograft fascia.<sup>22</sup>

However, there remains concern about the transmission of prions, the causative agent of Creutzfeldt-Jakob disease (CJD) and other forms of spongioencephalopathies. It is estimated that, with current methods of processing, the theoretical risk of a patient's developing CJD from an allograft is 1 in 3,500,000. This is significantly lower than the 1 in 10,000 to 1 in 100,000, overall risk in the general population of "naturally" acquiring the disease.<sup>23</sup>

Current FDA guidelines contain recommendations to exclude donors of tissue (musculoskeletal, ocular, integumental) who are diagnosed or have risk factors for tissue spongioencephalopathies, specifically classic CJD. However, current FDA regulations for human tissue do not address tissue spongioencephalopathies.<sup>24</sup> In an FDA guidance to industry on screening and testing donors of human tissue intended for transplantation, the agency recommends that the donor medical history screening interview should include questions to defer potential donors with a diagnosis or a known family history (blood relative) of CJD and those who have received human pituitary growth hormone or dura mater transplants.<sup>24</sup> Additionally, in 2002, the FDA updated a policy that would defer from blood donation anyone who spent three months or more cumulatively in the United Kingdom between 1980 and 1996.<sup>25</sup> This was done to help reduce the possible risk of transmission of CJD by blood and blood products. There have been no reports of transmission of CJD through transplantation of human tissues.<sup>26</sup>

### Intraoperative Fascia Preparation

Intraoperative preparation varies with each specific tissue bank recommendation. Common among all fascias is reconstitution by soaking in room-temperature saline for at least 20 minutes before placement. Additionally, the fascia must be folded over and figure-of-eight or horizontal mattress sutures used to prevent sutures' "pulling through" the longitudinally arranged collagen fibers.<sup>17,27</sup> The fascia should be pulled/distracted to confirm adequate tensile strength.<sup>28</sup>

Ideally, the fascia should be of sufficient length (at least 12 to 14 cm) to pass under the urethra and through the endopelvic fascia bilaterally. This allows the ends of the sling to scar into the retropubic space, thus improving its fixation.<sup>29</sup>

### SURGICAL TECHNIQUE

Surgery is performed under spinal or general anesthesia with the patient in the lithotomy position. Sequential compression hose and padded leg stirrups improve the safety of this position, especially if surgery is prolonged. After surgical preparation, a 16-Fr urethral catheter is inserted, and the balloon is used to identify the location of the bladder neck, which is marked on the vaginal epithelium with a marking pen. A midline vaginal wall epithelial incision or bilateral incisions centered at the bladder neck allow the vaginal epithelium to be dissected from the underlying pubocervical fascia. We prefer the latter technique, because it allows for creation of a tunnel for the sling beneath the bladder neck (Fig. 37-1), helping to prevent cephalad or caudal migration when the sling is tensioned.

**Figure 37-1** Sharp dissection of the subepithelial tunnel beneath the bladder neck for later passage of the sling.

If repair of a central defect cystocele is also required, a midline vaginal incision from the mid-urethra to the vaginal cuff is always used. With the bladder empty, the urethropelvic ligament is perforated bilaterally with scissors. The location of the hiatus should be at its lateral attachment to the inferior ramus and at the level of the bladder neck. The hiatus allows access to the retropubic space, which may then be dissected digitally, freeing the bladder from the symphysis pubis to create a space for the sling to traverse the retropubic space through the endopelvic fascia.

A 2-cm transverse midline abdominal skin incision is made down to the superior surface of the symphysis pubis. A double-pronged Pereyra ligature carrier (Cook Urological Inc., Spencer, IN) is then passed through the rectus fascia directly behind the pubic symphysis and lateral to the proximal urethra, with the needle tips emerging through the vaginal wall hiatus. This needle is digitally guided along its course from the rectus fascia to the vaginal hiatus by keeping the needle on the tip of a finger passed through the vaginal wall hiatus.

The ends of the allograft sling are transfixed and bound with a 0-0 Vicryl suture (polyglactin suture material; Ethicon Inc., Johnson & Johnson, Somerville, NJ) (Fig. 37-2). A 1-0 Prolene suture (polypropylene suture material; Ethicon Inc.) is placed through the bound ends (see Fig. 37-2). The free ends of the Prolene suture are attached to the ligature carrier and transferred across the retropubic space and out through the suprapubic incision. The opposite end of the sling is passed through the previously dissected tunnel and across the opposite retropubic space in a similar fashion. Sling tension is adjusted according to the requirements of the individual case, but usually, if there is sufficient urethral hypermobility, it is held away from the bladder neck (Fig. 37-3) as the Prolene suture on each side of the sling is

**Figure 37-2** Transfixion binding of the sling ends with 0-0 Vicryl prevents "pull out" of the suture.

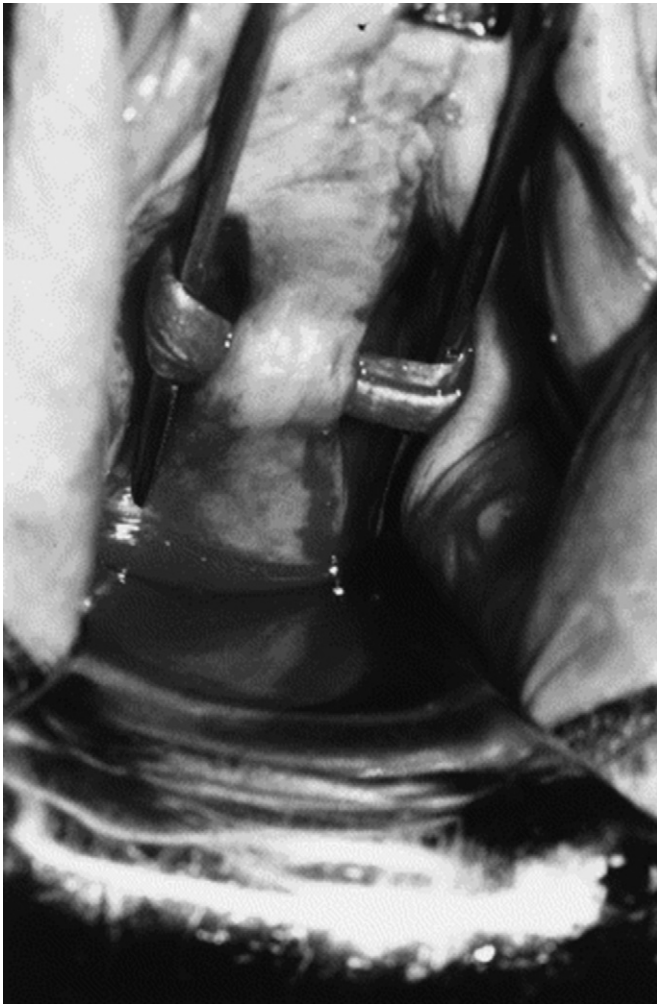

tied first over the rectus fascia and then the right side is tied to the left. Indigo carmine may then be given intravenously and cystoscopy performed to exclude bladder or ureteral injury and to confirm correct sling placement and tension. Visualization of free urine flow with the Crede maneuver and a full bladder confirms that the sling has not been made too tight. The vaginal incisions are then closed with 4-0 absorbable suture. A vaginal pack and suprapubic tube are usually unnecessary.

#### WHAT HAPPENS TO THE FASCIA IN FAILED CASES

Results using allograft fascia are mixed, and some authors have suggested that failure of allografts, as opposed to autologous fascia, may be due to problems with the material itself.<sup>30</sup> In hope of determining the validity of this belief, studies have been performed on cadaveric fascia in animal models and on fascia identified during re-explorations.

Dora and colleagues used a rabbit model to show that human cadaveric fascia tensile strength decreased up to 80% and stiffness decreased by 90% at 12 weeks; autologous fascia and polypropylene mesh did not have significant change in tensile strength or stiffness over the same time period.<sup>31</sup> In a rat model, Kim and associates found that cadaveric fascia decreased in toughness over 4 months.<sup>32</sup> Walter and coworkers also showed a decrease in tensile strength of the fascia after it was implanted in a rabbit vagina model for 12 weeks.<sup>33</sup> The clinical implications of these findings remain unclear.

Multiple authors have commented on the appearance of cadaveric fascia slings at the time of re-exploration. Fitzgerald explored 12 women who had received irradiated, freeze-dried grafts and found graft tissue in only 7 of them. The grafts showed an immune reaction and areas of disorganized remodeling and

**Figure 37-3** The sling is held away from the bladder neck as the sutures are being tied.

graft degeneration. It is unclear whether this is a normal host response, because none of the patients who experienced success underwent reoperation.<sup>10</sup>

Huang and associates reoperated on one patient after cadaveric fascia PVS and found the graft to be very friable. Histologic examination showed loosely packed fibroblasts with wavy collagen fibers and focal areas of edema and degenerative changes.<sup>30</sup>

Blander and Zimmern explored five “failed” cadaveric fascial slings and, on microscopic examination of the removed cadaveric fascia, found collagen with almost complete absence of cellularity and no evidence of capillary in-growth or rejection.<sup>34</sup>

Ultimately, the explanation for failure of some allografts remains unclear. Possibilities are many and include a persistent level of antigenicity,<sup>35</sup> an unsuitable environment for the allograft,<sup>30</sup> contamination by vaginal flora, host-versus-graft reaction, and undue stress on the graft.<sup>36</sup>

## RESULTS

During the middle to late 1990s, the enthusiasm for cadaveric fascial slings increased as allograft tissue became more widely available. The shortened operative time and decreased morbidity (due to the lack of a donor site) combined with longer-term follow-up increased the frequency with which the procedure was performed. Although minimally invasive techniques with synthetic material have increased in popularity over the last few years, it is important for the pelvic surgeon to maintain cadaveric fascia placement in the surgical armamentarium.

The outcomes for allograft fascia vary among authors (Table 37-1). Huang and associates showed a failure rate of 28% with recurrent incontinence within 6 months of surgery.<sup>30</sup> Fitzgerald and colleagues identified a greater than 20% material failure rate for freeze-dried, irradiated fascia.<sup>36</sup> In contrast, Amundsen and other showed an 87% satisfaction rate for freeze-dried, non irradiated fascia.<sup>27</sup> Elliot and Boone evaluated their experience with

**Table 37-1** Outcomes of Cadaveric Fascia Pubovaginal Slings

First Author and Ref. No.	Processing Method	N	Follow-up, Mean (mo)	% Improved (0-2 pads/day)	% Cure (0 pads/day)
Handa <sup>5</sup>	Freeze-dried, -IR	16	12	85	79

IR, gamma irradiation.

cadaveric fascia and found a 96% satisfaction rate with a mean follow-up of 15 months.<sup>29</sup> Walsh and coworkers showed complete resolution of stress urinary incontinence in 93% of patients at a mean follow-up of 13.5 months.<sup>37</sup>

## CONCLUSIONS

Allograft fascia for PVS offers decreased morbidity and operative time, compared with autologous fascia, while limiting the risk of

erosion and infection seen with synthetic material. Although appropriate screening has essentially removed the risk of disease transmission, the technique to process the fascia remains variable. With success rates similar to those seen with autologous fascia, allograft fascia offers the surgeon another material available for the treatment of stress urinary incontinence in women. Further investigations are needed to determine the most durable method of preparation.

# FASCIA LATA SLING

*Neil T. Dwyer and Karl J. Kreder*

Pubovaginal sling cystourethropexy is considered one of the gold standards of female stress urinary incontinence (SUI) surgery. The bladder neck sling can be performed using autologous, allograft, or synthetic material. The two autologous methods use either rectus or fascia lata fascia. This chapter summarizes the literature on the indications, surgical technique, and outcomes of using fascia lata to treat female SUI.

### HISTORY

The autologous sling used to affect the urethra as a method of urinary control was first mentioned in 1907 by Von Giordano, who described the use of gracilis muscle to wrap around the urethra.<sup>1</sup> The pyramidalis muscle was used to suture behind the urethra by Goebell in 1910.<sup>2</sup> Squier referred to the use of the levator ani muscles to augment bladder outlet resistance.<sup>3</sup> In 1942, Aldridge described the use of bilateral strips of rectus fascia passed inferiorly through the rectus abdominis muscles to support the urethra posteriorly.<sup>4</sup> In 1978, McGuire and Lytton described using an autologous fascial sling in 52 patients with SUI.<sup>5</sup> Forty-two of the patients had had previous corrective incontinence surgery. Postoperative urethral pressure measurements showed urethral pressure increase but no occlusion. Fifty patients had a successful outcome, and there were 2 failures. These results were further confirmed by Blaivas and Jacobs in 1991, when they observed 67 patients who had undergone a pubovaginal fascia sling repair and reported that 82% were completely dry and 9% were dramatically improved.<sup>6</sup>

The fascia lata sling was first described by Price in 1933.<sup>7</sup> Beck and colleagues examined the use of fascia lata as a suburethral sling for the treatment of recurrent urinary incontinence.<sup>8-10</sup> They first described the use of the fascia lata sling in 1974<sup>8</sup> and in 1988 reported their results in 170 patients.<sup>10</sup> They used the fascia lata suburethral sling after failed primary incontinence surgery in 69 cases and after multiple failed prior anti-incontinence repairs in 101 cases. The overall success was reported at 98.2%.<sup>10</sup>

Cadaveric fascia lata (CFL) has been used to repair tissue defects for a number of years, but its first use for incontinence surgery was reported in 1996.<sup>11</sup> Handa and colleagues used CFL in 16 patients, 14 with genuine SUI and 2 who had a previously placed synthetic graft that became infected. Eighty-eight percent were subjectively improved, and 79% of the patients with genuine SUI were objectively improved.<sup>11</sup>

The use of xenograft material for sling surgery has been reported as well. In 2002, a pilot study examined the use of bovine pericardium placed as a suburethral sling in 22 females.<sup>12</sup> At 20 months, 21 of 22 patients were cured with no incidences of erosion or rejection. Another study recently looked at the use of processed porcine small intestine submucosa (SIS) as a pubovagi-

nal sling in 152 female patients with SUI.<sup>13</sup> In this 4-year series, there was a 93.4% cure rate, with three additional patients demonstrating marked improvement. There was no erosion, infection, or rejection in the group.

Synthetic materials have been used for incontinence since 1961, with the use of nylon strips fashioned into a suburethral sling.<sup>14</sup> Numerous materials have been tried since then, including Silastic,<sup>15</sup> Gore-Tex,<sup>16</sup> Mersilene,<sup>17</sup> Marlex,<sup>18</sup> Prolene,<sup>19</sup> and Vicryl.<sup>20</sup>

### INDICATIONS

The indication for the use of a fascia lata sling can be stated simply as SUI. At first, fascia lata slings and suburethral slings were recommended for complicated SUI such as previous SUI corrective surgery and intrinsic sphincter dysfunction (ISD). Type 2 SUI was usually treated with a needle suspension or colposuspension, such as a Burch procedure. This stemmed from the progression in the development of various surgeries for the correction of SUI.

ISD has been associated with multiple etiologies. The presence of previous SUI corrective surgeries is a risk factor. A neurologic insult to the sacral area may result in compromise of the bladder's innervation and ISD. This insult could come from damage to the nerve roots as they leave the spine or via major pelvic surgery such as a radical hysterectomy. In addition, patients with diabetic neuropathy may also have peripheral neurologic problems interfering with sphincter function. Patients who have undergone previous radiation treatment are at risk of developing ISD-based SUI.<sup>21</sup> Another possible cause of ISD is estrogen deficiency: as women age, lower levels of estrogen may predispose to ISD.<sup>22</sup> Horbach and Ostergard examined 263 consecutive patients with urodynamic studies for urinary leakage.<sup>23</sup> In this population, 132 women had ISD, defined as urethral closure pressure lower than 20 cm H<sub>2</sub>O, and the only independent risk factor for ISD was age greater than 50 years.

ISD is classically diagnosed using video urodynamics, which shows an open bladder neck at rest. In addition, a low Valsalva (abdominal) leak-point pressure (VLPP) is seen (<60 cm H<sub>2</sub>O) in patients with ISD. Incontinent women with a VLPP greater than 90 cm H<sub>2</sub>O usually have type 2 SUI according to fluoroscopic assessment.<sup>24</sup> There is also correlation between worsening SUI subjective symptoms and a lower VLPP.<sup>25</sup> Urethral pressure profilometry has been used to define SUI in women. Weber performed an extensive review of published articles using urethral pressure profilometry and found the technique to be nonstandardized and poorly reproducible.<sup>26</sup>

The recommendations from the American Urological Association clinical guidelines panel summary report published in 1997

suggested that the standard patient should be informed about the four major surgical correction categories: retropubic suspension, transvaginal suspensions, anterior repairs, and sling surgeries.<sup>27</sup> According to the panel, the patient should understand that retropubic suspensions and sling surgeries carry a higher complication rate along with their higher rate of longer-term cure. The panel suggested categorizing patients as having urethral hypermobility, ISD, or both, although they acknowledged that there was no standardized method to make this diagnosis. These recommendations decreased the popularity and use of needle suspensions and anterior repairs as treatment options for women with SUI. In May 2007 the Urinary Incontinence Treatment Network, led by Albo and colleagues, published a large randomized study to examine the differences between a Burch colposuspension and an autologous fascial sling.<sup>28</sup> Six hundred fifty-five women were randomized to either the Burch or a fascial sling and followed for 24 months with standardized assessments. Seventy-nine percent of the women completed the assessments. Success rates were higher for the women who underwent the sling procedure versus the women who had a Burch (47% vs. 38%,  $p = 0.01$ ). Specific to stress incontinence, there was a 66% success rate in the sling group whereas the Burch group had a 49% success rate. Complications were higher in the sling group, with more urinary tract infections, voiding difficulty, and postoperative urge incontinence. Performance of prolapse repair with the stress incontinence surgery did not affect the outcomes between the groups.

This study demonstrates a significantly higher success rate with an autologous fascial sling versus a Burch colposuspension at only 24 months. The increased complications need to be considered in the decision-making process as well.

The recommendation to apply a particular surgery depending on the type or degree of SUI was suggested by Sand and associates in 1987.<sup>29</sup> They found a 54% failure rate in patients who underwent a Burch procedure and who had a mean urethral closure pressure (MUCP) lower than 20 cm H<sub>2</sub>O, whereas the patients with a MUCP greater than 20 cm H<sub>2</sub>O had an 18% failure rate. Koonings and coworkers compared 19 women with SUI and low urethral pressure to 106 patients with SUI and a normal urethral pressure.<sup>30</sup> The patients underwent a modified Pereyra procedure or a Burch colposuspension. The women with low urethral pressure preoperatively had a higher failure rate, regardless of the surgical procedure used, compared to patients with normal urethral pressure profilometry. These data suggest the limitations of colposuspension and needle suspensions but do not limit the indication of the pubovaginal sling.

Several studies have examined the use of pubovaginal slings in groups of female patients with type 2, type 3, or a combination of both SUI types. Kreder and Austin examined 28 female patients with SUI.<sup>31</sup> Eleven had ISD alone, and 16 had a combination of urethral hypermobility and ISD. The diagnostic definitions were obtained with the use of multichannel video urodynamics. ISD existed if the VLPP was lower than 60 cm H<sub>2</sub>O and the bladder neck was open at rest. Urethral hypermobility was defined via a pelvic examination with the patient performing a Valsalva maneuver and a cough. Overall, the patients in the sling group (17 with rectus fascia and 11 with fascia lata) had a 70% dry rate at an average of 22 months. The patients with ISD alone did poorly, with a 55% dry rate, whereas the patients with combination type 2/3 SUI had an 81% dry rate. One patient in the ISD group had a complete surgical failure.

In another study, by Zaragoza, 60 consecutive female patients with SUI were examined with multichannel video urodynamics.<sup>32</sup>

ISD was defined in 22 patients, who had a VLPP lower than 60 cm H<sub>2</sub>O (mean, 42 cm H<sub>2</sub>O), and 38 patients diagnosed with type 2 SUI had a mean VLPP of 95 cm H<sub>2</sub>O. At an average of 25.1 months after a rectus fascia pubovaginal sling procedure, 95% of the patients were completely continent. The three failures were due to urgency incontinence, which was present in all three patients preoperatively. The success rate was almost identical between the patients diagnosed with type 2 and those with type 3 SUI.

Finally, Cross and colleagues examined a large group of female patients diagnosed with SUI, all treated with a rectus fascia pubovaginal sling.<sup>33</sup> There were 134 patients who were contacted at an average of 22 months after surgery, and their initial diagnosis was type 2 SUI (45 patients), type 3 SUI (73 patients), or a combination of both (16 patients). The overall dry rate was 93%, as confirmed by video urodynamics: 96% of the type 2 patients, 89% of the type 3 patients, and 100% of the type 2/3 patients.

All three of these studies included patients who had had prior SUI surgery, patients with concomitant procedures, and patients with simple SUI (pure SUI, plus or minus urge urinary incontinence). These studies demonstrated the ability to use the pubovaginal sling in women with type 2 and/or type 3 SUI.

#### CHOICE OF FASCIA LATA SLING AND SOURCE

Autologous rectus and fascia lata are commonly used for pubovaginal slings as well as allogenic fascia. The advantage of autologous material is the lack of potential disease transmission and low erosion rates. Fascia lata offers advantages over rectus fascia such as greater tensile strength and lack of abdominal wall hernias related to graft harvest; moreover, it is rare that the patient's past surgical history would interfere with harvesting of a long strip of fascia lata.<sup>34</sup> The harvesting of autologous fascia adds operative time and possible morbidity to sling surgery, compared with synthetic and allograft fascia sources.

Allograft fascia lata is from a cadaveric source and has been used in sling surgery since 1996.<sup>35</sup> There is a theoretical advantage for the use of CFL compared with a synthetic source in that there is a lower risk of erosion, whereas the disadvantage is a chance of disease transmission.<sup>36</sup> Choe and Bell examined 16 allograft sources of tissue, including 8 freeze-dried gamma-irradiated CFL allografts.<sup>37</sup> Fourteen of the allografts contained DNA material, as determined from standardized DNA extraction techniques. FitzGerald and colleagues found donor antigens still present in CFL prepared via the freeze-dried and the Tutoplast techniques.<sup>38</sup> Hathaway and Choe took four commercially available human cadaveric allografts and subjected 10 of each type to DNA extraction. Thirty-nine (97.5%) of the allografts contained DNA with variable amounts.<sup>39</sup> The significance of the presence of DNA and antigens in the allograft material is unknown. The risk of contracting Creutzfeldt-Jacob disease from allograft material is approximately 1 in 3.5 million,<sup>40</sup> and the risk of human immunodeficiency virus (HIV) transmission is estimated to be 1 in 8 million.<sup>41</sup>

CFL is mainly made via two techniques: solvent dehydration with gamma irradiation (Tutoplast) or freeze-drying (tissue banks and FasLata). Both of these preparations require 15 to 30 minutes to rehydrate in saline before implantation.<sup>36</sup> A study by Lemer and associates examined the tensile strength of two types of CFL (solvent-dehydrated and freeze-dried), autologous rectus fascia, and cadaveric dermal grafts.<sup>42</sup> They found no significant difference between solvent-dried fascia lata, dermal graft, and autologous rectus fascia. Freeze-dried fascia lata had a signifi-

cantly lower maximum-load-to-failure rate than either of the other types tested. In contrast, Sutaria and Staskin examined the tensile strength after three methods of CFL preservation (freeze-dried/gamma-irradiated, freeze-dried, and solvent-dehydrated/gamma irradiated).<sup>43</sup> They found no significant difference in the tensile strength among the three CFL preparations. Choe and colleagues studied the biomechanical properties of full-strip slings and patch-suture slings using autologous tissue, cadaveric tissues, and synthetic materials.<sup>44</sup> For the full-strip slings, cadaveric tissues (including CFL) had the best tensile strength, followed by synthetics and then autologous tissue. In the analysis of patch-suture slings, the synthetic material was the strongest, followed by CFL and then autologous rectus fascia. Dora and coworkers examined the biomechanical properties of several sling materials in a time-dependent fashion.<sup>45</sup> They placed the

materials in rabbit models and tested them before implantation and again at 12 weeks. The tensile strength of polypropylene mesh and autologous fascia remained consistent with baseline. CFL and porcine xenografts decreased in tensile strength by 60% to 89%. Walter and colleagues further reviewed the change in tensile strength of three lots of freeze-dried CFL after implanting it into a rabbit model.<sup>46</sup> They demonstrated significant preimplantation variability in the tensile strength of the CFL. At 12 weeks, the samples were explanted and retested and showed a 90% decrease in tensile strength. The significance of variations in tensile strength among the various sling materials has not been shown to be clinically significant. Based on the earlier failure of some sling materials, the presence of tensile strength variations and degradation may play a role in long-term clinical success.

**Table 38-1 Outcomes of Cadaveric Fascia Lata Sling in Women with Stress Urinary Incontinence**

First Author and Ref. No.	Year	N	Follow-up, Mean (mo)	Method of Follow-up	% Cured/Improved	% Failure	CFL Preparation Method	Comments
Elliott <sup>68</sup>	2000	26	12-20 (15)	Subjective	77/15	7.6	Solvent-dehydrated	4 patients had no leakage preoperatively (3 with occult SUI)
Brown <sup>64</sup>	2000	104	(12)	Subjective	74/19	7	Freeze-dried	19% improved used 1-3 pads/day; 26% used $\geq 1$ pads/day
Soergel <sup>69</sup>	2001	12	(3)	UDS	33.3	66.6	Freeze-dried	Cure was no SUI (could have detrusor instability)
Huang <sup>70</sup>	2001	18	6.9-11.6 (9.2)	Subjective	72.7	27.8	Solvent-dehydrated	Failed within 3-6 mo
Carbone <sup>71</sup>	2001	154	6-16 (10.4)	Subjective	60/2	37.9	Solvent-dehydrated/ freeze-dried	Bone-anchored CFL: 16.9% reoperation rate for SUI failure

CFL, cadaveric fascia lata; SUI, stress urinary incontinence; UDS, urodynamic studies.

## CADAVERIC FASCIA LATA OUTCOMES

Using CFL for pubovaginal slings offers the advantage of decreased operative time and less patient morbidity.<sup>47</sup> The results from performing the procedure are less favorable than with their autologous counterparts. Table 38-1 displays the results of several series of patients undergoing CFL sling cystourethropexy. Overall, the follow-up periods were short and most studies used subjective assessment methods with varying definitions of postsurgical success. Numerous studies showed high failure rates using CFL slings, with postsurgical SUI rates ranging from 6% to 66.6% as early as 3 months postoperatively.

O'Reilly and Govier examined eight patients who had recurrence of SUI after CFL sling placement.<sup>48</sup> Five of the eight patients underwent urodynamic studies, which demonstrated ISD with lower VLPPs than the patients had had preoperatively. No other reason for failure was identified.

Carey and Leach examined the use of CFL for treatment of SUI and pelvic organ prolapse in patients at least 80 years old.<sup>49</sup> Thirty-one patients were followed up with a questionnaire at a mean of 21.4 months postoperatively. Fifty-five percent of the patients reported a 70% improvement in SUI symptoms, and 90% had no symptoms of pelvic organ prolapse recurrence. This compared similarly with the patients who were younger than 80 years of age. The moderate success in the elderly may be an acceptable use of CFL slings to decrease the morbidity of harvesting autologous fascia.

## SURGICAL TECHNIQUE

Preoperatively, patients are evaluated with a complete history, physical examination, urine analysis, multichannel urodynamic studies, and necessary ancillary tests according to their medical history. All patients receive perioperative intravenous antibiotics and compressive stockings, and mechanical antiembolism devices are applied.

### Fascia Lata Harvest

Once the patient is anesthetized, the lower limbs are positioned for fascia lata harvesting. Usually, we use the right side and preoperatively mark the patient accordingly, but either lower extremity may be used, depending on patient or surgeon preference or the presence of previous surgery. The stockings and antiembolism device are placed below the patient's patella on the right side. The right knee is elevated and supported with a 1-L bag of intravenous fluid or a suitable alternative pad or cushion. The extremity is internally rotated at the right hip and secured using 3-inch tape across the leg below the operative site. The operative site is prepped and draped as to expose the whole anterolateral aspect of the right thigh from the greater trochanter to distal to the patella. The anterior superior iliac spine (greater trochanter) and lateral femoral condyle are identified and marked. These landmarks identify the proximal and distal attachments of the fascia lata.

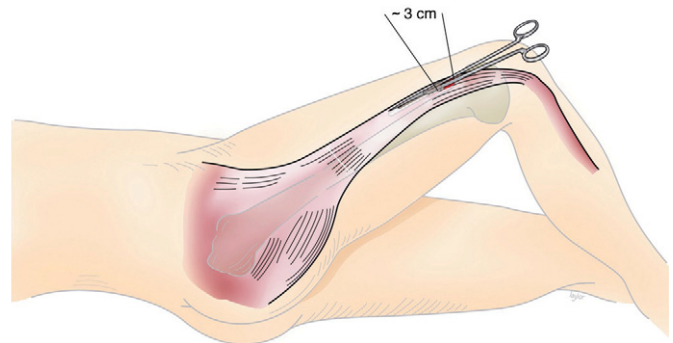

A 3-cm longitudinal incision is marked beginning just above the patella over the iliotibial band (Fig. 38-1). Dissection is carefully performed to the level of the fascia lata. At this point, two parallel incisions are made longitudinally in the fascia lata, approximately 2 cm apart. The autologous fascia lata is bluntly lifted off the underlying muscle and clamped as far distally as

**Figure 38-1** Patient's lower extremity in position for autologous fascia lata harvest. The incision is illustrated. (From Latini JM, Lux MM, Kreder KJ: Efficacy and morbidity of autologous fascia lata sling cystourethropexy. *J Urol* 2004; 171:1180-1184.)

**Figure 38-2** Crawford fascial stripper. (From Latini JM, Lux MM, Kreder KJ: Efficacy and morbidity of autologous fascia lata sling cystourethropexy. *J Urol* 2004; 171:1180-1184.)

**Figure 38-3** Incising the fascia lata medially and laterally, along the line of the fibers, using the Crawford fascial stripper. A 1.5 cm by 18- to 22-cm piece of fascia lata can be harvested using the technique. (From Latini JM, Lux MM, Kreder KJ: Efficacy and morbidity of autologous fascia lata sling cystourethropexy. *J Urol* 2004; 171:1180-1184.)

possible with a right angle clamp (3 to 4 cm) and transected to allow one free end. The free distal end of the fascia lata is secured with a 1-0 Prolene suture, and the proximal fascia lata is lifted off the muscle belly with the use of a thin malleable retractor. The retractor is passed superficial and deep to the fascia lata to separate it from both the adipose tissue and muscle fibers. Now the free distal end is placed under tension, and a Crawford fascial stripper (Fig. 38-2) is used to extend the fascial incisions proximally (Fig. 38-3). The Crawford fascial stripper is used to mobilize as much fascia lata as possible and divide it proximally before it is removed. Immediate compression is applied to the thigh to constrict any perforating vessels. The fascial strip is usually 20 × 2 cm in dimension, and a second 1-0 Prolene suture is attached to the proximal end of the fascia lata strip. While compression is maintained on the thigh, the fascia lata is immediately

**Figure 38-4** Sling cystourethropexy. **A**, Preparing to place the fascia lata autograft. **B**, Fascia lata autograft in position before the sutures are tied. (From Latini JM, Lux MM, Kreder KJ: Efficacy and morbidity of autologous fascia lata sling cystourethropexy. *J Urol* 2004; 171:1180-1184.)

placed in a basin of sterile saline until it is required for sling placement. The wound is irrigated and closed in three layers with no attempt to close the fascia lata. Before closure, the area is carefully checked to ensure that there is no evidence of arterial bleeders. Once the thigh closure is complete, a compressive wrap is applied to the thigh, and the stocking and antiembolism device is replaced. The compressive bandage is usually maintained for a total of 8 hours postoperatively, and the patient is encouraged to ambulate early. The stockings and mechanical antiembolism devices are maintained during the hospital stay.

The results of a study of this method of fascia lata harvest were reported by Latini and colleagues in 2004.<sup>50</sup> At an average of 4.4 years, 63 patients returned surveys, and charts were reviewed. Postoperatively, 47% of patients reported being able to walk pain-free immediately, and this number increased to 93% by postoperative day 7. One patient reported a hematoma which was treated conservatively. There were no infections, thrombotic events, or delays in hospital discharge related to the harvest site. Foley and Adamson obtain the fascia lata graft similarly, but with a Moseley fasciatome.<sup>51</sup> Of their 16 patients there were no immediate complications, and at 3 months the patients were uniformly satisfied with the cosmetic result.

Walter and coworkers described a different method of obtaining the fascia lata graft using two incisions.<sup>52</sup> The first was similar to the incision we use, described earlier, and the second was made 20 cm superiorly. The fascia was mobilized with long Metzenbaum scissors, and the final dimensions were 24 to 27 cm by 3 cm. Eleven percent of their 71 patients experienced an objective complication, but all were short-term. One patient required drainage of a hematoma, two had a seroma (treated conservatively), and five patients developed incisional cellulitis requiring oral antibiotics. They were able to monitor the patients for an average of 25 months, and 55 of 71 patients responded to a questionnaire. Of the responding patients, 45% listed 36 separate complaints related to the fascia lata harvest. Only 8% were rated as clinically significant, and their complaints included discomfort for two patients and unacceptable cosmesis for the third patient.

The authors noted that all patients younger than 60 years of age had at least one subjective complaint, whereas the patients with no complaints had an average age of 70 years. These data suggest higher rates of complication and patient dissatisfaction with fascia lata harvest when a fasciatome is not used. Perhaps the improved technical capabilities of a fasciatome allow for a speedier recovery with fewer long-term sequelae.

### Sling Placement

Once the fascia lata strip has been obtained and the thigh incision has been closed, attention is turned to the sling placement. The patient is repositioned into the dorsal lithotomy position, and the lower abdomen and vagina are prepared and draped in the standard fashion for a sling cystourethropexy. The method described for placement of the sling is a modification of the methods described by Beck and colleagues<sup>8-10</sup> and by McGuire and Lytton.<sup>5</sup> Initially, a small, transverse, lower abdominal incision is created, and dissection is carried down to the rectus abdominis fascia just superior to the symphysis pubis. A Foley catheter and a weighted vaginal speculum are placed. Silk stay sutures may be used to open the labia minor if they are redundant. The vaginal mucosa is incised longitudinally on either side of the urethra at the level of the bladder neck. A tunnel is then created in the retropubic space on either side of the urethra, using sharp and blunt dissection. This tunnel is dissected to the level of the posterior rectus abdominis fascia (Fig. 38-4A). A space is created between the urethra and the vaginal mucosa, and the fascia lata graft is placed in position posterior to the urethra. A tonsil clamp is then used to pierce the rectus abdominis fascia just lateral to the midline. The clamp is passed by fingertip guidance through the previously created retropubic tunnel to the vagina. The ends of the 1-0 Prolene sutures at one end of the sling are then grasped with the clamp and brought out through the abdominal incision. The procedure is repeated on the contralateral side (see Fig. 38-4B). The two sides of the sling are tied above the rectus fascia via the 1-0 Prolene. The knot is placed without any tension on the graft,

which is allowed to act as a hammock underneath the urethra. Cystoscopy is performed to ensure that no iatrogenic bladder or ureteral injuries have occurred. The abdominal and vaginal incisions are closed with absorbable sutures, and a saline-soaked vaginal pack is placed. A new Foley catheter is placed to provide postoperative bladder drainage. The vaginal pack is removed on postoperative day 1, and the catheter is removed on day 7 for a voiding trial. The patient is instructed to perform postvoid self-catheterization until residual urine volumes are consistently less than 100 mL.

### Suture Techniques

Intuitively, there are a number of methods to secure the fascia sling. Initially, the fascial sling was secured directly to the rectus fascia on each side. Subsequently, Govier and associates described a technique where they obtained a piece of fascia lata long enough (24 to 28 cm) to tie the two ends of the sling together over the rectus fascia without anchoring the sling directly to the rectus fascia.<sup>53</sup> In an attempt to improve urethral coaptation, Pérez and colleagues described securing the ends of the fascial graft to Cooper's ligament with or without crossing the ends of the graft across the midline.<sup>54</sup> To further enhance urethral coaptation, Ghoniem described wrapping the sling around the urethra at the level of the bladder neck in patients with myelomeningocele.<sup>55</sup> Once the sling is in place, several methods of securing it at the level of the bladder neck have been described. Suturing the mid-portion of the sling to the periurethral fascia was described by Gormley and associates.<sup>56</sup> A more complex method was described by Govier and coworkers, who used three interrupted absorbable sutures to tack the sling to the bladder and urethra.<sup>53</sup> The use of a submucosal tunnel appears to limit the need to secure the sling at the urethra.

### Sling Tension

Since the introduction of the sling, there have been problems with overcorrection of the urethral axis causing obstructive symptoms or urinary obstruction.<sup>57,58</sup> Most surgeons performing suburethral sling surgery would agree that proper sling placement using a tension-free technique is vital for an acceptable surgical outcome. Excessive sling tension has been identified as a significant risk factor for persistent postoperative urinary retention.<sup>57,58</sup> The technique we prefer takes the ends of the graft, which are brought up to the rectus abdominis fascia, allowed to settle into position by gentle traction on the Foley catheter, and secured above the rectus abdominis fascia as previously described. The urethra is carefully inspected after this procedure to ensure that it is in an anatomic position without evidence of overcorrection.

Numerous methods of adjusting sling tension intraoperatively have been reported. An intraoperative urethral manometry to create an intraurethral pressure of 50 to 90 cm H<sub>2</sub>O at the sling site was used by Beck and colleagues.<sup>10</sup> Endoscopic observation with direct visualization of mucosal "soft" coaptation was described by McGuire and colleagues as a method to adjust sling tension.<sup>59</sup> Alternatively, Govier described adjusting the sling tension until one finger could be placed between the suture and the anterior abdominal wall.<sup>53</sup> Rovner and coworkers used a cystoscope sheath placed transurethrally to maintain the urethral position while the sling was secured above the rectus abdominis fascia.<sup>60</sup> Nguyen and coauthors described the use of a cotton swab placed at the urethrovesical junction and maintained at an angle

between 0 and 10 degrees to the horizontal plane while the suspension sutures were tied down.<sup>61</sup>

### CLINICAL OUTCOMES

The results of the CFL sling have been discussed (see Table 38-1). The autologous fascia lata sling has been reported dating back to 1933.<sup>7</sup> Table 38-2 details some of the series of patients who have been examined. The cure rate from the autologous fascia lata sling ranges from 50% to 93%, and the improved rate represents another 2.3% to 27% of patients. Most of the studies had a failure rate of less than 10%, but one was as high as 27%. Only 3 of 13 studies used urodynamic studies to define cure; the remaining 10 studies used subjective data in the form of standardized and author-initiated questionnaires. The variability in assessment methods creates difficulty when comparing results from various studies. Overall, the successful trend of the autologous fascial sling is obvious. The autologous fascial sling has a higher success rate than its cadaveric counterpart.

### COMPLICATIONS

After a pubovaginal sling placement, the complications specific to the surgery are urinary retention, de novo urgency, and urge incontinence.

Latini and colleagues used autologous fascia lata and surveyed 63 patients at an average of 4.4 years after surgery.<sup>50</sup> Postoperatively, 93% of the patients walked pain-free by 7 days, and there were no harvest site complications.

The rate of development of de novo urgency after pubovaginal sling placement has been reported to be from 10.8% to 28%.<sup>31,62,63</sup> Flynn and Yap studied the outcomes of 134 women who underwent placement of a pubovaginal sling (63 CFL and 71 autologous fascia lata).<sup>62</sup> The follow-up was a mean of 29 months in the CFL group and 44 months in the autologous fascia lata group. The CFL group had recurrence of the SUI in 13% and urge urinary incontinence (UUI) in 24%, with half of these being de novo cases. The autologous fascia lata group had recurrence of SUI in 10% and a 16% rate of UUI, with only 2 of 11 cases being de novo in origin. Two patients had a bladder perforation which healed uneventfully after a week of catheter drainage. Overall, there were 23 urinary tract infections and 4 abdominal wound infections, with slightly more of each in the autograft group. The allograft group had one case of prolonged retention that resolved at 56 days; the autograft group had three cases, two of which resolved at 45 and 90 days. The last patient in the autograft group required vaginal urethrolisis. Brown and Govier had a median postoperative catheterization of 9 days in their 104 patients who underwent a CFL pubovaginal sling.<sup>64</sup> Their 46 patients in the autograft group had a median catheterization of 14 days. There were two cases of prolonged retention in the CFL group and three cases in the autograft group, with one of the latter requiring urethrolisis.

Miller and associates attempted to predict who is at risk for development of urinary retention after pubovaginal sling placement.<sup>65</sup> Urodynamics and clinical evaluation were performed in 73 women before and after sling surgery. The average time to efficient voiding was 3.9 days. Twenty-one women voided preoperatively without a detrusor contraction, and 4 went into postsurgery retention. The remaining women who had a preoperative detrusor contraction of at least 12 cm H<sub>2</sub>O did not develop postoperative retention. This study demonstrated that

DI, detrusor instability; FL, fascia lata; RF, rectus fascia; SUI, stress urinary incontinence; UDS, urodynamic studies; UUI, urge urinary incontinence.

the absence of a preoperative detrusor contraction is a risk factor for retention after pubovaginal sling placement.

Amundsen and associates reported finding 9 cases of urethral erosion in a population of 57 women referred for urethrolisis.<sup>66</sup> Six of the 9 patients had had fascia lata used for their sling (5 CFL, 1 autologous fascia lata). All were treated with transvaginal lysis, and in no case did SUI recur. Kammerer-Doak and colleagues reported 5 of 22 patients with CFL for pubovaginal sling developing vaginal erosion at a mean of 36.8 days after the procedure.<sup>67</sup> They also noted 3 of 11 cases of vaginal erosion after abdominal sacrocolpopexy. The only risk factor identified for erosion was the development of a postsurgical febrile episode.

## CONCLUSIONS

Fascia lata cystourethropexy is an appropriate choice for patients who require surgery for treatment of SUI. The success rate of the CFL sling ranges from 30% to 93.5%, and the failure rate can be from 6% to 66.6%. The autologous fascia lata sling has a higher success rate, from 50% to 93%, with a more acceptable failure rate of about 10%. Overall, the procedures are safe, with the autologous fascia lata causing more short-term patient morbidity than the CFL, which may be acceptable considering its improved outcomes.

# TENSION-FREE VAGINAL TAPE

*John J. Klutke and Carl G. Klutke*

Correction of female stress urinary incontinence (SUI) with the use of tension-free vaginal tape (TVT) was described in its present form in 1996.<sup>1</sup> Its unique features included intentional placement of support at the mid-urethra (previous surgical correction of SUI aimed to suspend the proximal urethra) and the use of a stress test to guide the surgeon in determining the degree of outlet resistance created. The biologically inactive nature of Prolene was recognized, and a Prolene mesh strip was placed to support the mid-urethra. The mesh was held in place by contact with adjacent tissue and was not separately fixed in place.

Ulmsten and colleagues recognized that correction of SUI carried a risk of interference with normal voiding.<sup>2</sup> TVT was designed to surgically correct support of the urethra at the level of the mid-urethra, the area where the pubourethral ligaments insert on the urethra. Ulmsten believed that the proximal urethra, the site of initiation of voiding, should be left in its normal, anatomically mobile state. The procedure was also designed to avoid excessive tension on the urethra by including a check mechanism in which mesh placement was adjusted based on a cough stress test. In order to do this, the patient had to remain awake and as close as possible to her normal state, eliciting the SUI.

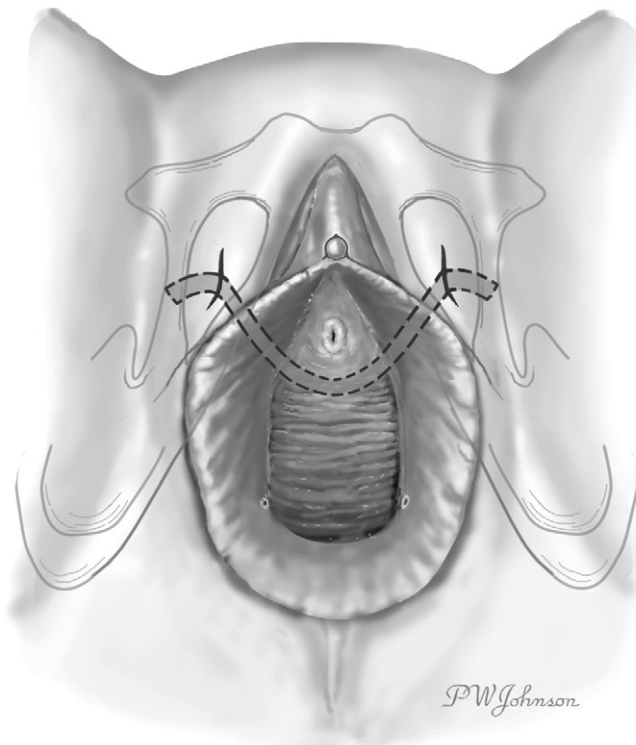

The procedure was introduced in the United States in November of 1998. It soon became enormously popular with gynecologists and urologists alike, and within 5 years it became the most commonly performed procedure for SUI. With this remarkable change in practice came reports of TVT-associated complications. Shortly after introduction of the TVT procedure into mainstream practice, bowel and large vessel injury were reported.<sup>3,4</sup> In some cases, complications resulting from TVT placement had fatal consequences. Such serious complications are exceedingly rare with TVT. Nonetheless, introduction of the procedure into mainstream use brought to light unique challenges inherent in training surgeons to perform it properly and the need to develop an effective credentialing instrument. Furthermore, it was recognized that serious adverse events can occur even when an expert performs the procedure.

### TECHNIQUE

Figures 39-1 and 39-2 illustrate the technique used in the TVT procedure. Use of a vaginal incision (see Fig. 39-1) as opposed to an abdominal incision (see Fig. 39-2) as the starting point for trocar passage is a defining feature for the procedure and verifies accurate placement of support at the mid-urethra. Although the direction of trocar passage has been hypothesized to increase the potential for bladder injury, three randomized comparisons of TVT to conventional sling operations with blind “up to down” mesh introduction showed no difference in the incidence of inadvertent bladder puncture.<sup>5-8</sup>

The procedure can and should be performed with the patient under local anesthesia and conscious sedation. Data have shown higher rates of voiding dysfunction and lower success rates with procedure deviations in which the cough stress test is not used.<sup>9,10</sup> The cough stress test with spinal anesthesia is misleading because of paralysis of the pelvic floor. The TVT procedure is pain free when performed properly and with adequate levels of local anesthetic.<sup>11</sup> In the absence of comparative studies with sufficient power to discern small differences in outcome when deviations from the original technique are used, it is our opinion that the TVT procedure should be performed as described by Ulmsten and colleagues,<sup>1</sup> using the cough stress test to guide placement.

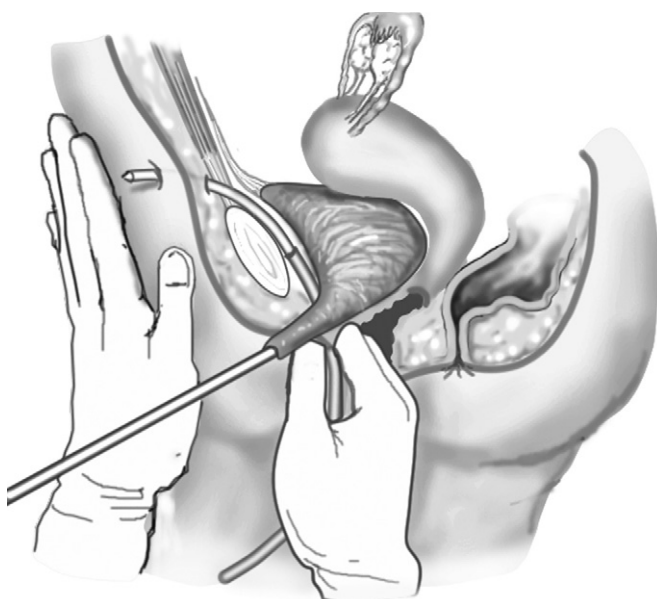

Figure 39-3 illustrates passage of the introducing trocars. This step is a coordinated motor task without visual input. In other words, placement of the device is “blind.” The tactual and kinesthetic cues involved in passing the trocar through the body are subtle. Bladder perforation is a relatively common complication, and cystoscopy is a required part of the procedure. Whether the procedure is performed by an expert or an amateur, unrecognized bowel injury is a possibility.

**Figure 39-3** Blind passage of the introducing trocars.

### PROOF OF CONCEPT

The published clinical experience with TVT is extensive and supports Ulmsten's promise of a simple, minimally invasive and highly effective solution to incontinence. Four studies have demonstrated minimal or no alteration in proximal urethral mobility after TVT procedure.<sup>12-15</sup> In a comparative study of colposuspension and TVT, Atherton and Stanton demonstrated that both procedures resulted in decreased mobility of the proximal urethra, but that statistically greater change was present after colposuspension.<sup>16</sup> It is apparent that cure of SUI is possible without affecting proximal urethral mobility.<sup>12</sup>

Urodynamic studies of voiding after the TVT procedure show conflicting results. Increased urethral resistance is demonstrated in two studies, but not in two others.<sup>17-20</sup> In a comparative study, Wang and Chen reported increased urethral resistance and decreased flow rates after colposuspension.<sup>19</sup> There was no difference in these measurements after TVT. Both increased and unchanged pressure transmission at the mid-urethra after TVT have been reported.<sup>20-22</sup> Conflicting measurements of urodynamic parameters after TVT may reflect small sample size in some of the studies or variable operator experience with the technique. They may also have resulted from the use of spinal anesthesia in two of the studies.<sup>19,20</sup> This is a deviation from the original technique, and with motor block of the pelvic floor affecting the cough stress test, it is conceivable that the degree of tension placed on the sling could be affected as well.

The rationale for performing TVT is to avoid overcorrection of anatomy and its systemic consequences. In a randomized comparative trial of TVT and colposuspension, significantly more women underwent corrective surgery for prolapse in the colposuspension group during the 2-year follow-up period.<sup>23</sup> Colposuspension, but not TVT, appeared to be causative in the development of the prolapse. There was a statistically significant increased incidence of voiding dysfunction in the colposuspension group at the 2-year follow-up. These findings highlight the importance of minimizing the changes induced in the system to restore continence, to minimize subsequent vulnerability to prolapse or the development of voiding dysfunction.

### CONNECTIVE TISSUE RESPONSE

With the present widespread use of synthetic material in reconstructive pelvic surgical procedures, the potential for vaginal healing complications warrants close attention. Mesh or suture introduced in the vagina is, ideally, biologically inert and restores structural support by stimulating connective tissue growth with minimal inflammatory response. Clearly, different materials vary in the host reaction that is elicited when they are implanted in the body. Biologically active materials should be avoided.

Polypropylene mesh placed near the bladder in rabbits is well accepted by the host without exaggerated inflammation.<sup>24</sup> The material is also well accepted in humans, with fibrosis but little inflammatory response to mesh placed in paraurethral tissue.<sup>25</sup> Pore size, dimension, and weave of the mesh may also play a role in the host reaction, but they have less impact than the bioactivity of the material itself.

Comparison of bioactivity of Prolene versus Mersilene (polyester) has been made in humans. During the development of the TVT procedure, a high incidence of rejection of urethral slings made of Mersilene, but not slings made of polypropylene, was noted. Given this observation, Falconer and associates correlated clinical outcome with slings of both materials with biochemical measurements of connective tissue taken by biopsy near the site of sling placement.<sup>26</sup> Histologic differences were apparent, with greater tissue inflammatory reaction recorded in the Mersilene group. Greater collagen was also present in the Mersilene group, suggesting an increased host response.

The best indicator of the biologic inactivity of Prolene mesh in humans has been the clinical experience that has accrued since introduction of the TVT procedure. Vaginal healing complications have been rare with the TVT technique. In a large analysis of complications associated with the TVT procedure, the inci-

dence of vaginal mesh extrusion was 0.7%.<sup>27</sup> Most of these complications are better termed exposures than erosions, because the technique allows for placement of the polypropylene mesh in the tissue without excessive tension, or hang, on the capillary bed of the surrounding tissue.

Several authors have described conservative management of vaginal mesh exposure (i.e., excision of the exposed fragment and closure).<sup>21,28-31</sup> Complete excision of mesh, technically a very difficult procedure with the potential for excessive blood loss and dissection injury to the urethra and bladder, appears to be unnecessary in most cases.

## EFFICACY

Efficacy was initially reported in 1998. Ulmsten and colleagues evaluated 131 consecutive cases performed at six centers.<sup>32</sup> All of the procedures were performed with the patient under local anesthesia. Outcome was determined by subjective and objective testing and was reported for the 1-year follow-up visit. Ninety-one percent of the study subjects were cured. The incidence of voiding dysfunction was minimal, with only one subject requiring catheterization for longer than 10 days.

Two other prospective studies were published in 1998. Nilsson reported cure in all of 31 consecutive patients who underwent the TVT procedure for SUI.<sup>33</sup> The procedure was performed with the patient under local anesthesia. Only one patient required catheterization for longer than 24 hours after the operation. Wang and Lo reported objective cure in 83% of 70 subjects after the TVT procedure for SUI.<sup>34</sup> In most cases, the surgery was performed with the patient under epidural anesthesia. Although still low, the incidence of voiding dysfunction was greater than in the other two studies, and the authors cited the choice of anesthesia as a potential explanation.

Soulie and colleagues,<sup>35</sup> Meschia and colleagues,<sup>28</sup> Nilsson and Kuuva,<sup>36</sup> and Olson and Kroon<sup>37</sup> published other prospective studies. This brought the total number of subjects studied prospectively to 900. Although these initial studies were observational and reported short-term follow-up, they suggested high

rates of efficacy with minimal voiding dysfunction, supporting the unique concepts that the TVT procedure introduced.

Ulmsten and coworkers, reported a study with 3-year follow-up in 1999, showed stable results that were comparable to those of previous studies.<sup>38</sup> Data with longer follow-up were available in 2001. Ninety consecutive patients were monitored for 5 years, with subjective and objective success rates reported to be 85%.<sup>39</sup> In other studies with long-term follow-up, Ulmsten's group reported cure in 82% of 34 women who underwent TVT for recurrent SUI, 74% of 49 women who had ISD, and 85% of 80 women who had mixed urinary incontinence.<sup>40-42</sup> Mid-term and long-term follow-up data are summarized in Table 39-1. Kuuva and Nilsson<sup>43</sup> and Jomaa<sup>44</sup> reported stable cure rates for TVT at 7-year follow-up.

Ward and Hilton reported a prospective randomized comparison of TVT to colposuspension in women with Genuine Stress Urinary Incontinence (GSUI).<sup>21,23</sup> Exclusion criteria were detrusor instability, voiding problems, prolapse requiring treatment, and previous surgery for incontinence or prolapse. A total of 344 subjects were recruited. Two years after surgery, objective cure rates for SUI were 63% for the TVT procedure group and 51% for the colposuspension group. These rates initially seem low in comparison to those typically reported for anti-incontinence operations in general, and it is important to consider the study design in interpreting the data. First, the study outcome was based on intent to treat, and those subjects who withdrew or were lost to follow-up were considered failures. Second, the criteria used to define cure in the study were stricter than those usually used: Only those subjects with less than 1 g of change in perineal pad weight after a 1-hour pad test were defined as cured. When cure was based purely on urodynamic findings, common practice in the urogynecology literature, TVT and colposuspension cured 89% and 85% of the subjects, respectively. These results suggest that, in a large group of randomly assigned patients, TVT was effective and appeared to be as effective as colposuspension in the treatment of SUI.

Operative complications were also described in the Ward and Hilton study.<sup>23</sup> In the initial 6-month follow-up report, the rate of operative complication was higher for the TVT procedure. The

Bowel perforation	0.036%	0	35 cases (0.005%)
Urethral erosion	0	0	30 cases (0.004%)
Urinary tract infection	17%	14.10%	Not reported
De novo detrusor overactivity	Not reported	1%	Not reported

most frequent complications, bladder and vagina penetration, were not serious (Table 39-2). Fifteen bladder perforations occurred in the TVT group and 3 in the colposuspension group. None of these complications led to further adverse effects. Estimated blood loss was greater during colposuspension, although there was one serious hemorrhage in the TVT group. Postoperative complications, especially voiding dysfunction, occurred most commonly after colposuspension. Significantly more women in the colposuspension group required a subsequent prolapse operation.

Other comparative studies have been published.<sup>5-8,45-48</sup> Although these studies reported on smaller numbers of patients and had limited power to determine differences in outcome, they suggested equal results for TVT compared with colposuspension, laparoscopic colposuspension, and sling procedures.

### BLADDER PERFORATION

A wide range of incidence of bladder perforation has been reported in prospective studies. In the hands of experts, the incidence of perforation is small, 1% or less. Others have encountered the complication more frequently, with a range of incidence from 4.4% to 71% reported in the literature.<sup>49</sup> Previous surgery has been cited as a contributing factor, but most perforations occurred in patients without scarring or distortion of the anatomy. Although proper patient selection plays a role in avoiding perforation, operator experience may be a more important factor.<sup>50</sup> Bladder perforation can be assumed to be due to improper trocar passage. This mechanism, taken as an error pathway, could also explain inadvertent bowel or vessel perforation. Bladder perforation does not have permanent implications for the individual patient, but it can be viewed as a sentinel event for operator error during introduction. It may therefore be related to the genesis of other complications resulting from operator error, which may have more serious implications for the patient.

Delayed penetration of the bladder or urethra has been reported.<sup>51</sup> This may represent delayed recognition or true migration of the tape. Urinary tract fistulas have also been reported.<sup>52</sup>

### OTHER COMPLICATIONS

Two national registry databases are available that report complications associated with the TVT procedure.<sup>52,53</sup> It appears that the incidence of most complications with TVT is low relative to colposuspension and sling procedures. Gynecare company data are also available and provide an estimate of the incidence of serious complications.<sup>54</sup> Reporting complications to the company is voluntary, and the incidence determined is likely an underestimation. Based on 700,000 TVT procedures performed worldwide, there were 49 cases of vascular injury, an incidence of 0.007%. There were 35 cases of bowel injury (0.005%). Seven deaths were reported as of December 31, 2004, all related to vascular or bowel injury.

### CONCLUSIONS

The emergence of the TVT procedure may represent the most significant development in incontinence treatment in the last 50 years. There is ample scientific data supporting its use. The procedure is highly effective and has long-lasting, if not permanent, results. Studies indicate that the procedure is safe when performed by well-trained individuals who have experience in pelvic anatomy. Nevertheless, there are troubling issues related to this blind procedure that is meant to be a mainstream solution to an extremely prevalent disorder. Complications are possible and can be fatal. The genesis of these complications is complex and includes operator error. Conventional prospective outcome studies, so useful in determining how well TVT works, explain very little about how it can go wrong. Clearly, there remains much work to be done in the area of anti-incontinence surgery.

# MIDURETHRAL TO DISTAL URETHRAL SLINGS

Peter R. Petros

## MIDURETHRAL TO DISTAL URETHRAL SLINGS

The first part of this chapter addresses the anatomic basis for the midurethral sling operations, and the second part describes the surgical techniques themselves.

### Short History of Midurethral Slings

The first prototype midurethral sling, the “intravaginal sling-plasty” operation, was performed in 1986. This operation<sup>1,2</sup> was based on the anatomic work of Robert Zacharin<sup>3</sup> and the observation that an implanted plastic fiber causes a controlled deposition of collagen. It was reasoned that a tape placed at the site of the pubourethral ligament, *without tension*, would create a scar tissue reaction and strengthen the weakened ligament. It was also reasoned that a midurethral tape placement without abdominal attachment would eliminate most of the postoperative pain and urinary retention associated with sling and colposuspension procedures. These hypotheses were proven in the prototype intravaginal slingplasty operations. The one remaining problem, a high rate of foreign body reaction to Mersilene, was resolved by using polypropylene.<sup>2</sup>

### Structural Anatomy

Without ligamentous support, the bladder, urethra, and vagina have no shape, strength, or function. Fibroligamentous attachments connect urethra and bladder base to the vaginal membrane

(Fig. 40-1), so any laxity of the underlying vagina may influence the urethra and bladder base. Stress urinary incontinence (SUI) is a mechanical process.<sup>1</sup> To better understand the pathogenesis and treatment of SUI, it is useful to examine how ligaments, fascia, and muscle forces all combine to give shape, strength, and function to the vagina. All the component structures in Figure 40-2 are interconnected, and all have a role in the functioning of the system. It follows that more than one damaged structure may need to be repaired for optimal restoration of a particular function.

**Figure 40-1** Unsupported organs have no strength, structure, or function. X indicates fibroligamentous attachments of distal urethra and bladder base to the vagina. The proximal urethra is not attached. PUL, pubourethral ligament; USL, uterosacral ligament.

**Figure 40-2** The suspension bridge analogy. The vagina is suspended anteriorly by the pubourethral ligament (PUL), posteriorly by the uterosacral ligament (USL), superiorly by arcus tendineus fascia pelvis (ATFP), and by attached fascia (f). Muscle forces (arrows) stretch the vaginal membrane against the suspensory ligaments to create shape and strength. PS, pubic symphysis; S, sacrum.

The labels *m* and *l* indicate the medial and lateral branches of the pubourethral ligament, *P*. *E*, external urethral ligament; *f*, Foley catheter; *H*, hammock. B, Schematic sagittal view. *EUL*, external urethral ligament; *PUL*, pubourethral ligament.

### Anatomy of the Urethra's Attachments

Figure 40-3 is a live anatomic study<sup>4</sup> of the structures involved in urethral closure. They are, in order of importance, the pubourethral ligament (P), the suburethral vaginal hammock (H), and the external urethral ligaments (E). The external ligament E attaches the external urethral meatus to the anterior surface of the pubic bone. The pubourethral ligament P descends from the posterior surface of the pubic bone.<sup>3</sup> Its medial part (m) attaches to the middle part of the urethra, and its lateral

**Figure 40-4** Anatomy of the vaginal hammock. Coronal section, cadaveric study. Arrows show direction of muscle forces. *H*, suburethral vaginal hammock; *LA*, levator ani also known as; pubococcygeus muscle *PCM*; *U*, urethra; *V*, vagina.

part (l) to the pubococcygeus muscle and, by extension, to the vagina.

In 1963, Robert Zacharin demonstrated that the vaginal hammock is inserted into the lateral closure muscles (Fig. 40-4). This anatomy is consistent with dynamic video radiographic studies and ultrasound observations (Figs. 40-5 and 40-6).

### Dynamic Anatomy of Urethral Closure

Abdominal ultrasound<sup>5</sup> (see Fig. 40-5B) demonstrates the contribution of the hammock and external ligament (E) to urethral closure. Closure occurs from behind, presumably by forward stretching of the hammock (H) against (E) by contraction of the pubococcygeus muscle (PCM).

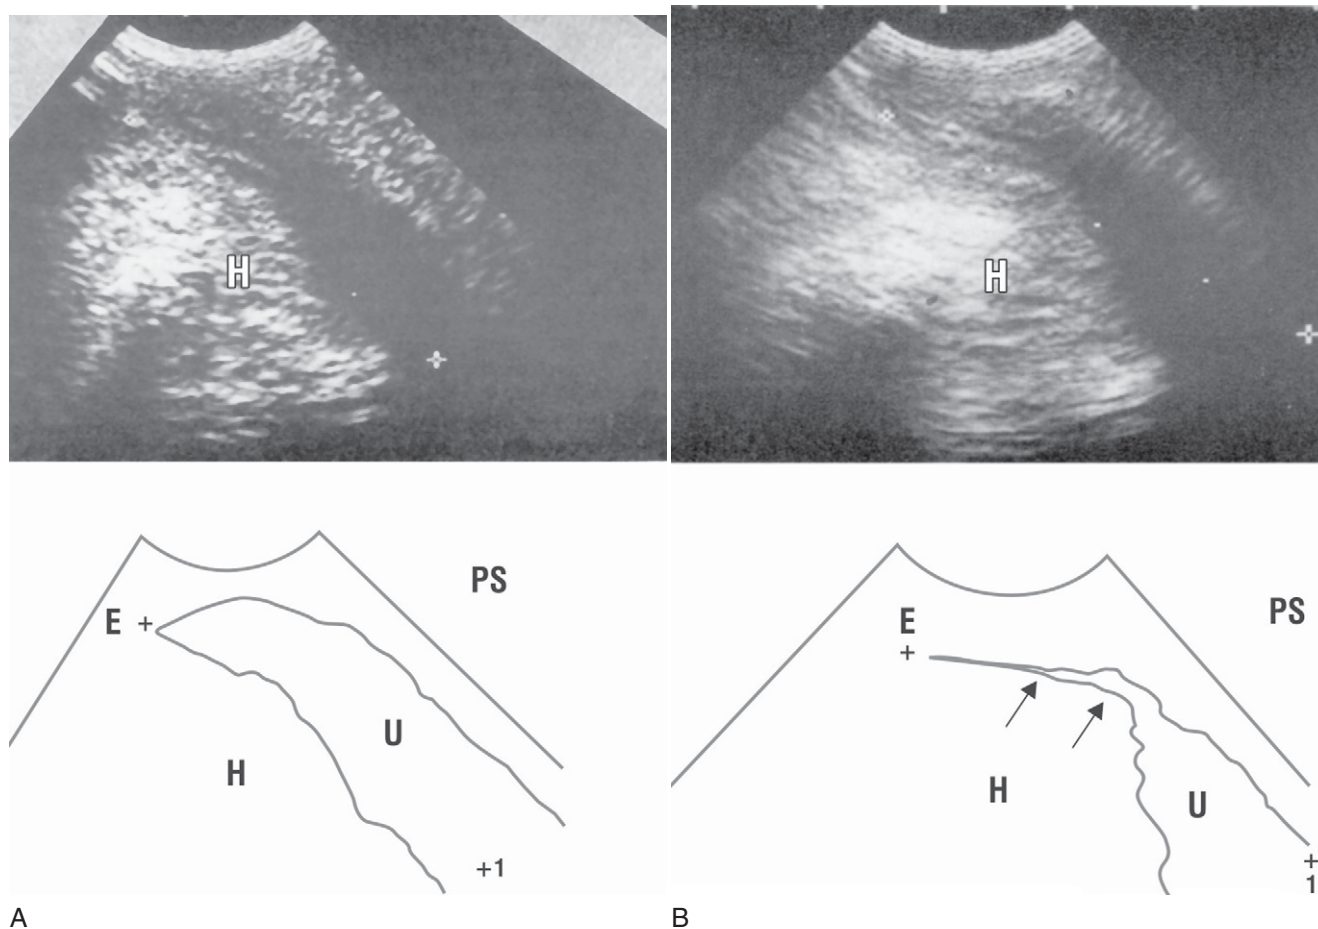

### Importance of Midurethral Anchoring for Closure and Micturition

The importance of a midurethral anchoring point is evident on the sequence of radiographs in Figure 40-6. During straining (see Fig. 40-6B, *arrow*), the distal urethra is pulled forward against the pubourethral ligament (PUL) for “urethral closure.”<sup>1</sup> The proximal urethra is stretched backward and downward against the PUL (*arrows*) for “bladder neck closure.”<sup>1</sup> During micturition (see Fig. 40-6C, *arrows*), the forward muscle force appears to relax, allowing the posterior urethral wall to be pulled open by the backward/downward muscle forces, right down to the PUL anchoring point. This opening vastly reduces the intraurethral resistance, facilitating the expulsion of urine. A surgical attachment at the bladder neck (Burch, fascial sling) may forcibly restrain the urethra from being stretched open during micturition, so that the detrusor has to expel urine through a narrower channel with a much higher resistance. The patient perceives this symptomatically as a slow flow, stopping and starting, incomplete emptying, and so on. From these radiographs it can be deduced that, whatever the operation performed for SUI, anchoring at or near the mid-urethra without excessive tension is an important factor in preventing postoperative urinary retention.

### Clinical Anatomy: “Simulated Operations”

The individual contribution of the PUL, hammock, and the external urethral ligament (EUL) to urethral closure can be demonstrated directly by the office technique of “simulated operations.” This technique also directly tests the theory underlying this work<sup>1</sup> for truth or falsity. A patient with known urine loss on coughing is tested with a full bladder in the supine position.<sup>7</sup>

**Figure 40-5** A, Abdominal ultrasound image and schematic diagram of distal urethra at rest. *E*, external urethral ligament attaching external meatus to the anterior surface of pubic bone; *H*, suburethral vaginal hammock; *PS*, pubic symphysis; *U*, urethral cavity. B, Same patient, image while straining. Note how the hammock is closed from behind (arrows). The ligament *E* needs to be firmly anchored for optimal action of the closure forces. (From Petros PE, Ulmsten U: An integral theory of female urinary incontinence. *Acta Obstet Gynecol Scand* 69[Suppl 153]:7-31, 1990.)

Pressing upward on the anterior vaginal wall at the level of mid-urethra with a hemostat during coughing (Fig. 40-7) provides a temporary anchoring mechanism and mimics a midurethral sling. This maneuver immediately reduces urine loss in approximately 70% to 80% of patients.<sup>7</sup> Taking a fold of the hammock with a second hemostat (“pinch test”)<sup>8</sup> usually restores complete continence in the remaining 20% to 30% of patients.<sup>7</sup> Anchoring the external urethral meatus may decrease urine loss in approximately 10% of patients. The synergistic actions of these structures can be demonstrated by anchoring one and then two structures simultaneously.

#### Anatomic Basis for Simulated Operations

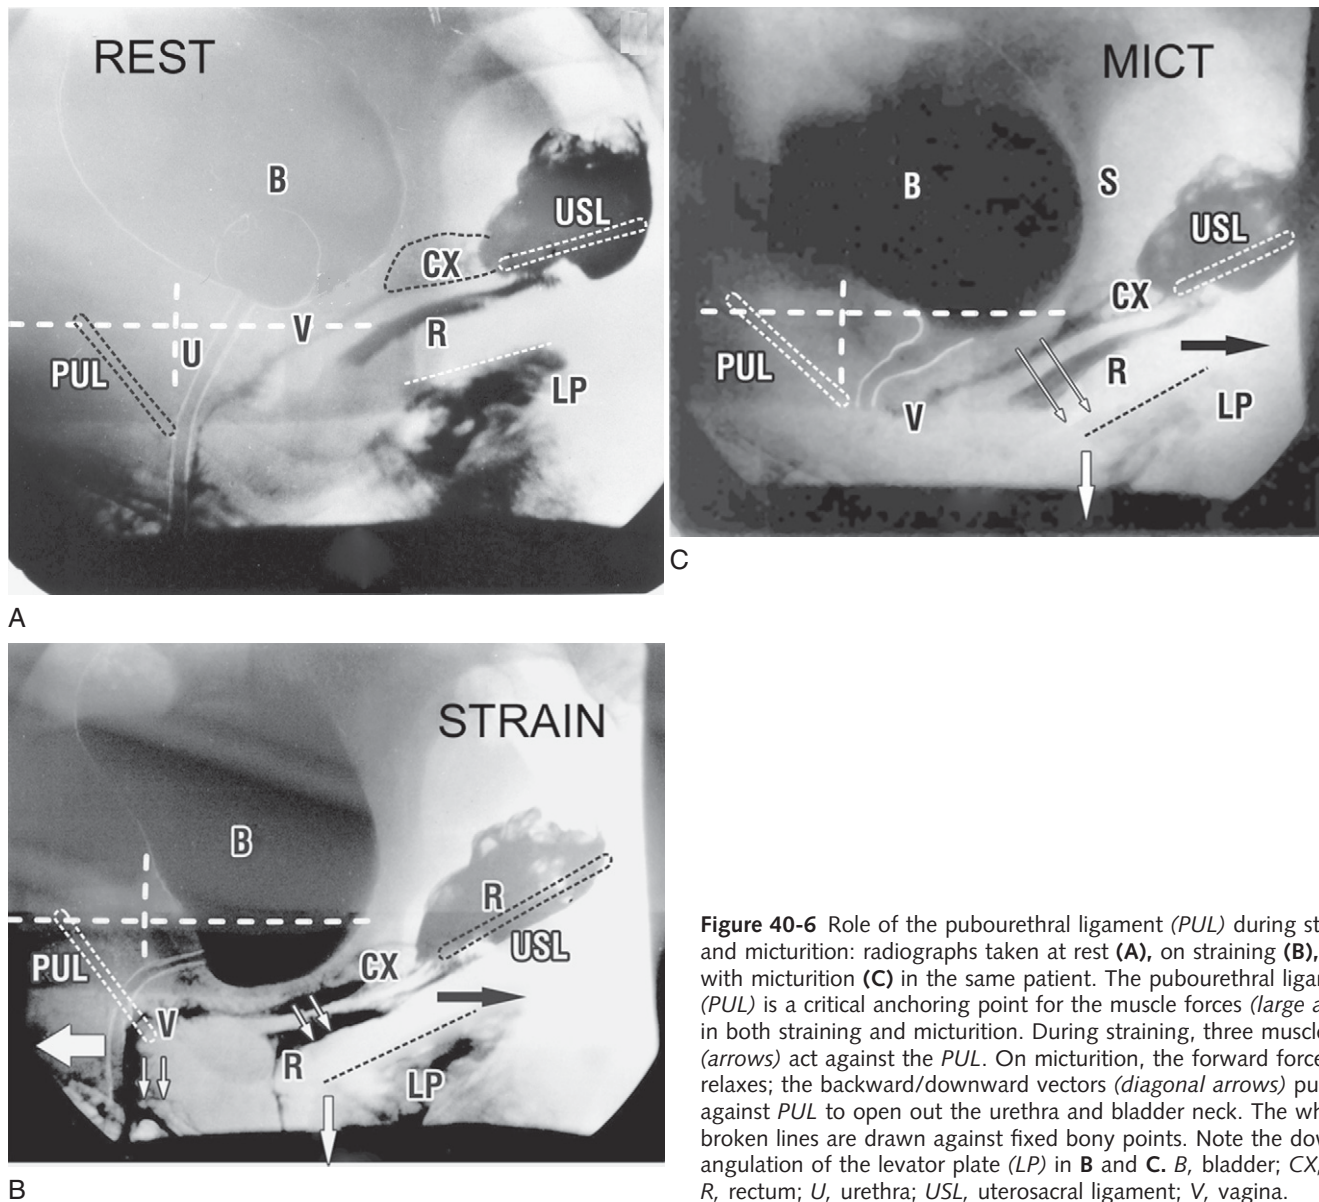

During closure, the backward muscle forces (see Fig. 40-7, arrows) stretch the vaginal membrane and the trigone backward against the PUL. This action tensions the urethral tube and the vaginal hammock.<sup>7</sup> The forward force, the anterior portion of pubococcygeus (PCM), then stretches the vaginal hammock (*H*) forward to close the urethra from behind. Finally, the downward force, the longitudinal muscle of the anus (LMA), rotates the vagina and bladder base in a plane around the PUL to close off the bladder neck and proximal urethra. A weak PUL cannot suffi-

ciently anchor the two backward forces (see Fig. 40-7), so the urethra is forcibly pulled from the closed (*C*) to the open (*O*) position during effort (Fig. 40-8). This is the clinical condition of SUI. It follows that a competent PUL is very important for stress continence control.

Figure 40-8 demonstrates the sequence of events in a patient with SUI. The anterior (*a*) and posterior (*p*) walls of the vagina are pulled backward and downward during straining (see Fig. 40-8B), opening out the outflow tract and causing urine loss (i.e., SUI). Midurethral anchoring (see Fig. 40-8C) restored normal bladder neck anatomy and continence in this patient. The sequence of events in Figure 40-8 indicates that the mechanism for causation of SUI is active opening out of the outflow tract by muscle forces, secondary to a lax midurethral anchoring point (see Fig. 40-7).

#### SURGERY

Five approaches to the tension-free midurethral sling are presented here: midline vaginal, suprapubic, paraurethral, trans-obturator, and subpubic. All work the same way anatomically.

**Figure 40-6** Role of the pubourethral ligament (*PUL*) during straining and micturition: radiographs taken at rest (**A**), on straining (**B**), and with micturition (**C**) in the same patient. The pubourethral ligament (*PUL*) is a critical anchoring point for the muscle forces (*large arrows*) in both straining and micturition. During straining, three muscle forces (*arrows*) act against the *PUL*. On micturition, the forward force relaxes; the backward/downward vectors (*diagonal arrows*) pull against *PUL* to open out the urethra and bladder neck. The white broken lines are drawn against fixed bony points. Note the downward angulation of the levator plate (*LP*) in **B** and **C**. *B*, bladder; *CX*, cervix; *R*, rectum; *U*, urethra; *USL*, uterosacral ligament; *V*, vagina.

### Surgical Anatomy: Importance of Repairing the Whole System

Surgery is about restoration of anatomy. Based on the anatomic evidence presented, reconstruction of all damaged structures contributing to urethral closure is recommended: a midurethral tape (obligatory), hammock repair (obligatory), and, if it is lax, repair of the EUL. The midurethral sling is the most important component<sup>7</sup> of the closure mechanism. However, each structure contributes differently within each patient. The differential contribution to SUI of the EUL, hammock, and PUL can be estimated by performing a simulated operation (see Fig. 40-7), supporting each structure in turn while asking the patient to cough. In patients with intrinsic sphincter defect, or ISD (maximal urethral closure pressure <20 cm H<sub>2</sub>O), it is advisable to repair all damaged structures so as to achieve optimal urethral closure. Using the paraurethral approach in a group of 11 patients with ISD, a cure rate of greater than

90% was achieved by repairing both the sling and the hammock.<sup>9</sup> A sling repair without hammock tightening achieved a 74% cure rate.<sup>10</sup>

### Midline Vaginal Approach

An 18-french catheter in the urethra is used as a splint to lessen the possibility of urethral perforation (Fig. 40-9). Place the vaginal epithelium under stretch. Make a full-thickness incision in the midline from meatus to mid-urethra. Dissect between vagina and urethra laterally with scissors. Proceed with perforation of the diaphragm with scissors between the periosteum and subpubic ligaments, creating a space sufficient for entry of the delivery instrument.

Making a hole in the perineal membrane is the most critical step, no matter which delivery instrument is used, because it confers built-in safety to what is, essentially, a blind procedure. The hole prevents excessive thrust and allows perfect control of

**Figure 40-7** The mechanism of a “simulated operation.” The hemostat mimics the anchoring effect of a normal pubourethral ligament (PUL). This allows levator plate (LP) and longitudinal muscle of the anus (LMA) forces (arrows) to rotate and close the proximal urethra and the pubococcygeus muscle (PCM) to stretch the vaginal hammock (H) to close the distal urethra. The urethral cavity converts from the open position, O, to the closed position, C. PS, public symphysis.

the instrument at all times, helping avoid the major complications of this procedure, damage to the bladder and major vessels. Furthermore, if the subpubic venous sinuses are breached, this can be identified, because the bleeding flows out through the hole. The bleeding can be controlled by applying digital pressure for 3 minutes against the pubic bone from below.

Once the tip of the delivery instrument has entered the diaphragm, move the delta wing handle so it is horizontal. This is another critical step, because the external iliac vessels may be only 1.5 to 2 cm lateral to the exit point of the delivery instrument. The instrument can only move upward if the delta wing is horizontal. No pressure is applied against the posterior part of symphysis pubis. Use fingertip pressure only to gently roll the tip of the instrument over the posterior surface of the pubic bone. This vastly reduces the incidence of bladder perforation. A resistance is met at the level of the rectus sheath. At this point, sufficient pressure is applied to “pop through” the tip. The insert is left in situ, and the procedure is repeated on the contralateral side. With both inserts now in situ, the bladder is filled with 500 mL of saline, and a cystoscopy is performed. A volume of 500 mL is required to distend the bladder sufficiently to ensure that there are no bladder folds obscuring the tape should perforation occur. Care is taken to search especially around the air bubble at the 11 and 1 o’clock positions, the most common perforation sites.

If a nonelastic tape is used, a no. 7 Hegar dilator is inserted to splint the urethra, and the tapes are pulled up one by one. Sufficient tension is exerted to ensure that the tape has no folds. At all times during this step, downward pressure is exerted on the dilator to minimize urethral constriction. At this point, the tape is directly inspected for excessive tightness. The tape should be touching the urethra without indenting it. If there is indentation, loosen the tape. The tape is left tension-free, and is not sutured in any way to the abdominal muscles.

If an elastic tape is used, a space should be left between the tape and the urethra to allow for postoperative retraction. Otherwise, the technique is similar.

### Hammock Tightening

It is recommended that hammock tightening be performed with all the techniques described in this chapter. With a no. 18 French Foley catheter in situ and using the tip of a short needle, the fascial tissue is firmly penetrated on both sides from the inside with a horizontal mattress suture so that the fascial tissue is brought toward the midline (see Fig. 40-9). It is essential to avoid contact with the tape during suturing. By taking the needle into the lower end of EUL, it is possible to tighten EUL and hammock using only one suture. If longer-term sutures are used, they need to be deeply anchored and cut onto the knot, otherwise they may surface and cause problems during intercourse.

### External Urethral Ligament Shortening

It is recommended that EUL shortening be performed with all the techniques described here, if the EUL is loose. With a no. 18 Foley catheter in situ, and using a 1-0 or 2-0 suture on a small needle, sutures are inserted into the ligament vaginal fascia, contralateral EUL and tied. A stronger repair can be made by incising each EUL downward almost to the bone, inserting a 0.5-cm length of tape, and suturing the incision sufficiently tightly to prevent its later extrusion. The EULs are not approximated with this technique.

### Paraurethral Approach

The paraurethral approach was first used in the Goebell-Frangenheim-Stoeckel sling in the early 1900s. It allows a more anatomically accurate restoration in that the hammock can be reattached to the closure muscles (Fig. 40-10). It is especially indicated if the vaginal sulcus is shallow. It has built-in safety, because the direction of instrument insertion is always upward. Its disadvantages are that it requires two incisions. Also, a tunnel has to be made in the tissue between vaginal epithelium and urethra, something that may be difficult to accomplish in patients with a deep paraurethral sulcus.

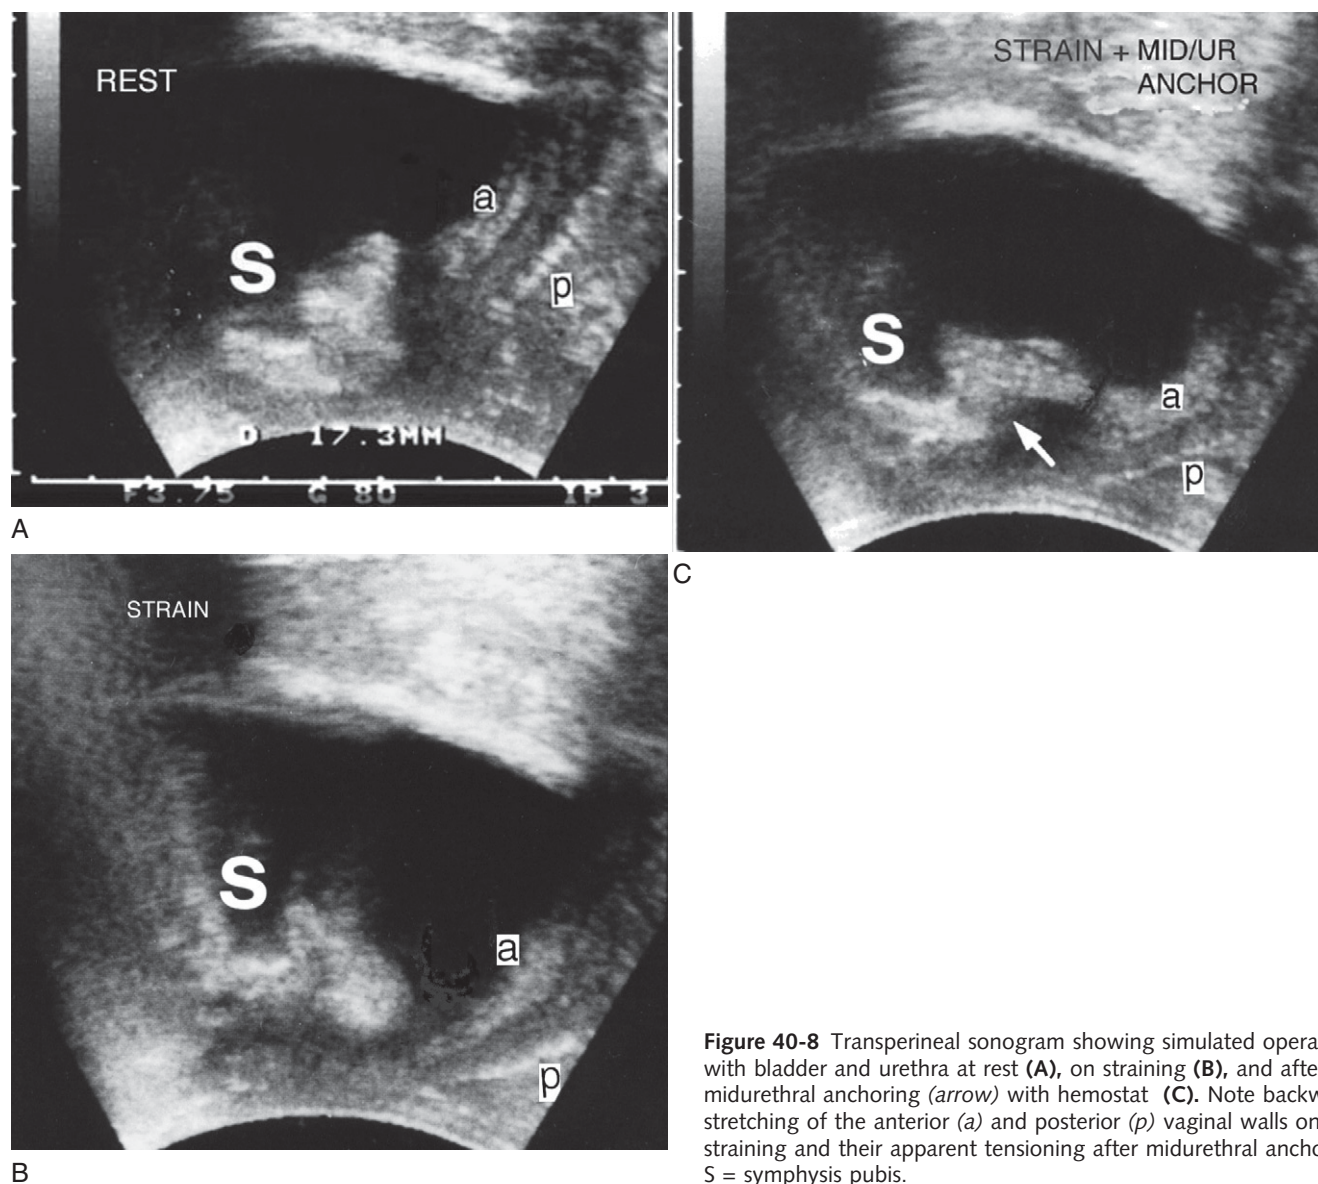

Two full-thickness longitudinal incisions are made in the lateral vaginal sulcus, extending from just below the level of the external urethral meatus to the level of the mid-urethra (see Fig. 40-10). A Foley catheter identifies the bladder neck.

A suburethral tunnel (TU in Fig. 40-10) is created between vagina and urethra at the level of the mid-urethra. The tape is inserted into the tunnel and brought through the anterior abdominal wall with the delivery instrument. Cystoscopy is performed. The tapes are pulled up one side at a time and adjusted for tension over a no. 7 Hegar dilator.

### Transobturator Approach

The transobturator approach is not strictly anatomic, because the PULs descend vertically. The entry point is from the medial border of the obturator foramen, at the level of the clitoris. This anatomy explains instances of bladder perforation with this method, suggesting that it may be prudent to perform cystoscopic examination after placement of the tape. The tape is horizontally disposed, so care needs to be taken that it sits at the mid-urethra. The transobturator approach avoids small bowel and major vessel perforation. Potential disadvantages are damage to the obturator nerve or vessels or to the urethra.

**Figure 40-8** Transperineal sonogram showing simulated operation with bladder and urethra at rest (A), on straining (B), and after midurethral anchoring (arrow) with hemostat (C). Note backward stretching of the anterior (a) and posterior (p) vaginal walls on straining and their apparent tensioning after midurethral anchoring. S = symphysis pubis.

### Suprapubic Approach

Anatomically, the suprapubic approach is similar to the midline vaginal approach, except that entry of the application instrument is from above downward.

### Potential Intraoperative and Postoperative Problems of the Suburethral Tension-Free Tape Slings

It is emphasized that inserting a suburethral sling with a delivery instrument is a blind procedure. The small bowel in the prevesical pouch, the bladder, the external iliac vessels, and the obturator nerves and vessels all lie within 2 cm of the track taken by the instrument. Creating a hole in the pelvic diaphragm directly below the bone and orienting the delivery instrument so that it can move only upward greatly reduce (but do not eliminate) the possibility of major complications.

### Difficulty with Passage of the Delivery Instrument

Often, the subpubic ligaments are strong. Dissect a space with scissors. Avoid excessive pressure on the delta wing handle, because this may make the point dig into the soft cartilage of the symphysis and obstruct upward movement. Always ensure that the delta wing is horizontal on re-entry.

### Retropubic Fibrosis from Previous Incontinence Surgery

Use dissecting scissors to create a plane of dissection between periosteum and scar tissue. Continue for 2.5 to 3 cm. This creates a plane between bone and scar tissue. If resistance continues, reinsert scissors and continue further dissection upward. Reinsert the delivery instrument. On rare occasions, it is only possible to insert one side of the sling. In such circumstances, attach the other side deep into the pubococcygeus muscles.

**Figure 40-9** Midline approach. The perspective is looking into the anterior vaginal wall. A midline incision is made. Hammock tightening supports the tape from below. *A*, external iliac artery; *PCM*, pubococcygeus muscle; *U*, ureter; *V*, external iliac vein.

### Scarring in the Rectus Sheath

Because of a previous abdominal operation, the surgeon may occasionally need to cut down onto the rectus sheath with a scalpel.

### Bleeding

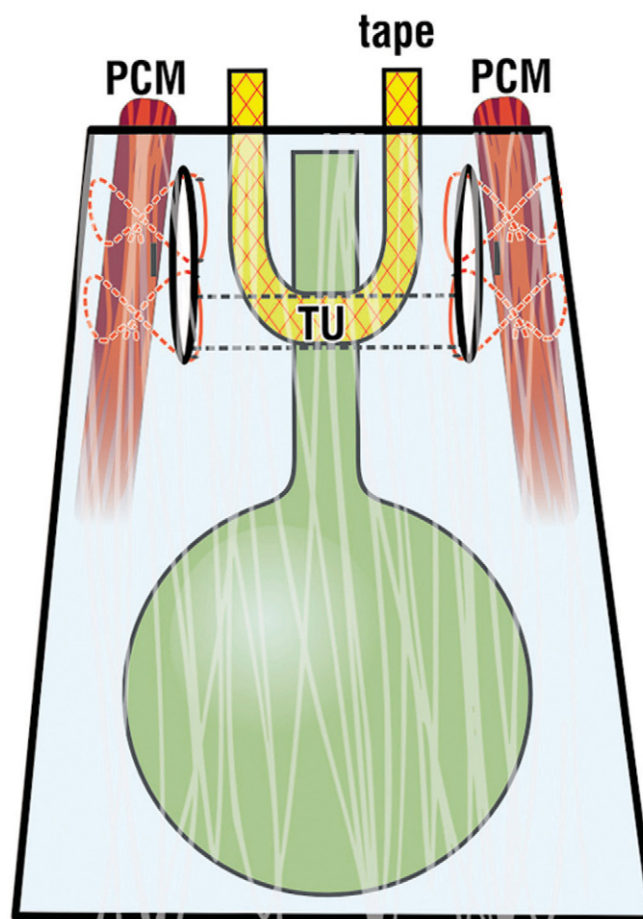

There are venous sinuses immediately below the pubic bone. As soon as the tape has been inserted, apply digital pressure for 2 to 3 minutes. If there is overt bleeding, insert a hemostatic gel along the tape from below and reapply digital pressure until the bleeding ceases.

### Bladder Perforation

Bladder perforation may occur in the superolateral surface, usually between 11 and 12 o'clock. If this occurs, remove the tape and reinsert it. Use a cystoscope with a sheath, and fill the bladder with 500 mL of fluid. Sometimes, there is no bleeding with perforation. The only sign of perforation may be the finding of a low bladder volume at the end of the operation due to extraperitoneal loss. If bladder perforation is suspected and cannot be identified, inject 1 ampoule of methylene blue into 100 to 200 mL of saline, fill the bladder, and look for suprapubic staining at the abdominal exit of tape.

### Urethral Constriction by the Tape

Failure to pass any urine at all within 48 hours usually indicates a tape obstruction that needs to be surgically relieved. In the few cases that have occurred in my experience, microscopic loops were used to identify the shiny fibrils of the tape, which is always under tension. The tape retracts immediately when touched (cut)

**Figure 40-10** Paraurethral approach. Paraurethral vaginal skin incisions are made. The tape is passed through a tunnel (*TU*) between the incisions. The perspective is looking directly into the vagina. *PCM*, anterior portion of pubococcygeus muscle.

gently with a sharp blade. Constriction can generally be avoided by pressing downward against an intraurethral no. 7 Hegar dilator when tightening a non-elastic tape, or leaving a space if elastic.

### Tape Rejection

This technology works by creating a foreign body reaction in the form of scar tissue to reinforce a damaged ligament. An excessive reaction is uncommon and may manifest as a purulent discharge. The pus is sterile and nonthreatening. A more common problem is tape slippage and surfacing into the vagina. This is also mostly benign, because the tape by that time is encased in a fibrous tissue cylinder. Almost invariably, the patient is afebrile, with a normal white blood cell count and a lack of bacterial growth on vaginal swabs.<sup>6</sup> To remove a partly rejected (surfaced) tape, place scissors on each side of the extruded tape, press upward against the vagina, and cut the tape. If there is significant infiltration of tissue into the tape, a segment may need to be excised and the vagina sutured.

### Tape Infection

A virulent organism such as streptococcus may cause a bacterial infection. Unlike a foreign body reaction, this is potentially serious, and the patient may present with pyrexia, swelling, and erythema at the site of the tape. Under no circumstances should

**Figure 40-11** Rat study at 2 weeks. Multifilament fibrils (PP) are surrounded by macrophages (M).

the sinus be excised, because attempts to do so may result in a pelvic abscess or even bacteremia. The best way to manage this complication is to take a swab and treat with antibiotics. Once the infection has settled, the tape should be removed in part or completely from the vagina. In the operating room, the sinus is located, and the tape is grasped and removed by pulling on it. An infected tape invariably just slips out. Intraoperative hematoma and obesity appear to be predisposing factors to infection, but the weave of the tape is not, because macrophages have been demonstrated to surround the fibrils as early as 2 weeks<sup>11</sup> (Fig. 40-11).

### Subpubic Approach: A Promising Direct-Vision "Micro" Technique

Although minimal morbidity is the norm, all midurethral sling operations, without exception, have a potential for major, even fatal complications, such as small bowel injury, obturator nerve injury, and external iliac and obturator vessel injury.<sup>12</sup> Ostergard<sup>12</sup> attributed such complications to the blind nature of these procedures. The growing list of serious complications<sup>12</sup> was the motivating factor behind the development of a safer delivery instrument, the tissue fixation system (TFS). The TFS consists of a polypropylene tape with two soft tissue anchors at each end (Fig. 40-12).

The anchors sit inside a plastic saddle and are ejected 0.5 cm into the tissues below the pubic bone by a stainless steel applicator. The TFS anchor works like a grappling hook, anchoring into the soft tissues below the pubic symphysis. The base of the anchor incorporates a one-way system for tightening of the tape. This is a crucial part of the TFS system, because muscle forces need an adequately firm ligament for the optimal contraction required to effect watertight urethral closure.

The TFS is performed under direct vision, so it avoids viscus, nerve, and major vessel injuries. It vastly decreases operating time (mean, 5 to 6 minutes). The operation is identical to the first part of a midline midurethral sling operation. A full-thickness midline incision is made into the vagina from just below the external urethral meatus to the mid-urethra. The vagina is dissected off the urethra with dissecting scissors, and the dissection is carried

**Figure 40-12** The tissue fixation system (TFS). A, soft tissue anchor; T, tape.

**Figure 40-13** Subpubic midurethral sling. The tape reinforces the pubourethral ligament, restoring contractility of all three muscle forces (arrows), so that the urethral tube is restored from the open (O) to the closed (C) position during effort. H, hammock; LMA, longitudinal muscle of the anus; LP, levator plate; PCM, pubococcygeus muscle; PS, pubic symphysis.

down just below the pubic bone. The TFS applicator is placed into the space and triggered so that the TFS anchor enters the perineal membrane (Fig. 40-13). The procedure is repeated on the contralateral side. The tape is tensioned just sufficiently for it to fit snugly on the urethra without indenting it over an 18-gauge Foley catheter. Both ends of the tape are cut 1.5 cm from the TFS anchor, and the hammock and EUL are tightened as described earlier. No cystoscopy is required. Intraoperative bleeding is minimal.

Results ( $N = 35$ ) at 9 months<sup>13</sup> and at 3 years are promising >80% cure (Petros PEP and Richardson PA, unpublished data).

All patients to date were discharged within 24 hours of surgery, with no postoperative urinary retention. No opiates were needed postoperatively for the anterior sling operations. No significant complications were encountered. Surgical cure for both SUI and ISD was equivalent to that previously described for tension-free tape slings.<sup>2,9</sup> The main potential disadvantage of the TFS is that the operation will not work unless the anchor grips into the target tissue. The cause of failure may be poor tissues or surgeon error in placement; both were encountered in the first group of patients. Half of the sling was found surrounded by a granuloma in one patient, and the operation failed in another four patients without tape surfacing. The operation was successfully repeated in four

of the five patients. In another patient with a “frozen” retropubic space, subpubic anchoring was not possible, and the anchor required more lateral anchoring.

## CONCLUSIONS

The importance of a midurethral sling for continence control is now well accepted. Future challenges are the application of less invasive methods, how to more accurately assess the other connective tissue structures contributing to continence control, and how best to repair them.

# DISTAL URETHRAL POLYPROPYLENE SLING

*Nasim Zabihi, M. Grey Maher, and Larissa V. Rodríguez*

The sling procedure, first described in 1907 by Von Giordano, has been used for the treatment of female stress urinary incontinence (SUI) for almost 100 years.<sup>1</sup> This procedure was reintroduced in 1978 by McGuire and Lytton, who used autologous rectus fascia suspended under the bladder neck for the treatment of intrinsic sphincter deficiency.<sup>2</sup> In the past 25 years, a significant number of surgical procedures have been devised for the treatment of SUI, including multiple sling variations. A meta-analysis of various surgical techniques used in the treatment of SUI revealed that slings have similar durability to retropubic suspensions and are more efficacious than transvaginal suspensions and anterior repairs.<sup>3</sup> In the past decade, slings have gained popularity, because new surgical techniques, sling materials, and anchoring methods have led to decreased surgical morbidity and convalescence time while providing good durability and ease of placement.

Given this widespread popularity, many new procedures, materials, and packaged kits have emerged. Most sling procedures can be categorized by location of the sling (proximal urethra and bladder neck versus middle to distal urethra), choice of sling material (autologous graft, xenograft, cadaveric graft, or synthetic material), anchoring method, sling length, and degree of penetration into the retropubic space. This chapter discusses mid-distal urethral slings and describes the surgical technique and clinical outcomes of the distal urethral polypropylene sling (DUPS) procedure.

### MID-DISTAL TO DISTAL SUBURETHRAL SLINGS

Slings were classically reserved for the treatment of SUI in the absence of urethral hypermobility. Although the exact mechanism by which slings restore continence remains elusive, the introduction and success of the mid-distal to distal slings have expanded understanding of the urethral support and continence mechanism. Klutke and colleagues demonstrated that anatomic correction of bladder neck hypermobility was not necessary to cure SUI.<sup>4</sup> The tension-free vaginal tape (TVT), introduced in 1996, has been shown to be an effective treatment for SUI.<sup>4-18</sup> Studies have demonstrated the TVT procedure to be as effective as open colposuspension, with documented cure rates of 81% and an improvement rate of 94%.<sup>19</sup> Given the success of the TVT and based on the same anatomic principle and mechanism of action, other procedures such as SPARC (American Medical Systems, USA), Safyre (Promedon, Argentina), SABRE (Mentor Corporation, USA), and the transobturator tape (TOT; Mentor), among others, have been described for the treatment of SUI. All of these procedures involve the placement of a synthetic sling at the level of the mid-distal to distal urethra and are available as

commercially packaged kits that include placement needles or passers and prefabricated slings. The primary difference is the approach to placement (i.e., from the suprapubic area to the vagina or from the vagina to the suprapubic area), sling length, passage through the retropubic region or not, and variations in the hardware necessary for placement. The special equipment requirements along with the high cost of the packaged kits make it difficult to use these devices in many parts of the world. Additionally, many of these techniques are done blindly without finger guidance, which can lead to high rates of bladder perforation and rare but major complications such as bowel or major vessel injuries resulting in severe morbidity.<sup>20-22</sup>

DUPS uses the same anatomic location and therapeutic principles as the other mid-distal slings described mentioned earlier, and it has been shown to be effective in the treatment of SUI.<sup>23,24</sup> However, it has a lower risk of major injuries, because the sling is placed under tactile guidance through the retropubic space. The sling used is a 10 × 1 cm, short piece of soft, loosely woven mesh with large pores attached to absorbable sutures. Although the sutures traverse the retropubic space, the mesh itself traverses only 2 to 3 cm on each side into the retropubic space, because the presence of a small segment of mesh in the retropubic space is an important factor to cure SUI. Most of the other slings are self-fixating to the abdominal wall or the obturator muscle; DUPS uses a short segment of mesh attached to absorbable sutures for temporary support of the mesh until it becomes incorporated. This avoids complications such as infection or inguinal pain secondary to nerve entrapment from the suprapubic fixation while providing adequate attachment and fixation to the retropubic space. Additionally, these mesh properties lessen the chance of complications such as mesh erosion into the urethra. DUPS is a simple, quick, and inexpensive procedure with a lower risk of major complications compared with other slings.

### SURGICAL TECHNIQUE

The patient is placed in high dorsal lithotomy position. The lower abdomen and genitalia are prepared and draped in sterile fashion, the labia are retracted laterally with stay sutures, and the bladder is emptied with a 16-Fr urethral Foley catheter. A weighted vaginal speculum is used for exposure. An Allis clamp is used to grasp the anterior vaginal wall just proximal to the meatus. Two oblique lateral incisions are made in the anterior vaginal wall (Fig. 41-1). Another Allis clamp is placed at the distal end of each of the oblique incisions, and the dissection is carried out laterally over the glistening periurethral fascia toward the ipsilateral shoulder. The retropubic space is entered at the level of the mid-

**Figure 41-1** Two oblique lateral incisions are made in the anterior vaginal wall.

distal to distal urethra, using curved scissors directed parallel to the urethra just under the pubic bone (Fig. 41-2).

A fine right angle clamp is then used to create a suburethral tunnel in the anterior vaginal wall, 1.5 cm from the urethral meatus (Fig. 41-3). The sling, which is a 1 × 10 cm, thinly woven, soft polypropylene (Ethicon, Inc., NJ) mesh with 1-0 polyglactin (Vicryl) sutures placed at each end, is then transferred underneath the suburethral tunnel (Fig. 41-4). The next step is to transfer the ligature attached to the sling through the retropubic space.

One fingerbreadth cephalad to the symphysis pubis, a small puncture wound is made with a no. 15 scalpel. A double-pronged needle (Cook Urological, Spencer, IN) is passed under finger guidance through the fascia and retropubic space to the level of the oblique vaginal incision (Fig. 41-5). This prevents vascular and bowel injuries, because the needle is transferred under direct control just posterior to the pubic bone. The polyglactin sutures previously placed at the edge of the soft polypropylene mesh are transferred to the suprapubic incision. This maneuver is done bilaterally, and cystoscopy is performed to rule out bladder or urethral perforations.

To ensure a tension-free sling, one Allis clamp is placed through each vaginal incision, and the mesh is grasped and held firmly in the horizontal plane (Fig. 41-6) while the assistant ties

**Figure 41-2** The retropubic space is entered at the level of the mid to distal urethra using curved scissors.

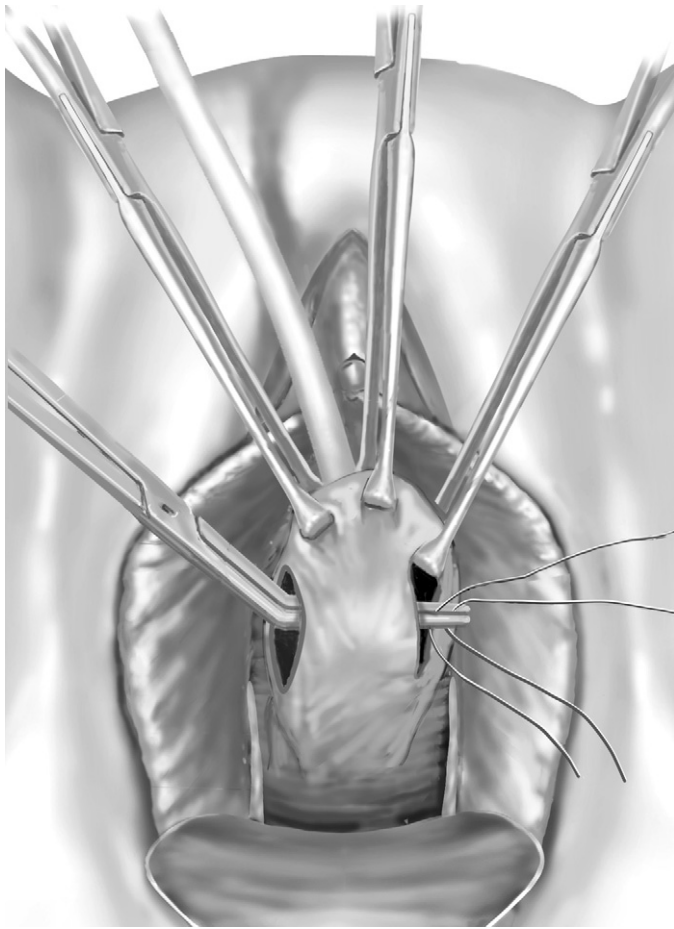

the polyglactin sutures suprapubically, 1 mm below the skin level and not immediately above the fascia. The vaginal incisions are closed with 3-0 polyglactin running stitch, and the suprapubic puncture wound is closed with a 4-0 polyglactin subcuticular stitch. A vaginal pack and dressing are applied.

In the recovery room, 2 hours after the procedure, the vaginal pack and the Foley catheter are removed and the patient is discharged home. If the surgeon prefers to keep the bladder drained, the patient can be sent home with the urethral catheter, or a suprapubic tube (SPT) can be placed at the beginning of the case. We place an SPT only if concomitant extensive vaginal reconstruction or hysterectomy has been performed. If a suprapubic tube is left in place, it is capped before discharge, and the patient is instructed to record her postvoid residuals; it is removed once the residuals are less than 50 mL.

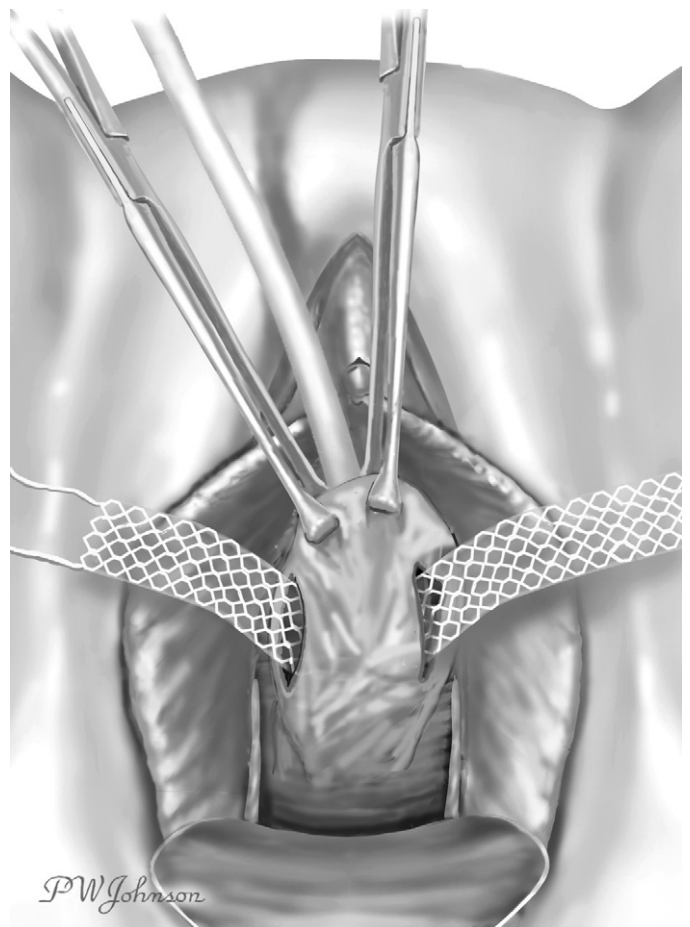

### SURGICAL OUTCOMES

A total of 840 patients have undergone the DUPS procedure at the University of California, Los Angeles Medical Center. The procedure is durable with equivalent 1-year and 5-year outcomes.<sup>24,25</sup> The original cohort, which included 69 patients, was monitored for 5 years. This cohort represented a complex

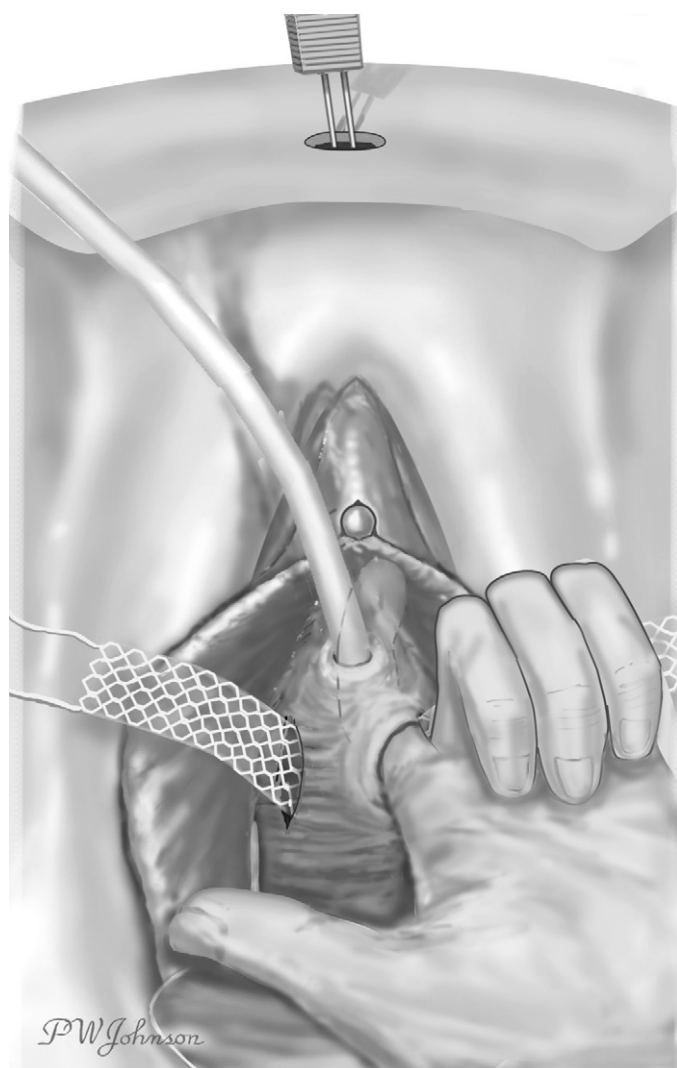

**Figure 41-3** Suburethral tunnel is created in the anterior vaginal wall using a fine tipped right angle clamp.

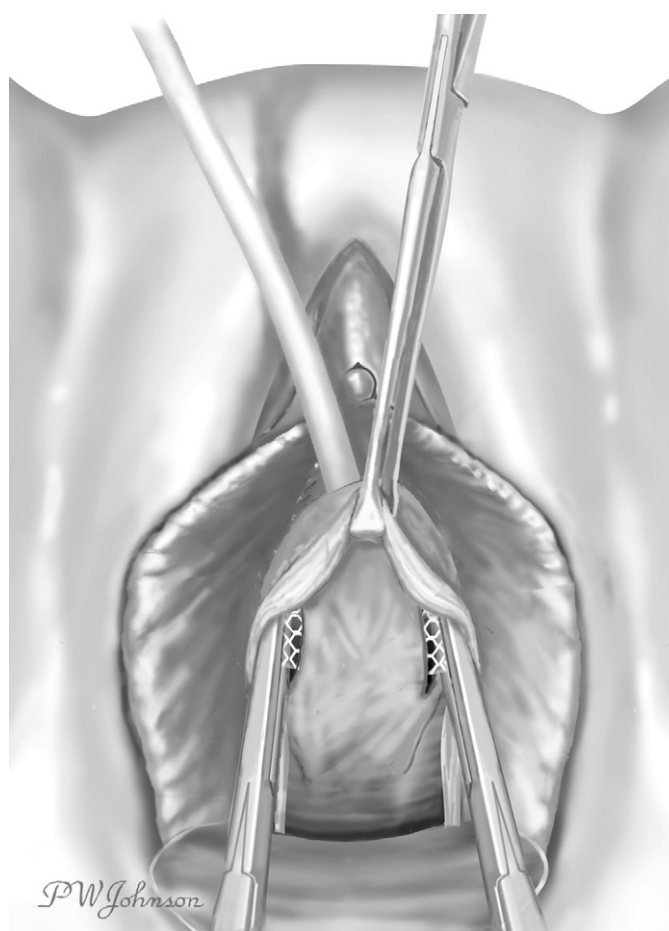

**Figure 41-4** The mesh is transferred under the previously created tunnel.

**Figure 41-5** A double-pronged needle is passed under finger guidance from the suprapubic stab wound, through the retropubic space, to the level of the oblique vaginal incision.

group of patients, as expected in a tertiary referral center: 52% percent had prior failed anti-incontinence therapy, 36% underwent concomitant prolapse surgery, and 54% suffered from mixed urinary incontinence. There were no intraoperative complications.

To report their outcomes, the authors used patient self-assessment questionnaires to eliminate physician bias, because studies have shown that evaluation of treatment outcomes using patient self-assessment tools demonstrates lower cure rates compared with physician assessments and that objective cure rates and clinical outcomes do not always translate to patient satisfaction.<sup>26-29</sup> Patients completed a symptom questionnaire and the short form of the Urogenital Distress Inventory (UDI-6).<sup>30,31</sup> They also answered a global quality-of-life question related to urinary symptoms and recorded the quantity of pads used per day. Seventy-two percent of the patients denied any symptoms,

**Figure 41-6** Allis clamps are used to hold the sling in the horizontal plane.

74% denied any bother from SUI, and 93% reported that they had SUI less than once per week and were rarely bothered by symptoms of SUI. The average pad usage decreased by 74% ( $P < .05$ ), and 56% reported wearing no pads at all. Patients, on average, reported a symptom improvement of 81% after surgery, and 62% of patients reported a 90% or greater improvement. At a minimum follow-up of 5 years, none of the patients had permanent retention or had undergone removal of the sling material for pain, infection, or mesh erosion.<sup>32</sup>

A multicenter randomized trial documented objective cure rates of 63% for TVT and 51% for colposuspension.<sup>33</sup> The cure rates of DUPS at 72% are similar but slightly better than those of other sling procedures when the assessment is done by subjective, patient-driven questionnaires.<sup>33,34</sup>

## CONCLUSIONS

The DUPS is an effective, safe, simple and inexpensive procedure for the treatment of SUI. It offers effective therapy while eliminating the prohibitive cost and equipment requirements associated with the use of other prepackaged slings.

# THE SPARC SLING SYSTEM

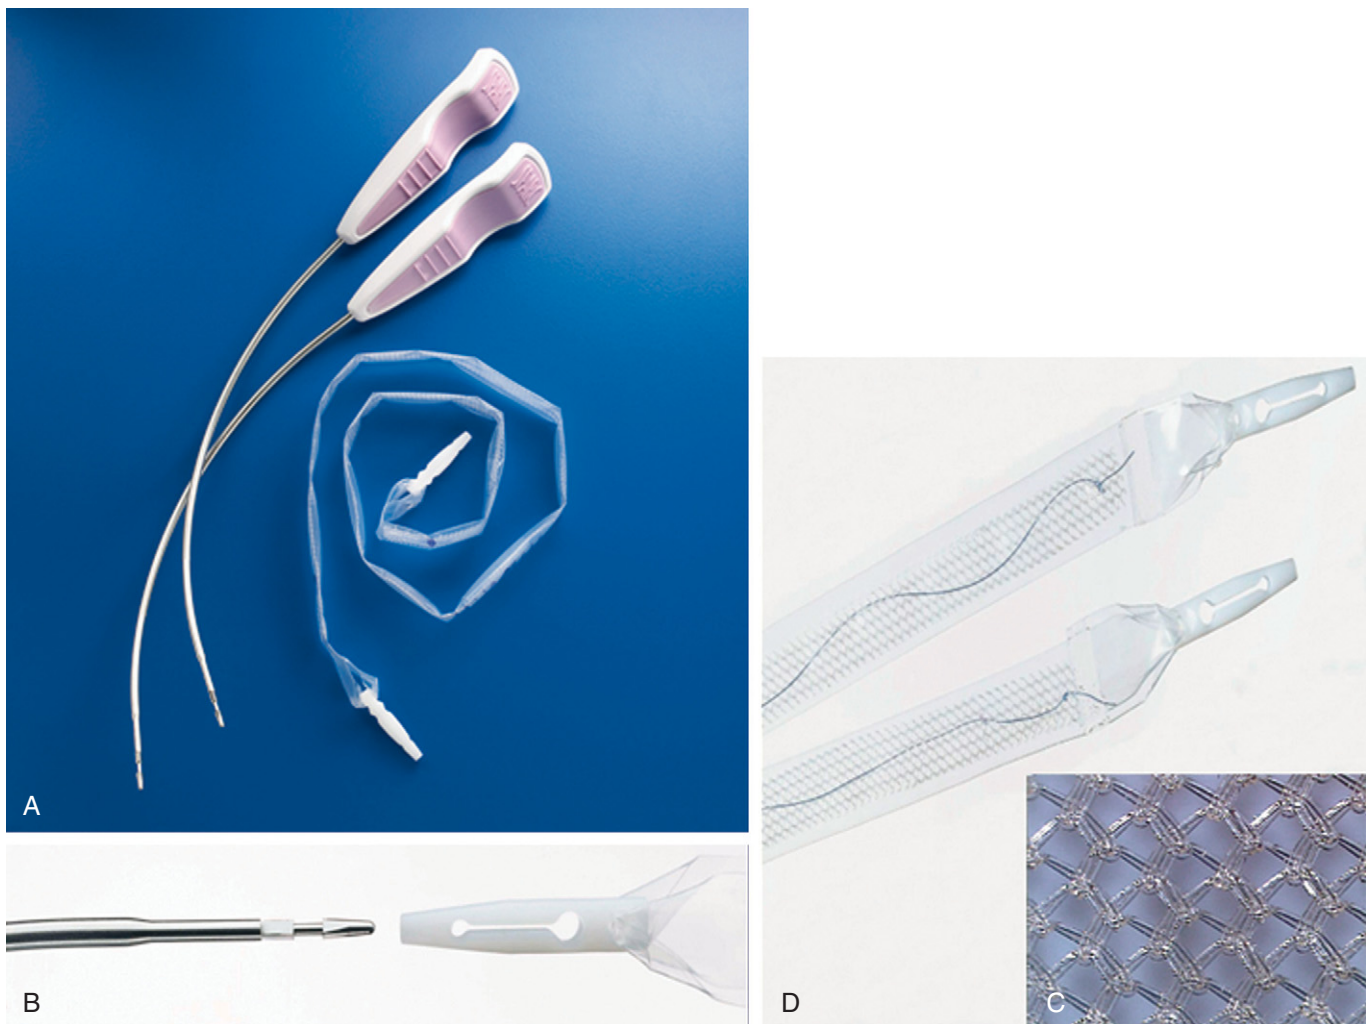

David R. Staskin and Renuka Tyagi

The SPARC Sling System (American Medical Systems, Minnetonka, MN) is a minimally invasive pubovaginal sling procedure using a loosely knitted, self-fixating, 1-cm wide, 4-0 polypropylene mesh, which is placed at the level of the mid-urethra by passing the suspension needle via a suprapubic-to-vaginal approach.<sup>1-3</sup> The placement of pubovaginal slings in the treatment of genuine stress urinary incontinence has historically been effective, with excellent long-term outcomes.<sup>4</sup> This variation of surgical technique results from the drive to decrease surgical morbidity associated with autologous fascia harvesting; it also

minimizes the risk of intraoperative complications from minimally invasive sling placement without affecting surgical outcomes (Fig. 42-1).<sup>5-12</sup>

### MECHANISM OF ACTION

Continence results from multiple factors: resting urethral tone, active sphincter contraction, external compression, pressure transmission, and integrity of anatomic configuration. The

**Figure 42-1** (A) Suspension needles: disposable ergonomic, 0.118 inches diameter, 8.2 inches long, and noncutting. (B) Connector-dilators: create the sling tract and enable the suspension needles to be of small diameter, minimizing trauma; do not require sling attachment and tract formation until the needle position has been confirmed; permit untwisting of the mesh after attachment. (C) Mesh sling: biocompatible 4-0 loosely knitted polypropylene. (D) Plastic sheath: permits smooth placement of self-fixating mesh.

success of midurethral sling techniques has prompted a re-evaluation of the pathophysiology of genuine stress urinary incontinence and the paradigm for its surgical correction. The mechanism of action for midurethral slings is presumed to be mimicking of the support provided by the pubourethral ligaments and suburethral fascial support.<sup>13</sup>

The importance of urethral stabilization from rotational motion has generally been accepted and was introduced as the “integral theory” based on data collected during radiologic evaluation of micturition.<sup>14</sup> This correlated with structures documented on anatomic dissection and was dubbed an “anatomic hammock.”<sup>15</sup> The importance of urethral configuration suggests that midurethral support prevents separation of the posterior urethral wall from the anterior urethral wall during rotational motion around the inferior portion of the pubic ramus, which appears integral to continence.<sup>16</sup> Suburethral support and stability, in conjunction with urethral coaptation, appears to be the critical factor in the restoration of continence, and elevation of the bladder neck may no longer be a prerequisite.

## SURGICAL TECHNIQUE

### Positioning

A standard or modified lithotomy position may be elected based on surgical preference and concomitant procedures, with a supine pelvis-inclined (Trendelenburg) position recommended. Adequate distal vaginal exposure for a 1.5-cm midurethral incision is required; however, vaginal retraction sutures or a complex retractor is usually not required for sling placement alone. A weighted speculum and placement of a Foley catheter (14 to 18 Fr) through the urethra to completely drain the bladder is preferred.

### Anesthesia

Anesthesia may be selected according to patient and surgeon preference and may include any of the following: general, regional, or local anesthesia with/without intravenous sedation. If a local anesthetic is elected, it should be noted that the primary source of discomfort for the patient is contact with the periosteum of the pubic bone during needle passage. Local injections should include two approaches: the abdominal surface, with local anesthesia of the abdominal skin, rectus fascia, and muscle; and a paravaginal approach, to anesthetize the inferior border of the pubic ramus.

### Incisions

Two parallel, 15-blade stab incisions are made above the pubic symphysis 1.5 cm from the midline (3 cm apart). The surgeon should avoid incisions lateral to this area to keep away from the ilioinguinal nerve exiting from the external ring (Fig. 42-2).

Next, the bladder neck should be identified, the submeatal fold may be elevated using an Allis clamp, and a midline incision is performed through the vaginal mucosa over the mid-urethra. This incision, centered over the mid-urethra, may vary between 1.5 and 3 cm (Fig. 42-3). If the procedure is performed without local anesthetic, a saline injection at the level of the mid-urethra, extending laterally, may be elected to aid in development of the plane of dissection between the vaginal epithelium and the peri-

**Figure 42-2** Suprapubic transverse stab incisions placed 1.5 cm from the midline at the upper margin of the pubic symphysis.

**Figure 42-3** The vaginal mucosal incision is placed at the level of the mid-urethra, as demonstrated in this image by the “starburst” marks over the urethral meatus and bladder neck. The incision may vary in total length between 1.5 and 3 cm.

urethral fascia. Metzenbaum scissors are used to create a sub-mucosal tunnel to the inferior border of the pubic ramus at the level of the mid-urethra bilaterally. The tunnels may be narrow enough for just the needle and connector dilator to traverse the distance, or they may be wide enough to accommodate insertion of a fingertip. With the “narrow tunnel” approach, the fingertip is placed in the paravaginal fornix, outside the incision, in order to palpate needle perforation through the endopelvic fascia (recommended).

**Figure 42-4** Initial placement of the SPARC needle through the suprapubic incision directly onto the pubic symphysis with the handle directed toward the surgeon. Throughout passage of the needle, the surgeon's hands remain on the needle shaft, and the needle handle is used only as a visual reference point.

**Figure 42-5** Perforation of the rectus fascia above the pubic symphysis by the needle is followed by immediate 90-degree rotation of the needle. The handle of the needle is now directed toward the ceiling, and the needle is advanced along the posterior surface of the pubic bone.

### Needle Passage

Effective needle passage is divided into two phases: entrance into and traversing of the retropubic space first, followed by perforation of the endopelvic and periurethral fascia. Needle passage may be described in five steps:

1. *Approach to the anterior surface of pubic symphysis:* Holding the needle itself with the fingertips of both hands, pass the needle from the stab incisions above the pubic symphysis directly down on the bone. During this maneuver, the needle handle is pointed toward the surgeon (Fig. 42-4).
2. *Perforation of the rectus fascia and rotation around the superior surface of the pubic symphysis:* Slide the tip of the needle along the superior surface of the bone and then direct it downward to perforate the rectus fascia and muscle. Grasping the needle itself near the end with the fingertips rather than the handle permits more control of the straight portion of the curved needle. After fascial perforation, the needle handle should rotate to 90 degrees (up toward the ceiling) as the needle is advanced, to keep the tip of the needle on the posterior surface of the pubic bone (Fig. 42-5).
3. *Traversing the retropubic space:* Guide the needle inferiorly, with the handle rotated 10 degrees medially—"walking downward along the bone," again with the fingertips, until the endopelvic fascia is encountered (Fig. 42-6).
4. *Palpation of the needle tip at the endopelvic fascia:* Grasp the handle of the needle; palpate the needle tip with the alternate index finger beneath the vaginal wall and guide it to the desired point of perforation. Locate the needle point beneath the vaginal wall with the finger and guide it to the perforation point. The perforation point is as lateral as possible against the inferior border of the pubic ramus, at the level of the mid-urethra (Fig. 42-7).
5. *Perforation of the endopelvic/periurethral fascia and exposure of the needle tip through the vaginal incision:* To perforate the fascia, push the needle through the endopelvic and periure-

thral fascia without placing the finger within the vaginal incision (recommended) or by placing a fingertip in the incision. Once the needle perforates the fascia and can be felt beneath the epithelial layer, it can be guided through the dissected tunnel. Be sure the needle has perforated the fascia before directing it medially. If necessary, allow needlepoint perforation of the vaginal epithelium, withdraw the needle, and then guide it out of the incision. Failure to completely perforate the fascia before medial direction of the needle out of the incision decreases the distance between the perforation point and the urethra (Fig. 42-8).

The following guidelines are suggested to avoid intraoperative complications during needle passage.

1. To avoid perforation of the bladder, keep the tip of the needle on the superior, then posterior portion of the symphysis pubis *at all times*.
2. To avoid urethral trauma, pass the needle directly against the surface of the inferior portion of the pubic ramus at the level of the mid-urethra onto the lateral tip of the index finger, while deviating the urethral catheter medially with the superior surface of the finger.
3. Major vessel injury should be avoided by adhering to the surface of the pubic bone. The inferior epigastric artery and vein and the endopelvic veins are subject to inadvertent trauma with any needle passage. The iliac and obturator veins are not in the direction of needle passage or the force vector of perforation with suprapubic needle passage, in contrast to the situation with periurethral fascia or endopelvic fascia perforation from the vaginal approach.
4. Small and large bowel injury should similarly be avoided by maintaining the needle tip against the pubic bone during passage. Bowel should not be adherent to the pubic bone *except* in the case of prior abdominal surgery that entered the retropubic space or the presence of a lower abdominal incisional or inguinal hernia.

**Figure 42-6** Retropubic advancement of the needle is performed with the needle tip against the posterior surface of the pubic bone and the handle rotated 10 degrees medially. The needle is advanced inferiorly until the tip is palpable with a finger in the vagina.

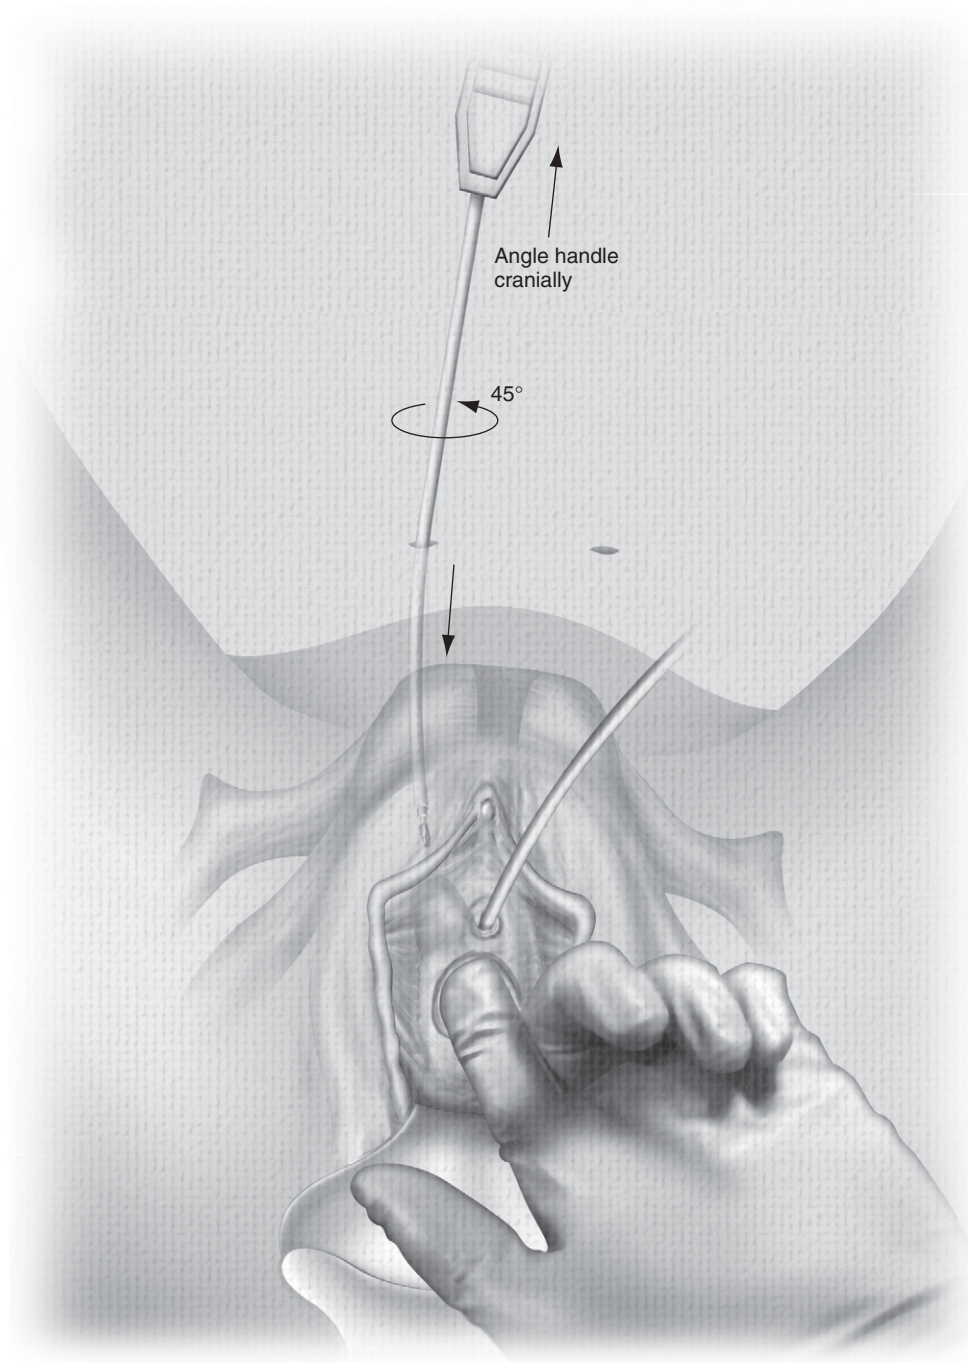

### Cystoscopy

After both needles have been passed, cystoscopy is performed with a minimum of 350 mL in the bladder to ensure that the needles are not in a bladder fold or “mucosal pinch.” Needle perforation, if present, is often noted at 10 or 2 o’clock near the bladder neck, and additional care should be taken to view the urethra on scope insertion and/or removal. The bladder may be left distended on removal of the scope.

### Sling Attachment and Transfer

Sling attachment and transfer is performed as follows:

1. The plastic sheath containing the sling material may be irrigated with sterile saline or water before attachment to aid in smooth removal of the plastic.
2. The sling is positioned for attachment to the needles by facing the markings toward the surgeon. The center of the sling is clearly marked with arrows radiating from the center (Fig. 42-9).
3. The connectors are attached to the needle tips using gentle pressure until a “snap” is felt and heard.
4. The surgeon confirms that the sling is correctly positioned flat and with the markings on the outside of the mesh. The connectors can be twisted on the needle tips to adjust the sling position.
5. The needles are directed into the retropubic space by placing the index finger at the tip of the connector and pushing the connector-needle up into the retropubic space. This “pushing” maneuver minimizes disruption of the periurethral and endopelvic fascia. The surgeon should avoid pulling the handle of the needle until the white connector has been “pushed” back into the retropubic space through the endopelvic fascia.

**Figure 42-7** Perforation of the endopelvic fascia under guidance of the finger in the vagina. The needle tip is palpated with a finger in the vagina that is concurrently displacing the urethra medially. The needle is positioned on the lateral edge of the finger and then advanced through the endopelvic/periurethral fascia.

6. The needle handle is used to complete retrograde removal of the suspension needle. Gentle traction on the needle at the level of the skin permits complete needle removal with minimal dilation at the skin level. The sling is pulled through the skin incision for several centimeters on each side.
7. Before adjusting sling tension, the plastic sheath should be re-examined at the vaginal incision for leakage from the

bladder. If there is any suspicion of leakage, a repeat cystoscopy should be performed. If the sling is identified within the bladder, it should be cut closely below the white dilator-connector, withdrawn within the plastic sheath, and repositioned with an alternative “free suspension needle” by suturing the plastic to the needletip. The Foley catheter is now replaced for drainage of the bladder.

**Figure 42-8** Vaginal exposure of the needletip. The needles are guided through the previously dissected submucosal tunnels and out the vaginal incision, either with a fingertip within the tunnel or with palpation through the mucosa.

### Sling Tensioning and Fixation

The sling tension is adjusted by pulling the sling up through the suprapubic incisions against a spacer placed in the vaginal loop, or, based on individual surgeon preference, against a large scissor or dilator (e.g., no. 8 Hagar). Optimal sling tension is demonstrated when slight movement of the instrument within the mesh loop initially occurs.

The sling and plastic sheath are cut at the level of the “blue dots” below the dilator-connectors (Fig. 42-10). Hemostats are placed on each of the cut plastic sheaths, using care to avoid the mesh (Fig. 42-11). The suburethral spacer is stabilized with one hand as the plastic sheath on each side is removed with the other. The mesh is then cut below the skin level, with gentle traction on the ends to allow retraction of the mesh beneath the skin level (Fig. 42-12).

### Closure

Steri-Strips are applied to the suprapubic incisions, and the vaginal incision is closed using a running 2-0 absorbable suture.

**Figure 42-9** Sling attachment. The sling connectors are positioned adjacent to the needletip with the sling markings adjacent to the connector and in the center of the sling facing toward the surgeon. Gentle pressure is applied to the connectors until they “snap” onto the needletips.

**Figure 42-10** Cutting of the plastic sheath. The plastic sheath and sling material are cut below the blue dots to allow for removal of the sheath.

**Figure 42-11** Sheath removal. Hemostats grasp the plastic sheath alone and are used to remove the sheath. The spacer should be stabilized as the plastic is removed.

### CONCOMITANT PROCEDURES

If additional pelvic organ prolapse repair procedures are planned, apical and anterior vaginal repairs may be completed before placement of the SPARC sling. In particular, if a cystocele repair is planned, it should be performed with repair of the bladder base but *not* the bladder neck area. A Kelly repair is not recommended, because it may elevate bladder neck support and may disrupt the pressure transmission to the mid-urethra by altering bladder neck motion with reference to the sling. In addition, use of a separate incision, if possible, for placement of the SPARC sling avoids extension of a hematoma or drainage from the cystocele repair and prevents resultant disruption of the incision over the sling.

### POSTOPERATIVE CARE

The patient is sent to the recovery room with a Foley catheter in place. It is important, especially after an epidural or spinal anesthesia, that the patient be fully ambulatory and free of any residual anesthetic before the voiding trial, to avoid iatrogenic anesthetic retention.

The active voiding trial is performed as follows:

1. Fill the bladder via the Foley catheter to 300 mL or until full, and remove the catheter.
2. Measure the void. A void of greater than 200 mL (two-thirds of capacity) or a residual measured by ultrasound of less than 100 mL (one-third of capacity) is considered adequate for discharge.
3. If the residual is greater than 100 mL, the patient is rechecked after an additional void. The patient may be discharged with a leg bag and the voiding trial repeated in the office the next day.

### Managing Postoperative Retention

The SPARC procedure results in placement of the sling below the mid-urethra with no tension and minimal disruption of normal proximal urethral mobility. This change in sling placement has resulted in a substantial decrease in urinary retention, similar to other minimally invasive pubovaginal slings.<sup>17</sup>

**Figure 42-12** Excess mesh is cut below skin level at the suprapubic incisions. Gentle traction on the mesh allows the ends to retract beneath the skin.

Loosening of the SPARC sling may be initiated intraoperatively if the sling is tensioned too tightly during removal of the plastic sheath, or postoperatively if the patient presents with urinary retention or symptomatic impaired voiding. The tensioning suture within the sling mesh provides a restraint to sling stretching during loosening of the sling tension. The sling can be

loosened by placing a right angle beneath the sling and then pulling the sling down with a right angle clamp or with a 1-0 Prolene suture that has been placed around the sling. Postoperative sling adjustment should be done within 2 to 3 weeks after implantation, because local tissue in-growth and biodegradation of the tensioning suture soon begin to affect the ability to “move” the sling. Pulling on the sling will result in a “pop” and slight patient discomfort at the suprapubic site, indicating that the sling has moved at the rectus fascia layer.

Late postoperative retention that does not improve with conservative management or early adjustment of sling tensioning may be addressed with urethrolysis. A midline urethrolysis may be performed if there has been no significant tissue in-growth into the sling. If significant in-growth exists, a lateral approach is recommended to avoid urethral injury. After identification of the sling, a nerve hook or right angle clamp may be used to mobilize the sling and hold it on tension. The sling may be transected with scissors, after which the sling tension is adjusted.

### Managing Postoperative Sling Extrusion

The disadvantages of synthetic mesh graft include the risks of infection, rejection, extrusion, and erosion. Erosion should refer to the entrance (or placement) of the sling within the urinary tract (the bladder or urethra), whereas extrusion refers to the migration or exposure of the sling material into the vagina. Extrusion of sling mesh into the vagina can be managed immediately in the postoperative period by thorough antibiotic irrigation and wound closure. Delayed closure may involve mobilization of the vaginal edges. Observation and conservative management until the vaginal wall completely heals over the sling mesh may be elected for late extrusion. If the vaginal wall heals “through the mesh,” the exposed portion of the mesh should be excised, with the vaginal wall closed primarily or left to heal secondarily.

Complication rates with artificial materials may be underreported, because erosion can occur relatively late, at 1 to 4 years postoperatively. In fact, the American Urological Association Female Stress Urinary Incontinence Clinical Guidelines Panel recommended 5-year follow-up as a true test of time for such continence procedures. Initial success with a novel graft material must therefore be judged cautiously until long-term results are available. Given the fact that the midurethral polypropylene slings are made of loosely knitted mesh and are placed under no tension, the incidence of significant problems appears to be lower than previously anticipated, in the region of 1% to 6%.<sup>17-18</sup>

# PERCUTANEOUS VAGINAL TAPE SLING PROCEDURE

*Sandip P. Vasavada and Raymond R. Rackley*

The classification of stress urinary incontinence (SUI) has evolved from fundamental anatomic findings to a more physiologic description of urinary leakage secondary to increases in abdominal pressure. Although considered by some as controversial, intrinsic sphincter deficiency (ISD) often coexists in the setting of urethral hypermobility. Conventional management has largely been with bladder neck sling placement. Recent changes to the etiologies of SUI have led to changes in these beliefs.<sup>1</sup> Currently, it appears that the degree of ISD and the degree of anatomic displacement of urethral support determine the fundamental basis for selection of surgical treatment options.

There exists a strong interest in maintaining a simple, effective, and minimally invasive approach to the management of SUI that may, in fact, address almost all types of incontinence. To this end, the tension-free vaginal tape (TVT; Gynecare, Johnson & Johnson, Somerville, NJ) was devised in the mid 1990s as an alternative to other synthetic and biological mesh placements suburethrally. Data that are now becoming available reveal that success (depending on how measured) is quite good and durable.<sup>2-4</sup> Accordingly, the advent of the TVT procedure and its accordant success has yielded the development of the percutaneous vaginal tape (PVT), which allows placement of a synthetic polypropylene mesh tape suburethrally in an antegrade fashion.<sup>5</sup> The technique is similar to TVT in that it places a synthetic sling below the mid-urethra in a tension-free fashion, but it uses the widely available generic polypropylene mesh and Stamey needle passers for antegrade passage. The mesh itself can be tailored to size, offering the surgeon flexibility in the management of more severe types of incontinence or complex situations or anatomy.

This chapter describes the methods used for successful sling placement at the level of the mid-urethra of a synthetic tape in an antegrade fashion (PVT, using a percutaneous ligature carrier). This technique allows the surgeon an opportunity to reliably cure SUI without the significant added costs that other commercially available devices may have. This technique has recently been studied in a noninferiority testing fashion and compared with the “gold standard” midurethral mesh sling, the TVT.

### PATIENT SELECTION

When the procedure for TVT was introduced, all female patients with SUI who had maximized their nonsurgical treatment were considered candidates for this procedure.<sup>2,3</sup> As with all anti-incontinence procedures, relative contraindications included an active urinary tract infection and anticoagulation therapy. Although no procedure is 100% effective, recent studies on the outcomes of patients undergoing the TVT procedure provide an opportunity to make some basic selection criteria for ensuring a

high rate of successful outcomes.<sup>2-4</sup> As described in the following paragraphs, there may be potential patient selection limitations for midurethral slings that are not inherent in the traditional pubovaginal sling placed at the proximal urethra and bladder neck.

In general, moderate to severe obesity is not a contraindication; obese patients appear to have minimal operative and post-operative complications with the TVT procedure.<sup>6</sup> Successful outcomes are achieved when the TVT procedure is performed in patients undergoing concomitant pelvic organ prolapse repairs. Major complications of vascular injury and bowel injury leading to death are unique to the TVT procedure as secondary consequences of blindly passing large trocars in a retrograde, retropubic fashion. Although major vascular bleeding and possibly bowel injuries have been rarely reported with other anti-incontinence procedures, the inability to reliably prevent these complications from occurring at all has been the major reason for surgeons' opting to place the midurethral sling using small, percutaneous ligature carriers in an antegrade, retropubic fashion.<sup>5,7</sup> By this method, the ligature carrier can be safely guided along the posterior aspect of the symphysis pubis, thereby decreasing risks for vascular or bowel injury.

Because the sling material for PVT and TVT are placed at the mid-urethra, continence is provided by midurethral kinking or “knee kinking” of the urethra during active movement of the urethra with Valsalva or stress maneuvers. This has several important implications in regard to patient selection. First, although several reports have shown that correction of the hypermobile proximal urethra and bladder neck demonstrated by magnetic resonance imaging (MRI) and Q-tip testing is not required for a successful outcome, successful outcome appears to be dependent on a hypermobile urethra that induces ISD.<sup>8</sup> The midurethral placement of the sling is at the fulcrum of the mobile urethra and does not affect displacement of the urethra and bladder neck as defined by Q-tip testing. However, for the sling to provide a continence mechanism, the urethra must be actively “bent” over the midurethral sling, in order to prevent urinary leakage during stress maneuvers. Therefore, patients with a mobile urethra demonstrating significant hypermobility (>30 degrees) with SUI in the absence of a bladder contraction would seemingly have the highest probability for a successful outcome.

Alternatively, patients with severe ISD at rest with or without hypermobility are more likely to have less favorable outcomes. Severe ISD is indicative of an open bladder neck at rest and is not affected by a midurethral sling that is placed tension-free without causing an increase in urethral resistance at rest. Even in cases of severe ISD and a hypermobile urethra, leakage may occur with an open bladder neck before any urethral movement begins to

**Figure 43-1** Marking of a midline anterior vaginal wall incision over the mid-urethra. (Courtesy of the Cleveland Clinic Foundation, copyright 2002.)

provide coaptation by “kinking” of the midurethral sling. No prospective reports have been published on preoperative leak point pressures before TVT placement and postoperative leak point pressures on failed cases of TVT.

## OPERATIVE TECHNIQUE OF PERCUTANEOUS VAGINAL TAPE PLACEMENT

### Midurethral Sling

Obtain vaginal exposure via the dorsal lithotomy position. Use a marking pen to draw the abdominal percutaneous puncture and midurethral vaginal wall incision sites. Place a 16-Fr urethral catheter into the bladder (Fig. 43-1).

### Vaginal Incision

Use a scalpel to make a midline anterior vaginal wall incision at the level of the mid-urethra. Develop a pocket of space at the level of the mid-urethra between the vaginal wall and underlying urethral and paraurethral tissue by dissecting the vaginal wall tissue off laterally with the curved Mayo scissors from the 1.5- to 2.0-cm midline incision to the lateral anterior vaginal sulcus. No true entry into the retropubic space is required (Fig. 43-2). When the pocket of space is completed laterally to the junction of the inferior aspect of the pubic ramus and the urethropelvic complex

(Fig. 43-3), one can proceed with antegrade passage of the needle carrier.

Before the percutaneous ligature carrier is passed (Fig. 43-4), the bladder should be emptied of all fluid. The patient's position on the operating table should result in placement of the symphysis pubis in a near-vertical plane; this usually means keeping the patient's torso and head in a level horizontal position or slightly in a Trendelenburg position.

Small (5 mm) puncture sites using the no. 15 scalpel blade through the abdominal skin overlying the top of symphysis should be made on either side of a finger placed in the midline. This maneuver allows easier manipulation of the ligature carrier for the antegrade approach by avoiding any resistance at the skin level. It also provides a visual location for avoiding perforation of the skin and rectus fascia too laterally for both approaches, which could lead to the reported complication of ilioinguinal nerve or inferior epigastric vascular damage. Attention to staying on the posterior or back side of the symphysis is required to prevent entering the rectus muscle and fascia too far cephalad from its insertion on the symphysis. Furthermore, passage anterior to the symphysis is not recommended at the present time with this approach. By taking the time to create the pocket of space at the level of the mid-urethra and to identify the correct anatomic structures (urethra medially, arcus tendineus levator ani laterally, and the inferior aspect of the pubic ramus and

**Figure 43-3** Suburethral pocket opened to confluence of endopelvic and periurethral fascia. (Courtesy of the Cleveland Clinic Foundation, copyright 2002.)

urethrovaginal complex anteriorly), one facilitates the safest movement of the Stamey needles in a vertical direction that minimizes the likelihood of urethral or bladder injury.

When using the percutaneous ligature carrier, we fashion the free sling from a large sheet of polypropylene mesh (PML, Ethicon, Somerville, NJ) to approximately the same size as supplied in the TVT kit (1.2 mm wide by 30 cm long). Using 1-0 Ethibond suture, we simply weave suspending sutures into each end of the Prolene sling for placement into the ligature carrier.

Cystoscopy is performed to inspect for foreign body material within the urinary tract, and it is best to do this inspection when the ligature carrier for PVT is still within the retropubic space. Inspection must take place with a full bladder and use of the 30- and 70-degree lenses. If the ligature carrier has been placed through the bladder, simply extract the device and try again. No further precautions need be taken postoperatively in cases of bladder entry, as long as the entry is recognized and corrected. Unlike bladder perforations, trocar injury of the urethra rarely occurs. It is not advisable to proceed with placement of a synthetic graft next to a healing urethral injury with limited surrounding intervening tissues, because doing so might result in erosion and infection of the graft material. Instead, terminate the procedure and return at a later date to repeat the surgery.

#### *Positioning the Sling*

After completion of the procedure on both sides, the next step is to set the midurethral sling to stabilize, not suspend, the urethra. The sutures placed into the sling are passed into the Stamey needle passer, and the sling and sutures are transferred into the retropubic position. Although the tension-free vaginal tape contains no surrounding plastic sheath, it is easily manipulated through the surrounding tissues and can be set into place (Figs. 43-5 and 43-6).

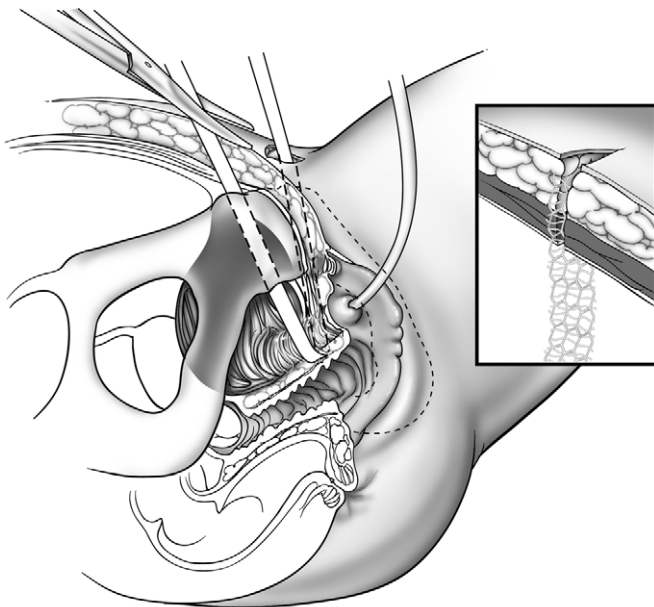

**Figure 43-4** Antegrade passage of a ligature carrier through the retropubic space in a percutaneous vaginal tape procedure. (Courtesy of the Cleveland Clinic Foundation, copyright 2002.)

**Figure 43-5** Ensuring a loose position of the synthetic sling at the mid-urethra. A curved Mayo scissor tips or open Kelly clamp is used to ensure a “tension free” placement. (Courtesy of the Cleveland Clinic Foundation, copyright 2002.)

**Figure 43-6** Lateral or sagittal view of percutaneous vaginal tape sling in place before the excess tape is cut suprapubically. (Courtesy of the Cleveland Clinic Foundation, copyright 2002.)

We prefer to place the tips of the curved Mayo scissor between the urethra and the sling to ensure ample looseness of the sling material. We have not found the intraoperative cough/stress test for determination of sling tension useful in patients undergoing the PVT, because many patients with documented SUI never leak in the supine or lithotomy position. Therefore, we typically verify that the sling is “tension free” with the placement of open Mayo scissors or a Kelly clamp between the sling and the periurethral tissue.

Once proper positioning of the sling is achieved, the remaining excess sling material at the abdominal skin site for the PVT is cut below the level of the skin. The vaginal incision site is irrigated with copious amounts of an antibiotic or iodine solution, and the incision closed with a running absorbable suture. The skin edges of the abdominal puncture site are approximated with skin adhesive closures. A vaginal pack and urethral catheter are placed for patients remaining in the hospital overnight; otherwise, the bladder is drained and a urethral catheter and vaginal pack are not usually placed in patients planned for same-day discharge from the recovery room.

#### POSTOPERATIVE CARE

Many surgeons who perform the TVT or PVT procedure with the patient under local anesthesia and sedation without concomitant prolapse repairs have opted to send patients home the same day without a catheter if a voiding trial is successfully completed. If the patient cannot void immediately after the procedure in the recovery room or the bladder was perforated during the procedure, catheter drainage for a brief period of 1 to 2 days may be required, with a voiding trial completed on an outpatient basis. After the procedure, patients are given an oral cephalosporin for several days, as well as oral medications for pain control.

#### RESULTS

We recently sought to evaluate whether the PVT was inferior to the established gold standard midurethral synthetic sling (TVT). All women who attended the Urology Outpatient Clinic at our institute complaining of SUI that was objectively (by office supine stress test) or urodynamically demonstrated and in whom midurethral sling surgery (TVT or PVT) was indicated were invited to participate and given an explanation of the study. Those who agreed to participate were given the informed consent document to read, understand, and sign. Patients were nonrandomly allocated into either the TVT or the PVT group according to the type of sling procedure typically performed by the treating surgeon. Nine different surgeons participated in this Institutional Review Board–approved study.

Patients who had previously failed anti-incontinence procedures, women with mixed incontinence, and those with SUI associated with pelvic organ prolapse were included in this study. Exclusion criteria were Valsalva-induced detrusor instability, neurogenic lower urinary tract dysfunction, and voiding dysfunction defined urodynamically as a voiding pressure greater than 50 cm H<sub>2</sub>O, maximum flow rate lower than 15 mL/sec, or residual urine volume greater than 100 mL.

### Evaluation of Effectiveness

Patients' perception of their symptoms and quality of life were assessed by asking them to complete three validated questionnaires before the operation: the Patient Global Subjective Score (Global, a visual analogue scale), the Incontinence Impact Questionnaire–Short form (IIQ-7), and the Urogenital Distress Inventory–Short form (UDI-6). One year after the operation, changes in the patients' symptoms, their quality of life, and treatment outcome were reassessed by mailing four questionnaires for the patients to complete and return: the three previously mentioned instruments and the Anti-Incontinence Surgery Response Score (AISRS), a postoperative-only scoring system. Patients were also asked to complete a 24-hour voiding diary and a 24-hour pad test as components of the AISRS; instructions for both were sent to patients by mail.

### Evaluation of Safety

Safety of the procedure was assessed by recording intraoperative complications, such as bleeding necessitating blood transfusion and bladder perforation, and the following postoperative complications: erosion of sling material into the genitourinary tract; infection, whether at the surgical wound (abdominal or vaginal) or in the sling; de novo urgency; and bladder outlet obstruction. Outlet obstruction is defined by any of the following criteria: history of new-onset irritative symptoms (frequency, urgency, or urge incontinence) or obstructive symptoms (hesitancy, intermittency, weak stream, or sense of incomplete evacuation of the bladder); postoperative postvoid residue (PVR) equal to or greater than 100 mL; or urodynamic criteria of Chassagne and colleagues<sup>9</sup> (i.e., maximum flow rate of  $\leq 15$  mL/sec and detrusor pressure at maximum flow rate of  $>20$  cm H<sub>2</sub>O).

### Operative Techniques

The TVT procedure was carried out according to the technique described by Ulmsten and associates,<sup>3</sup> and the PVT was performed according to the technique we described earlier.<sup>5</sup> All patients were sent home on the same day without a catheter if a voiding trial was successful. If a patient could not void or the bladder was perforated during the procedure, catheter drainage for 1 to 2 days was required, and a voiding trial was completed on an outpatient basis.

### Outcome Measures

The primary outcome measure was the AISRS.<sup>10</sup> Patient responses were classified as cure, good, fair, poor, or failure according to the AISRS. For example, the patient was considered cured if she scored 0—that is, she had no stress or urge urinary incontinence episodes, she considered herself to be cured, and the total weight gain of the pad on her postoperative 24-hour pad test was less than 8 g.<sup>10,11</sup> Secondary outcome measures were Global, IIQ-7, and UDI-6.

Our sample size was based on testing the noninferiority of PVT to TVT on the primary outcome measure of being cured (score of 0) on the AISRS. We used a noninferiority “delta” of 10%, defined as the smallest true difference in the distribution of the AISRS such that PVT would still be considered noninferior to TVT. Assuming a 90% cure rate for both groups, we needed 226 total patients (113 patients in each group) to have 80% power

to conclude noninferiority of PVT. With our recruited sample size of 191 patients, we had about 75% power to show noninferiority under these assumptions. In our data analysis of the AISRS, we conservatively used a smaller delta of 5% than we had planned for in the AISRS analysis.

In regard to the safety analysis, with our sample size of 191 we had little power (31%) to show noninferiority on any of the binary complication outcomes using an equivalency delta of 5%. Nonsignificant results for complications are therefore not interpreted as evidence of no difference between the groups.

Sample size calculations were made using the sample size software Unify POW, a macro for the SAS system.<sup>12</sup>

### Statistical Analysis

PVT and TVT groups were compared on baseline variables including demographics, medical history, diagnosis, surgical variables, and incontinence questionnaires (IIQ, UDI, and Global), using chi-square tests for binary variables and either *t* tests or Wilcoxon rank-sum tests for ordinal or continuous variables, as appropriate. We also compared those with and without complete follow-up data for the AISRS, the UDI, and the IIQ on baseline factors to determine whether responders and nonresponders were similar at baseline.

One-tailed noninferiority tests of PVT versus TVT were made for the primary and secondary outcomes, using both univariate and multivariate methods, although all conclusions were based on the multivariate results. We adjusted for as many baseline covariates as possible in attempts to negate any assignment bias or baseline differences (due to nonrandomization). The usual tests for superiority of either PVT or TVT were done as well.

Tests for superiority of PVT or TVT were also performed. In the univariate case, we used chi-square tests for the AISRS and either two-tailed *t* tests or Wilcoxon rank-sum tests for ordinal outcomes. In multivariate analysis, we used the usual tests for significance from the logistic regression and cumulative logic regression analyses described earlier. For the change in Global score, we used cumulative logic regression to adjust for the covariates, and we reported the estimated odds ratio for having a higher change in TVT versus PVT.

## RESULTS

A total of 278 women met the study criteria and, with input from their physician, chose to be treated with either TVT or PVT. Seventy-seven patients (27.7%) did not fully complete the questionnaires and were excluded from analysis (51 in the TVT group and 26 in the PVT group); 49 of these 77 patients were not willing to complete the follow-up even when contacted by telephone, and 28 were lost to follow-up because we were not able to contact them. The remaining 191 patients (72.3%) responded and followed our protocol; 99 (51.8%) of them underwent TVT, and 92 (48.2%) underwent the PVT procedure. Of the 191 patients, 107 (56%) were compliant to perform the entire study protocol, including the three domains of the AISRS (questionnaire, 24-hour voiding diary, and 24-hour pad test) and the three questionnaires of the secondary outcome measures; 84 patients (44%) refused to perform both the 24-hour pad test and the 24-hour voiding diary, whereas 60 patients (31%) refused to perform the 24-hour pad test only.

**Table 43-1 Effectiveness of TVT versus PVT Based on AISRS Score\***

Analysis	% Cured		Chi-Square P Value	Superiority		Noninferiority

### AISRS: Primary Outcome Assessment

Multivariate analysis showed the noninferiority of PVT to TVT in the proportion cured ( $P = .002$ ) after adjusting for baseline covariates and follow-up months, but PVT was not found to be superior to TVT ( $P = .06$ ). We used a logistic regression model to assess the association between AISRS cured (yes/no) and procedure (TVT or PVT) while adjusting for all preoperative baseline covariates, including associated prolapse, previous operation (yes/no), preoperative diagnosis of stress incontinence versus mixed incontinence, age, and duration of postoperative follow-up in months (Table 43-1). Of the preoperative covariates assessed, only age was significantly associated with the outcome ( $P = .008$ ). Higher age was associated with lower odds of success (odds ratio, 0.68; 95% confidence interval [CI], 0.52 to 0.90). The covariate-adjusted noninferiority test, using a delta of 5%, was significant ( $P = .022$ ), so we concluded that PVT is not inferior to TVT (i.e., at least not 5% worse) on the AISRS cure score. Using bootstrap resampling, we also obtained a one-tailed upper limit estimate for the difference between PVT and TVT on the predicted probability of being cured after adjusting for covariates. This estimated upper limit was -3.3% (PVT 3.3% better), which is 8.3% lower (i.e., better in favor of PVT) than the +5% tolerance we had set.

Our naïve (i.e., unadjusted) univariate analysis revealed that PVT had a higher proportion "cured" in the test for superiority (chi-square  $P = .025$ ), with the 95% CI ranging from 0.05 to 0.30 better than TVT (see Table 43-1). The estimated odds ratio from logistic regression indicated that TVT patients were only about half as likely to be cured as PVT patients. The univariate noninferiority test was then, of course, significant as well ( $P = .002$ ), meaning that there was evidence to reject the null hypothesis and conclude that PVT is not inferior to TVT based on the AISRS.

### Secondary Outcome Measures

Table 43-2 compares PVT and TVT on change from baseline to last follow-up on the secondary outcome measures. Univariate and multivariate results for superiority and noninferiority tests are given, along with estimated 95% CIs for the difference (TVT minus PVT) in mean or median change. In testing for the superiority of either TVT or PVT, we found no significant differences

between treatment groups (Table 43-3), evidenced by zero being included within the confidence limits for each score and P values greater than .05.

In univariate analysis, PVT was shown to be noninferior to TVT for both IIQ and UDI (using three-point and two-point buffers, respectively) in change from baseline, but not for change in global assessment (one-point buffer).

In multivariate analysis adjusting for all available covariates, noninferiority of PVT was found only in the change in IIQ score ( $P = .038$ ). The covariate-adjusted one-tailed upper 95% confidence limit for the change in IIQ was 2.8 (favoring TVT); this is significant because it is lower than the prespecified delta of 3.0. The adjusted one-tailed upper limit for UDI is above the prespecified delta (and therefore nonsignificant). We used cumulative logic regression for the Global assessment, because the data were far from normally distributed and linear regression was not appropriate. The odds of having a higher change score after PVT was an estimated 1.4 (95% CI, 0.69 to 2.7) times higher than for TVT. This method did not allow assessment of noninferiority of the Global assessment, but the odds ratio CI is quite wide and does not suggest noninferiority.

For each of IIQ ( $P = .005$ ), UDI ( $P < .001$ ), and Global ( $P = .005$ ) scores, higher or increasing age was significantly associated with less improvement in the score (negative correlation). For both the IIQ and the UDI, patients with stress incontinence patients had significantly more improvement than did patients with mixed incontinence; the adjusted mean (and standard error) for the difference in score between these two groups was 4.7 (1.6) for the IIQ and 3.4 (0.89) for the UDI. None of the other covariates was significant at the .05 level, but they were retained in the multivariate models to improve the inference regarding PVT and TVT.

Nine surgeons performed the procedures, but we were not able to make a meaningful adjustment for surgeon because most surgeons did either PVT or TVT surgery exclusively. For example, the PVT procedures were done by one of two surgeons who respectively performed 68% and 26% of the PVTs (together, 94.5%) but only 13% of the TVT procedures. Likewise, 77% of the TVT procedures were done by one of three surgeons, and two of them performed only one PVT surgery each.

does it bother you?) showed that, for the combined TVT and PVT groups, 65% of patients decreased their score (65%), 30% stayed with the same degree of urge, 7 patients (5%) had *de novo* urge after the midurethral sling procedure. There was no difference between TVT and PVT on the change categories ( $P = .72$ , Wilcoxon test). In both groups, there was a large postprocedure increase in the proportion of patients with a score of zero.

### Complications

The overall incidence of complications in the combined groups was 20% (38 patients). A summary of procedure-related complications is shown in Table 43-4. There was no difference between treatment groups in the proportion of patients with any specific complication. Median blood loss in both groups was comparable: 50 mL for the TVT group, 68 mL for the PVT group, with no significant difference ( $P = .65$ ). According to our definition, a total of 25 women (13%) met the criteria of bladder outlet obstruction, 12 in the TVT group (12%) and 13 in the PVT group (14%) ( $P = .68$ ). A total of 15 patients underwent urethrolisis to relieve obstruction (5 after TVT and 10 after PVT), with no significant difference between the two procedures in rate of urethrolisis. In the remaining 10 patients, obstruction was managed by clean intermittent catheterization and was relieved within 3 months with no need for any further intervention ( $P = .18$ ).

### DISCUSSION

Preliminary reports and the experience at our own institution suggest that the techniques of midurethral synthetic sling placement of TVT and PVT are reproducible, easy to master, and minimally invasive with respect to tissue handling. The combination of these advantages provides the opportunity to perform these procedures under local anesthesia with sedation when applicable, to minimize the time of postoperative bladder drainage, and to shorten the time of convalescence.

Although no absolute contraindications for using these procedures to treat SUI have been established based on a review of the current literature, midurethral sling procedures such as TVT or PVT should be performed with caution on patients with severe

ISD without hypermobility (a low leak point pressure of  $\leq 60$  cm H<sub>2</sub>O) until more available data are available.

Complications exist with all anti-incontinence procedures, and there is a growing database of information on adverse events unique to these procedures that will place proper perspective on their respective incidences. We have tried to outline the anatomic considerations when performing these procedures as well as suggestions for the technical methodology that should minimize patient morbidity, avoid patient mortality, and produce the highest rate of durable success.

As with all surgical endeavors associated with reconstructive surgery, modifications of the best procedures continue to evolve. Although the TVT procedure appears to be the most recent step toward this goal, modifications such as the PVT procedure will surely continue to evolve the technique of midurethral sling formation. At present, PVT does not appear to be inferior to TVT based on our retrospective review. A prospective study may confirm this finding, but this more economical way of viewing the data may allow us to draw some of the same inferences.

### CONCLUSION

While the long-term results of minimally invasive synthetic sling procedures are maturing, enthusiasm for considering the TVT and PVT procedures stems from the incorporation of techniques acquired from traditional sling procedures. Learning to stabilize the urethra and bladder neck instead of performing suspension sling procedures has greatly reduced the rate of urinary obstruction and the concomitant morbidity of urgency and urge incontinence in contemporary reports of all sling procedures, proximal or midurethral.

Because of the reduced tension placed on synthetic slings that are made of a mesh material with large interstices instead of tightly woven and impermeable, less potential for graft erosion is currently being reported. With future studies reporting the preoperative urodynamic profile of the patients undergoing these unique procedures, better inclusion and exclusion criteria for performing these procedures will be established. Furthermore, cost-effective solutions to midurethral sling placement may allow expanded use of these techniques around the world.

# TRANSOBTURATOR APPROACH TO MIDURETHRAL SLING

*Carl G. Klutke and John J. Klutke*

Surgery for stress urinary incontinence has changed rapidly in the past decade. This change was preceded and to some extent catalyzed by critical appraisal of anti-incontinence surgery as an empirical therapy that, at best, provides a compensatory abnormality to restore continence. Implicit in this view is the acceptance that surgery has the potential to upset the balance of neurologic and anatomic factors that govern the bladder and its outlet. The rationale for recent innovation has been to limit the detrimental effect on this balance that can result from surgical therapy.

A few specific concepts have been introduced to limit the impact of surgery on normal function. It is recognized that mobility of the proximal urethra is normal and, in fact, important for the initiation of voiding. Surgery should avoid interference with the mobility of this structure if possible. The use of a cough stress test can minimize the potential to cause voiding disturbance by providing a physiologic feedback to guide the surgeon in applying outlet resistance. The notion of surgical wounding and its effect on the nervous system, a concept that has been explored in the anesthesia literature, has been applied in the arena of anti-incontinence surgery, leading to the employment of local anesthesia as a means of pre-emptive block to reduce negative neurologic consequences.

It is appropriate to attribute much of the recent improvement in surgical therapy of incontinence to the work of Ulf Ulmsten. Ulmsten's original thinking and his insistence on scrutinizing the concepts that he formulated with rigorous scientific methodology are laudable, and his work represents a milestone in the evolution of surgical practice.<sup>1-3</sup> His tension-free vaginal tape (TVT) procedure has become the "gold standard" for anti-incontinence surgery. Improvement in technique will need to incorporate its innovative features.

The improvement offered by the transobturator sling (TOT) over other midurethral slings is a reduction in the incidence of penetration injuries during sling introduction. Although complications associated with the TVT procedure are uncommon, stress incontinence is an exceedingly common condition. Now, with experience with TVT totaling hundreds of thousands of women, it has become apparent that serious complications can result from the procedure and from the other retropubic sling procedures that copy it. Injury to the colon, small bowel, ureter, urethra, bladder vasculature, tube, and ovary have been associated with the procedure, as have erosions of the sling material into the vagina, bladder, and urethra.<sup>4-6</sup> Bleeding, hematoma, abscess formation, retention, and voiding dysfunction can occur. The most feared of these complications is bowel perforation. If this occurs during blind sling introduction, its recognition is not immediate, yet it is potentially fatal, especially if diagnosis is delayed. The extent to which this particular complication is

related to human error is probably irrelevant. The fact is that TVT is a blind procedure, with needle passage occurring in proximity to the bowel. Bowel perforation is to some extent related to the technique involved in retropubic midurethral sling placement, and even experienced surgeons can encounter it.

Limitations are also inherent in the therapeutic effect that the procedure offers. Connective tissue abnormalities are recognizable in women with incontinence, but surgery does not restore the connective tissue to its predisease state. Midurethral slings result in a dense, collagen-rich structure in the anterior vagina, rather like a ligament. Such a structure is not normally present in the vagina. Although the procedures are effective, they do not correct the underlying defect responsible for stress incontinence, which remains unknown. Although improvement of outcome may be possible with modification of the basic theme of the midurethral sling procedure, all approaches currently share this theoretical limitation.

## DESCRIPTION

In the continuing effort to evaluate and improve surgical therapy for incontinence, the TOT approach has recently reached mainstream clinical practice.<sup>7</sup> It is a type of midurethral sling that incorporates midurethral placement, the use of local anesthesia, and a cough stress test (Fig. 44-1). No technique is without surgical risk, but TOT seems to offer less risk than retropubic midurethral sling procedures do. TOT logically avoids the potential for bowel or large vessel injury, because it avoids blind retro-pubic needle passage.

**Figure 44-1** Axial view of transobturator, suburethral sling.

In most respects, the TOT and retropubic TVT procedures are identical. Both use an identical hammock-like strip of polypropylene placed beneath the mid-urethra to support it from above. The main difference is in technique: with TOT placement, the introducer needle remains superficial to the urogenital diaphragm. Because the introducer needle is not allowed to pass through the retropubic space, the risk that the needle tip could cause injury to bladder, bowel, or blood vessels is lessened. The TOT sling and its instruments have been approved by the U.S. Food and Drug Administration for the treatment of stress urinary incontinence in females. This chapter discusses anatomy pertinent to TOT route, the technique itself, and the published literature supporting its use.

## ANATOMY

The fact that the obturator foramen is unfamiliar to most urologists has to do with its lack of urologic surgical applications and not with any inherent danger of dissection in the area. Most urologists consider this part of the pelvis to be an end point, not a gateway, and are unfamiliar with its anatomy. The obturator foramen is not without common surgical applications, however. Access to the obturator vessels through the obturator foramen for vascular bypass, for instance, is a classic approach for relief of vascular insufficiency in the lower extremity.<sup>8</sup> Veterinary surgeons predate urologists in the treatment of stress incontinence in female dogs via this approach.<sup>9</sup> The advantages of TOT sling placement now makes a complete understanding of the anatomy of the obturator foramen relevant to the urologist as well.

The obturator foramen is an oval opening in the anterior ventral bony pelvis formed by the confluence of the pubic and ischial bones. The obturator membrane is a thin fibrous sheet which almost completely closes the obturator foramen. Its fibers are arranged in interlacing bundles, mainly transverse in direction; the uppermost bundle is attached to the obturator tubercles and completes the obturator canal for passage of the obturator vessels and nerve in its lateral aspect. Both obturator muscles are continuous with this membrane: the obturator internus padding the inner aspect and the obturator externus its outer surface.<sup>10</sup>

The obturator nerve arises from the ventral divisions of the second, third, and fourth lumbar nerves. It descends through the fibers of the psoas major and emerges from its medial border. It runs along the lateral wall of the pelvis above and in front of the obturator vessels to the upper lateral part of the obturator foramen. Here it enters the thigh to innervate the muscles of adduction. The obturator artery and vein that supply and drain the muscles of the medial thigh course together with the nerve through the foramen laterally. The anatomic location of the nerve and vessels in the upper outer part of the obturator foramen allows for safe passage of introduced trocars along the medial aspect of the foramen.<sup>11</sup>

The obturator foramen, its membrane, the obturator internus muscle, and its surrounding fascia lie external to the endopelvic fascial lining of the pelvis and the peritoneal cavity. Normal passage of the introducing needle during the TOT sling procedure avoids both spaces. Anatomic studies in cadavers have demonstrated that, when properly positioned, the TOT sling travels in a horizontal plane across the origin of the adductor muscles and through the inferior margin of the obturator foramen. The sling then passes through the internal obturator muscle, above

the pedicle of the internal pudendal artery, through the levator ani muscle, past the tendinous arc of the pelvic fascia, and beneath the middle third of the urethra.<sup>12</sup> There are no major blood vessels or viscera along this route. Kocjancic and colleagues demonstrated that properly placed TOT tape lies 2 cm away from the urethra and 4 to 5 cm from the obturator nerve and vessels in the obturator foramen. The angle formed between the tape and the urethra is approximately 15 degrees, which does not place extra anatomic strain on the urethra.<sup>13</sup> Despite the theoretical increased safety of this approach, improper placement of the needle device increases the risk of vesical and/or vaginal perforation.

## TECHNIQUE

This section describes our technique for placement of a TOT sling. It is not meant as a definitive description, nor is it intended to supplant surgical training in the operating room by an experienced teacher.

### Preoperative Assessment

The TOT sling, like all midurethral slings, is primarily indicated for patients with stress incontinence with urethral mobility. Documentation of stress incontinence, either on an office cough stress test or by formal cystometry, is the first step toward a satisfactory outcome. Our own preference is to perform a urodynamic study, because this not only provides an accepted, objective documentation of the incontinence but also gives an indication of other aspects of bladder behavior, such as tone (compliance), reflex excitability, and sensation, which may indicate the need for additional therapy in other areas. A vaginal examination or cotton swab test is important to identify a fixed or nonmobile urethra, which may result in failure for midurethral slings.

Contraindications to the TOT sling procedure include the following:

- Pure urge incontinence
- Fixed urethra
- Underlying bleeding diathesis
- Anticoagulant medication
- Anesthetic contraindications (to local anesthesia with intravenous sedation)
- Hip deformity precluding dorsolithotomy position

The patient should be given a thorough explanation of the procedure with a full review of the potential risks and potential complications, specifically including the possibility of blood loss; infection; injury to bladder, urethra, or vagina; tape exposure; failure; and general risks. A fully informed consent, documented in the chart, will help to alleviate problems later on.

### Anesthetic Considerations

The TOT sling procedure can be performed with the patient under local anesthesia with intravenous sedation, spinal anesthesia, or general anesthesia. It is our strong preference to use local anesthesia if possible. This approach is less morbid from an anesthetic standpoint, and, more importantly, it is the only way to ensure an adequate stress test. Properly placed, the local anesthetic does not paralyze the musculature of the pelvic floor and ensures that biofeedback will accurately determine the degree of

resistance necessary at the bladder outlet. Local anesthetic injected into the areas of the pelvis through which the sling will pass also creates tissue “hydrodissection,” which allows easier passage of the needle. Finally, the administration of local anesthetic is a “trial run” of the needle passage and gives the surgeon a better feel for the anatomy of individual patient’s pelvis. A long-acting local anesthetic with or without epinephrine is recommended.

If local anesthesia with intravenous sedation is chosen, close communication between surgeon and anesthesiologist is required. Although TOT sling placement is a short procedure, it requires deeper sedation for some segments (local anesthetic injection and actual needle passage) and minimal sedation for some segments (resistance adjustment and completion of the procedure). For this reason, it is imperative that both the operating surgeon and the anesthesiologist be acquainted with the steps of the operation and that the surgeon keep the anesthesiologist apprised of its progress. Our typical intravenous sedation regimen includes 2 mg versed administered while the patient is in the holding area, 2 mg fentanyl administered in the operating room, and a Diprivan titrated infusion before local anesthetic administration.

### Preparation

Because the surgery is focused on the vagina and perineum only, patients are positioned in the high dorsolithotomy position, and a full vaginal and perineal preparation is performed. The surgeon positions the table to height preference, and the anesthesiologist confirms adequate sedation before local anesthetic administration.

Local anesthesia is injected with the intent of anesthetizing all areas of soft tissue involved in dissection and ultimate placement of the sling. We use a long-acting local agent such as 0.25% Ropivacaine or Marcaine and plan on giving 40 to 45 mL in total for the procedure. Needles used for this purpose include a 25-gauge 1.5-inch needle for skin and vaginal epithelium, and a 20-gauge spinal needle for deeper infiltration. Infiltration sites ultimately include the skin over perineal incision sites, the anterior vaginal wall, and the intervening soft tissue.

### Confirmation of Landmarks, Incisions, and Dissection

A number of visual and palpable landmarks must be recognized for proper placement of the tape. The adductor muscle tendons, inferior pubic ramus, external urethral meatus, clitoris, bladder neck, inguinal-gluteal folds, and, in nonobese patients, the obturator foramen itself can be either seen or palpated in the course of planning the incision sites. Two sets of incisions are then made: a 1-inch, sagittal vaginal incision placed midway between the bladder neck and the external urethral meatus, and two perineal skin stabs overlying the left and right medial obturator foramina at the level of the clitoris one fingerbreadth lateral to the inguinal-gluteal fold. It is important to incise the vagina deep to the vaginal epithelial layer, to avoid problems of wound healing later on.

Having made the incision in the vagina overlying the mid-urethra, the surgeon must identify the tissue plane between urethra and vagina and develop this plane laterally to allow digital palpation of the medial edge of the ischiopubic ramus. Once the plane is developed, the 20-gauge spinal needle is used to administer local anesthetic into the soft tissue between the perineal stab incisions and the vaginal incision.

### Needle Passage

The goal of needle passage is to place the sling from mid-urethra to perineum while avoiding damage to the bladder, bladder neck, and urethra; penetration of the vaginal epithelial layer; and injury to the obturator nerves and vessels. Whether this is accomplished by an “outside-in” approach or an “inside-out” approach at this stage of procedural evolution is largely a matter of personal preference. We have been most comfortable with passage of the needle from the perineal stab incisions, through the obturator foramen, and then, under fingertip guidance, out the vaginal incision. After the needle is through the vaginal incision site, the sling is attached and withdrawn through the perineal stab, and the same procedure is carried out on the other side with the other end of the sling.

Once the sling is in place, cystoscopy is used to confirm that the urethra and bladder are intact and were not penetrated during sling placement. Whether cystoscopy is required in all cases of TOT sling placement is a matter of conjecture at present, but reports of bladder and urethral injury exist, and we recommend the use of a zero-degree 17-Fr cystoscope for complete visualization of urethra and bladder neck in all cases in which the possibility of injury cannot otherwise be ruled out.

### Cough Test

If local anesthesia and intravenous sedation have been employed, a cough test can be performed to guide tensioning of the TOT sling. The bladder is filled with normal saline to the volume at which leakage was previously demonstrated. The patient is placed in a reverse Trendelenburg position, and the weighted vaginal speculum, instruments, and retractors are removed from the vagina. The surgeon and anesthesiologist should assess the awake status of the patient and confirm a strenuous cough effort. With leakage per urethra as a starting point, we adjust tension on the sling by pulling the free ends incrementally until leakage ceases. The overall goal is to place as little resistance at the outlet of the bladder by the tape as is necessary to stop leakage with cough.

### Completion of Procedure

Once proper tensioning is complete, excess tape is excised flush with the perineal skin, with care taken to avoid injuring the surrounding skin. Closure of the vaginal incisions with absorbable suture, such as 2-0 polyglycolic acid, is accomplished. Noting that vaginal exposure due to improper wound healing of the vaginal incision is one of the more common complications, we recommend careful placement of interrupted sutures, making sure that no sling is involved with the closure. The perineal stabs can be closed with Steri-Strips. Finally, before the patient is transported to the recovery room, the surgeon must confirm hemostasis and estimate blood loss.

### Recovery Room Check

In the recovery room, confirmation of complete bladder emptying must be documented. If a cough test in the operating room was performed, the volume instilled should also be emptied. Uncommonly, short-term catheter drainage may be required. Discharge instructions, including limitation of strenuous activity and abstinence from sexual activity for at least 6 weeks from the date of surgery, should be given and documented. Patients are given postoperative prescriptions including analgesics, short-term antibiotics, and stool softeners to avoid postoperative constipation.

## COMPLICATIONS

The most common reported complication of TOT urethral sling placement is de novo urge urinary incontinence, which has been reported in 2% to 7% of patients.<sup>14-16</sup> Short-term urinary obstructive symptoms have been reported in 1% to 3%.<sup>14-16</sup> Short-term obstruction can be managed by intermittent or indwelling catheterization; however if symptoms persist longer than 1 week, we recommend early sling loosening.<sup>17</sup> Other reported complications include pain; dyspareunia (<1%); bladder neck laceration (<1%); perforation of the bladder, vagina, or urethra (1%); and delayed erosion of the sling into the vagina or urethra (1% to 3%).<sup>18-21</sup> Significant injury to major blood vessels or bowel has not been reported. There has been no reported mortality.

## CLINICAL OUTCOMES

Because the TOT approach is relatively new, only short-term efficacy for the treatment of stress incontinence has been demonstrated. Subjective cure and improvement rates of 83% to 93% and 5.4% to 9.4%, respectively, have been reported with follow-up ranging from 3 months to 1 year.<sup>16,21</sup> Aside from these subjec-

tive reports, at least one study has demonstrated significant improvement in urinary pad usage, sexual function, and overall quality of life after TOT sling placement.<sup>19</sup> The TOT sling was evaluated in patients who had previously undergone anti-incontinence surgery and was found to provide with cure rates of 79% and improvement rates of 9.2%.<sup>21</sup> The procedure has been demonstrated to be equally efficacious in obese and nonobese patients and in women older than 70 years.<sup>22,23</sup> TOT sling concomitant with pelvic organ prolapse repair has also been evaluated, with results showing 87.2% cure and 7.7% improvement in stress incontinence symptoms at a mean follow-up of 12 months.<sup>24</sup>

## CONCLUSION

The TOT approach to suburethral sling placement is an exciting modification in the management of stress urinary incontinence in women. Like the TVT procedure, the TOT approach is a minimally invasive procedure with good short-term efficacy but has the added benefit of avoiding deep penetration of the pelvis. Additional prospective studies with longer follow-up are needed before the TOT sling can replace the gold standard TVT.

# CADAVERIC FASCIAL SLING USING BONE ANCHORS

*Sarah A. Rueff and Gary E. Leach*

Transvaginal slings are now considered the primary procedure of choice for female stress urinary incontinence (SUI).<sup>1</sup> Although historically female SUI was thought to be caused by either urethral hypermobility or intrinsic sphincter deficiency (ISD), it is now accepted that all patients with SUI have some component of ISD. Therefore, regardless of the cause, a sling procedure may be the first line of treatment recommended. We first began performing the cadaveric transvaginal sling (CaTS) procedure with bone anchors in 1998. Early results showed patient outcome and continence rates to be comparable to those obtained with other techniques and sling materials.<sup>2</sup>

## PREOPERATIVE EVALUATION

A thorough preoperative evaluation is essential before intervention for SUI. Gynecologic history should include number of vaginal deliveries and prior anti-incontinence procedures. Micturition history should include type of incontinence present, type and number of pads used, and a measure of degree of “bother” via questionnaire analysis. The stress-related leakage, emptying ability, anatomy, protection, inhibition (SEAPI) incontinence score is a subjective assessment of patient symptoms and impact on quality of life (Table 45-1).<sup>3</sup> Physical examination should focus on assessment and documentation of degree of urethral hypermobility. A thorough examination of the anterior and posterior vaginal wall and the uterus or vaginal cuff should be performed with the patient both supine and standing. Associated pelvic organ prolapse should be repaired simultaneously with the sling procedure. Patients who have undergone prior anti-incontinence procedures may have urethral fixation secondary to scarring at the bladder neck and will require urethrolisis at the time of sling placement. A focused neurologic examination should document any deficits with further evaluation as indicated. Preoperatively, urodynamic evaluation is performed in all patients to confirm SUI and document abdominal leak point pressure. In addition, urodynamic evaluation excludes underlying bladder dysfunction, such as detrusor overactivity or poor compliance, and evaluates the patient’s ability to empty the bladder.

## CADAVERIC FASCIA

The use of autologous fascia for transvaginal sling, using either rectus fascia from the anterior abdominal wall or fascia lata from the lateral thigh, has been previously described.<sup>4,5</sup> Fascia lata is known to be universally strong regardless of patient age or medical condition. When compared, fascia lata has reproducibly

three to four times greater tensile strength than rectus fascia.<sup>6</sup> Rectus fascia can become attenuated and scarred as a result of cesarean section, abdominal hysterectomy, or other abdominal procedures. However, harvesting fascia inevitably increases operative time, morbidity of the procedure, postoperative pain, and length of hospital stay. For that reason, cadaveric fascia lata (CFL) has become a popular choice for sling material.

Our fascia of choice is a non-frozen CFL, Tutoplast (Mentor Corporation, Santa Barbara, CA). Tutoplast preparation involves a five-step process that includes solvent-dehydration and gamma-irradiation. The process is summarized as follows:

1. *Screening:* The U.S. Food and Drug Administration serologically screens potential donors and rejects those with a medical or social history that places them at risk of infectious disease or malignancy. The fascia is then inspected and must meet stringent cleanliness, structure, quality, and size standards.
2. *Processing:* The first step in the cleaning process involves osmotic treatment with various concentrations of saline solution in order to destroy bacteria and viruses and remove most of the antigens from the tissue.

**Table 45-1 SEAPI Incontinence Score**

Stress-related leakage (“S”)	0 = No urine loss 1 = Loss with strenuous activity 2 = Loss with moderate activity 3 = Loss with minimal activity
Emptying ability (“E”)	0 = No obstructive symptoms 1 = Minimal symptoms 2 = Significant symptoms 3 = Only dribbles or retention
Anatomy (“A”)	0 = No descent with strain 1 = Descent, not to introitus 2 = Through introitus with strain 3 = Through introitus at rest
Protection (“P”)	0 = Never used 1 = Certain occasions 2 = Daily, occasional accidents 3 = Continually, frequent accidents or constant leakage
Inhibition (“I”)	0 = No urge symptoms 1 = Rare urge urinary incontinence (UUI) 2 = UUI once/week 3 = UUI at least once/day

From Raz S, Erickson DR: SEAPI QNM incontinence classification system. *NeuroUrol Urodyn* 11:187-199, 1992.

3. *Denaturation*: The second step of the cleaning process involves treatment with NaOH and H<sub>2</sub>O<sub>2</sub> that removes the remainder of antigens and destroys prions (Creutzfeldt-Jakob Disease) and viruses (hepatitis, HIV). Limited exposure to NaOH allows this to be accomplished without significant alteration of the collagenous structure.
4. *Preservation*: Extraction of water from the tissue is accomplished via organic solvents, resulting in preservation of a dense collagenous structure without a chemical residue.
5. *Gamma irradiation*: The tissue is cut to various sizes, packaged, and sterilized with gamma irradiation. Radiation is limited to less than 25,000 Gy (2.5 Mrad) to limit weakening of the fascia.

The strength and quality of solvent-dehydrated CFL have been compared to those of freeze-dried CFL, another commercially available preparation. Solvent-dehydrated CFL was found to have significantly greater stiffness, maximum load to failure, and maximum load per unit of graft.<sup>7</sup>

Many authors have published their outcomes using either the solvent-dehydrated or the freeze-dried CFL, and their results have confirmed a difference in the tissue quality. Boone published results on 26 women who underwent pubovaginal sling with solvent-dehydrated CFL (Tutoplast) for SUI.<sup>8</sup> Minimum follow-up was 12 months. The outcome revealed that 25 (96%) of the 26 patients were “significantly” improved: 77% wore no pads postoperatively, and an additional 15% wore no more than 1 pad per day. No patients required an additional operation for incontinence.

On the other hand, Raz’s group published results on 154 consecutive patients with SUI who underwent pubovaginal sling placement using freeze-dried CFL.<sup>9</sup> With an average time to follow-up of 10.6 months, 58 (38%) of the 154 patients had recurrent SUI and 26 (17%) required a second operation for SUI. With an average time to reoperation of 9 months, the authors noted that the fascia was either absent, fragmented, or attenuated. Brubaker’s associates reported similar results.<sup>10</sup> Thirty-two patients underwent pubovaginal sling placement with freeze-dried CFL and were available for short-term follow-up. Although 22 (69%) of the 32 patients were objectively dry, the remaining 10 (31%) had recurrent SUI by 6 months’ follow-up. Eight patients underwent reoperation for SUI, and in 7 (87.5%) of them little or no fascia remained at the urethrovesical junction. Fascial strands that were present were sent for histologic analysis and showed evidence of autolysis and degeneration.

As is evident, all commercially available CFL preparations are not the same. The method used to prepare the tissue ultimately affects its tensile strength and surgical results with its use. We prefer to use the nonfrozen cadaveric fascia to avoid the synthetic sling materials that have been associated with higher rates of erosion and/or infection.<sup>11,12</sup>

## BONE ANCHORS

The incorporation of bone fixation in the treatment of SUI was first described with the Marshall-Marchetti-Krantz vesicourethropexy.<sup>13</sup> Since that time, a number of techniques have been described that involve fixation of suspension sutures directly to the pubic bone, which avoids the risk of nerve entrapment that

can occur with attachment to the rectus fascia. Leach described a technique using a needle to place the suspension sutures into the pubic bone,<sup>14</sup> and Benderev later incorporated the use of bone anchors for suture placement.<sup>15</sup> Nativ and colleagues were the first to employ transvaginal bone anchors using a handheld drill in 1997.<sup>16</sup> Their procedure allowed cystourethropexy to be performed entirely transvaginally and was subsequently modified into a sling procedure.

The advantages of transvaginal bone anchor fixation are many. Because the procedure is performed completely transvaginally, no abdominal incisions are required, and postoperative pain is decreased. Suture placement via bone anchors does not require needle or suture passage through the retropubic space and therefore reduces the risks of bleeding and bladder perforation. There has been speculation that perforation of the endopelvic fascia during sling placement may increase the risk of postoperative vaginal prolapse and recurrent SUI.<sup>17</sup> The CaTS procedure, described later, does not involve perforation of the endopelvic fascia and minimizes the potential risks of postoperative prolapse or sling failure.

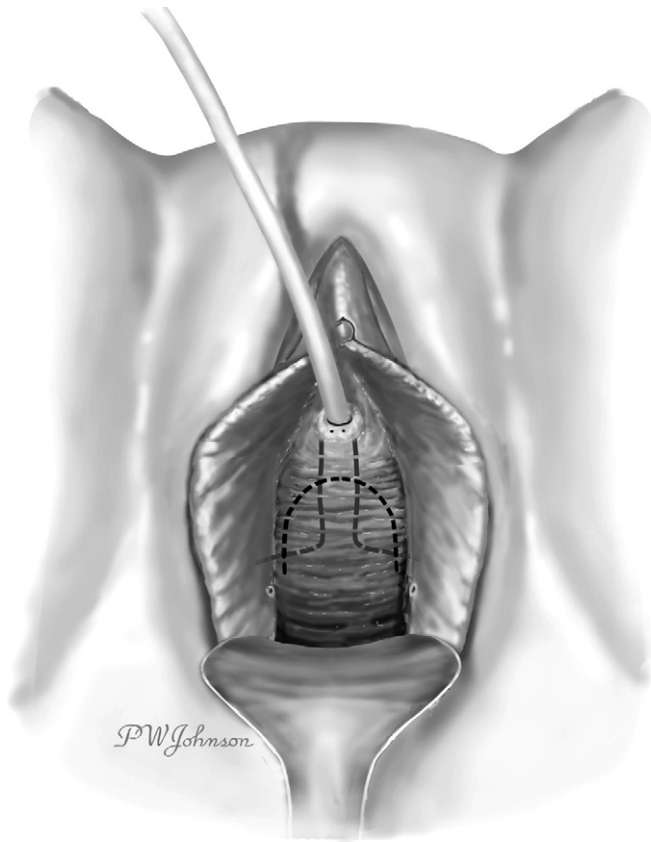

The risk of osseous complications associated with the use of transvaginal bone anchors appears to be less than that reported with suprapubic anchor fixation. Frederick and coworkers published a review of the osseous complications within their prospective cohort of patients in addition to those of 15 other published reports. Among a total of 1228 patients, the incidence of osteitis pubis was 2 (0.16%), and the incidence of osteomyelitis was 1 (0.08%).<sup>18</sup> A prior review published by Rackley and colleagues in 2001 reported no osseous complications among 314 patients who had undergone transvaginal bone anchor with sling placement, compared to a 0.86% incidence associated with suprapubic placement of bone anchors.<sup>19</sup> The incidence of osseous complications with the Marshall-Marchetti-Krantz retropubic urethropexy has been reported to be 0.76%.<sup>20</sup>

## PREOPERATIVE PREPARATION

Before cadaveric transvaginal sling with bone anchors (CaTS) procedure is performed, the urine is confirmed to be sterile. Patients are taught self-catheterization preoperatively. In the event that a patient is unable to learn self-catheterization or has documented incomplete emptying preoperatively, consideration of placing a suprapubic tube intraoperatively should be made. Preferably, patients with vaginal wall atrophy should use estrogen vaginal cream for 4 to 6 weeks before surgery. Patients are instructed to use one-third of an applicator of estrogen three times a week to improve the quality of tissue and postoperative healing properties. A povidone-iodine vaginal douche is performed on the night before and on the morning of surgery. Perioperative antibiotics are given. We prefer to use a first-generation cephalosporin, ampicillin, or vancomycin (if the patient is allergic to penicillin) combined with an aminoglycoside.

Transvaginal repair of associated pelvic prolapse is performed with the CaTS procedure. A thorough discussion of the risks and complications of sling surgery is undertaken before repair. Patients are counseled regarding the possibility of prolonged or permanent urinary retention, recurrent SUI, and persistent or de novo urgency symptoms that may require treatment in the future.

**Figure 45-1** An inverted U-shaped incision is made from the mid-urethra to the bladder neck.

### OPERATIVE PROCEDURE

The procedure is performed with the patient in the dorsal lithotomy position. A Foley catheter is placed, and a Scott retractor (Lonestar, Houston, TX) is secured to the medial buttocks with towel clamps. The anterior vaginal wall is infiltrated with saline, and the Foley balloon is palpated at the bladder neck. An inverted U-shaped incision is made from the mid-urethra to the bladder neck (Fig. 45-1). The flap is mobilized proximally to the bladder neck, but not further, to prevent proximal migration of the sling. Lateral dissection at the bladder neck is performed to clear the undersurface of the pubic bone for bone anchor placement. Perforation of the endopelvic fascia is not necessary, so the risk of significant bleeding and bladder injury is reduced. Patients with significant scarring or urethral fixation due to prior surgeries may require urethrolisis before sling placement. Releasing the urethra from surrounding scar tissue allows the sling to provide adequate compression after placement.<sup>21</sup>

Our preference for bone anchor placement is the InFast drill system (American Medical Systems, Inc. Minneapolis, MN), which changes tone to signify firm placement into the bone (Fig. 45-2). Before placement of the bone anchors, the bladder is placed on drainage, and the bladder and bladder neck are retracted medially. A polypropylene suture with its anchor attached are threaded onto the drill, and the drill is positioned flush with the undersurface of the bone (Fig. 45-3). The drill is activated until a change in tone is audible; then it is removed, and the suture is

**Figure 45-2** Transvaginal drill for bone anchor placement changes tone to signify firm placement into the bone.

**Figure 45-3** The drill positioned on the undersurface of the pubic bone for bone anchor placement.

firmly pulled to confirm anchor placement. The process is repeated on the opposite side.

The CaTS procedure is performed using a 2 cm × 7 cm piece of nonfrozen CFL presoaked in antibiotic solution. The edge of the fascia is folded over to allow cross-hatching of the fibers and to minimize the chance of suture pull-through.<sup>22</sup> An 18-gauge needle is used to allow atraumatic passage of the suture through the folded edge (Fig. 45-4). The bladder neck suture is placed more medially than the distal suture in order to keep the fascia tight against the bladder neck (Fig. 45-5). One side of the sling is secured in place up to the pubic bone. The distal edge of the sling is secured in place using a 2-0 absorbable suture to prevent the sling from rolling toward the bladder neck. The free edge of the fascia is folded over, and the appropriate position of the contralateral sutures is determined (Fig. 45-6). The fascia should lie firmly against the urethra without excessive tension. In our experience, the use of a right angle clamp placed between the urethra and the sling while deciding proper tension can result in the sling's being tied too loosely. Once the proper position is

**Figure 45-4** An 18-gauge needle is used for atraumatic passage of the suture through the fascia. The edge of the fascia is folded over to minimize suture pull-through.

**Figure 45-5** The proximal suture is passed more medial to the distal suture to place the sling snugly against the bladder neck.

determined, the sutures are passed through the fascia and tied firmly against the pubic bone (Fig. 45-7). Before the procedure is completed, cystoscopy is performed with both a 70-degree lens to rule out bladder injury and a 0-degree lens to rule out urethral injury. Irrigation with antibiotic solution is performed throughout the procedure. The vaginal incision is closed with 2-0 absorbable suture. A Betadine-soaked vaginal pack and Foley catheter are left in place.

#### POSTOPERATIVE CARE

The vaginal packing and Foley catheter are removed on the morning of the first postoperative day. Fluid intake is restricted to 1500 mL/day. A voiding trial is administered, and a residual urine measurement is obtained via intermittent catheterization. Eighty percent of patients void to completion immediately after surgery. If residual urine is greater than 100 mL, the patient is instructed on self-catheterization. If a suprapubic tube was placed intraoperatively, residuals are checked in this manner. Patients are continued on intravenous antibiotics for 24 hours postoperatively and then begun on oral antibiotic (cephalexin or fluoroquinolone) for 1 week to minimize the risk of osteitis pubis

**Figure 45-6** The distal edge of the sling is secured in place with 2-0 absorbable suture to prevent it from rolling toward the bladder neck. The free edge is folded over to determine proper tension and position of the contralateral sutures.

**Figure 45-7** Final sling position at the mid-urethra with sutures tied and appropriate amount of tension.

or a wound infection. Patients are routinely discharged on postoperative day 1 with oral analgesics and stool softeners in addition to antibiotics. Patients with elevated postvoid residuals are instructed to continue to monitor at home via self-catheterization or suprapubic tube until residuals are consistently less than 100 mL. In the event that a patient is unable to learn or is uncomfortable performing self-catheterization, she can be discharged with a Foley catheter and return for a trial of voiding in the office. At the time of discharge, patients are instructed to do no heavy lifting or straining and to observe pelvic rest (i.e., no intercourse, no tampons) for 6 weeks postoperatively.

Patients are seen for follow-up at 1 week, 6 weeks, 6 months, 12 months, and yearly thereafter. Evaluation should consist of urinalysis, postvoid residual urine measurement, and physical examination, as well as determination of subjective SEAPI scores. Patients are also administered a confidential, validated continence and satisfaction questionnaire every 6 to 12 months post-

operatively, the results of which are entered into a prospective patient database.

**RESULTS**

The CaTS procedure has been performed on a total of 484 patients aged 23 to 90 years old (mean, 63.7 years). Of these, 414 (85.5%) have had a minimum questionnaire follow-up of 6 months (range, 6 to 78 months; mean, 30.2 months). Distribution of follow-up data is presented in Figure 45-8. According to the confidential patient-driven questionnaire, 89 (22%) of 414 patients reported 100% improvement in their incontinence symptoms; 195 (47%) reported greater than 80% improvement, and 279 (67%) reported 50% improvement or better. Mean SEAPI scores were significantly decreased from 5.5 preoperatively to 2.7 postoperatively ( $P < .001$ ). Overall, 241 (58%) of 414 patients were more than 80% satisfied with the procedure on a visual analogue scale (mean satisfaction, 68%; median, 90%). Two hundred ninety-five patients (72%) would have the surgery again, and 292 (71%) would recommend the surgery to a friend.

One hundred thirty patients (31%) reported less than 50% improvement in incontinence symptoms and were considered “failures.” Thirty-three (8%) complained of recurrent SUI, 56 (13.5%) complained of mixed urinary incontinence, 14 (3.4%) complained of urge urinary incontinence, and 27 (6.5%) were unsure regarding the type of incontinence responsible for their dissatisfaction. Recently, we evaluated multiple preoperative

variables in an attempt to determine risk factors for failure (Table 45-2). The variables considered were

1. Preoperative urinary urgency
2. Preoperative urge urinary incontinence
3. Detrusor overactivity on preoperative urodynamic evaluation
4. Abdominal leak point pressure less than 50 cm H<sub>2</sub>O
5. History of prior anti-incontinence procedure
6. Presence of cystocele requiring concurrent repair

The presence of preoperative urge urinary incontinence was the only considered variable associated with an increased risk of failure ( $P < .01$ ). Conversely, the presence of a concurrent cystocele was found to be associated with a significant decrease in failure ( $P < .05$ ), perhaps due to a redistribution of the forces at the mid-urethra and bladder neck over the entire anterior vaginal wall. Time to failure is shown in Figure 45-9. Notably, 100 (77%) of the 130 failures occurred after 12 months’ follow-up.

Of 209 patients who complained of urinary urgency preoperatively, 71 (34%) experienced persistent urge symptoms postoperatively. Of 205 patients without preoperative urinary urgency, 20 (10%) developed de novo urge symptoms. Prolonged urinary retention (>30 days) occurred in 7 patients, 1 of whom required urethrolisis. Osteitis pubis occurred in 2 patients and was

Figure 45-8 Distribution of questionnaire follow-up for the cadaveric transvaginal sling (CaTS) procedure.

Figure 45-9 Time to failure after the cadaveric transvaginal sling (CaTS) procedure.

Table 45-2 Relation of Preoperative Variables to Failure of the Cadaveric Transvaginal Sling Procedure

Preoperative Variable	Present	Absent	Failure Rate		P Value
			Present	Absent	
Urinary urgency	197	133	54/197 (27%)	31/133 (23%)	.44
Urge incontinence	124	206	44/124 (35%)	41/206 (20%)	<.01
Leak point pressure <50 cm H <sub>2</sub> O	84	246	24/84 (29%)	61/246 (25%)	.56
Detrusor overactivity	72	258	22/72 (31%)	63/258 (24%)	.29
Concurrent cystocele	232	98	52/232 (22%)	33/98 (34%)	.04
Prior anti-incontinence procedure	71	259	20/71 (28%)	65/259 (25%)	.65

managed conservatively with nonsteroidal medications. Wound separation occurred in 9 patients, but all eventually healed secondarily with conservative management. There have been no mortalities associated with the CaTS procedure.

## CONCLUSION

Transvaginal slings are considered first-line treatment for SUI. The choice of nonfrozen CFL avoids the need to harvest the patient's own fascia intraoperatively and consequently reduces

operative time, postoperative pain, and length of hospital stay. Whereas early results with the CaTS procedure were very encouraging and comparable to those obtained with other materials and techniques of placement, long-term results have been less durable, with failure rates approaching 30%. To improve continence results, we are currently exploring other materials and approaches for sling placement. The CaTS procedure remains an excellent option for patients who wish to avoid the use of synthetic materials. Familiarity with this technique is recommended as part of the armamentarium of a surgeon's transvaginal sling procedures.

# RADIOFREQUENCY TREATMENT FOR THE MANAGEMENT OF GENUINE STRESS URINARY INCONTINENCE

*Emily E. Cole and Roger R. Dmochowski*

Genuine stress incontinence (SUI) affects a substantial and increasing proportion of the female population.<sup>1-4</sup> It is well accepted that SUI is often associated with substantial quality-of-life disruption and desire on the part of the sufferer for improvement in or resolution of attendant symptomatic bother. A recent outcomes analysis suggested that women seeking therapy for genuine SUI would accept symptom improvement as an important and positive outcome aspect even if cure were not obtained.<sup>5</sup> The referral and usage trends for surgical interventions such as colposuspensions and suburethral slings suggest that, for women with less advanced symptoms, factors including patient fear or reluctance about surgical morbidity rates, recovery times, and other lifestyle concerns cause these procedures to be employed in a relatively small percentage of the overall affected population.<sup>2,6,7</sup> In addition, despite minimal invasiveness and positive safety profiles, nonsurgical modalities have in many cases been plagued with unfavorable compliance rates and chronic treatment requirements, as well as questionable effectiveness and durability.<sup>8,9</sup>

For the large population of less symptomatically bothered patients who desire treatment for their condition, the application of radiofrequency (RF) energy to the endopelvic fascia has been proposed as a new category of less invasive, first-line surgical intervention. In other disciplines, RF microremodeling has been shown to be well suited for the treatment of disorders characterized by the inappropriate passage of luminal contents through a dysfunctional anatomic and/or physiologic barrier, for example in fecal incontinence<sup>10</sup> and gastroesophageal reflux disease.<sup>11</sup> The RF energy procedure aims to treat genuine SUI by correcting the laxity and elasticity of the fascial “hammock”<sup>12</sup> supporting the urethra and bladder neck via thermally induced tissue shrinkage and contraction.<sup>13</sup> Specific heating of the endopelvic fascia denatures collagen fibers, causing acute contraction (shrinkage) of the treated tissue while also stimulating a fibrotic response.<sup>14</sup> In subsequent weeks, collagen in-growth and scar tissue formation further shrink and stabilize the endopelvic fascia, reducing its compliance to intra-abdominal pressure increases and stabilizing the position of the bladder neck.<sup>15</sup> This summary introduces the theoretical principles behind RF treatment of genuine SUI and reviews available literature describing approaches and results of currently available RF modalities.

### THEORETICAL PRINCIPLES

The pathophysiology of genuine SUI is generally attributed to loss of passive support of the urethra due to tissue injury, stretch-

ing, or loss of stability, and/or lack of functioning neurologic control of the muscles of the pelvic floor and urethra.<sup>12,16-18</sup> Passive support weakness may provide inadequate support to the urethra, resulting in urethral hypermobility and poor urethral compression during stress events and periods of increased physical activity, leading to urine leakage.<sup>19-21</sup> A compounding effect of passive support failure is displacement of the urethra, which results in unequal distribution of sudden intra-abdominal pressure to the bladder and urethra, with the bladder pressure overcoming the pressure within the descended urethra, thereby further contributing to episodes of uncontrolled urine loss.

Developers of RF treatment hypothesized that if the collagen-rich endopelvic fascia in women with genuine SUI could be shrunk, and thus stabilized, through a direct application of controlled heat, these non-neurologic continence mechanisms could be positively affected and continence restored. It was envisioned that this could be accomplished via a minimally invasive approach with a very low associated risk of surgical complications.

### ENERGY-TISSUE INTERACTIONS

The ability of heat to effect shrinkage of collagen-containing tissue is a function of several characteristics of the collagen molecule, which is triple-helical and fibrillar in structure. The intramolecular hydrogen bonds, or cross-links, that maintain the triple-helical configuration are thermally labile, whereas the intermolecular bonds that maintain the fibrillar structure are thermally stable. Heat in the range of 60°C to 80°C will disrupt the intramolecular cross-links, causing the helix to unwind, while the heat-stable fibrillar structure remains intact. This results in shrinkage on the longitudinal axis along with swelling of the fibrils.<sup>13</sup>

The clinical use of RF energy to achieve tissue shrinkage via collagen denaturation is well documented in the literature.<sup>13,22-25</sup> In this context, RF energy is applied to the tissue via direct contact with electrodes, and tissue heating occurs as the tissue resists the flow of the RF current. Heat conducts from high to low temperature regions in the tissue, creating a three-dimensional thermal effect. This thermal effect is specific to the amount of RF energy delivered, the tissue resistance, and the electrode configuration.

These concepts were modeled after studies demonstrating tissue shrinkage via RF energy. Hecht and colleagues described the use of monopolar RF energy to treat bovine joint capsular tissue *in vivo*.<sup>13</sup> They found that the application of RF energy was followed by tissue reaction and concomitant degradation of collagen with the ensuing build-up of new collagen over a 12-week

period, resulting in remodeling of the joint capsular tissue. The primary treatment effect was heat-induced tissue shrinkage associated with the denaturation of collagen; maximal shrinkage occurred at temperatures ranging from 60°C to 80°C. Post-treatment histologic evaluation revealed that thermal effects were localized to the region of RF energy application. Subsequent evaluations showed a tissue healing response characterized by fibroblast and capillary proliferation that ultimately resulted in complete tissue healing at 12 weeks. Chen and associates performed a series of experiments on fresh bovine heart tendons.<sup>26</sup> The tissue was mounted in a tension-free holder, and the amount of shrinkage was measured as a function of time and temperature. The study showed that maximal tissue shrinkage occurred only if the thermal treatment time and temperature exceeded a certain threshold. Notably, a temperature of 70°C effected near-maximal shrinkage when applied for a minimum of 30 seconds. Temperatures lower than 70°C demonstrated significantly diminished capacity for effective shrinkage regardless of the duration of the heat application. This information was used to develop an RF energy treatment algorithm for shrinking the endopelvic fascia to restore continence in women with genuine SUI.

### TREATMENT METHODOLOGY

Based on the theoretical and experimental information described, a commercially available RF bladder neck suspension procedure was developed. The SURx Transvaginal System (SURx System, CooperSurgical, Inc. Trumbull, CT) is composed of a small bipolar RF generator and a sterile, single-use applicator that allows application of RF energy to the tissue. The applicator has a handle, a trigger, and a 270-degree rotational tip with microbipolar electrodes and a saline drip at the distal end of the probe. Additionally, there is a thermistor located between the electrodes for accurate monitoring of treatment tissue temperatures.

The specific treatment area for the RF procedure is an area of the endopelvic fascia located at least 1 cm lateral to the mid-urethra on each side. The targeted treatment area can be assessed laparoscopically or transvaginally, with both approaches facilitating treatment of the same tissue (on the superior or inferior surface, respectively).

All patients should be carefully screened preoperatively with a comprehensive history and physical examination, voiding diary, and urodynamics if possible. Patients should demonstrate objective SUI and should have evidence of urethral hypermobility on physical examination. Most transvaginal RF procedures can be performed in an outpatient setting with general or regional anesthesia.

The patient is placed in the dorsal lithotomy position, a Foley catheter is placed, the bladder is actively emptied, and the balloon is inflated. Hydrodissection of the vaginal wall is recommended, using an appropriate dilute vasoconstrictive solution (20 U vasopressin in 50 mL injectable saline or epinephrine at a 1:200,000 dilution in injectable saline) to minimize excess bleeding. A 2- to 3-cm incision is made 1 cm lateral to the urethra centered at the level of the mid-urethra. This incision is carried through the full thickness of the vaginal mucosa, and further dissection is performed to expose a 1.5 × 2 cm area of the inferior aspect of the endopelvic fascia. Care must be taken not to disrupt the underlying fascial layer. It is recommended that the treatment area be kept as dry as possible with continuous suction, because this may affect eventual outcomes.

After dissection, the tip of the applicator is applied to the underlying endopelvic fascia with enough pressure to cause deflection of the tissue. The SURx RF system is used to deliver a minimum of 70°C to the target tissue for a minimum of 30 seconds to achieve the desired shrinkage and associated therapeutic effect. The system uses low-power (15 W) bipolar RF energy to produce a volume of treated tissue meeting the 70/30 criteria ( $\geq 70^\circ\text{C}$  for at least 30 seconds) for effecting shrinkage, as described by Chen and associates.<sup>26</sup> The RF energy is activated, and application of RF energy is accomplished by drawing the RF device tip over the fascia in a slow, sweeping manner along the longitudinal axis, making sure that both tines of the applicator tip are equally in contact with the tissue until all exposed endopelvic fascia has been treated. Care must be taken to remain 1 cm lateral to the urethra at all times during the procedure. Treatment of one side should be concluded based on aural feedback from the RF generator indicating that adequate thermal effect has been imparted to the underlying tissue on the basis of changes in recorded treatment impedance. Thermal effect within the tissue can be confirmed by visualizing blanching and shrinkage. The procedure is then repeated on the contralateral side.

After delivery of the RF energy, the incisions are irrigated and closed, and the Foley catheter may be removed. The patient is transferred to the recovery suite until the anesthesia effects are no longer present and spontaneous voiding has occurred (usually 2 to 4 hours). Based on clinical judgment, patients may be discharged home on the day of treatment.

The technique for the laparoscopic approach is similar. Laparoscopic ports should be placed according to surgeon preference to facilitate access to the pelvis. A combination of blunt and sharp dissection may be used to expose the endopelvic fascia. Treatment can be delivered to the superior aspect of the endopelvic fascia in a manner similar to that described for the transvaginal approach. Care should be taken to remain 1 cm lateral to the urethra, which can be confirmed by locating the Foley catheter so that it traverses the urethra and bladder neck. Treatment is typically applied to the fascia from this point at approximately the level of the mid-urethra to the beginning of the arcus tendineus.

### RESULTS

Initially, two prospective investigational device exemption (IDE)-approved clinical trials were conducted to demonstrate the safety and comment on the efficacy of the RF procedure.<sup>27,28</sup> A total of 214 patients with genuine SUI were enrolled at 16 U.S. study sites; 94 (44%) underwent a laparoscopic approach, and 120 (56%) underwent the transvaginal approach. Once access to the endopelvic fascia was gained, treatment was carried out bilaterally as previously described. Clinical efficacy at 12-month follow-up was assessed for both groups. Diagnosis of genuine SUI was based on patient history and objective demonstration of leakage during physical examination. All women had urethral hypermobility as determined by an abnormal cotton swab test ( $>30$  degrees). Detrusor overactivity was excluded by cystometry. Patients who were taking antidepressants or  $\alpha$ -adrenergic or anticholinergic medications, as well as those with grade III or IV anterior prolapse or other vaginal support defects, were excluded from analysis. Patients included in the study had had previous unsuccessful outcomes after at least 3 months of conservative, noninvasive therapies such as Kegel exercises or electrical stimu-

lation of the pelvic floor. No patient was receiving any active incontinence therapy. Cure was described as a negative Valsalva test on physical examination and improvement was defined as decreased daily episodes or pad use. Results are shown in Table 46-1. There were no reported device-related events during the study time, and an excellent safety profile was demonstrated (Table 46-2). On further data assessment, two treatment parameters emerged that had a significant impact on procedure efficacy: the relative dryness of the surgical field (excessive fluid in the surgical field was noted to cause energy dissipation and resultant superficial, insufficient treatment) and the continuity of thermal delivery to the treatment area (numerous intermittent energy applications as a result of multiple “on/off” cycles resulted in inadequate thermal effect in the targeted tissues).

Additional follow-up of the original patient cohort was undertaken using the same measurement criteria. The average long-term follow-up was  $38 \pm 3.51$  months in the laparoscopic group and  $30 \pm 3.29$  months in the transvaginal group. An actuarial survival analysis of objective and subjective outcomes from the 6-month evaluation out to  $30 \pm 3.3$  months is shown in Figure 46-1.<sup>29</sup>

## FUTURE DIRECTIONS

Recently, the RF concept has been explored further, and a transurethral modality for the delivery of RF energy has been described. Appell and coworkers described a system introduced by Novasys (Novasys Medical, Inc., Newark, CA) that consists of a 21-Fr transurethral RF microremodeling probe connected to an RF generator.<sup>30</sup> An intravenous line carrying sterile, room-temperature water is routed through a pump on the RF generator

to the probe, providing irrigation to the mucosa overlying the submucosal treatment sites during RF delivery. The system is monopolar, and a standard return electrode (“grounding pad”) is placed on the patient and connected to the RF generator.

Cystoscopic visualization is not required. After transurethral passage into the bladder lumen, a balloon on the probe tip is insufflated and then palpably anchored within the bladder outlet, identical to positioning a Foley catheter. Four 23-gauge needle electrodes are simultaneously deployed, and the needle tips are advanced through the mucosa and into the submucosa (Fig. 46-2). RF is delivered to the four needles for 60 seconds, microremodeling four submucosal tissue targets. A series of rotational maneuvers between periods of RF delivery should place the four needles in nine different positions (for a total of 9 minutes of RF delivery). This treatment resulted in the microremodeling of 36 microscopic, submucosal, circumferential targets ranging from the bladder neck cranially, to the middle aspect of the proximal urethra caudally.<sup>30</sup>

This pilot study randomized 110 women to an RF treatment group and 63 to a sham treatment group. Improvement of 10 points or greater on the Incontinence Quality of Life (I-QOL) score—a magnitude of improvement with a demonstrated responsiveness to patient satisfaction with treatment and to 25% or greater reduction in both incontinence episode frequency and stress pad weight—served as a subjective outcome measurement. Change in mean leak point pressure (LPP) served as an objective outcome measurement. Adverse events were recorded for each group. The 12-month RF safety profile was identical to that of the sham group (Table 46-3). Seventy-four percent of the patients with moderate to severe genuine SUI experienced at least 10 points of I-QOL score improvement after RF remodeling, compared with 50% of those who underwent sham treatment ( $P = .03$ ). Twenty-two percent of women with mild genuine SUI who received RF treatment reported improvement, compared with 35% of those who received sham treatment ( $P = .2$ ). Women who underwent RF treatment demonstrated an increase in mean LPP at 12 months ( $13.2 \pm 39.2$  cm H<sub>2</sub>O), whereas women in the sham treatment group demonstrated a reduction in mean LPP at 12 months ( $-2.0 \pm 33.8$  cm H<sub>2</sub>O) ( $P = .02$ ).<sup>30</sup>

## SUMMARY

Tissue responses induced by RF thermal energy are well described and reproducible.<sup>12,13</sup> Acute effects include denaturation of collagen fibers, which results in loss of collagen fibril integrity. At 1 week, a more generalized granulation response is seen, and by 21 days after treatment, fibroplasia and fibrosis response are predominant. By 6 weeks after treatment, the expected fibrotic healing response continues to progress, and inflammatory cellu-

**Figure 46-1** Actuarial survival analysis of objective and subjective outcome measures. IEF, Incontinence episode frequency; QOL, quality of life.

**Figure 46-2** Novasys® radio frequency device position at bladder neck with RF probes deployed into urethra. Transurethral approach.

lar components are minimal.<sup>15</sup> The final histologic result is fibrotic tissue that replaces the elastic endopelvic fascia. This process shortens, stiffens, and thickens the fascia, increasing support of the bladder neck, and changes the collagen structure of the tissue. RF thermal tissue treatment has been used in dermatology, in orthopedics, and for treatment of varicose veins.<sup>28</sup> The contractile response to RF energy has also been applied to the treatment of tissue within joints to shorten and strengthen tendinous ligamentous attachments.<sup>27</sup>

The endopelvic fascia may demonstrate loss of integrity that usually is caused by pregnancy and childbirth.<sup>31,32</sup> However, other women, such as athletes, can also suffer from genuine SUI.<sup>33</sup> Loss

of integrity of the pelvic floor is manifested by bladder descensus with resultant urethral hypermobility during stress events, such as coughing or other activities that increase abdominal pressures. Accepted treatments that stabilize the bladder neck include retropubic suspension and pubovaginal sling; however, these procedures are associated with known complication risks. Early studies indicate that the RF procedure offers a safe and effective means to impart shrinkage of the endopelvic fascia, replacing elastic tissue with inelastic tissue. This shrinkage decreases the elasticity of the endopelvic fascia and stabilizes the proximal urethra and bladder neck, recapitulating the suburethral tissue used as a backboard for urethral closure.

The need to balance procedure “tolerability” issues with expectations for objectively measured efficacy has been explored and validated in recent discourse<sup>31-33</sup> and has particular applicability when addressing the population with mild to moderate SUI. For this large patient group, the risks and considerations associated with more invasive procedures may be viewed differently than they would by those with a more advanced disease state. Issues such as the need for a Foley catheter or self-catheterization postoperatively, even for a brief time after surgery, become salient for the patient who is considering treatment for mild to moderate SUI. Likewise, most of these patients may be unwilling to assume the restrictions on future pregnancy that are inherent to sling and suspension procedures. Heightened sensitivity to the risks of viral or prion transmission with the use of biomaterials may also more significantly influence patient preference in cases of mild to moderate SUI.

Several aspects of the RF thermal energy approach may not be explicitly apparent to the patient but may contribute to the overall favorable risk profile of the procedure and warrant consideration by the physician. The shallow incision and dissection used in this procedure provides a therapeutic option for genuine SUI that does not involve the blind passage of needle or trocar devices, thereby minimizing the potential for injury to the bladder, bowel, and major vessels. Further, the use of thermally induced shrinkage to tighten the periurethral tissue inherently avoids the use of implanted materials to provide structural

support, thereby eliminating the concerns of proper sling placement and the potential for foreign material erosion in the near or long term.

More comprehensive studies with longer-term follow-up are needed to determine the true efficacy of this relatively new treatment modality; however, the RF tissue shrinkage procedure pro-

vides a compelling risk-to-benefit profile that is of particular relevance to physicians treating mild to moderate genuine SUI. The avoidance of permanently implanted foreign materials and the corresponding positive impact on procedure morbidity and patient lifestyle distinguish it as a uniquely conservative first-line surgical intervention for this patient group.

# SURGERY FOR REFRACTORY URINARY INCONTINENCE: SPIRAL SLING

*Arthur Mourtzinou, M. Grey Maher, Shlomo Raz,  
and Larissa V. Rodríguez*

Treatment of stress urinary incontinence (SUI) caused by urethral hypermobility or intrinsic sphincter deficiency with urethral sling procedures may yield success rates of up to 80% to 90%, depending on the definition of success.<sup>1-5</sup> In a minority of patients, however, there is persistence or worse incontinence after surgical therapy. Female patients with urethral incompetence and severe incontinence due to multiple failed surgeries, neurologic injury, or congenital anomalies represent a unique surgical challenge. Patients with neurologic conditions may have sacral arc lesions with paralysis of the skeletal musculature and an open urethra. Other patients who have failed multiple sling and anti-incontinence procedures may have severe symptoms of SUI and an open urethra with a low Valsalva leak point pressure (VLPP). These patients often have an incompetent, difficult to compress urethra, most likely resulting from a combination of urethral denervation and violation of the periurethral fascia, as well as their underlying risk factors for SUI.<sup>6</sup> These patients have low chances of cure after repeat anti-incontinence surgery, and they are more likely to suffer from complications including retention.<sup>7</sup> In this patient population, a routine sling procedure providing only posterior support will not typically yield an appropriate response. Management options include placement of a “tight” pubovaginal sling, with the intent of putting the patient in urinary retention, or constructing an artificial urinary sphincter (AUS). Many of these patients are often forced to undergo bladder neck closure with continent catheterizable augmentation.

This chapter describes a transvaginal sling procedure in adult women that encircles the urethra, providing circumferential coaptation. The spiral sling is a salvage procedure for a small, yet severely affected group of female patients with a totally incompetent urethra. The procedure was initially described in patients with congenital or neurologic diseases.<sup>8</sup> It has more recently been described in patients with multiple failed surgeries for SUI.<sup>9</sup> In our experience, it provides better outcomes and fewer complications than the AUS.

In addition, we discuss the AUS as a treatment option for the female patient with urinary incontinence. The AUS is an effective alternative to the urethral sling for the treatment of urinary incontinence caused by primary urethral sphincter insufficiency (type III SUI).<sup>10</sup> The AUS is a synthetic device that includes an internal cuff made of silicone rubber with Dacron reinforcement and is designed to provide a uniform circumferential compression on the urethra. Continence or cuff inflation is maintained by continuous pressure in the cuff, which is modulated by the pressure balloon, which in turn is usually positioned in the pre-vesical space. The patient manipulates a labially placed pump to open the cuff before voiding. The American Medical System

(Minnetonka, MN) AS-800 is the currently used model; it may be implanted via a transvaginal,<sup>10,11</sup> transabdominal,<sup>12</sup> or laparoscopic transperitoneal approach.<sup>13</sup> In this chapter, we limit our discussion to the transvaginal approach.

### EVALUATION OF THE PATIENT

The preoperative evaluation should include a standard history and physical examination, radiographic evaluation, and videourodynamic studies. Multiple prior anti-incontinence operations, radical pelvic surgeries, orthopedic conditions, or neurologic disorders (myelomeningocele, sacral cord tumor, or peripheral neuropathy) are important historical data. A thorough neurologic examination of the lower extremities and perineum may elucidate abnormal sensory and motor responses in the lower lumbar and sacral cord segments. A formal pelvic examination may reveal evidence of a urethral diverticulum, abscess, or mesh erosion in patients with a history of an anti-incontinence or vaginal prolapse procedures.

Complex videourodynamic study and cystourethroscopy should be performed to rule out any definitive evidence of voiding dysfunction, detrusor overactivity, intrinsic sphincter deficiency, or abnormal urethral and bladder pathology. Radiographic evaluation may include a standing voiding cystourethrogram with resting and straining views. In many tertiary centers, videourodynamic testing is done with the patient in the sitting position. Cystourethroscopy can also assess bladder trabeculation and rule out the presence of any urethral pathology.

The patient’s clinical history of incontinence is important in the overall assessment; these patients typically have incontinence of nonresistance due to an incompetent urethra. When selecting patients for surgery, we do not rely solely on a low VLPP. A patient with clinically significant incontinence (incontinence of nonresistance) may not always have a low VLPP.

### THE SPIRAL SLING

#### Surgical Technique

A 1 × 15 cm, thinly woven polypropylene (Ethicon, Inc., Somerville, NJ) mesh is prepared, and a 1-0 polyglactin suture is applied at each end. The patient is positioned and prepared in a similar manner as for the AUS (described later). A 16-Fr Foley catheter is inserted per urethra, and the bladder is emptied. A weighted speculum is then placed into the vagina for exposure.

**Figure 47-1** Two oblique lateral incisions are made in the anterior vaginal wall.

An Allis clamp is used to grasp the anterior vaginal wall just proximal to the meatus. Two parallel distal oblique incisions are made in the anterior vaginal wall (Fig. 47-1). One additional Allis clamp is placed at the distal portion of each of the oblique incisions to aid in the exposure. The dissection is carried out laterally, over the glistening periurethral fascia, toward the ipsilateral shoulder. The retropubic space is entered, and a complete urethrolysis is performed by detaching the urethropelvic ligaments from the arcus tendineus fascia pelvis and freeing all retropubic adhesions (Fig. 47-2). The urethral dissection is started in the midurethral area just proximal to the pubourethral ligaments and carried proximally to free the rest of the urethra and the bladder neck. The dissection is maintained close to the periosteum of the pubic bone to avoid injuries to the dorsal venous complex, bladder, and urethra. The dorsal aspect of the urethra is freed from the pubis. A suburethral tunnel is created in the anterior vaginal wall, 1.5 cm from the urethral meatus, with a fine, right angle clamp connecting the two oblique incisions (Fig. 47-3A).

A Derra clamp is used to pass the 1 × 15 cm soft polypropylene mesh dorsally, between the urethra and the pubis. The ends of the mesh are crossed ventrally through the previously made vaginal tunnel with a right angle clamp. This maneuver creates a complete circle of mesh around the urethra. A suprapubic puncture is made just above the symphysis. A double-pronged needle

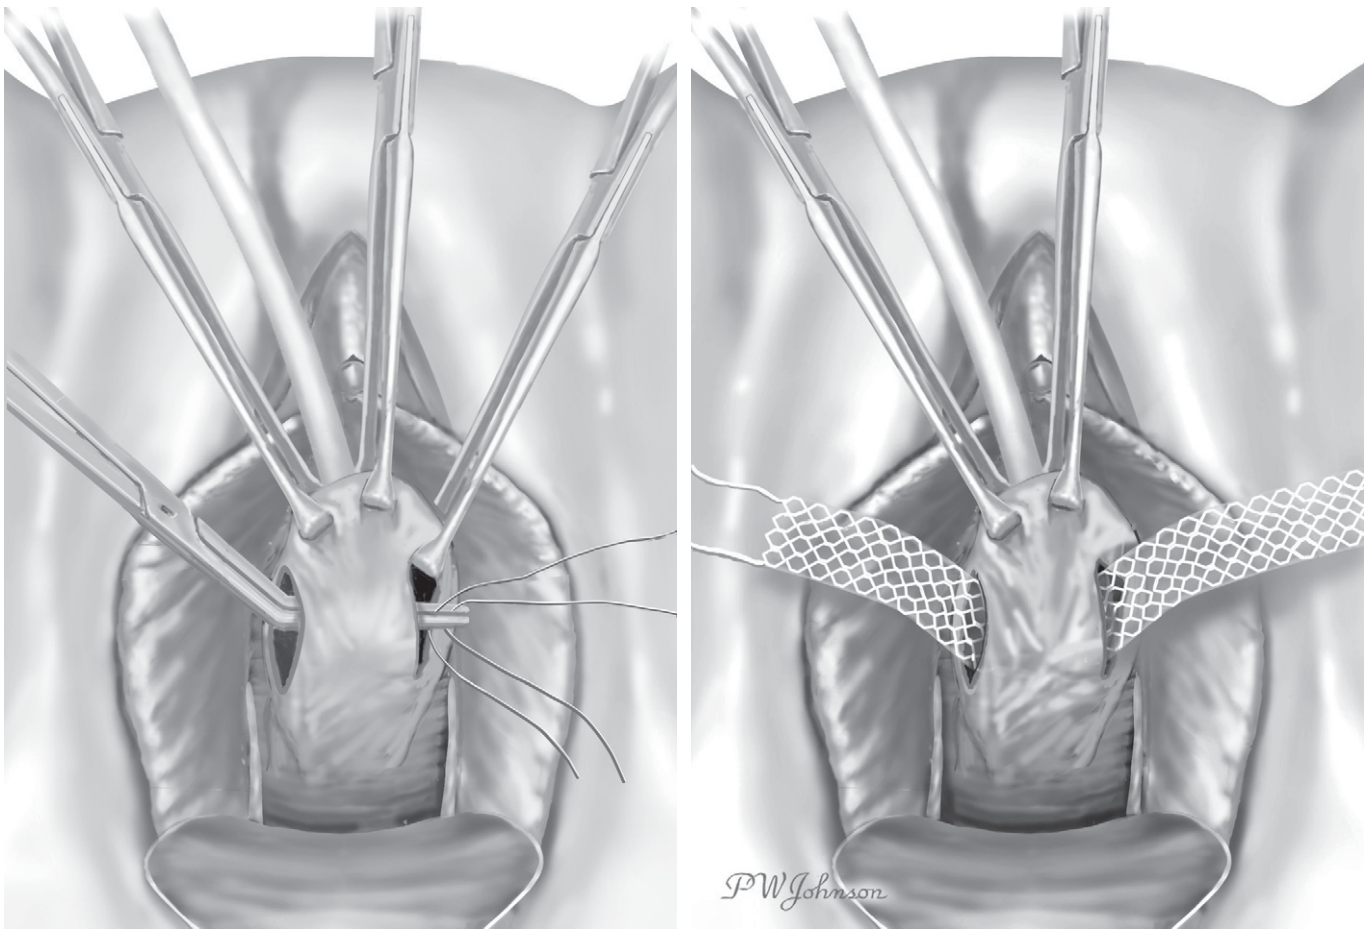

**Figure 47-2** The retropubic space is entered at the level of the mid-urethra to distal urethra using curved scissors.

(Cook Urological, Inc., Spencer, IN) is passed under finger control through the fascia and retropubic space to the level of the oblique vaginal incision. The previously placed 1-0 polyglactin sutures from the polypropylene mesh are transferred to the suprapubic incision. This is repeated on the contralateral side. Cystoscopy is performed to rule out bladder or urethral perforation.

To ensure securing of the sling under no tension, one Allis clamp is placed through each vaginal incision to firmly hold the sling in place in a horizontal plane while the assistant ties the sutures suprapubically under no tension. The suture knots are located approximately 3 to 4 mm below the skin. The retropubic space is irrigated with Betadine solution. The vaginal incisions are closed with 3-0 polyglactin sutures. The suprapubic incision is closed with a 4-0 polyglactin subcuticular stitch. A vaginal pack and suprapubic dressing are applied. Drainage of the bladder is accomplished with either a suprapubic catheter, a urethral catheter, or clean intermittent catheterization taught to the patient preoperatively.

Postoperatively, the vaginal pack is removed in the recovery room approximately 2 hours after completion of the procedure. Patients can be sent home on the day of the procedure if they are tolerating oral intake and their pain is under adequate control, or they may be admitted for 24-hour observation. Patients with a urethral catheter may be instructed to return to the office for a

**A** **B**  
**Figure 47-3** The mesh is transferred under the previously created tunnel.

voiding trial in 5 to 7 days. In those with a suprapubic tube, the catheter is capped and the patient is instructed to void every 3 hours and record the postvoid residual volume. The suprapubic tube is left in place for at least 1 week and is removed once postvoid residuals are less than 50 mL. The patients are discharged home with empiric antibiotic coverage for 5 days.

### Discussion

Between August 1999 and February 2006, 93 patients underwent placement of a spiral sling.<sup>8</sup> Patients with congenital or neurologic diseases were initially the candidates for this procedure. Since March 2002, however, the technique was expanded to include those patients with multiple failed surgeries for SUI and an incompetent “lead pipe” urethra. The initial results of the spiral sling procedure in 47 patients with congenital and neurologic anomalies were recently reported in the literature.<sup>8</sup> Of the 47 patients, 7 were lost to follow-up. The mean age of the remaining 40 patients was 59.0 years (range, 23 to 86 years). This represented a complex cohort of patients, with 98% having failed a prior anti-incontinence surgery. The patients had undergone a mean of 2.6 previous anti-incontinence surgeries and used an average of 6 pads per day. There were two patients who had previous augmentation cystoplasty and were performing intermittent self-catheterization but had significant SUI between catheteriza-

tions. All patients were considered candidates for urethral closure and continent diversion as a salvage procedure.<sup>8</sup>

In this group of 40 patients, the average follow-up was 12 months (range, 6 to 37 months). There were no intraoperative complications. The de novo urge incontinence rate was 7.4%. Of the 27 patients with preoperative urge incontinence, 9 (33%) had resolution of their symptoms with the procedure. One of the patients had persistent refractory urge urinary incontinence and subsequently underwent a sacral neuromodulation procedure. No patient experienced de novo retention after the spiral sling. The four patients who were performing intermittent self-catheterization preoperatively continued to do so after the procedure. There were no urethral or vaginal erosions. Overall, three patients underwent eventual bladder neck closure and continent augmentation and were considered failures.<sup>8</sup>

Patients were evaluated with self-assessment questionnaires. Questionnaires consisted of a validated short form of the Urogenital Distress Inventory (UDI-6), a standardized symptom questionnaire that assessed the presence or absence and frequency of symptoms, and a urinary symptom-specific global quality of life (QOL) questionnaire validated for the evaluation of patients with benign prostatic hyperplasia.<sup>4,14</sup> Forty patients were included in the analysis with a minimum of 6 months follow-up; 65% reported never having symptoms of SUI, and 87% reported symptoms of SUI never or less than once per week.

On the UDI-6 questionnaire, 68% reported never being bothered by symptoms of SUI, and 95% reported never or rarely being bothered by SUI. The mean number of pads decreased from 6.0 preoperatively to 0.9 postoperatively ( $P < .005$ ). Seventy-eight percent of patients reported greater than 90% improvement. Overall, patients reported a mean improvement in symptoms of 87% after surgery (on a scale of zero to 100%).<sup>8</sup>

The technique was recently described in 46 non-neurogenic patients with multiple failed surgeries for SUI.<sup>9</sup> The mean age of the study population was 62 years, and the mean follow-up was 15 months (range, 6 to 45 months). All patients had failed a prior anti-incontinence surgery. There were no intraoperative complications, and, postoperatively, there were no cases of permanent urinary retention requiring transvaginal urethrolysis. On patient-driven subjective assessment, 49% of patients reported never experiencing SUI, and 72% experienced no or rare episodes of SUI. Overall, patients reported a mean improvement of 84%, with a decrease in daily pad use from 5.5 to 1.0. In addition, there was no statistically significant difference between preoperative and postoperative symptoms of incomplete bladder emptying ( $P > .05$ ).

A review of the literature for alternatives to bladder neck closure revealed no existing circumferential sling procedure in the adult population. Mingin and colleagues described a trans-abdominal technique of a urethral sling using rectus muscle wrapped around the urethra for pediatric patients with congenital urethral incompetence.<sup>15</sup> Of the 37 patients reported, 92% remained dry between catheterizations. The pediatric population is unlike our target population, because these adult patients had undergone approximately three anti-incontinence surgeries with subsequent scarring and more difficult coaptation. The mechanism of cure of the transvaginal spiral sling is not completely understood. It most likely supports the midurethral segment while preventing urethral descent and improving pressure transmission to the urethra. In addition, unlike a routine sling procedure, the spiral sling also provides circumferential coaptation to the urethra at the time of increased intra-abdominal pressures.

#### ARTIFICIAL URINARY SPHINCTER: TRANSVAGINAL APPROACH

The AUS is no longer commonly performed worldwide for SUI in the female population. The need for multiple revisions, the short length of the female urethra as compared to that of the male, and the difficulty encountered in placing an AUS in patients with multiple prior operations has limited its use. In this section, we discuss the transvaginal insertion technique and surgical outcomes.

#### Surgical Technique

The AUS is composed of three parts: the inflatable cuff, the pressure-regulating balloon or reservoir, and the pump (Fig. 47-4). The cuff is placed circumferentially around the bladder neck, the reservoir is positioned in the prevesical space, and the pump is put in the labia majora. When the pump is squeezed, fluid moves from the cuff to the balloon reservoir. This decompression of the cuff opens the bladder neck and allows the patient to void. After 1 to 2 minutes, the reservoir automatically reinflates the cuff, which then reestablishes urethral coaptation and continence.

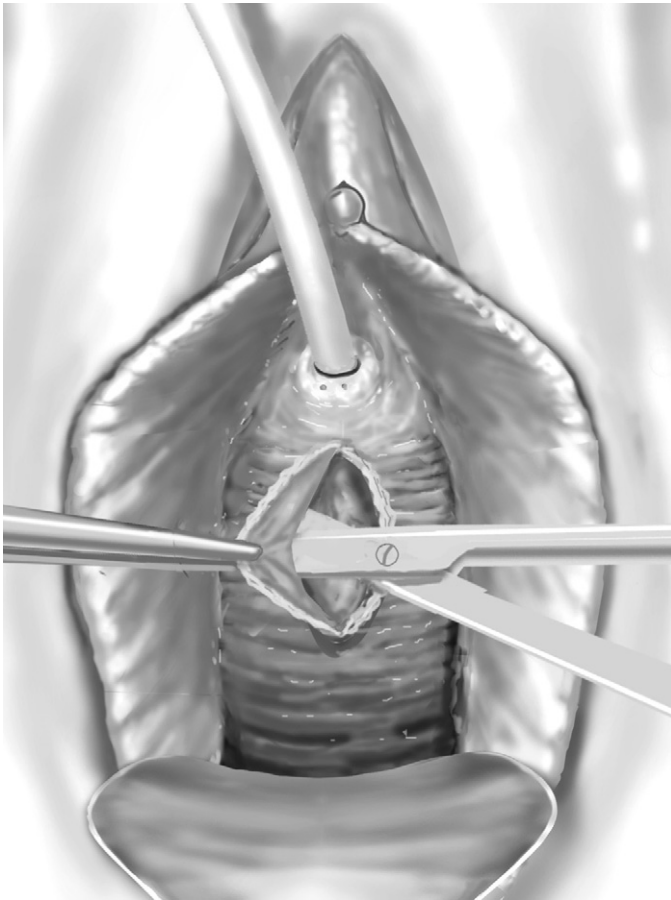

**Figure 47-4** The AS-800 artificial urinary sphincter in the female.

The advantage of the transvaginal technique is that it allows dissection of the urethrovaginal plane under direct vision. Preoperative parenteral antibiotics (gentamicin and vancomycin) are given before the operation. The patient is placed in high dorsal lithotomy position with the knee and hip at 90 degrees of flexion. The lower abdomen and genitalia are prepared and draped in the usual sterile surgical fashion. The labia are retracted laterally with stay sutures. A 14-Fr Foley catheter is inserted per urethra, and the bladder is emptied. A weighted speculum is then placed into the vagina for exposure.

A vertical incision is made in the anterior vaginal wall between the mid-urethra and proximal bladder neck. A plane under the vaginal wall is created on each side of the incision with sharp dissection. The scissors are first pointed laterally to the pubic ramus and then upward, toward the ipsilateral shoulder of the patient (Fig. 47-5). If the patient has not had a previous bladder neck operation, blunt finger dissection may be performed to separate the endopelvic fascia from its lateral attachments to the pubic ramus. Using this combination of sharp and blunt dissection, the retropubic space is then entered lateral to the bladder neck.

Attention is next directed to the anterior aspect of the proximal urethra or bladder neck to free its attachments from the overlying pubic symphysis. To achieve this, a combination of sharp and blunt dissection is used. Overly aggressive dissection may lead to an unintentional cystotomy or urethral injury. If the dissection of the anterior side of the urethra proves to be difficult due to dense scarring from previous retropubic operations, a separate suprameatal incision above the external meatus may be used. After the proximal urethra has been freed circumferentially, a Derra clamp is passed around the urethra from left to right. The cuff-measuring tape is grasped and passed around the urethra (Fig. 47-6), and the circumference of the urethra is measured. If the circumference is equivocal, it is best to choose a slightly larger size. Using a curved clamp, the appropriate size AUS cuff is placed around the proximal urethra (Fig. 47-7). If the pump is to be inserted into the right labium majoris, the cuff is withdrawn from right to left. The opposite is true if the pump is placed on the left side. After the cuff is locked in place, it is rotated 180 degrees so that the hard-locking button lies on the anterior

**Figure 47-5** Using a combination of sharp and blunt dissection, the retropubic space is entered lateral to the bladder neck.

**Figure 47-6** A Penrose drain is placed around the bladder neck to demonstrate the completed circumferential dissection.

aspect of the urethra, away from the anterior vaginal wall (Fig. 47-8).

On the side where the pump and balloon are to be placed, a 4-cm transverse suprapubic incision is made and carried down to the fascia. The anterior rectus sheath is incised transversely, the prevesical space is developed bluntly adjacent to the bladder, and the reservoir is inserted into the prevesical space. In females, the 51- to 60-cm H<sub>2</sub>O pressure balloon reservoir is routinely used. The fascial incision is closed with a running 1-0 delayed absorbable suture. The cuff tubing is attached to the tubing passer and then withdrawn up to the suprapubic incision. From the suprapubic incision, a subcutaneous tunnel is created through which the pump will be inserted into the labium majoris. The pump is passed to the level of the urethra with the deactivation button facing anteriorly. A Babcock clamp is used to secure the pump in position.

The reservoir is filled with 22 mL of a solution composed of Hypaque and normal saline according to the instructions specified by the manufacturer. The tubings are trimmed to the appropriate lengths and then irrigated to remove any air or debris from the system. A straight Quick Connector is placed between the pump and the balloon reservoir. A right angle Quick Connector attaches the pump to the cuff. The AUS is cycled several times to ensure proper functioning of the system and then left in the deactivated position. Both wounds are irrigated copiously with Betadine solution and closed in multiple layers with delayed absorbable sutures to ensure good coverage of the prosthesis with healthy overlying tissue.

A vaginal packing with Clomycin ointment is placed and then is removed 2 hours postoperatively. The Foley catheter is removed just before discharge. The patient usually voids without difficulty after removal of the Foley catheter. If the patient is stable and pain is adequately controlled, she is discharged home on the same day. A prescription for a 2-week course of oral antibiotics (Keflex) and pain medication is given to each patient. The patient returns to the office in 6 weeks for activation of the AUS.

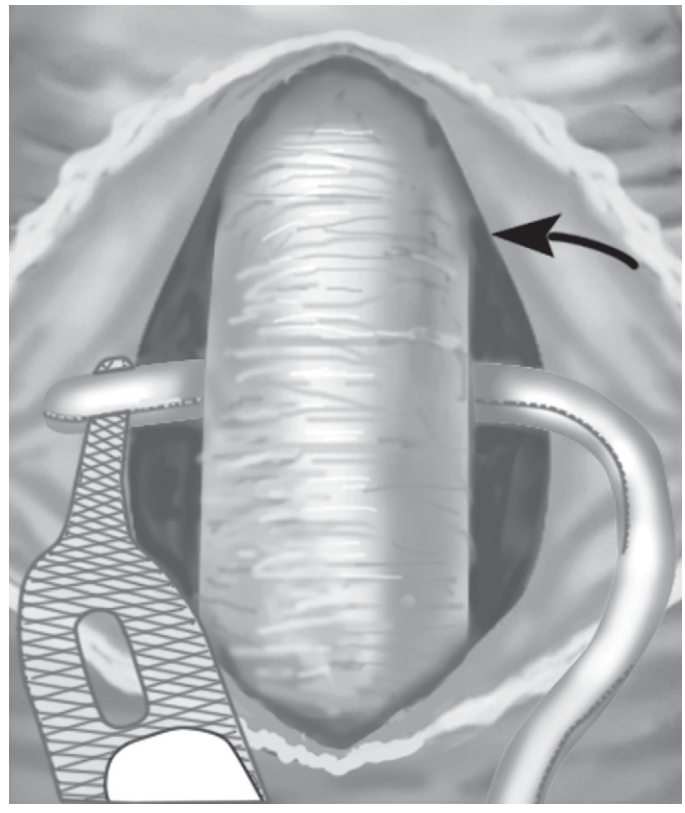

### Discussion

The AUS in the female population differs from the suburethral sling in that it does not provide a backboard or urethral support; it attempts to mimic the sphincter mechanism of the urethra with circumferential compression.<sup>16</sup> The few published reports of the AUS implanted through the transvaginal approach described favorable outcomes. Appell reported a continence rate of greater than 90% in 19 patients with a follow-up of 3 years.<sup>10</sup> Three patients required revisions for inadequate cuff compression and connector leak. Abbassian described a similar transvaginal technique in four patients, all of whom were dry at 14 months' follow-up.<sup>17</sup> Costa and colleagues evaluated the efficacy of the AS-800 system in women using a modified surgical procedure through an abdominal approach. Of the 190 patients with working devices, continence was achieved in 88.7% and 81.8% of those with non-neurogenic and neurogenic bladders, respectively, at a mean follow-up of 3.9 years.<sup>18</sup>

C

D

**Figure 47-7** The cuff of the artificial urinary sphincter is passed around the bladder neck and then locked in place.

**Figure 47-8** The cuff is rotated so that the hard-locking button lies anterior to the urethra, away from the anterior vaginal wall.

One major disadvantage of the AUS is the risk of erosion of the device. Device erosion has been attributed to poor circulation, low-grade infection, technical difficulties, and shifting of the cuff.<sup>17</sup> With the introduction of a newly improved cuff design and in situ activation-deactivation control assembly in the AS-800 model in 1983, the incidence of mechanical malfunction dramatically decreased.<sup>11</sup> However, the risk of revision surgery still remained high. Thomas and associates reported 12-year follow-up in 68 patients who underwent placement of an AS-800 model AUS. Despite an 81% continence rate, 46% required removal or replacement for erosion or infection.<sup>19</sup> They concluded by recommending an AUS for patients with SUI after failure of one anti-stress incontinence operation and not as a last resort.

## CONCLUSIONS

The AUS is a viable alternative treatment modality for the female patient with a nonmobile, well supported urethra and a history of unsuccessful anti-incontinence operations. The advantage of the transvaginal approach for placement of the AUS is that it offers the surgeon the ability to dissect through the urethrovaginal plane under direct vision. However, many patients require revision surgery due to malfunction, erosion, or infection of the device.

The spiral sling is an effective salvage transvaginal procedure that may be considered for a small subset of female patients with nonfunctional urethra as a last resort before urethral closure procedures. This includes patients with urethral incompetence caused by neurologic disease, congenital anomalies, or iatrogenic injury from multiple failed anti-incontinence surgeries. The initial outcomes look promising, but longer follow-up will better define its role in refractory female incontinence and demonstrate the durability of the spiral sling.

# MIXED URINARY INCONTINENCE

*Karen E. Smith and Edward J. McGuire*

### DEFINITION AND PREVALENCE

The term mixed urinary incontinence (MUI) has been defined by the International Continence Society as a condition characterized by symptoms of both stress and urge incontinence, or a combination of leakage associated with urgency as well as with exertion.<sup>1</sup> However, this is a term that can apply both to a combination of incontinence symptoms and to a combination of urodynamic findings in the same individual.

Studies have reported variable prevalence estimates for MUI symptomatology, ranging historically from 30% to 50%.<sup>2</sup> According to the more recent National Overactive Bladder Evaluation (NOBLE) study, which relied on census data from the year 2000, approximately one third (34.4%) of the 14.8 million women with urinary incontinence were defined as having MUI.<sup>3</sup> Mixed symptoms appear to be more prevalent in clinical-based than in population-based epidemiologic studies.<sup>4</sup> Sandvik and colleagues<sup>5</sup> summarized eight articles and demonstrated that as many as 61% of incontinent women reported MUI. In contrast, Hampel and associates<sup>6</sup> reported that 29% of women with incontinence had MUI, based on the average prevalence from 21 epidemiologic studies.

It is well recognized that incontinence symptoms poorly predict the true etiology of an individual patient's incontinence. Several studies have demonstrated that mixed symptoms are much more common than mixed conditions.<sup>7</sup> Cardozo and Stanton<sup>8</sup> reported that, of those patients presenting with MUI symptoms, more than 50% had only stress urinary incontinence (SUI) and approximately 40% had only detrusor instability as seen on urodynamics. Sandvik and colleagues<sup>5</sup> found that, of the 46% of patients presenting with MUI symptoms, only 44% were diagnosed with a mixed condition. This trend was also demonstrated by a sample of 950 incontinent women evaluated at Duke University: 52% presented with mixed symptoms, but only 14% had mixed conditions.<sup>9</sup>

Several studies have attempted to define MUI using findings seen on urodynamics, namely the coexistence of SUI and detrusor overactivity. Prevalence of MUI in urodynamic studies ranges from 36% to 56% of patients. However, the characteristics of these groups have often not been clearly defined, and therefore these studies have comprised patients with many different pathologic processes, most likely including those with abnormal compliance.<sup>10</sup> Furthermore, 50% of patients with motor urge incontinence can have a normal cystometrogram (CMG),<sup>11,12</sup> whereas normal patients can exhibit uninhibited bladder contractions of unknown significance on CMG. Therefore, the true prevalence of MUI as defined by urodynamics is difficult to estimate.

The condition known as MUI has historically lacked a unified definition. The symptom complex itself has not been well defined. Specifically, there are those with both urge and stress inconti-

nence, often referred to as overactive bladder (OAB) or wet OAB, and those with stress incontinence plus urge symptoms but without urge incontinence, called dry OAB.<sup>13</sup> Furthermore, because some studies have been based on symptoms and others have been based on urodynamic findings, meaningful comparison of the results of different studies is often difficult. Given the lack of a strict universal definition, as well as the limitations of any urodynamic study, the quoted prevalence of MUI is probably inaccurate, and the true prevalence is almost impossible to determine.

### IMPLICATIONS OF MIXED URINARY INCONTINENCE

Several studies have shown that women with MUI symptoms typically report more severe incontinence than do women with either SUI or urinary urge incontinence (UII) alone. In the Norwegian Epidemiology of Incontinence in the County of Nord-Trøndelag (EPINCONT) study,<sup>14</sup> "severe incontinence," as defined by validated instruments, was seen in 38% of women with MUI, compared with 28% of those with UII and 17% of those with SUI. Furthermore, more women with MUI (47%) were bothered by their incontinence, compared to women with UII (36%) or SUI (24%). Bump and coworkers<sup>4</sup> conducted a secondary analysis of data from the duloxetine study group and found that the 171 women (31%) with baseline MUI complained of more severe urinary incontinence than did those with SUI.

The negative personal impact of MUI on patients with this condition appears to be significant. Coyne and associates<sup>15</sup> sought to examine the impact of urinary incontinence on health-related quality of life (HRQOL). A case-control study of 171 incontinent women showed that respondents with UII or MUI reported not only significantly greater ratings of urinary urge intensity and more incontinence episodes, but also significantly worse HRQOL, compared to patients with isolated SUI.

### ETIOLOGY

Before being able to critically evaluate the theories proposed to explain the etiology of MUI, it is important to note the following facts, some of which may seem counterintuitive. First, of those women with SUI who also complain of urgency, frequency, and/or urge incontinence, 50% to 75% of them are cured of their urge symptomatology by surgery for SUI.<sup>16-23</sup> Furthermore, overall cure rates are poor for those patients with MUI treated with anticholinergics alone.<sup>19,24</sup> Several theories have addressed the potential causes of mixed symptomatology, although not all of them can reconcile these facts.

One theory is that MUI is the result of a patient's having two separate conditions. The greater perceived severity of MUI is

attributed to the additive effects of the two conditions being more severe and bothersome than the effect of a single condition.<sup>4</sup> However, this would not explain the poor response rates of anticholinergics in these patients or the fact that surgery may cure most of these symptoms.

An alternative explanation is that mixed symptoms are a result of more severe incontinence rather than the presence of two conditions.<sup>4</sup> As stated previously, women with more severe incontinence are more likely to report mixed symptoms. In the study by Bump and associates,<sup>4</sup> as the severity of incontinence improved during treatment, mixed symptoms resolved. Furthermore, in patients with severe SUI, the bladder may never completely fill, thereby leading to an essentially defunctionalized bladder and concomitant urge symptomatology. Severity of incontinence causing a mixed symptom complex is perhaps a reason for resolution of these symptoms once a successful anti-incontinence surgery is completed.

Others suggest that these symptoms may be the result of a behavioral adaptation in the woman with SUI. For instance, the patient may empty her bladder more frequently in an attempt to reduce stress-induced leakage and therefore induce symptoms of frequency and urgency.<sup>25</sup> These symptoms may represent a false interpretation of impending stress-induced leakage. The patient rushes to the toilet to protect herself from stress-induced leakage at the perception of the first or normal desire, which may result in a learned behavior that the patient develops and reinforces over time. These patients are seen as having SUI with “pseudo-urgency syndrome.”<sup>26</sup>

Other theories have lent support to an actual link between SUI and detrusor overactivity. One such theory is that, in patients with SUI, traction on or stretching of the pelvic nerves as a result of poor pelvic floor support and severe urethral hypermobility causes this symptom complex.<sup>19</sup> When the bladder neck is stabilized to prevent this stretching, both SUI and UUI are corrected. A solid experimental background has suggested a link between the pelvic floor, pudendal innervation, and detrusor inhibition. Artibani<sup>27</sup> suggested that decreased inhibition from the pelvic floor or the urethra, caused by pelvic floor or urethral deficiency, can lead to increased efferent activity and subsequent detrusor overactivity. In his opinion, the best support for this hypothesis is given by the positive clinical results of pelvic floor electrical stimulation and rehabilitation.

Mahoney and colleagues<sup>28</sup> proposed that “micturition reflex instability” may result from malfunction of the detrusor reflex or instability of the pudendal nucleus, which innervates the pelvic floor muscles and external sphincter. He proposed that detrusor instability is the result of hyperexcitability of the sacral micturition reflex center, due to either its underinhibition or overfacilitation. Pathologic relaxation and weakness of the striated muscles of the pelvic floor and perineum can result in underactivity of the perineodetrusor inhibitory reflex, causing underinhibition of the sacral micturition reflex center, and may predispose a patient to detrusor instability.

Other scientists, who support a correlation between urethral afferents and the micturition reflex, suggest that it is rather urine entering the proximal urethra that stimulates the urethral afferents and therefore the voiding reflex.<sup>29</sup> It is widely held that urethral relaxation occurs in the initial phase of micturition. In the healthy adult, urine enters the urethra only during micturition. However, urine is present in the urethra in patients with SUI because of poor pelvic support and/or sphincteric deficiency. It is proposed that the entry of urine into the proximal urethra

could act as a stimulus to potentiate or even initiate a detrusor contraction.<sup>29</sup>

Urethral instability, as seen as fluctuations in urethral pressure, is evidenced in women with detrusor instability. In one study, urethral instability was reported to have occurred in 42% of patients with detrusor instability and was associated with the sequence of urethral relaxation before an unprovoked contraction.<sup>30</sup> In a report by Low,<sup>31</sup> bladder and urethral pressures were simultaneously measured during bladder filling in 77 women with idiopathic detrusor instability. Low found that 85% of patients developed urethral relaxation 5 seconds before detrusor contraction. He concluded that the involuntary detrusor contractions were preceded by a fall in urethral pressure, similar to that observed in normal voiding. Hindmarsh and coworkers<sup>32</sup> also demonstrated urethral relaxation preceding detrusor contractions in a series of patients with detrusor instability, not only supporting the concept that urethral instability can be associated with unstable bladder contractions but also suggesting that detrusor instability may be initiated from the bladder outlet region or proximal urethra.

Mahony and colleagues<sup>33</sup> described two urethrodetrusor reflexes that could increase the excitability of the micturition reflex and trigger a detrusor contraction when activated by urine flow across urethral mucosa. The theory that urine or fluid in the posterior urethra could result in a detrusor contraction has been supported by several animal models. As early as 1931, Barrington<sup>34</sup> reported that running water through the urethra or distending the proximal urethra in the cat caused contraction of the detrusor. Also using the cat model, Kiruluta and colleagues<sup>35</sup> noted that urethral perfusion triggered spontaneous bladder contractions of such intensity that bladder filling was not possible. More recently, Jung and associates<sup>29</sup> sought experimental support for the hypothesis that stimulation of urethral afferent nerves can induce reflex detrusor contractions. By measuring urethral perfusion pressure and isovolumetric bladder pressure with catheters inserted through the bladder dome of female rats, they demonstrated that fluid passing through the urethra can result in activation of the mechanosensitive urethral afferents, which can in turn increase the excitability of the micturition reflex.

Therefore, in patients with SUI, leakage of urine into the proximal urethra may stimulate urethral afferents and facilitate the voiding reflex. This would imply that SUI can induce and/or increase detrusor instability. There is little direct support for this theory in humans,<sup>4,36</sup> and some believe that the effect may be species specific. However, the fact that this phenomenon has not been demonstrated convincingly in humans may be a result of study design. For example, although Sutherst and Brown<sup>36</sup> did not detect such facilitatory reflexes in the human, they believed that the transurethral catheter might have interfered with the activation of afferent receptors that respond to flow through the urethra. Furthermore, not all women with MUI symptoms have both urodynamically proven SUI and detrusor instability. Absence of urodynamic “proof” may be a result of an inhibitory effect of the patient during the study.

In short, it is likely that women with MUI symptoms have SUI as their primary problem and that detrusor overactivity results secondarily when urethrodetrusor facilitative reflexes are activated, either because an incompetent bladder neck allows urine to enter into the proximal urethra during physical activity or because of traction on the pelvic nerves due to a weakened pelvic floor.

## IMPORTANCE OF URODYNAMICS

An accurate diagnosis is essential for effective treatment of the incontinent patient. Although a detailed history is important, symptoms alone are often a poor guide to a final diagnosis. The urologist is therefore encouraged to rely on a combination of symptoms, physical findings, and objective testing. In addition to a routine evaluation, secondary testing in patients with mixed symptomatology should include urine cytology and cystourethroscopy to rule out pathologic conditions of the bladder, especially carcinoma *in situ*.

Urodynamic evaluation is integral in determining the true underlying etiology of a patient's incontinence, especially in the patient with mixed symptomatology. Videourodynamic evaluation, which combines the use of fluoroscopy with measurement of bladder and urethral pressures, allows simultaneous evaluation of structure and function and is the preferred method.<sup>37</sup>

The most important reason to perform videourodynamic studies in a patient with MUI is to rule out poor bladder compliance. A high-pressure or poorly compliant bladder poses significant risk to ureteral and renal function. It can be caused by a number of conditions, including neurologic conditions, prolonged catheter drainage, radiation therapy, prior pelvic or urethral surgery, interstitial cystitis, and obstructive uropathy. If there is suspicion of altered bladder compliance in any incontinent patient, that patient should undergo urodynamic testing to determine the condition of the bladder's storage function. Poor compliance adversely influences the outcome of any procedure done to increase bladder outlet resistance and could create a situation in which the upper tracts are at risk from high bladder pressures. Fortunately, urodynamic testing is accurate and sensitive in the diagnosis of poor compliance.

## CONSERVATIVE THERAPY

### Anticholinergics

There is a paucity of data specifically addressing anticholinergic therapy in patients with MUI, and the results have historically been less than optimal. In patients with MUI, anticholinergic therapy has been associated with significant resolution of the urge component symptoms in only 50% to 60% of patients, while not improving the stress component.<sup>19,26</sup> Patients report poor satisfaction because of poor response, side effects, and need for continuous treatment.<sup>26</sup> Poor response has been thought to be secondary to the fact that the SUI component is not addressed with medical therapy.<sup>26</sup>

More recently, Kreder and colleagues<sup>38</sup> compared the efficacy of Tolterodine in those with urge-predominant MUI versus UUI in a single-blind, multicenter trial. They found a 67% and 75% decrease in incontinence episodes in the MUI and UUI groups, respectively, with a "dry rate" of 39% and 44% in the two groups, respectively. There were no significant intergroup differences in success rates. The Mixed Incontinence Effective Research Investigating Tolterodine (MERIT) study, a multinational, double-blind, placebo-controlled trial, examined the efficacy of antimuscarinic therapy in patients with urge-predominant MUI.<sup>39</sup> In total, 854 patients MUI were studied, with 634 (74.5%) reporting UUI as their initial symptom. After 8 weeks of treatment, 76% in the drug group reported improvement, compared with 53% in the placebo group. There was no difference in

response of those who experienced UUI as their initial symptom compared with those who noted SUI first in this study.

Several studies have directly compared surgery to drug therapy for patients with MUI. Karram and Bhatia treated 52 patients with MUI with either Burch colposuspension or medical therapy. They found no significant difference in cure rate between the two groups, and their recommendation was primary medical treatment for patients with MUI.<sup>18</sup> A more recent prospective, randomized study by Osman compared patients with MUI and a normal CMG undergoing surgery to those undergoing treatment with anticholinergic therapy.<sup>26</sup> One third of patients received a 6-month course of an anticholinergic, whereas the remaining patients underwent surgery for SUI. In the surgery group, patients underwent either a Burch colposuspension or pubovaginal sling placement, depending on their Valsalva leak point pressure. A group of 20 patients with pure SUI were also used as a control. No patient in the drug group became dry. In contrast, among those who underwent surgery for SUI, 87% in the Burch group and 83% in the pubovaginal sling group were both stress and urge continent after surgery. After therapy, persistent UUI was seen in 43% of patients who received anticholinergic therapy compared to 13% and 12% of those in the Burch and sling groups, respectively.

### Behavioral Therapy, Biofeedback, and Pelvic Floor Rehabilitation

Behavioral therapies such as timed voiding, avoidance of bladder irritants, and bladder retraining have been used with some success in patients with both SUI and UUI. Additionally, pelvic floor electrical stimulation or biofeedback has been used successfully in both UUI and SUI, with excellent success rates and high levels of patient satisfaction.<sup>40</sup> Several studies have investigated the response of pelvic floor stimulation in patients with MUI specifically. Sand<sup>41</sup> found a greater than 50% improvement in approximately 38% of subjects, with 8% being completely dry after 8 weeks of treatment. In this study, symptoms of urgency, frequency, and stress incontinence improved significantly, whereas symptoms of UUI remained relatively stable. Bent and colleagues<sup>42</sup> reported a 52% success rate in patients with MUI, whereas Caputo and associates<sup>43</sup> reported a 70% response rate in these patients. Siegel and coworkers<sup>40</sup> studied patients with both UUI and MUI undergoing 20 weeks of pelvic floor electrical stimulation, either daily or every other day. Treatment resulted in significantly lower urge and stress leakage, with decrease in urge episodes and total number of voids and improvement in quality-of-life measures. Overall, 72% of patients were satisfied with their therapy.

When compared directly to drug therapy, electrical stimulation has been shown to have better results and higher patient satisfaction. Goode<sup>44</sup> studied 197 women with UUI or MUI in a randomized controlled trial comparing biofeedback-assisted behavioral treatment with anticholinergics and placebo. The biofeedback group demonstrated the best results, with an 80% decrease in incontinence episodes, 78% of patients being "completely satisfied", and 97% wanting to continue treatment. A modified crossover trial was conducted, which showed that combination treatment is more effective than monotherapy with either drug or biofeedback alone, a finding supported by other studies.<sup>40,41,45</sup>

In short, treatment of patients with MUI can be challenging and should be tailored to the individual. In those patients with

MUI, it is wise to direct treatment at the dominant symptom first. When in doubt, it is most reasonable to proceed with conservative treatment of the urge component before consideration of surgical therapy for SUI.<sup>2</sup> In that small proportion of patients whose symptoms may be improved enough with drug therapy alone, surgery may be prevented.

## SURGICAL TREATMENT

As stated previously, as many as 75% of women with MUI are cured of their urge component by surgery aimed at correcting their SUI. These encouraging results were demonstrated in several studies and seem to hold regardless of the actual procedure performed. Improvement of urge symptoms by providing support for the bladder neck can be seen in studies in which support was achieved by temporary, nonsurgical means. For example, Kondo and coworkers reported that, in a group of 20 women with symptoms of MUI, 85% had an improvement of 50% or better with the use of a bladder-neck support prosthesis.<sup>46</sup>

To date, few studies have specifically addressed the resolution of urge symptomatology in MUI patients undergoing a Burch colposuspension. Scotti and colleagues<sup>47</sup> evaluated 46 patients with both mixed symptoms and urodynamically diagnosed genuine SUI and detrusor instability who underwent a Burch colposuspension. The study demonstrated an overall resolution of urge incontinence in 56.5% of patients. More recently, Osman<sup>26</sup> demonstrated resolution of urge incontinence in 87% of patients with MUI and a normal CMG who had undergone a Burch colposuspension. Langer and colleagues<sup>48</sup> evaluated 127 women who underwent a Burch colposuspension, of whom 33% had preoperative urge incontinence and 55% had urgency. Only 9% of the patients with preoperative urge incontinence still had this complaint at 1 year after surgery, whereas 25% of those patients with preoperative urgency still complained of this postoperatively at 1 year.

Serels and colleagues<sup>19</sup> evaluated 36 patients with urodynamically diagnosed Valsalva-induced detrusor instability who underwent various types of pubovaginal sling procedures, including in situ vaginal wall sling, free swing vaginal wall slings, rectus fascia slings, cadaveric fascia slings, and synthetic slings. Preoperatively, 21 patients (58%) had MUI. Cure of SUI was achieved in 92% of these patients, and 75% demonstrated resolution of their urge incontinence.

McGuire and Lyton<sup>16</sup> and Fulford and colleagues<sup>20</sup> both reported resolution of urge symptomatology in 69% of patients after pubovaginal sling, and 74% of patients in a study by Morgan and associates<sup>21</sup> had resolution. Osman<sup>26</sup> reported resolution of urge incontinence in 83% of their patients who had undergone a pubovaginal sling procedure.

The tension-free vaginal tape (TVT) procedure is a relatively new suburethral sling procedure, first described in 1996. To date, few studies have evaluated the effect of the TVT on patients with MUI. Segal and colleagues<sup>49</sup> reviewed outcomes of 98 patients with pure SUI and MUI who underwent a TVT procedure. After TVT, 63.1% of those with preoperative UUI had resolution; 57.3% of those with preoperative urgency, frequency, and nocturia had resolution of symptoms; and 57.7% of those who used anticholinergics preoperatively no longer needed to do so.

The transobturator (TOT) tape procedure was first described in 2001 by Delorme as the newest minimally invasive suburethral sling procedure. Long-term studies are not available at this point.

However, in his original article published in 2004, Delorme<sup>50</sup> described outcomes of 32 incontinent patients who underwent TOT, 18 of whom had MUI, with a minimum of 1 year follow-up. Among the 18 patients with preoperative MUI, 10 (55%) had either resolution or improvement in their urge component, 7 (39%) had no change in their symptoms, and 1 (5%) reported worsening of urge symptoms. There are currently no studies examining the use of collagen injections specifically in patients with MUI.

## Voiding Dysfunction after Anti-incontinence Surgery

Up to 40% of patients develop voiding dysfunction after anti-incontinence surgery.<sup>51</sup> There is no good method to identify with certainty preoperatively who will have persistent, worsened, or new-onset symptoms.<sup>25,49</sup> Voiding disorders addressed here include urethral obstruction, de novo urgency and urge incontinence, and persistent or worsening urgency in patients with preoperative urge symptoms.

Urethral obstruction is an uncommon but disturbing complication of anti-incontinence surgery, the incidence of which is reported to be 1% to 11% in the literature.<sup>52,53</sup> Patients with voiding dysfunction due to urethral obstruction usually present with new-onset urgency or urge incontinence and incomplete bladder emptying, which is suggested by an elevated postvoid residual volume. A complete workup is warranted but may be inconclusive, because obstruction may be present even in the face of normal emptying. It can be difficult in certain cases to differentiate among obstructive symptoms, new urge symptoms, and worsening of urge symptoms in the patient with preoperative MUI.

De novo urge syndrome implies the development of new symptoms of frequency, nocturia, urgency, and/or urge incontinence after surgery for SUI. Most series report that 7% to 15% of patients develop de novo urge symptoms,<sup>12</sup> with some reporting this phenomenon in up to 30% of patients after anti-incontinence surgery.<sup>49,54</sup> Specifically, de novo detrusor overactivity has been cited to occur in 5% to 32% of patients after a retropubic suspension, in 11% after a needle suspension, and in 3% to 24% after pubovaginal sling procedures,<sup>53</sup> with a few studies citing irritative bladder symptoms in up to 50% of those undergoing suburethral sling procedures.<sup>49</sup> De novo detrusor overactivity is seen in 6% to 15%<sup>49</sup> of patients undergoing a TVT. Segal and colleagues<sup>49</sup> reviewed outcomes of 98 patients with pure SUI or MUI who underwent a TVT procedure. Postoperatively, de novo urge incontinence symptoms developed in 9.1% and de novo urgency in 4.3%. In a recent study by Nilsson and associates,<sup>55</sup> which looked at 7-year follow-up data on patients undergoing TVT, de novo urge symptoms were present in 6.3% of patients. The two studies published on outcomes of TOT to date cited de novo urgency occurring in 2 (14%) of patients, in Delorme's study,<sup>50</sup> and in 0.8% of patients, in a more recent study by Spinosa and colleagues.<sup>56</sup> It has been suggested that de novo irritative voiding symptoms may be more bothersome to the patient than the original SUI.

Persistent or worsening urge symptomatology in patients with preoperative urge symptomatology can also occur. Historically, it is estimated that 25% of patients who had these symptoms preoperatively still have them postoperatively.<sup>12</sup> However, the prevalence of this symptom may be even higher than previously thought. A meta-analysis of several hundred articles in the literature was done by the Female Stress Urinary Incontinence Clinical

Guidelines Panel,<sup>53</sup> which looked at probability estimates for treatment complications, including the presence of urinary urgency, after surgery for SUI. They found that, for retropubic suspensions, 66% of patients with urgency and detrusor instability preoperatively had persistent postoperative urgency, whereas 36% of patients with urgency and no detrusor instability preoperatively had persistent postoperative urgency. For sling procedures, 46% of patients with urgency and detrusor instability preoperatively had persistent postoperative urgency, compared with 34% of patients with urgency and no detrusor instability preoperatively. In general, if urgency and detrusor instability are present preoperatively, there is a significant risk that these symptoms will persist postoperatively, and the prevalence may be higher than previously thought. It is also clear that patients with persistent UUI after pubovaginal sling placement have the lowest degree of satisfaction with the procedure.<sup>21</sup>

### Etiology

Many have questioned the exact causes of de novo urge/UUI and persistent urge symptomatology after anti-incontinence surgery, and several different theories exist.

Some have suggested that de novo urge/UUI and/or worsening of urge symptoms may be caused by obstruction.<sup>57</sup> The question of whether normal voiding physiology and function are altered by surgery has been the subject of much debate. The potential physiologic changes in voiding function that might occur after a particular outlet-enhancing procedure are not entirely understood. Some studies suggest that successful anti-incontinence procedures can normally result in an increase in urethral resistance during voiding, suggesting obstruction,<sup>58-60</sup> but others have not demonstrated this phenomenon.<sup>61,62</sup> Because some patients with postoperative de novo UUI are indeed clinically obstructed, one must maintain a high index of suspicion for obstruction in any patient with de novo urge syndrome after surgery.

Osman<sup>26</sup> suggested that the pathogenesis of preoperative urge symptomatology may not be the same as that of persistent or residual symptoms after surgery, and that persistent symptoms may be related to outlet obstruction. In their study, those patients who had persistent symptoms of UUI after surgery had a significant decrease in their maximum flow rate on uroflowmetry, a finding that was not seen in those who were cured of their UUI. They concluded that residual urgency after surgery may be caused by iatrogenic relative obstruction.

Another possibility for the development of new postoperative urge symptoms is that the symptoms may have actually been present preoperatively. Patients may have had prior MUI symptoms, with symptoms of urge and/or UUI that were minimized preoperatively by their stress component. Once the SUI was corrected, urge symptoms may have become more prominent and bothersome.

Others argue that patients with SUI, who may have denervation of the pelvic floor, suffer more injury to the autonomic nerves of the bladder, bladder neck, and urethra from dissection during anti-incontinence surgery.<sup>61</sup> Further denervation is thought to cause detrusor supersensitivity and overactivity. There is some evidence against this, however. For instance, the TVT is placed without tension at the level of the mid-urethra, with no significant dissection in this area. It should therefore result in a lower rate of voiding dysfunction. However, as previously stated, up to 15% of patients undergoing TVT develop de novo urge

symptoms, suggesting that there is an alternate explanation for these symptoms. Also, the Ingleman-Sundberg procedure, a relatively underused surgical therapy for severe, intractable motor urge incontinence, consists of transvaginal dissection of the perivesical fascia from the area of the trigone, including purposeful division of the terminal branches of the pelvic nerves. In a study by Westney and associates,<sup>63</sup> long-term cure or improvement was seen in 68% of patients who underwent this procedure.

In patients with severe intrinsic sphincteric deficiency and resultant bladder defunctionalization, the sudden ability to store urine may cause new symptoms of urgency. Furthermore, symptoms in the immediate postoperative period may be due in part to surgically induced inflammation and edema. In most of these cases, symptoms resolve with nonsurgical measures, such as anticholinergic medications and timed voiding. In Serels' study<sup>19</sup> of patients undergoing pubovaginal sling procedures, 5 (24%) of 21 patients had persistent UUI postoperatively, and an additional 8 had persistent urgency. All patients with urge and UUI were improved or cured with anticholinergics. In a study by Cross and colleagues,<sup>22</sup> of the 26 patients (19%) with de novo urgency/UUI, all but 4 had resolution of their symptoms within 3 months. These 4 patients (3%) with persistent UUI had ultimate resolution of symptoms with medication and timed voiding.

Finally, some argue that urge symptoms may not resolve after surgery because the repair aimed at fixing their SUI incontinence has failed. Fulford and colleagues,<sup>20</sup> who reported persistent urge in 31% of their patients, attributed these symptoms to failure to achieve bladder neck closure at rest.

### CONTROVERSIES CONCERNING PREDICTORS OF POOR OUTCOMES

As previously stated, the postoperative course of urge symptomatology in patients with MUI is unpredictable. Several studies over the years have attempted to describe preoperative predictors of poor outcomes. We address here the more common controversies surrounding surgical therapy in patients with MUI.

#### Does the Presence of an Urge Component Predict Failure of an Anti-incontinence Procedure?

In several studies in the 1970s, an unexpectedly high incidence of detrusor instability was found in women who failed surgical procedures for SUI.<sup>64</sup> Other studies tended to confirm these early findings, and a general feeling that detrusor instability was the major reason for failure of these operations to cure SUI emerged. For example, in a study by Karram and Bhatia<sup>18</sup> of patients with MUI undergoing Burch colposuspension, all failures in the surgical group were thought to be due to persistent detrusor instability. The authors recommended medical over surgical therapy for patients with MUI. This in turn led to efforts to treat detrusor control problems in women presenting with symptomatic SUI with conservative measures, which, as previously stated, did not yield very promising results.

This finding was not supported by later studies. Colombo and colleagues<sup>65</sup> studied 44 women with MUI who underwent a Burch colposuspension, compared with matched controls with pure SUI. At 2 years, the cure rate for SUI was 75%, compared with 95% in the control group; however, there were no obvious findings on urodynamics that could explain this discrepancy. In fact, most failures were due to inadequate urethral support. The

authors did not find any preoperative CMG parameter that predicted outcome in their study. Alcalay and associates<sup>66</sup> studied late outcomes after colposuspension operations and noted that detrusor instability identified preoperatively had no influence on outcome at 10 to 20 years.

In a recent study by Chou and coworkers,<sup>67</sup> which compared patients with pure SUI and MUI undergoing pubovaginal sling placement, cure rates for SUI were similar, with 97% in SUI group and 93% in the MUI group being cured. However, those patients with MUI who failed or who were merely improved had greater urgency and UUI episodes preoperatively. Univariate analysis of MUI cases showed that the higher the number of urgency or UUI episodes preoperatively, the more likely it was that the pubovaginal sling would fail.

So, the literature has been divided on this topic. As previously discussed, definitions of MUI have varied widely, with some studies using strict urodynamic definitions for MUI. We know that as many as 50% of patients with UUI do not demonstrate an unstable detrusor contraction on CMG, leading us to assume with relative certainty that patients with symptoms of UUI and a negative CMG have the same condition as those with a positive CMG. This creates an obvious bias and obscures the true effect of MUI on outcomes, because we are not able to prove with any certainty which patients may have been selected to be in the “wrong” group. In short, we do not believe that presence of a positive CMG has a bearing on the success of a procedure done for SUI, and therefore its presence should not be used as a factor to exclude patients from surgical treatment.

### What Factors Predict Persistent Urgency/Urges Incontinence or Resolution of Symptoms?

To date, published series designed to identify risk factors for persistent postoperative urgency have been contradictory. In short, currently no consistent preoperative risk factor has been identified that predicts either resolution or persistence of urge symptomatology.

There has been historical controversy surrounding the question of whether preoperative UUI is a predictor of persistent urge symptoms in patients with MUI who undergo surgery for SUI. Furthermore, it had been suggested that the presence of urodynamically proven detrusor instability predicts persistent symptoms. In a study by Chaikin and colleagues,<sup>68</sup> the presence of UUI preoperatively was a risk factor for persistent UUI after 10 years of follow-up in 41% of patients who underwent a pubovaginal sling procedure.

Some studies have suggested that high pressure motor urge, or detrusor instability as seen on urodynamics, compared to low pressure motor urge, is a risk factor for persistent urge and/or UUI. These results were seen in patients who underwent anterior vaginal repair in a study by Jorgensen and associates<sup>69</sup> and in patients treated with retropubic bladder neck suspensions in a study by Lockhart and colleagues.<sup>70</sup> This finding was also demonstrated in a series of patients who underwent pubovaginal slings by Schrepferman and associates.<sup>71</sup>

Several others also did not find any preoperative or clinical variable predictive of outcome and disputed the use of preoperative urodynamics to predict resolution of urge/UUI postoperatively. McGuire and Savastano<sup>72</sup> demonstrated that women with demonstrable detrusor instability did no better or worse than those with detrusor instability diagnosed only by history.

Demarco and colleagues<sup>73</sup> also noted that CMG had no predictive value in determining postoperative outcome in patients who underwent pubovaginal sling procedures.

Other studies have focused on the predominant symptom or timing of symptoms in patients with preoperative MUI in predicting persistence of urge symptoms postoperatively. Studies have demonstrated that, if the stress symptoms predominate and SUI is objectively demonstrated, surgical repair alleviates urge symptoms in most patients.<sup>2</sup> However, if urge symptoms predominate, or if the degree of SUI seems minimal in comparison with the severity of the urge symptoms, repair of the SUI may not be helpful at all and may even intensify the patient's symptoms.<sup>74</sup> Scotti and coworkers<sup>47</sup> studied 46 women with both symptoms and urodynamic findings of MUI who underwent Burch colposuspension. They found that UUI resolved with surgery in 78.6% of those in whom the stress component preceded the urge component by history, compared with only 22.2% of those in whom the urge component preceded the stress component.

### What Factors Predict Development of De Novo Urgency/Urges Incontinence?

Others have attempted to predict preoperatively who may develop de novo urge/UUI. The presence of isolated detrusor instability on preoperative urodynamics has not been shown to predict development of de novo urgency.<sup>75</sup> In a study by Morgan and colleague<sup>21</sup> of 247 patients who underwent pubovaginal sling placement, there was no variable that predicted the development of de novo urgency with or without incontinence. Overall, no preoperative urodynamic parameter has been found to significantly correlate with development of new urge/UUI.

### EVALUATION OF POSTOPERATIVE VOIDING DYSFUNCTION

When evaluating a patient with de novo or worsening urge/UUI symptoms, it is imperative to rule out urinary retention. This can be done with a simple postvoid residual volume measurement. Once retention has been ruled out, it is suggested to wait at least 6 weeks before undertaking a complete formal evaluation, because residual symptoms may be a normal consequence of the healing process. Most cases resolve with nonsurgical measures, such as anticholinergic medications and timed voiding.

A careful history is important, because urge symptomatology may have been present preoperatively but downplayed due to severe SUI symptoms. A temporal relationship between the onset of symptoms and the anti-incontinence procedure is integral to diagnosing urethral obstruction but may be less clear in a patient with preoperative urge symptoms, as in the patient with MUI. Information on whether retention was present postoperatively and for how long may suggest an obstructive picture. Obstructive symptoms, such as a slow, dribbling stream, straining to void, needing to lean over or back to void, hesitancy, intermittency, and sensation of incomplete emptying, are often present along with irritative symptoms.

As previously stated, an elevated postvoid residual volume, routinely accepted as a value greater than 60 mL, is suggestive of obstruction or intrinsic detrusor dysfunction in a patient with evidence of complete bladder emptying preoperatively. A urine

culture is done to rule out infection, a common cause of irritative symptoms. A 3-day voiding diary may be helpful as well.

On pelvic examination, the anterior vaginal wall is examined specifically for the appearance of the bladder neck and proximal urethra. Urethral tethering and fixation to the underside of the pubis is detected visually by the appearance of a fixed horizontal groove on the anterior vaginal wall in the region of the bladder neck. Direct palpation of the urethra and bladder neck to assess mobility and degree of scar is important, as is evaluation for pelvic prolapse. A large cystocele, for example, can exert traction on the pelvic nerves, resulting in *de novo* urge symptoms and UUI. Additionally, a cystoscopy may be done to rule out a foreign body (e.g., a suture) or occult neoplasm.

If urge symptoms and/or UUI persist, urodynamics with fluoroscopy should be done. The development of altered compliance is very unusual, but if this condition occurs, the possibility of an original occult detrusor component should be considered. It is also important to observe the bladder neck during a Valsalva maneuver to rule out hypersuspension or an anatomic point of obstruction.

Others have relied on pressure-flow studies to evaluate for obstruction, because obstruction can occur even in the presence of normal emptying. This is often difficult to prove, because there are no strict urodynamic criteria to define urethral obstruction in female patients. However, several studies have stated that a detrusor pressure greater than 30 to 40 cm H<sub>2</sub>O and peak flow rate of less than 15 mL/second suggests obstruction in women. Carr and Webster<sup>76</sup> demonstrated that only 22% of patients in their series of women undergoing urethrolisis met these obstructive parameters, but 56% of patients met these criteria in a study by Nitti and Raz.<sup>77</sup> Nevertheless, 75% of patients treated with urethrolisis responded with good results. Some believe that obstruction can be recognized by the observation of a sustained, high-pressure detrusor contraction resulting in a reduced-amplitude flow rate.<sup>78</sup> Preoperative pressure-flow data can be useful, because a direct comparison can be made.

We recommend relying on a multimodal approach, using a combination of symptoms, physical examination, fluoroscopic and/or pressure-flow data, and a high degree of clinical suspicion.

### TREATMENT OF REFRACTORY POSTOPERATIVE URGE SYMPTOMS AND DYSFUNCTIONAL VOIDING

In the absence of obstruction, we recommend conservative therapy with timed voiding, limited consumption of bladder irritants, anticholinergics, and biofeedback, especially in patients with dysfunctional voiding.

Cases in which conservative treatment has failed are obviously more difficult to treat. Botox injection into the detrusor muscle has been used for refractory urge symptoms.<sup>78</sup> Injection of Xylocaine and steroids periurethrally has been used to treat external sphincter spasticity and dysfunctional voiding.<sup>78</sup> Botox injection into the external sphincter has resulted in significant subjective improvement in voiding in 67% of patients after a single dose.<sup>79</sup> Smith and associates<sup>80</sup> demonstrated the efficacy of this treatment for functional urethral obstruction and detrusor acontractility after pubovaginal sling surgery. Finally, neuromodulation has also been used with some success.<sup>78</sup>

### CONCLUSION

MUI is a common yet poorly understood entity that is surrounded by controversy, inconsistent definitions, and many differing opinions. Several potential etiologies exist, none of which has been proven definitively. However, it is likely that the cause is multifactorial, and perhaps different among patients presenting with similar symptoms. Given that a large proportion of patients are cured of their urge component by surgery aimed at correcting their SUI, we believe that the etiologies in those cases are related to severity of incontinence, facilitation of the urethrodetrusor reflex due to urine entering the proximal urethra, and/or traction on the pelvic nerves due to laxity of the pelvic floor. However, other patients may respond to more conservative therapy, namely anticholinergic medications and biofeedback, suggesting a potential alternative etiology in these cases.

It is still unknown which patients with MUI will respond to surgery and whose symptoms will remain unchanged or even intensify. It is well documented that patients with persistent urge symptoms after surgery have less satisfaction with the procedure, even if they are cured of their SUI. Patients with MUI who undergo definitive surgical therapy for their SUI need extensive counseling preoperatively to prepare them for potential adverse outcomes. Because of this, we recommend a brief trial of conservative therapy in certain patients with urge-predominant MUI, because some will improve and may not require surgery.

In short, tailoring treatment to fit the individual patient can often result in successful resolution of both the urge and the stress components in this very challenging group of patients.

# COMPLICATIONS OF INCONTINENCE PROCEDURES IN WOMEN

*Chad Huckabay and Victor W. Nitti*

Stress urinary incontinence (SUI) is a common problem that affects millions of women in the United States. Various treatments exist, including physiotherapy, medications, devices, periurethral bulking agents, and more definitive surgeries. In contrast to less invasive therapies, surgery for SUI is associated with relatively high success rates. However, it also has potentially higher risks of morbidity and, rarely, mortality. Typically, surgery for SUI involves restoring support to the bladder neck, proximal urethra, or mid-urethra. Traditionally, anti-incontinence procedures have been broadly categorized as anterior repairs, transvaginal needle suspensions, retropubic suspensions, and sling procedures. More recently, midurethral synthetic slings, done in a minimally invasive fashion, have become the most popular procedures to treat SUI.

In addition to procedure-specific complications, there are a number of complications that are common to all types of incontinence surgery. Although complication rates vary, they have been reported to approach 50%. This chapter discusses the types of complications encountered when performing the various procedures with respect to their temporal occurrence (intraoperative, sequelae of intraoperative complications, then early and late postoperative problems). To better avoid complications, the surgeon should know how to thoroughly evaluate SUI in each individual patient. Careful preoperative planning is crucial, as is knowledge of specific surgical techniques. These factors inherent to avoiding complications are discussed elsewhere in this text. In this chapter, we focus specifically on the complications themselves.

### INTRAOPERATIVE COMPLICATIONS

#### Bleeding

A thorough history should uncover any bleeding diathesis. Significant bleeding is infrequent in either transabdominal or transvaginal approaches, occurring in 0.6% to 10% of cases.<sup>1</sup> In one study,<sup>2</sup> of 117 women who underwent Marshall-Marchetti-Krantz (MMK) cystourethropexy, 20 lost more than 500 mL of blood and 5 lost more than 1200 mL. Intraoperative bleeding during transabdominal approaches most commonly occurs in the retropubic space, owing to its rich network of venous complexes. If bleeding cannot be controlled by suture ligating, packing may be used.

During transvaginal procedures, bleeding commonly occurs at two points. The first is during the dissection of the vaginal wall off of the periurethral fascia. If this dissection is too deep, bleeding can be encountered. It is important to carry out dissection just above the glistening white surface of the fascia. This can be

more difficult in cases of previous surgery, and greater care should be taken to ensure that the proper plane is dissected. The second point at which bleeding may occur is with perforation of the endopelvic fascia. This bleeding can be difficult to control, because the vessels responsible may not be directly visible. We have found that the best way to control this bleeding is to place the sling (or suspension sutures) and transfer them to the suprapubic region expeditiously. Also, a vaginal packing placed after closure of the vaginal wall helps to tamponade bleeding. The retropubic space is a contained space, and bleeding is usually self-limited. If vaginal packing is ineffective, a Foley catheter balloon has been reported to achieve transvaginal tamponade.<sup>3,4</sup> Rarely, embolization may be done. Recently, Zorn and colleagues reported successful embolization of massive retropubic hemorrhage from a branch of the obturator artery injured during placement of a tension-free vaginal tape sling (TVT).<sup>5</sup>

With the widespread use of TVT and other midurethral slings, surgeons should be aware of problems related to bleeding specific to this procedure. Nilsson and Kuuva reported a retropubic hematoma rate of 3.3% and an additional 3.3% of patients with blood loss of greater than 200 mL.<sup>6</sup> Flock and associates reported that a pelvic hematoma larger than 300 mL and requiring surgical intervention was found in 1.2% of patients.<sup>7</sup> In 7 cases (2.1%), increased intraoperative blood loss (250 to 400 mL) was managed by cauterization, compression, or tamponade.<sup>7</sup> Others have reported hemorrhage rates of 0.9% to 2.5% with TVT.<sup>8-10</sup> In the Austrian registry of 2795 TVT procedures, 0.7% of the patients required laparotomy for bleeding control or evacuation of hematomas.<sup>11</sup> Kuuva and Nilssons<sup>12</sup> reported an incidence of 0.1% for injury to major vessels and nerves in their cohort of 1455 patients.

For the TVT procedure, the trocars are usually placed blindly, and knowledge of pelvic anatomy is crucial in avoiding disastrous complications. Deviation of curved trocars laterally can cause injury to the external iliac vein<sup>13</sup> or artery<sup>14</sup> and to the obturator neurovascular bundle. Cephalad displacement of the TVT trocar can cause injury not only to bowel but also to the iliac vessels more proximally. Patient movement during a TVT procedure performed with local anesthesia can directly cause deviation from the intended path of the trocar. Anatomic dissections and cadaver studies have shown that the TVT trocars pass an average 4.9 cm from the external iliacs and 3.2 cm from the obturator vessels.<sup>15</sup> With the transobturator (TOT) approach to placement of the TVT, the device passed on average  $1.1 \pm 0.4$  cm from the most medial branch of the obturator vessels. The mean distance to the obturator nerve was  $2.5 \pm 0.7$  cm.<sup>16</sup> Currently, 30 cases of major blood vessel injury have been reported, including 2 fatalities.<sup>17</sup> No significant bleeding complications have been reported with the TVT placed in a transobturator route. In most cases, bleeding

after TVT procedures is self-limited and no specific intervention, other than perhaps transfusion, is required. However, in cases of large blood loss, open exploration or embolization may be necessary.<sup>5,11</sup>

### Bladder and Urethral Injuries

Historically, injuries to the bladder and urethra occurred as a result of perforation during dissection or inadvertent placement of a suture or needle through the bladder or urethra. Today, most injuries to the urinary tract, and to the bladder specifically, are secondary to trocar injury at the time of minimally invasive midurethral sling placement. Cystoscopy during incontinence surgery is critical to rule out such injuries.

If injury to the bladder, bladder neck, or urethra occurs as a result of needle or trocar passage or suture placement, it is usually recognized during cystoscopy, after suspension sutures or pubovaginal slings have been transferred. In our experience, this occurs more commonly in cases in which the needle is passed “blindly” rather than under direct finger guidance. If the injuries are small and are not associated with tearing, the sutures or instruments can simply be removed and replaced. The small perforation should heal with several days of catheter drainage. Larger injuries should be repaired with absorbable suture, and urethral tears should be treated with at least 5 to 7 days of catheter drainage. If a urethral injury occurs, absorbable suture may close the defect, depending on size and location. For TVT and similar devices, the trocar should be removed and another pass of the trocar should be performed. Bladder injury due to intravesical trocar passage may be treated with 48 to 72 hours of continuous bladder drainage with a Foley catheter. Bladder perforation from the TVT trocars occurs in 1.1% to 25% of TVT cases.<sup>12,18-22</sup> The higher rates of bladder perforations occur in cases of previous failed anti-incontinence surgeries causing retropubic scarification. There may be a propensity for bladder perforations to occur opposite the side of the surgeon’s dominant hand.<sup>23</sup>

It is paramount to find intravesical TVT sling material during the initial placement, because secondary postoperative detection may require significant retropubic surgery. It is important to fill the bladder with at least 250 mL of irrigant or to near bladder capacity, because folds of mucosa may otherwise hide the tape. The 70-degree lens shows the anterolateral bladder wall, and the 0- and 12-degree lenses show the urethra optimally. Buchsbaum and colleagues<sup>24</sup> reported on bladder injuries identified not by cystoscopy but by having high fluid/irrigant leakage from trocar or incision sites. Shobieri and coworkers<sup>25</sup> reported a series of occult bladder injuries with TVT seen not on initial cystoscopy but only after removal and retrieval of trocars on second cystoscopy. In the TOT passage of synthetic midurethral tapes, case reports exist, and one series reported a 0.5% incidence of bladder perforations; hence, we recommend cystoscopy in this procedure as well.<sup>26,27</sup> Using an inside-to-outside technique of TOT trocar passage, de Leval<sup>28</sup> reported no instances of bladder perforation or visceral injuries in a series of 107 patients. The technique clearly holds promise, and further randomized studies to determine efficacy and complications of this technique should be performed.

Injuries occurring during transvaginal procedures that are closer to the bladder neck should be repaired primarily. These commonly occur when the vaginal dissection is done deep to the periurethral fascia and the surgeon attempts to perforate into the retropubic space. These injuries tend to be larger than trocar

or needle perforations, and primary closure is usually recommended. If such an injury is found, a two-layer closure with absorbable sutures (e.g., polyglycolic acid) can usually be accomplished transvaginally. A drain can be placed in the retropubic space percutaneously from the suprapubic area, in much the same way that the suspension needle is passed, but this is rarely needed. Infrequently, a retropubic approach must be taken to ensure proper closure of a massive injury. If there is a history of prior pelvic radiation therapy in a patient who has sustained a bladder injury, tissue interposition (i.e., omentum, labial fat pad) is recommended.<sup>29,30</sup>

If an injury at or near the bladder neck occurs, we usually recommend against placing a synthetic sling in such cases, because the risk of erosion is probably increased. However, we have successfully placed autologous fascial slings in under such circumstances.

For retropubic procedures, bladder repair is usually easy, as long as the injury is recognized. If an injury is suspected but cannot be found, the bladder can be filled with methylene blue or other irrigant to better identify leakage. Cystoscopy also may be instrumental. We prefer a primary two-layer closure with absorbable sutures. Depending on the size of the injury and the quality of the closure, a drain may be placed for several days, but usually this is not necessary in the absence of infection. In any case, the bladder should remain on catheter drainage for 5 to 7 days.

### Ureteral Injuries

Injuries to the ureters are much less common than bladder and urethral injuries. They may be encountered in retropubic operations (e.g., MMK, Burch) as well as transvaginal procedures (needle suspensions and pubovaginal slings), and they usually occur near the ureterovesical junction.<sup>31</sup> Rosen and colleagues,<sup>32</sup> in a review article, reported 19 ureteral injuries in the literature secondary to Burch colposuspension (Table 49-1). It is important to emphasize that there may also be a risk of ureteral kinking with overcorrection, as described in the original article.<sup>33</sup> Erikson and associates reported a 1% rate if unrecognized ureteral obstruction.<sup>34</sup> Perforating injuries can be managed by removing the suture and stenting the ureter. If the injury is severe, ureteral reimplantation may be necessary. Ureteral injuries should be suspected if, on cystoscopy during anti-incontinence procedures, no efflux is seen from the ureteral orifices. If a delayed diagnosis of ureteral obstruction or laceration is made postoperatively, the patient may present with unexplained flank pain, fever, or drainage. An intravenous urogram, retrograde ureteropyelography, or computed tomographic urogram will usually delineate the injury. Immediate retrograde ureteral stenting is recommended. If this

**Table 49-1 Ureteral Injury or Kinking with Burch Colposuspension**

Authors and Ref. No.	N	Ureteral Injury/Kinking (%)
Klutke et al. <sup>152</sup>	97	0
Harris et al. <sup>153</sup>	60	6.7
Eriksen et al. <sup>3</sup>	75	1.3
Galloway et al. <sup>154</sup>	50	2
Korda et al. <sup>155</sup>	174	1.1
Petri <sup>156</sup>	1500	0.2

is not possible, stenting can be performed in an antegrade fashion. If this fails, open repair with removal of suture and sometimes ureteroneocystostomy are necessary. Ureteral injuries are uncommon with transvaginal procedures and usually involve the inclusion of the ureter in the suspension sutures. If this is recognized intraoperatively (when indigo carmine is not seen excreted from the ureter), the suspension sutures should be removed. It may be helpful to place a stent before replacing the suspension suture, but this is rarely needed. If such an injury is discovered after surgery, during the postoperative period, it is handled in the same fashion as described previously. We know of no cases of ureteral injuries associated with TVT.

### Other Injuries

If the peritoneum is inadvertently incised during either approach, it should be closed with an absorbable suture. Bowel injuries are rare but can occur with transfer of sutures or slings and with TVT and similar procedures. They may also occur with placement of a suprapubic tube. A small bowel laceration and small perforations of the colon below the peritoneal reflection can usually be closed primarily. However, perforations of the colon above the peritoneal reflection in unprepared bowel may require proximal colostomy if significant spillage occurs intraperitoneally. Bowel injuries have not been reported with the TOT procedure. The traditional TVT trocars passed retropubically may cause bowel injury when the trocars do not “shave” the posterior aspect of the pubis and are directed more cephalad. The risk of bowel perforation is small, but several cases have been reported.<sup>8,35-38</sup> Patients with prior transperitoneal pelvic surgeries are at highest risk. Peyrat recommended preoperative computed tomography in women with a history of multiple abdominal and retropubic surgeries, which increase the risk of bowel adhesion to the pubis.<sup>39</sup> Patients typically present with abdominal pain, peritoneal signs, or leakage of feculent material from suprapubic incision sites. High suspicion levels for bowel injury should be maintained for those patients complaining of abdominal pain after TVT. A small bowel obstruction caused by intraperitoneal TVT performed with concomitant vaginal hysterectomy for prolapse was reported.<sup>40</sup>

### Sequelae of Intraoperative Injuries

#### Fistula

A fistula may develop after a surgical injury to the urinary tract. Unrecognized bladder or urethral injury may lead to a vesicovaginal or a urethrovaginal fistula, respectively (Fig. 49-1). If intraoperative cystoscopy is routinely used as described by Stamey,<sup>41</sup> urethral and bladder injuries should be recognized, thereby decreasing the risk of subsequent fistula formation. Some instances of unrecognized injuries missed by cystoscopy may be detected when fluid leakage is more than expected from incision sites. Methylene blue or sterile infant formula may also be instilled into the bladder to aid detection. Kuuva and Nilsson, in a nationwide analysis of complications associated with TVT in 1455 patients, found only one case for an incidence of 0.7/1000 of vesicovaginal fistula.<sup>12</sup>

#### Nerve Injury

Three types of nerve injury may occur during incontinence surgery. The first is a result of intraoperative positioning. The

**Figure 49-1** Urethrovaginal fistula after major urethral injury during anti-incontinence procedure.

most common nerve injured is the common peroneal nerve; injury is caused by direct compression of the nerve against the leg support while the patient is in the dorsal lithotomy position. A femoral nerve palsy may result from hyperflexion of the hip wherein the thigh is brought too cephalad and in a prolonged position may cause postoperative weakness of the thigh extensor muscles. A second type of nerve injury involves direct trauma to the nerve during surgery. Intraoperative events may pose injurious risk to the ilioinguinal nerve as it travels in the vicinity of suprapubic transverse incisions, needles, slings, and trocar passages. Geis and Dietl first reported ilioinguinal nerve entrapment by TVT.<sup>42</sup> Local anesthetic injections along the nerve can aid in diagnosis and treatment without the need for TVT removal. Patients present with lower abdominal wall pain radiating into the groin, labia majora, or upper inner thigh. Certainly, the obturator nerve is at risk in placement of midurethral synthetic slings (e.g., TVT, TOT).<sup>21,43,44</sup> A third type of nerve injury involves disruption of the innervation of the urethra and surrounding structures. Some evidence suggests that vaginal dissection may affect this innervation. Zivkovic and colleagues<sup>45</sup> showed that vaginal dissection, especially during endoscopic bladder neck suspension, can worsen preexisting perineal neuropathy in patients with SUI. Vaginal innervation seems to be concentrated on the anterior vagina<sup>46</sup> and may be affected by anti-incontinence operations. Modification of innervation of the anterior vaginal wall could account for postoperative discomfort with intercourse.<sup>47</sup> It is unknown whether alterations in neuroanatomy are responsible for some cases of sexual dysfunction after anti-incontinence procedures. Mazouni and associates<sup>48</sup> reported that 25.6% of patients who were monitored prospectively with questionnaires had some deterioration of sexual function after TVT placement. Glavind and Tetsche<sup>49</sup> found that 23% of previously sexually active women reported improved sexual life. Maaita and colleagues<sup>50</sup> reported no change in sexual function after TVT procedures. Only prospective studies using validated symptom questionnaires will delineate the impact of TVT and incontinence treatment on sexual functioning.

## EARLY POSTOPERATIVE COMPLICATIONS

### Voiding Dysfunction

Immediate postoperative urinary retention is the most common type of voiding dysfunction encountered after any anti-incontinence procedure (Table 49-2). Kelly and colleagues<sup>51</sup> reported acute urinary retention requiring catheterization in 41% of 114 women who underwent modified Pereyra bladder neck suspension. Twenty-seven percent of women undergoing MMK cystourethropexy had postoperative urinary retention, according to Parnell and associates.<sup>52</sup> Yalcin and coworkers<sup>53</sup> noted that 3.2% of patients had temporary voiding dysfunction after TVT. In most of these patients, urinary retention (complete or partial) is transient, secondary to postoperative edema of the bladder neck and urethra, and resolves with catheter drainage. The estimated probability of temporary urinary retention lasting longer than 4 weeks is 5% for retropubic and transvaginal suspensions and 8% for sling procedures.<sup>54</sup>

Various options for drainage are available, including suprapubic tube drainage. Occasionally, a suprapubic tube is placed intraoperatively in anticipation of immediate postoperative urinary retention. This is kept in place until normal emptying resumes (usually 1 to 4 weeks). Suprapubic tube placement is less common with midurethral synthetic slings, because most patients void within 24 hours after surgery. Intermittent catheterization or an indwelling urethral catheter may also be used. It has been our experience that normal emptying occurs a bit sooner after retropubic procedures compared with transvaginal suspensions or traditional pubovaginal slings. Permanent retention is much less common (see later discussion).

Irritative or storage symptoms, including frequency, urgency, and urge incontinence, are also common after incontinence surgery. Usually, this is not a problem in the immediate postoperative period, if the patient is well prepared. It is important to be sure that the patient is emptying well; if not, intermittent catheterization should be considered. In the patient who is emptying well, a trial of anticholinergic drugs can be used. Sometimes, however, it is only time that will cure this problem. Postoperative voiding symptoms are likely to persist for up to 4 weeks. Patients with preoperative urgency are more likely to have continued urgency postoperatively (13% to 68% for pubovaginal slings and 22% to 79% for retropubic suspensions) than those with no preoperative urgency (3% to 45% and 0% to 33%, respectively).<sup>54</sup>

### Infection

Urinary tract infections (UTIs) in the immediate postoperative period are uncommon, provided that preoperative urine cultures are negative and perioperative antibiotics are employed. If patients present with acute symptoms of a UTI, including increased irritative symptoms, during the first few months after surgery, urine culture should be obtained, and if it is positive the patient should be treated with appropriate antibiotics. Debodinance and colleagues<sup>55</sup> found an incidence of UTI of 4.5% in a series of 800 patients having anti-incontinence procedures, of whom 281 had TVT. UTI rates are usually related to length of catheterization. Rarely, a patient develops recurrent postoperative UTI despite complete emptying of the bladder. In these cases, cystoscopy should be performed to rule out suture or sling erosion (see later discussion). However, in our experience, there are a small number of patients who develop recurrent UTI after incontinence surgery with no obvious cause.

The incidence of wound infections varies from 2% to 16%.<sup>56-58</sup> The wound infection rate after TVT was 0.4% in a single series.<sup>9</sup> Predisposing factors are no different than those for any other surgery and include obesity, diabetes, immunocompromise, and reoperation. The vagina is a contaminated space; therefore, we routinely cleanse the vagina with a Hibiclens or povidone sponge before the surgical preparation to minimize infection. Perioperative antibiotics are important in the prevention of infection. We routinely use ampicillin and gentamicin perioperatively for the prevention of infection. An oral cephalosporin or quinolone is used for 7 days postoperatively.

Pelvic infections and abscess are rare occurrences. Appropriate management should include broad-spectrum antibiotics and usually surgical drainage (vaginal or abdominal) depending on size. Neuman managed two infected hematomas after TVT with ultrasound-guided aspiration and antibiotics, avoiding open surgery and removal of TVT material.<sup>59</sup> One case of necrotizing fasciitis with massive debridement after TVT has been reported, but it is questionable whether this was primarily related to the TVT or whether seeding or contamination of incision sites from a distal infected extremity occurred.<sup>60</sup>

## DELAYED OR LATE POSTOPERATIVE COMPLICATIONS

### Pain

After needle suspension, some patients experience a chronic suprapubic pain that may radiate down the medial aspect of the inner thigh or cause a pulling sensation. This is thought to occur because of entrapment of the sensory branches of the ilioinguinal nerve or the genital branches of the genitofemoral nerve as the suspension sutures are tied to the rectus fascia.<sup>61</sup> This complication was noted in as many as 8% to 16% of patients in early series.<sup>62</sup> The passage of needles and trocars closer to the midline and adjacent to the pubic bone should reduce the risk of this complications. Hilton and associates<sup>63</sup> reported two cases of chronic vaginal and pelvic pain of unknown etiology in patients who were eventually found to have eroded intraurethral/bladder neck TVT. We also have seen patients with pain out of proportion to physical examination findings who were subsequently found to have urethrally eroded TVT.

TVT, tension-free vaginal tape.

### Suture Erosion

Rarely, a patient presents with postoperative irritative symptoms and/or recurrent UTI secondary to a permanent suture that has “eroded” into the bladder (Fig. 49-2A). These sutures, or slings in the case of TVT,<sup>64</sup> may act as a nidus for stone formation. It is more likely that this phenomenon occurs due to unrecognized placement of sutures into or through the bladder rather than an actual erosion. Most of the time, suture erosion can be treated endoscopically by cutting the suture, which often retracts through the bladder wall, or by using the holmium:yttrium-aluminum-garnet (YAG) laser to ablate the suture and/or stone (see Fig. 49-2B).<sup>65</sup>

### Infection and Erosion of Slings Material

#### Vaginal Extrusion

The exposure of synthetic material uncovered by vaginal epithelium is more properly termed vaginal *extrusion* rather than vaginal *erosion* (Fig. 49-3; Table 49-3). Vaginal extrusion is

uncommon. Possible reasons for this complication are subclinical infection, inadequate vaginal incision closure, impaired wound healing, and tape/sling rejection. For the TVT, local vaginal flaps around the extruded site can be created and advanced over the exposed tape. Alternatively, the exposed tape can be excised, with vaginal flaps used to close the defect. A small area may be observed and treated with local estrogen cream, allowing re-epithelialization. Vaginal extrusion rates for TVT and polypropylene slings have varied from 0% to 4.4%.<sup>10,12,66-69</sup> Other materials, such as polyester multifilament (Mersilene), silicone, polytetrafluoroethylene (Gore-Tex, Teflon), or even multifilament polypropylene, have higher extrusion and infection rates.<sup>70</sup> Pore size less than 10  $\mu\text{m}$  increases the risk of infection, because bacteria may enter the interstices but macrophages and neutrophils larger than 10  $\mu\text{m}$  cannot penetrate the pores of the mesh to fight infection. Monofilament polypropylene also may have better incorporation into surrounding tissues, because its pores allow passage of fibrocytes.

Infected type I mesh can usually be removed partially or in the segment involved. TVT is a macroporous type I mesh with

**Figure 49-3** Vaginal extrusion of synthetic tape material and bone anchors used to fix the sling. Note primarily the existence of granulation tissue. Granulation tissue in the vagina often is associated with underlying foreign body extrusion through the vaginal epithelium, although the foreign body itself may be obscured.

pores larger than 75  $\mu\text{m}$  that allow bacteria, macrophages, and fibroblasts to enter the pores.<sup>71</sup> An exception is when type I mesh has been anchored to tissue using permanent multifilament sutures that harbor infection. Types II and III mesh usually have to be removed entirely if they become infected. Type III mesh has microporous portions that allow sequestration of bacteria but not macrophages.<sup>72</sup> TVT extrusion in the lateral vaginal fornices may result from improper placement of the sling during the TOT technique when the vaginal epithelium is inadvertently punctured with the trocar.

#### *Urethral Erosions*

Urethral erosion is quite uncommon. Leach and coworkers<sup>54</sup> reported an erosion rate of 0.003% with autologous slings and 0.02% with synthetic slings. It most likely results from dissection too close to the urethra with thinning and devascularization of tissues, placement of the sling between the urethra and periurethral fascia, excessive tension, or direct urethral injury including perforation that is missed. If the periurethral fascia is disrupted beneath the urethra, then it is best to repair the periurethral fascia before placement of the suburethral sling. In the use of trocars, more caution should be used when passing trocars toward the urethra rather than away, because the surgeon usually has less precise control of the distal aspect of the trocar. Small (seemingly

**Figure 49-4** Intravesical tension-free vaginal tape found on cystoscopy for recurrent urinary tract infections. Pain in the suprapubic or vaginal/perineal area may also be a presentation of intravesical or intraurethral suburethral sling placement.

inconsequential) movements of the proximal aspect of trocars translate to much larger ranges of movement in the distal trocar. Finger guidance is very helpful when trocars are passed toward the urethra.

A high index of suspicion must be maintained, because the presentation of urethral erosion can be quite delayed and of variable symptomatology. Patients may have dysuria, irritative or obstructive symptoms, recurrent incontinence, pain, vaginal discharge, UTIs, hematuria, pyuria, or other symptoms and signs. Slings can be removed endoscopically by cutting each end of the eroded material.<sup>73,74</sup> We prefer an open approach via transvaginal suburethral incision in which all eroded material is removed from the urethral wall. Repair of the urethra with absorbable suture should be performed, and a catheter should be left in place for 5 to 10 days, depending of the extent of the injury. In severe cases, local flaps may be necessary to cover the repair and prevent fistulization.

For intravesical synthetic sling erosions or placements, the holmium:YAG laser may ablate the intravesical portion of the sling. For more complicated cases, an open retropubic approach may be needed for complete excision (Fig. 49-4).

#### *Osteitis Pubis and Osteomyelitis*

Osteitis pubis is a noninfectious inflammation of the periosteum overlying the symphysis pubis that usually occurs 1 to 8 weeks after the inciting event. It manifests with symptoms and signs of suprapubic pain and tenderness, adductor spasm, elevated erythrocyte sedimentation rate, and a “waddling” gait. It has been historically associated with the MMK cystourethropexy, and its incidence ranges from 1% to 10%, depending on the series.<sup>52,75,76</sup> Plain film radiography is usually diagnostic; however, on occasion, a bone scan may be necessary to demonstrate increased activity in the area of the pubis. With osteitis pubis, there may be a delay in radiographic appearance after clinical symptoms of 3 to 4 weeks. Although the symptoms are disabling, they usually resolve over time with conservative management consisting of bed rest and anti-inflammatory agents.

Several modifications of the needle suspension and bladder neck sling that involve anchoring of the suspension/sling to bone have been described.<sup>77-80</sup> The theoretical advantages of bone anchoring have not been proven in randomized, controlled studies. Goldberg and colleagues<sup>81</sup> reported that three (1.3%) of their patients who underwent suprapubic bone-anchored bladder neck suspension later developed osteomyelitis requiring debridement, removal of bone anchors, and long-term intravenous antibiotics. Others have reported cases of osteomyelitis after various incontinence procedures using bone anchoring devices.<sup>82-85</sup> Both osteitis pubis and osteomyelitis may be characterized by the absence of fever, symmetric bony destruction of the symphysis, pelvic pain and gait disturbances, a delayed onset of symptoms, and failure to improve with antibiotics alone. In a literature review, Frederick and coworkers<sup>86</sup> found the incidence of osteitis pubis and osteomyelitis to be 0.16% and 0.08%, respectively, after transvaginal bone anchor fixation. It is unknown whether removal of bone anchors is helpful, and this is not absolutely indicated unless associated infection exists.

### Chronic Voiding Dysfunction and Retention

The true incidence of iatrogenic voiding dysfunction after anti-incontinence surgery is unknown and varies among the different types of procedures. In a large series of 503 patients that compared Burch colposuspension to Stamey endoscopic needle suspension, voiding dysfunction was noted to be the most frequent complication (12.1%).<sup>87</sup> Voiding dysfunction after incontinence surgery is usually the result of obstruction, detrusor overactivity, or detrusor failure. In general, this complication, especially when it includes de novo urgency, is the most common complication after any anti-incontinence surgery.

### Obstruction and Incomplete Emptying

A potential complication of all procedures to correct SUI is iatrogenic outlet obstruction leading to voiding dysfunction. This may cause urinary retention (partial or complete), obstructive voiding symptoms, or storage symptoms such as frequency, urgency, and urge incontinence.

The true incidence of voiding dysfunction and iatrogenic obstruction after incontinence surgery is unknown and is probably underestimated. Estimates of 2.5% to 24% have been reported for various procedures.<sup>88-92</sup> In a 1997 review, urinary retention lasting longer than 4 weeks occurred in 3 to 7% of retropubic suspensions, 4 to 8% of transvaginal suspensions, and 6 to 11% of slings. For the same procedures, urinary retention longer than 4 weeks occurred in 3% to 7%, 4% to 8%, and 6% to 11%, respectively. The incidence of permanent retention for all three procedures was thought to be less than 5%.<sup>54</sup> Chaikin and colleagues found postoperative de novo urge incontinence in 3%, persistent urge incontinence in 23%, and unexpected permanent urinary retention in 2% of patients undergoing pubovaginal sling procedures.<sup>93</sup> For the same procedure, Morgan and colleagues reported de novo urgency in 23% and de novo urge incontinence in 7%; five women had retention after 3 months requiring urethrolisis. Interestingly, they reported a 74% resolution of urge incontinence (although concomitant anterior colporrhaphy may have contributed,  $P = .07$ ) and return to normal voiding in 92% at 1 month postoperatively.<sup>94</sup> Reported rates of urinary retention after TVT placement have ranged from 1.4% to 9%.<sup>8,12,95-99</sup> Others have

described rates of voiding dysfunction after TVT as being 2% to 4%.<sup>100</sup>

Dunn and colleagues recently performed an extensive literature review to determine the incidence of “voiding dysfunction” after incontinence procedures.<sup>17</sup> They searched the Medline data base from 1966 to 2001 for various procedures. All available reports were retrospective collections, case reports, or case cohort series. Rates of voiding dysfunction varied from 4% to 22% after Burch colposuspension, 5% to 20% after MMK urethropexy, 4% to 10% after pubovaginal sling, 5% to 7% after needle suspension, and 2% to 4% after TVT. Although it cannot be said that all patients with voiding dysfunction in these series were obstructed, it can be inferred that a number were.

In patients with preexisting urgency symptoms, postoperative urgency occurs more frequently. The large review sponsored by the American Urological Association in 1997 suggested that postoperative urgency occurred in 36% to 66% of patients undergoing retropubic suspensions, in 54% after transvaginal procedures, and 34% to 46% after slings.<sup>54</sup>

The rate of true “obstruction” may be underestimated, because irritative and obstructive symptoms tend to be overlooked in the face of normal emptying.

Whether a procedure causes an obstruction is largely based on technical factors such as suture placement or sling tension. Sutures too medial, close to the urethra, can cause urethral deviation or periurethral scarring. In addition, if sutures are tied too tightly overcorrection and “hypersuspension” of the bladder neck may result, kinking it shut. Even when properly performed, certain procedures designed to correct anatomic incontinence will cause an increase in urethral resistance. In a prospective interval analysis of patients undergoing endoscopic bladder neck suspension, Coptcoat and associates showed a ninefold increase in urethral resistance at two months after suspension in a small group of 7 patients.<sup>101</sup> A sling, whether at the bladder neck or at the mid-urethra, can certainly cause obstruction if it is too tight. There is no precise way to determine tension, but available techniques have kept obstruction rates reasonably low, although not zero.

The key to a diagnosis of obstruction in women is a high index of suspicion and thorough evaluation. Many women void by relaxing pelvic floor muscles, and some may augment voiding by straining. Even a slight degree of increased outlet resistance with “relative obstruction” can cause considerable voiding dysfunction. The diagnosis of obstruction after anti-incontinence procedures can be inferred if a patient remains in urinary retention despite having had normal emptying before surgery. A history of normal voiding and emptying before surgery is one of the most important factors in deciding on treatment. A review of preoperative urodynamic testing can be helpful. If such studies are not available or if the patient empties well but has irritative or obstructive symptoms, then a repeat evaluation is necessary.

No universally accepted urodynamic criteria for the diagnosis of female bladder outlet obstruction exists, and this is even more true for obstruction after SUI surgery.

Sometimes obstruction is obvious (high-pressure/low-flow voiding dynamics), but many women who are obstructed after SUI surgery do not demonstrate such voiding dynamics on urodynamic studies. Carr and Webster performed fluorourodynamic studies on all patients but eventually offered urethrolisis even to women with normal study findings when a clear temporal relationship between surgery for incontinence and the onset of voiding symptoms could be demonstrated.<sup>102</sup> Nitti and Raz

performed video urodynamics on all patients and reported that voiding dynamics had little effect on the outcome of surgery, and, in fact, all four women who failed to generate a detrusor contraction during urodynamics voided successfully after urethrolisis.<sup>103</sup> Foster and McGuire had similar findings.<sup>104</sup> We no longer believe that a complete urodynamic evaluation is necessary for those with retention or high postvoid residual volumes, provided that they had normal emptying preoperatively.<sup>103</sup> A patient with incomplete emptying who emptied adequately before SUI surgery should not be excluded from urethrolisis, even if hypocontractility or failure to generate a detrusor contraction occurs. Occasionally, unanticipated urodynamic findings are seen, such as learned voiding dysfunction. The utility of urodynamics may be considered as follows. First, for the patient in retention, urodynamics can provide valuable information (such as detrusor overactivity or significantly impaired compliance, the latter being an absolute indication for intervention) and can confirm a diagnosis of obstruction but should not exclude the patient from urethrolisis, even if there is no contraction or impaired contractility. Urodynamics may also identify learned voiding dysfunction. Second, for the patient with storage symptoms with normal emptying, urodynamics can diagnose obstruction and, equally as important, rule out obstruction. It can help to provide a specific diagnosis that is useful in directing therapy, especially if obstruction can be ruled out.

Endoscopic evaluation of the urethra may show scarring, narrowing, occlusion, kinking, or deviation. These findings are especially helpful in cases in which urodynamic findings are equivocal. The urethra and bladder should be carefully inspected for eroded sutures, sling material, or the presence of a fistula. This is facilitated by the use of a rigid scope with a 0- to 30-degree lens and little or no beak to allow for complete distention of the urethra. In cases in which intervention is anticipated, endoscopy should be done routinely, either before surgery or at the time of surgery before incision. Radiographic imaging may be done independent of videourodynamics. A standing cystogram in the anterior-posterior, oblique, and lateral positions, with and without straining, assesses the degree of bladder and urethral prolapse and displacement or distortion of the bladder. A voiding cystourethrogram can assess the bladder, bladder neck, and urethra during voiding to determine narrowing, kinking, or deviation. Although imaging is not mandatory, it can be extremely useful in equivocal cases.

When discussing intervention for obstruction after incontinence procedures, it is important to distinguish between midurethral synthetic slings, such as TVT, and other procedures, such as traditional pubovaginal sling, retropubic suspension, and needle suspension, because the timing and type of intervention vary. With midurethral synthetic slings, intervention is usually done sooner and is less invasive. With other procedures, longer periods of postoperative obstruction and retention are common, and intervention is usually deferred for weeks to months.

No consistent preoperative parameters, such as urethrolisis or sling incision, predict success or failure of intervention. Several studies failed to show any correlation between urodynamic findings and the likelihood of successful voiding after urethrolisis.<sup>103-105</sup> Without dispute, those women who have retention and increased postvoid residuals after incontinence surgery (but who had normal emptying preoperatively) are good candidates for urethrolisis. The patient's history of new voiding difficulties may be one of the most significant indicators of obstruction, independent of any other findings.

For traditional pubovaginal sling, needle suspension, and retropubic suspension procedures, most of the literature on intervention concerns patients at least 3 months out from surgery. Disappointed, uncomfortable patients with retention or significant irritative symptoms may be hard to convince that waiting is suitable. Therefore, there has been a trend to more early intervention perhaps at 1 to 2 months, especially for patients with significant retention requiring catheterization. Some patients may choose to continue intermittent catheterization indefinitely, especially if they have had marked improvement of very severe incontinence.

One can also attempt to cut suspension sutures from above in cases of obstruction after transvaginal needle suspensions. One or both sutures may be cut. In cases of pubovaginal sling, the sling may be cut in the midline after a vaginal incision has been made. However, sometimes obstruction can be effectively treated only with a formal urethrolisis. With synthetic midurethral slings such as the TVT, it has been our practice to intervene early, often within 7 to 10 days for patients in retention. In the early postoperative period, these slings can often be loosened or cut with the use of local anesthesia, occasionally in an office setting.

### *Techniques for Treating Postoperative Obstruction*

For the synthetic midurethral slings, sling loosening techniques, urethral dilation, and sling incision alone can be performed within a shorter postoperative period before significant scarring occurs. Of note, we rarely perform sling loosening procedures and do not advocate urethral dilation.

### **Synthetic Midurethral Sling Loosening or Lysis**

For those patients with retention within approximately 2 weeks after placement of a TVT sling, an office procedure may be used. After infiltration with local anesthetic, the previous incision is opened (usually by removal of the suture used to close the incision), and the sling is found by direct inspection or palpation. A right angle clamp is placed around the tape. During the early postoperative period (up to about 10 days), the tape may be pulled down or loosened. After longer periods of time, it is usually necessary to cut the tape. We have found this technique to be effective in relieving obstruction and the recurrence of SUI to be small. For those surgeons who are uncomfortable doing this in an office setting and for anxious patients, the same procedure may be done in the operating room. In cases of obstruction beyond 2 weeks, the lysis of the TVT sling is best performed in the operating theater, and in more chronic cases this is imperative. Scarring and patient discomfort are factors to consider, because more extensive dissection may be needed to identify and cut the sling. It is imperative to identify the sling, which may be more difficult if it has rolled onto itself in a band, and then transect the sling (Figs. 49-5 and 49-6). The suburethral portion of the sling may also be excised at the surgeon's discretion. Simply cutting or loosening a midurethral synthetic sling has yielded excellent results.<sup>10,95,97,106</sup> Klutke and colleagues reported resolution of obstruction in all 17 of their patients, and recurrent SUI in 1 patient.<sup>95</sup> Rardin and associates found that impaired bladder emptying resolved in 100% of 23 patients, with 61% remaining continent, 26% having partial recurrence, and 13% having complete recurrence of SUI.<sup>97</sup>

### **Transvaginal Pubovaginal Sling Incision**

Intervention for obstruction caused by pubovaginal slings is usually done after a longer period of time than with midurethral

**Figure 49-5** Obstructing tension-free vaginal tape (TVT) has twisted into a 2-mm band. A right angle clamp can be placed between the TVT and the periurethral fascia, and the TVT can be isolated and cut.

**Figure 49-6** Obstructing tension-free vaginal tape. Note fibrous incorporation of sling material. After the sling is cut in the midline, a distinct "pop" and retraction of sling material occurs. Simultaneous dropping of the urethra occurs as well.

synthetic slings; the dissection is usually more extensive, so general or regional anesthesia is required. Transvaginal incision of the pubovaginal sling alone (autologous, allograft, xenograft, or synthetic) may effectively eliminate obstruction with similar results to formal urethrolisis. We, along with others, use a simple sling incision as first-line treatment.<sup>107-110</sup> We believe that this procedure, rather than formal urethrolisis, may limit morbidity, potential injury to soft tissue or nerve, and fibrosis from surgical dissection. Commonly, the sling is encased in scar. Initial painstaking dissection may be aided by placing a cystoscope or Walther sound in the urethra with cephalad deflection of the working end, both to bring the bladder neck down and to palpate the ridge caused by the sling. Allis clamps placed on each side (or on one side) of the sling with downward traction may facilitate dissection (Fig. 49-7). If scarification is dense, not allowing identification of the sling in the midline, it can be isolated lateral to the midline, off of the urethra. If the sling cannot be clearly cut, then formal urethrolisis should be performed (Table 49-4).

### Transvaginal Urethrolisis

Because sling incision alone is commonly performed today, we offer repeat formal transvaginal urethrolisis to these patients if obstruction remains. We prefer transvaginal urethrolisis, as originally described by Leach and Raz,<sup>111</sup> as a primary operation (rather than retropubic urethrolisis), because it is easier, is less morbid with quicker recovery times, and is highly effective.

We begin with intraoperative cystoscopy, even if cystoscopy was previously performed clinically. We exclude foreign bodies, sutures, stones, and erosion of suture or sling. Sagittal rotation of the scope with simultaneous anterior vaginal palpation is useful. Leach and Raz (1984) originally described the most commonly used transvaginal procedure (Fig. 49-8).<sup>111</sup>

Carey and colleagues reported the use of a Martius labial fat pad flap with transvaginal urethrolisis with success in 87% of patients.<sup>112</sup> The Martius flap may decrease the risk of recurrent fibrosis and provide some urethral support; with any future surgery, a sling may be placed outside the fat pad, thus decreasing the risk of urethral injury. We reserve it for selected cases (e.g., repeat urethrolisis, extensive fibrosis). We usually divide the robust fat pad flap midway along its longitudinal axis and wrap the flap around the urethra, effectively supporting the undersurface and retropubic surface of the urethra.

If a vaginal approach is not feasible due to the patient's anatomy, or if the surgeon prefers, urethrolisis can be performed via a retropubic approach. We advocate an approach similar to that described by Webster and Kreder.<sup>105</sup> They reported excellent results with a retropubic takedown in which all adhesions from the prior cystourethropexy are sharply incised and complete mobility of the anterior vaginal wall is restored. The procedure is completed by performing an obturator shelf repair to prevent rotational decent and placing an omental pedicle to fill the retropubic dead space and prevent further scarring. In this case, careful sharp dissection is done to completely free the urethra from the undersurface of the pubic bone.

Urethrolisis may also be performed by a suprimeatal approach, making a small inverted U-shaped incision above the urethral meatus and dissecting the urethra dorsally. This is usually done without any other major dissection or resuspension. A Martius labial fat pad flap can be interposed.

Regardless of the technique chosen, when formal urethrolisis is performed, we recommend a complete freeing of the urethra

**Figure 49-7** **A**, After an inverted U or midline incision and wide dissection of flaps, the sling is isolated in the midline and incised. A right angle clamp may be placed between the sling and the periurethral fascia to avoid injury to the urethra. **B**, The sling is freed from the undersurface of the urethra toward the endopelvic fascia. Ends may be excised or left in situ. Release of the sling causes a distinct drop in the urethra, with increased mobility of the urethral sound/cystoscope. Without retropubic space entry, we preserve lateral support and do not free it from the posterior pubic bone. (From Nitti VW, Carlson KV, Blaivas JG, Dmochowski RR: Early results of pubovaginal sling lysis by midline sling incision. *Urology* 59:47-52, 2002.)

in the retropubic space, because it is often quite adherent to the pubic bone.

In selected cases (e.g., extensive mobilization or SUI coexisting with obstruction), it may be desirable to resupport the urethra at the time of urethrolysis. Resuspension or sling may be done. Currently, our practice is to consider this only if the patient had SUI before urethrolysis or if support structures were severely compromised during urethrolysis. We rarely find this to be the case. Resuspension does increase the risk of persistent obstruction, and because most patients are distraught about obstruction, we believe it is best to take care of this problem and deal with recurrent SUI at a later time should it occur. Patients may be salvaged with transurethral collagen injections if SUI recurs. Goldman and colleagues reported a 66% response rate to collagen in women with recurrent SUI after transvaginal urethrolysis.<sup>113</sup> Additionally, the option of other procedures for SUI at a later date exists.

Urethrolysis is 65% to 93% effective for relieving iatrogenic obstruction.<sup>102-105,109,113-116</sup>

In patients who fail to void satisfactorily after urethrolysis, repeat urodynamics does not give conclusive information as to the cause of the failure.<sup>103</sup> Explanations include poor contractility insufficient to overcome even the reduced outlet resistance and persistent obstruction. In some patients, this continued obstruction is the result of intrinsic damage to the urethra from surgery and is not caused by periurethral fibrosis and scarring. In such cases, urethrolysis will not relieve the obstruction. It is possible that some failures “reobstruct” after a complete urethrolysis.

### Chronic Irritative Symptoms and Urge Incontinence

After any anti-incontinence procedure, irritative voiding symptoms (frequency, urgency, urge incontinence) can persist or develop de novo. Irritative symptoms are more likely to be present postoperatively if they were present preoperatively. In the study by Kelly and colleagues, both preoperative and postoperative symptom analyses were obtained in 114 women who

**Table 49-4 Summary of Series on Urethrolysis and Sling Incision/Loosening for the Treatment of Obstruction after Incontinence Surgery**

Author and Ref. No.	N	Type of Urethrolysis	Success (%)*	Recurrent SUI (%)†
Zimmern et al. <sup>160</sup>	13	Transvaginal	92	N/A

Klutke et al. <sup>95</sup>	17	TVT incision and/or loosening	100	6
Rardin et al. <sup>97</sup>	23	TVT incision	100 (retention) 30 (urge sx cured) 70 (urge sx improved)	39 (two-thirds less SUI than before TVT)

\*Success is usually defined as cure or significant improvement in presenting symptoms (resumption of normal bladder emptying for patients in retention; resolution of symptoms for patients with obstructive symptoms or frequency, urgency, or urge incontinence). In some series, success for specific symptoms is noted.

†Recurrent SUI is defined as the percentage of patients without SUI before urethrolysis who experienced SUI after urethrolysis. N/A, not applicable; SUI, stress urinary incontinence; sx, symptoms; TVT, tension-free vaginal tape.

underwent modified Pereyra bladder neck suspension.<sup>51</sup> If urgency symptoms were present postoperatively, there was a statistically significant correlation with a poor objective and subjective outcome. In the large review sponsored by the American Urological Association, persistent postoperative urgency occurred in 36% to 66% of women undergoing retropubic suspension, 54% of those with transvaginal procedures, and 34% to 46% of those with slings.<sup>54</sup> (The higher percentage reflects patients with documented detrusor overactivity, and the lower percentage reflects patients who had preoperative urgency without overactivity.) Among patients who had no urgency and no detrusor overactivity preoperatively, de novo urgency occurred in 8% to 16% of those with retropubic suspensions, 3% to 10% of those with transvaginal suspensions, and 3% to 11% of those with slings (all ranges represent 95% confidence intervals).<sup>54</sup> No major statistical differences existed between the various procedures regarding postoperative urgency rates.

If irritative symptoms are present chronically after incontinence surgery, it is important to rule out obstruction as a cause. If obstruction exists, consideration may be given to sling lysis or urethrolysis. Chronic irritative symptoms not associated with obstruction are often difficult to manage. Anticholinergics, biofeedback, behavioral modification, or neuromodulation may be used. Age may play a role, because Allahdin and coworkers<sup>117</sup> found a higher rate of postoperative urgency in a group of patients aged 70 to 90 years. They found rates of urgency up to 60%, with 44% de novo urgency in this older group.<sup>118</sup> Occasionally, postoperative dysfunctional voiding is discovered, and this is effectively treated with biofeedback and patient education about changes in the lower urinary tract after surgery. In refractory cases, augmentation cystoplasty may be considered. In cases of de novo or worsened symptoms, consideration may be given to

urethrolysis, although there are no data to support its success in patients without obstruction.

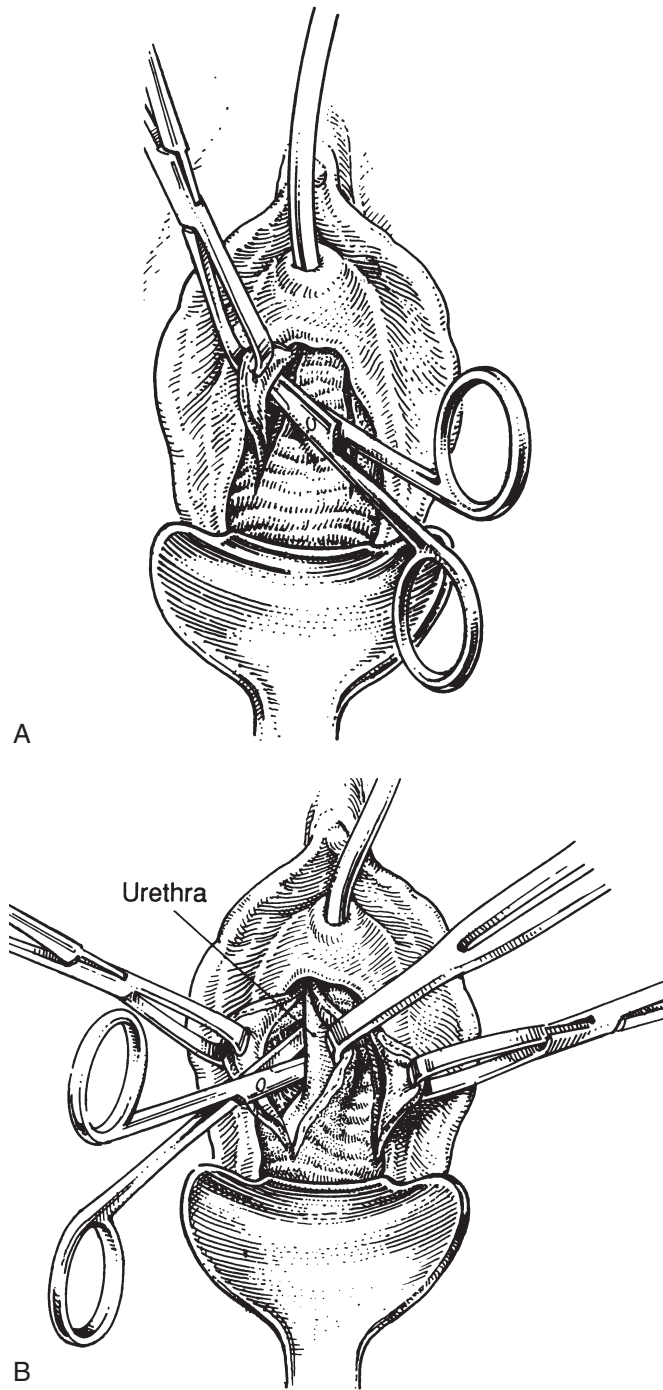

Conversely, some have improved overactive bladder symptoms after anti-incontinence procedures. After TVT, Segal and colleagues reported resolution of urgency in 63.1% of patients with preoperative mixed incontinence symptoms.<sup>119</sup>

### COMPLICATIONS OF LAPAROSCOPIC SUSPENSIONS

Previously reported trials of laparoscopic colposuspension have had success rates of 40% to 100%.<sup>120-126</sup> However, these trials were nonrandomized, they had short follow-up times, and a number of factors, including patient selection and severity of incontinence, were not clearly defined.

Su, TH and coauthors<sup>127</sup> published results of a prospective trial comparing conventional colposuspension to laparoscopic colposuspension in 92 patients with 1 year follow-up. Although the reported success rates were significantly lower in the laparoscopic group (80.4% versus 95.6%), blood loss, hospital stay, and complication rates (17.4% versus 10.8%) were higher in the traditional colposuspension group. Moehrer and colleagues<sup>128</sup> found, in comparing laparoscopic with open colposuspension, that perioperative complications (including UTIs, dysuria, hematuria, voiding difficulties, wound infections, and retropubic hematoma) were slightly more frequent, but not significantly so, with the laparoscopic approach. The incidence of bladder injuries was higher with the laparoscopic technique.<sup>128</sup>

In randomized trials of laparoscopic colposuspension and TVT, Valpas and associates<sup>129</sup> found no difference in cure rates at 6 weeks' follow-up, but the TVT procedure was associated with

**Figure 49-8** Transvaginal urethrolysis. **A**, An inverted U-shaped anterior vaginal wall incision is made after subepithelial injection of local anesthetic with epinephrine. The apex of the “U” is midway between the bladder neck and the urethral meatus. If a midline incision is made, it should extend from the mid-urethra to 2 cm behind the bladder neck. Sharp dissection is performed laterally beneath the vaginal epithelium on each side to the level of the pubic bone. The endopelvic fascia is perforated sharply at the level of the urethra on each side. The retropubic space is entered.

**B**, Vaginal epithelial flaps are reflected laterally, and the “glistening” periurethral fascia is exposed. With sharp and blunt dissection, the urethra is mobilized laterally and circumferentially from the distal one third to the bladder neck. Attachments to the undersurface of the pubic bone are excised or swept down with the index finger retropubically. After initial mobilization, we place a long-nose right angle clamp around the urethra (ventrally or cephalad) under direct vision and pull through a Penrose drain. Downward traction on the Penrose further aids visualization and sharp dissection of all retropubic attachments. The index finger then may be placed completely around the urethra and against the posterior pubic bone. (From Nitti VW, Raz S: Obstruction following anti-incontinence procedures: Diagnosis and treatment with transvaginal urethrolysis *J Urol* 152:93-98, 1994.)

injury is the most common intraoperative complication and can be repaired laparoscopically.

#### Complications of the Artificial Urinary Sphincter

The current artificial urinary sphincter (AUS) device, the AS-800 (American Medical Systems, Minneapolis, MN), may be placed by a retropubic or transvaginal approach.<sup>132-135</sup> The abdominal approach has been supported, but dissection through the urethrovaginal septum may be difficult due to extensive scarring. In 1988, Appell described vaginal placement of the artificial urinary sphincter and reported a 100% success rate in 34 women with no increase in device infection or erosion rate.<sup>133</sup>

Although continence rates with the AUS are favorable (60% to 100%), the advent of periurethral bulking agents and modifications in sling surgery has created a limited role in women with intrinsic sphincter dysfunction. Mark and Webster compared the results of the AUS with those of the pubovaginal sling in 77 patients with intrinsic sphincter dysfunction.<sup>136</sup> Both procedures were favorable, with success rates of 84% and 91%, respectively. Complications associated with AUS implantation include erosion, infection, device failure, and intraoperative injury to the urethra, bladder, and/or vagina. Inadvertent injury to these organs should not necessarily preclude implantation of the device<sup>137</sup> but may affect the explantation rate.<sup>137,138</sup> In the series of Costa and associates,<sup>138</sup> 51 of 206 patients had intraoperative injuries, and 14 required explantation of the device at a median of 11 months after implantation. Risk factors for explantation include age, type and number of prior surgeries, elapsed time between last procedure and AUS insertion, and perioperative injury. Risk of erosion has decreased since the introduction of a modified cuff, but concerns of late urethral atrophy still exist. The reoperation rate for revision was reported to be 9% to 22% over a 2.5- to 3-year period.<sup>133,135</sup> Unlike in men, where infection is usually localized to the perineum and superficial abdominal wall, in women an infected device could result in a pelvic abscess requiring drainage.<sup>135</sup>

less analgesic use, shorter hospital stay, and faster return to normal voiding. Persson and colleagues<sup>130</sup> found no difference in cure rates at 1 year follow-up. In a separate trial of 33 patients randomized to undergo a laparoscopic Burch procedure, there were two cases of intravesical sutures, one bowel injury, three conversions to laparotomy because of adhesions, four patients with postoperative hematocrits lower than 28%, one ileus, and one pulmonary embolism.<sup>131</sup> A systematic review found laparoscopic colposuspension to have a 9% higher risk of failure after up to 18 months of follow-up.<sup>128</sup> Complications of laparoscopic surgery for SUI are similar to those of open surgery. Bladder

**Figure 49-9** **A**, Large submucosal tumor in lateral bladder wall of a patient with a history of periurethral collagen injection for intrinsic sphincter dysfunction. **B**, After resection, the tumor was found to be a collagenoma from previous collagen displacement of periurethral injection. **C**, Magnetic resonance image showing bladder neck collagenoma causing obstruction.

### Complications of Periurethral Bulking Agents

Periurethral bulking agents are placed submucosally, usually by injection, into the intrinsically damaged urethra and serve to increase coaptation and raise urethral resistance to increases in abdominal pressure (Fig. 49-9). Bulking agents can be delivered by a transurethral or a periurethral route.<sup>139</sup> Polytetrafluoroethylene (PTFE) paste, introduced in the 1970s, was the first bulking agent used.<sup>140</sup> There has been documented evidence of PTFE particle migration.<sup>141</sup> This has led to concerns regarding the safety of this procedure and has limited its use in the United States.

Glutaraldehyde cross-linked (GAX) collagen is the most widely used agent.<sup>142-144</sup> GAX collagen (Contigen, C.R. Bard Inc., Covington, GA) is a highly purified 35% suspension of bovine collagen in a phosphate buffer containing at least 95% type I collagen and 1% to 5% type III collagen. Due to a 1% to 4% reported incidence of allergic reaction to GAX collagen, all patients are skin-tested 1 month before planned treatment. Some patients have experienced delayed hypersensitivity reactions despite preoperative skin testing.<sup>145</sup>

The U.S. Food and Drug Administration approved the bulking agent Durasphere (Advanced UroScience, St. Paul, MN), which

consists of nonabsorbable pyrolytic carbon-coated zirconium oxide beads suspended in a water-based carrier gel. Target bead size ranges from 251 to 300  $\mu\text{m}$ , which is greater than the 80- $\mu\text{m}$  threshold for particle sizes associated with migration in tissue.<sup>145</sup> The pyrolytic carbon is nonreactive, has no associated antigenicity, and does not require preoperative skin testing. Complications associated with Durasphere are similar to those associated with collagen. The incidences of acute urinary retention and urgency may be higher with Durasphere (24.7% versus 16.9%, respectively) than with bovine collagen (11.9% and 3.4%, respectively).<sup>146</sup> Although Durasphere is reported to be nonmigratory,<sup>146</sup> Pannek and colleagues observed migration into local and distant lymph nodes, but this has unknown clinical significance.<sup>147</sup>

Complications associated with injection of periurethral bulking agents are rare and usually self-limited. The most common is transient urinary retention lasting 24 to 48 hours. Most series report transient retention rates of 1% to 10%.<sup>142-144,148,149</sup> One series reported a rate of 60%.<sup>150</sup> Retention beyond 48 hours is unusual. One series reported that 6% of patients had transient retention of 2 weeks.<sup>150</sup> Our own experience is that difficulty in emptying occurs in about 1% of patients and almost always

resolves within 24 hours. Transient hematuria has been reported in 2% to 16% of cases.<sup>142,148</sup> Transient irritative voiding symptoms, including urge incontinence, may occur in 8% to 10% of patients.<sup>149,150</sup> The incidence of UTI is similarly low (0% to 12%).<sup>148-151</sup> Complications reported with periurethral bulking agents resolve quickly and are usually minor.

## CONCLUSION

Pelvic floor surgeons treat SUI with a variety of effective procedures. Performing a thorough evaluation before treatment achieves the best short- and long-term results. Use of the appropriate surgical procedure for an individual patient lessens the likelihood of complications and morbidity. However, complications are unavoidable with surgical procedures. Patients should be informed of common potential complications, and their treatment, before surgery. A well-informed patient, one who understands a range of treatments and surgeries as well as their success and complication rates, will be the most satisfied patient.

# FEMALE SEXUAL FUNCTION AND DYSFUNCTION

*Irwin Goldstein*

Why is there a chapter concerning women's sexual function and dysfunction in a textbook entitled *Female Urology*? The answer should be obvious. Urologists and gynecologists who practice "female urology" will encounter women with sexual health concerns.<sup>1,2</sup>

A woman's general health is a fundamental human right. If this is accepted, then urologic health and gynecologic health are fundamental human rights. If this is accepted, then sexual health should be a fundamental human right. If sexual health is a woman's fundamental human right, then health care providers need to be educated on the fundamentals of women's sexual health care delivery.<sup>3,4</sup>

The goal of a female urologic practice must be to maximize "female urology" health care delivery to all women, and this includes maximizing sexual health care delivery to women. Currently, there are limited numbers of female urology health care professionals offering comprehensive psychological and biologic sexual health care for women.

It is the objective of this chapter to help the interested female urologist to achieve the goal of maximizing sexual health care delivery to all their women patients. The aim is to provide relevant, evidence-based clinical information to help diagnose and treat specific biologic-based sexual health pathophysiologies. It is neither logical nor rational to continue to focus sexual health care delivery primarily on males with sexual health concerns, as is currently occurring in medicine.

It is not within the realm of this chapter to thoroughly discuss psychological management of sexual health issues in women. Even though health care professionals need to be holistic in managing female (and male) sexual dysfunction, the goals of this chapter are to educate the biologic-focused health care professional on how to identify the pathologies associated with the sexual health concerns and to provide evidence-based safe and effective biologic management strategies. A clinical, biologic-based paradigm is presented at the end of the chapter, founded on results derived from emerging basic science and evidence-based data drawn from clinical research.

Ideally, state-of-the-art sexual health care for afflicted women and couples will be directed from medical school-based sexual medicine centers that are devoted to the study, diagnosis, and treatment of men and women with sexual disorders. These facilities will be composed of multidisciplinary groups, including female urologists. Cases in such multidisciplinary centers would be managed by a team of allied health care professionals, mental health care professionals, and physical therapists, under the direction of sexual medicine physicians who may be board-certified in urology or female urology.

## SEXUAL HEALTH

According to the World Health Organization,<sup>3</sup> sexual health "refers to a state of physical, emotional, mental, and social well-being related to sexuality." All women have the right to a "positive and respectful approach to sexuality and sexual relationships, having pleasurable and safe sexual experiences, free of coercion, discrimination and violence." Moreover, "For sexual health to be attained and maintained, the sexual rights of all persons must be respected, protected and fulfilled."<sup>3</sup>

The World Association of Sexual Health has stated<sup>4</sup> that women (and men) have the right to sexual equity—the freedom from all forms of discrimination regardless of sex, gender, sexual orientation, age, race, social class, religion, or physical and emotional disability." Women (and men) also have the right to sexual pleasure—sexual pleasure is a source of physical, psychological, intellectual, and spiritual well-being.

## What are the Barriers to Providing Women's Sexual Health Care in the Female Urology Practice

Physicians in general and female urologists in particular face a challenge in finding the time and opportunity to discuss their women patient's sexual health concerns, especially with the increasing and growing demands for other health care issues, including the significant financial pressures of providing "managed care." Additionally, most physicians have limited training in the diagnosis and treatment of sexual health concerns. Currently, American medical schools devote on average less than 10 hours to sexual medicine education.<sup>5</sup> Independent of the physicians, patients are also often unwilling or too uncomfortable to initiate a discussion about their own sexual problems.<sup>6</sup>

Sexual medicine issues are complex, and it is often difficult to separate psychological issues and interpersonal relationship concerns from biologic disorders.<sup>7</sup> There are only limited evidence-based data available for diagnosis and management. Sexual health concerns are, in general, secondary to mind, body, and relationship issues that are interrelated in unique and individual ways and molded with distinct couple dynamics to cause the particular sexual problem.<sup>7</sup> Psychological factors include previous sexual trauma and abuse, sexual neuroses, sexual inhibitions or idiosyncrasies, and interpersonal relationship issues.<sup>8</sup> Biologic factors may involve such pertinent aspects as aging; exposure to vascular risk factors; urologic conditions such as interstitial cystitis, previous radical cystectomy, and recurrent urinary tract infections; gynecologic conditions such as endometriosis, previous hyster-

**Figure 50-1** Examination of the genitalia exposed to a normal hormonal milieu reveals a well-defined and robust clitoral glans and corona, bilateral frenular tissue, bilateral labia minora, shiny vaginal lubricating material, and vaginal rugae. The clitoral prepuce is retracted.

ectomy, childbirth, infertility issues, and sexually transmitted infections; inflammation; abnormal immunologic conditions; abnormal hormonal states (Figs. 50-1 and 50-2); tumors; mechanical compartment syndromes; blunt or penetrating traumatic injury; tissue weakness with organ prolapse; and others. Sexual health problems may also stem from the contribution of the male partner in women's sexual health.<sup>1,7,8</sup>

### Why Should Female Urology Practice Expand to Include Women's Sexual Health Care

Female urologists offer urogynecologic health care to women, and this should include comprehensive sexual health care. Over the last 30 years, urologic specialists have led the many advances realized in the biologic-based knowledge in sexual medicine.<sup>9</sup> Furthermore, urologists have revolutionized the therapeutic armamentarium for contemporary management of biologic-focused men's sexual health care.<sup>9</sup> Practically, female urologists are in a unique position to understand that female peripheral sexual organs are an essential component of the anatomy and physiology of the peripheral genitalia and pelvic floor constituents.

Many population-based studies have revealed a high prevalence of sexual health concerns in women of all ages.<sup>2,8,10-15</sup> A woman's sexual problems can cause significant personal distress in approximately 25% of those with sexual health concerns, including a diminution of self-worth and self-esteem, a reduction in life satisfaction, and a decline in the quality of her relationship with her partner.<sup>10-15</sup> Many investigations have shown that a satisfying sex life is important to most women throughout most of their lives.<sup>16</sup> As life expectancy increases, there are increasing numbers of aging women.<sup>17</sup> Sexual health concerns are more common among aging women than among younger women.<sup>10-15</sup> The number of postmenopausal women worldwide in the year 2000 was 569 million; that number is projected to grow to 967 million by 2020 and to 1.2 billion by 2030.<sup>17</sup> As a result of the controversy concerning hormone therapy that followed the

**Figure 50-2** Examination of the genitalia exposed to an abnormally low hormonal milieu reveals an atrophied, poorly defined clitoral glans. The corona and bilateral frenular tissue are not visible. The clitoral prepuce is phimotic, the vaginal rugae are absent, and the vestibular tissue appear erythematous.

release of the Women's Health Initiative findings in 2002<sup>18</sup> millions of menopausal women altered and or discontinued hormone therapy practices, and this directly influenced many women's subsequent vaginal physiology and sexual interest states.<sup>19</sup> As the decline in estrogen production begins in transition to menopause, sexual dysfunction becomes common, often interfering with women's interest in, and satisfaction with, sexual activity.

It is important to note the existence of the International Society for the Study of Women's Sexual Health (ISSWSH), an international, multidisciplinary, academic, clinical, and scientific organization. The purposes of ISSWSH are to provide opportunities for communication among scholars, researchers, and practitioners about women's sexual health; to support the highest standards of ethics and professionalism in research, education, and clinical practice relative to women's sexual health; and to provide the public with accurate information about women's sexual health. Interested health care professionals should visit the organization's web site, (<http://www.isswsh.org>) for more information. More detailed information about ISSWSH and the management of women's sexual health concerns may be found in the multidisciplinary textbook written primarily by ISSWSH members entitled, *Women's Sexual Function and Dysfunction: Study, Diagnosis and Treatment*.<sup>20</sup>

## EPIDEMIOLOGY AND CLASSIFICATION

There are limited population-based epidemiologic studies of women with sexual health concerns.<sup>2,8,10-15</sup> Based on current published information, the following is the most contemporary, internationally consensed classification system.<sup>21</sup>

*Women's sexual interest/desire disorder:* Absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies and a lack of responsive desire. Motivations (here defined as reasons/incentives) for attempting to become sexually aroused are scarce or absent. The lack of interest is considered to be beyond a normative lessening with life cycle and relationship duration.

*Subjective sexual arousal disorder:* Absence of or markedly diminished feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of sexual stimulation. Vaginal lubrication or other signs of physical response still occur.

*Genital sexual arousal disorder:* Complaints of absent or impaired genital sexual arousal. Self-reports may include minimal vulval swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensations from caressing genitalia. Subjective sexual excitement still occurs from nongenital sexual stimuli.

*Combined genital and subjective arousal disorder:* Absence of, or markedly diminished feelings of, sexual arousal (sexual excitement and sexual pleasure) from any type of sexual stimulation as well as complaints of absent or impaired genital sexual arousal (vulval swelling, lubrication).

*Persistent sexual arousal disorder:* Spontaneous, intrusive and unwanted genital arousal (e.g., tingling, throbbing, pulsating) in the absence of sexual interest and desire. Any awareness of subjective arousal is typically but not invariably unpleasant. The arousal is unrelieved by one or more orgasms and the feelings of arousal persist for hours or days.

*Women's orgasmic disorder:* Despite the self-report of high sexual arousal/excitement, there is either lack of orgasm, markedly diminished intensity of orgasmic sensations or marked delay of orgasm from any kind of stimulation.

*Dyspareunia:* Persistent or recurrent pain with attempted or complete vaginal entry and/or penile vaginal intercourse.

*Vaginismus:* Persistent difficulties to allow vaginal entry of a penis, a finger, and/or any object, despite the woman's expressed wish to do so. There is variable involuntary pelvic muscle contraction, (phobic) avoidance and anticipation/fear/experience of pain. Structural or other physical abnormalities must be ruled out/addressed.

*Sexual aversion disorder:* Extreme anxiety and/or disgust at the anticipation of/or attempt to have any sexual activity.

Laumann and associates, in a U.S. population-based study of more than 1700 women, observed that more than 40% reported sexual health concerns.<sup>15</sup> In that investigation, the most common sexual health concern was lack of sexual desire, followed by inability to achieve orgasm, lack of pleasure from sex, and pain during sex. Poor health, emotional problems or stress, decline in social status, and having ever been forced sexually were among the factors associated with low desire, arousal disorder, and sexual pain. A worldwide survey of more than 27,000 men and women aged 40 to 80 years assessed the relevance of sex and the prevalence of sexual dysfunction.<sup>22</sup> In that survey, women's sexual health concerns were classified into five subcategories: lack of interest in sex, inability to achieve orgasm, lubrication difficulties (dryness), sex not pleasurable, and pain during sexual intercourse (dyspareunia). The percentage of women who reported having at least one sexual health concern on a frequent or persistent basis was 39%. The percentage of women who reported having only one of the five sexual health concerns ranged from 10% for "dyspareunia" to 21% for "lack of interest in sex."<sup>8,22</sup>

Contemporary international prevalence data concerning women's sexual health problems, are represented in Table 50-1.<sup>2,8,10-15,22</sup>

**Table 50-1 Estimated International Prevalence of Women's Sexual Health Concerns from Various Studies**

Concern	Current Prevalence (%)	1-Year Prevalence (%)	Lifetime Prevalence (%)
Problems with sexual desire or sexual interest	7		31
Problems with excitement or pleasure		23	20
Lubrication difficulties or vaginal dryness		20	19-23
Infrequent orgasm or difficulties in reaching orgasm			4-41
Inability to experience orgasm			
For several months	16*		
For 2 months or longer	18 <sup>†</sup>		
More than 50% of the time	25 <sup>†</sup>		
Pain during or after sex	3-48		17-19 (population-based) 10-20 (clinic-based)
Any problem with desire, arousal, orgasm, or pain	33-35 <sup>‡</sup>		
Any current sexual problem	45 <sup>§</sup>		
Any sexual problem	43		

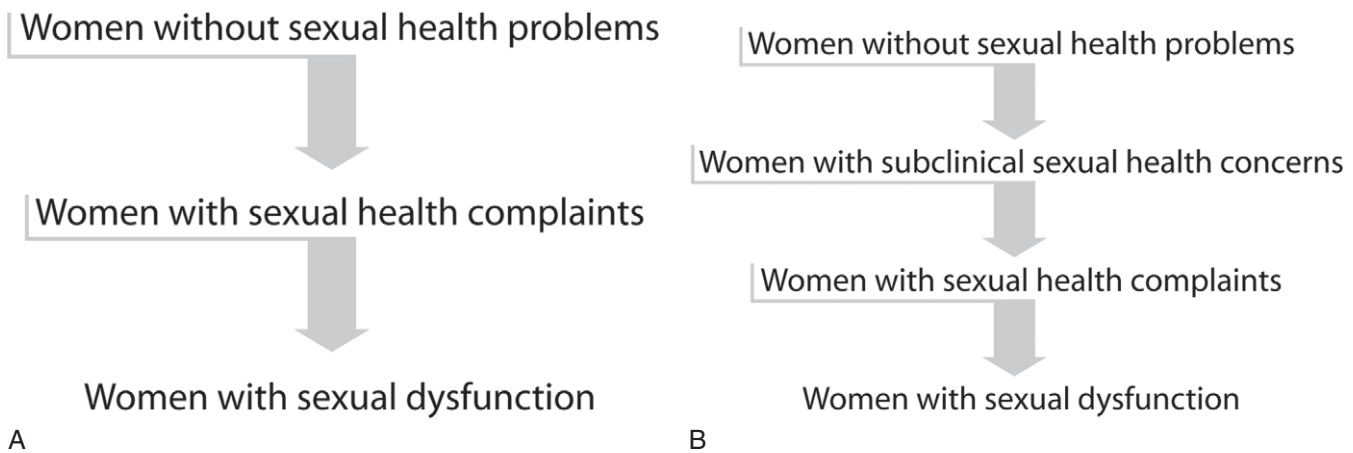

\*Estimate is from a single population-based study.

<sup>†</sup>Both estimates are from a single population-based study.

<sup>‡</sup>Estimates are from two population-based surveys using similar instruments.

<sup>§</sup>Estimate (1-month prevalence) is from a single national study.

Data from references 2, 8, 10-15, 22.

**Figure 50-3** **A**, It is proposed that, in the clinical spectrum of women's sexual function/dysfunction, there is an as yet undefined continuum of conditions that gradually blend into each other such that it is difficult to say where one stage becomes the next. In the continuum hypothesis of women's sexual health complaints, there are women without sexual health problems, women with specific conditions of frank sexual dysfunction, and an intermediate group including women with sexual health complaints. **B**, In the continuum hypothesis of women's sexual health complaints, the intermediate stage may begin in some asymptomatic women with a recognizable subclinical stage in which abnormal testing or laboratory values may be a harbinger that precedes overt symptoms and distress.

### The Continuum Hypothesis for Women's Sexual Health Concerns

In various medical conditions, there are those individuals who are free of a specific condition and there are those, at the opposite end of the spectrum, who are afflicted with the overt clinical manifestations of the condition. The same must hold true for women's sexual health conditions. There likely is an as yet undefined continuum whereby women without sexual health problems ultimately develop the condition of frank sexual dysfunction. A continuum may be considered as a continuous series of events that blend into each other so gradually and seamlessly that it is impossible to say where one stage becomes the next.

One hypothesis is that women without the condition first develop an intermediate stage involving complaints of problems with sexual desire, arousal, lubrication, sensation, orgasm, and pain without any accompanying personal distress.<sup>23</sup> The pathophysiology is most likely multifactorial and may be secondary to medical conditions such as hormonal milieu changes or vascular disease; psychological conditions such as depression; medications that may contribute to symptoms, such selective serotonin reuptake inhibitors and antipsychotics; or any other social or relationship issues that may play a role, such as a history of sexual abuse or partner-related issues. Ultimately, when personal distress results as a consequence of the persistence or intensity of the sexual symptoms, the problem is considered to have evolved into frank sexual dysfunction (Fig. 50-3A).<sup>23,24</sup>

Consistent with the hypothesis that sexual health concerns exist in a continuum, one may then introduce the additional concept of an earlier intermediate stage. The idea of a subclinical stage of women's sexual health concerns, one that occurs before the onset of overt symptoms but is recognized clinically by abnormal questionnaire results and/or laboratory values, comes from recent prospective, multi-institutional studies.<sup>25,26</sup> With the goal of defining androgen levels in a premenopausal population, prospective candidates underwent an initial interview to identify those "free of sexual health problems." Women who met inclu-

sion and exclusion criteria subsequently underwent determination of androgen levels and completion of a validated sexual function questionnaire on which low scores indicated poor sexual function. A subgroup of women from that study, who perceived themselves as having no deficits in sexual function and presented to take part in the study as the control population, were found to have scores on the validated sexual function questionnaire consistent with sexual health problems. These abnormal findings precluded their inclusion in the control group. We subsequently attempted to better characterize the women in this group by recording androgen levels. In these asymptomatic women with low validated sexual function questionnaire scores, androgen levels were found to be virtually indistinguishable from those of women with symptomatic sexual dysfunction and significantly lower than those of women who denied sexual concerns and scored higher on the validated sexual function questionnaire.

The concept of a subclinical stage of a medical condition is well established in the literature. For example, subclinical hypothyroidism<sup>27</sup> is considered to exist when there is an abnormally elevated thyroid-stimulating hormone level in a patient who has not yet manifested obvious or evident symptoms of hypothyroidism (e.g., fatigue, depression, osteoporosis, weight gain). Other scenarios of subclinical medical conditions are well described, such as impaired glucose tolerance, elevated liver function tests,<sup>28</sup> or abnormal electrocardiogram associated with early coronary atherosclerosis.<sup>29</sup> The term *subclinical* refers to those situations in which abnormal testing or laboratory values may be a harbinger that precedes overt symptoms of the condition.

There is a previously undefined population of women who claim an absence of sexual health problems on initial clinical interview but who are found to have validated psychometric questionnaire scores consistent with the presence of sexual health concerns and androgen levels comparable to those seen with androgen insufficiency. It is hypothesized that the development and progression of women's sexual health problems follows a continuum. In this continuum hypothesis, women without sexual health complaints may progress first through a subclinical

stage, followed by a symptomatic stage, and subsequently develop frank sexual dysfunction when the sexual problem becomes clinically meaningful and is associated with personal distress (see Fig. 50-3B). Future research studies are needed to assess the relevance of these intermediate stages of women's sexual health, in general, and the subclinical state of female sexual dysfunction, specifically. In particular, it would be of interest to investigate the role of any prophylactic management strategies, psychological and biologic, that may halt the development of future overt clinical symptoms and/or frank sexual dysfunction.

## PHYSIOLOGY AND PATHOPHYSIOLOGY

### Effect of the Male Partner who has Erectile Dysfunction

Whereas substantial investigation has taken place on the effects of selective phosphodiesterase type 5 (PDE5) inhibitors in men with erectile dysfunction (ED), little attention has been given to the sexual responses of their female partners. A typical inclusion criterion in the trials of such drugs was the existence of a stable heterosexual relationship. Participation of the woman was voluntary and was limited to assessments of treatment satisfaction. The female partners of men with ED were thought to unconditionally support their partners' sexual treatment. The issues relating to the perspective of the woman, her well-being, quality of life, sexual function and sexual satisfaction, in relation to either existing or successfully treated ED, were not taken into consideration.

Couples share their sexual dysfunctions. Women with men who have ED may have their own sexual function adversely affected. What are the scientific data available concerning changes in sexual function among those women whose partners have ED? Blumel and colleagues examined a sample of 534 otherwise healthy women who had ceased sexual activity with their male partners. It was noted that, in the cohort younger than 45 years of age, ED was the most frequently cited reason for cessation of the woman's sexual activity.<sup>30</sup>

Initial studies were, however, obtained with data from the man's perspective. Past research in this area involved inquiries addressed to men with ED about the effect of their sexual problem on their women partners. One study showed significant improvement in the marital interaction score when men with ED used a selective PDE5 inhibitor.<sup>31</sup>

Contemporary research has finally begun to address the issue from the woman's perspective. Data from several investigations are derived from the woman herself, as her own study subject. Cayan and colleagues performed a prospective study assessing the sexual function of women with men who had ED.<sup>32</sup> The study involved 38 such women, as well as a control group of 49 women whose male partner did not have ED. Women's sexual functions, including sexual arousal, lubrication, orgasm, satisfaction, pain, and total score, were significantly diminished among women with men who had ED. Among those women whose male partners received treatment (penile prosthesis insertion, oral PDE5 inhibitor treatment) for their ED, significant improvements in sexual arousal, lubrication, orgasm, satisfaction, and pain in the women were identified.

Montorsi and Althof investigated thoughts and views on intercourse satisfaction in 930 women whose male partners were taking a selective PDE5 inhibitor to manage ED.<sup>33</sup> These women

had significantly higher intercourse satisfaction than did women whose men were using a placebo.

Chevret and coworkers developed and validated the Index of Sexual Life to measure sexual function of women in relationships with men with ED.<sup>34</sup> Such women were found to have significantly diminished sexual drive and sexual satisfaction compared to women whose male partners did not have ED.

Oberg and colleagues examined data from a nationally representative Swedish cross-sectional population investigation of sexual life, attitudes, and behavior.<sup>11</sup> A total of 926 women, aged 18 to 65 years, were sexually active in a steady heterosexual relationship during the 12 months before the investigation. Data from women who claimed personally distressing sexual dysfunctions quite often, almost all the time, or all the time were compared with data from women who had no sexually dysfunctional distress. Women reporting distress due to low sexual interest or orgasmic dysfunction were very likely to have a partner with an ED (odds ratios, 47.6 and 20.0, respectively).

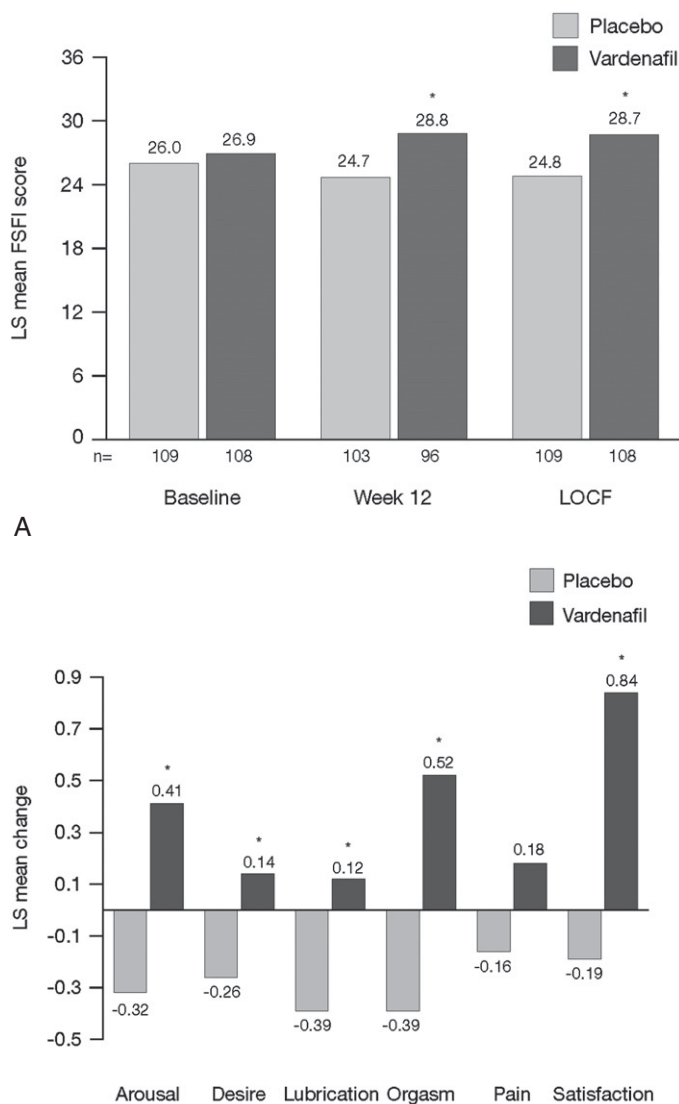

In the Female Experience of Men's Attitudes to Life Events and Sexuality study,<sup>35</sup> data were analyzed from 283 women in eight countries whose male partners had ED. They were asked questions comparing their sexual activity, sexual function, and beliefs about sexuality before and since their partner had experienced difficulties with erection. Data were stratified by the man's self-reported degree of ED (mild, moderate, or severe). Women whose partners had ED reported a lower frequency of sexual activity currently, compared with before their partner developed erectile difficulties. Significantly fewer women reported that they experienced sexual desire, sexual arousal, orgasm, or sexual satisfaction ("almost always" or "most times") currently, compared with before their partner developed erectile difficulties. There was a significant correlation between the reduction in the woman's frequency of orgasm, and her reduction in sexual satisfaction, and the degree of her partner's self-reported ED. Women had the lowest frequency of orgasm and the lowest satisfaction with the sexual experience when their partners had severe ED.

Scientific data were obtained from a double-blind, multicenter, 3-month, randomized trial involving men with ED who had been in a stable heterosexual couple relationship for at least 6 months.<sup>36,37</sup> In this trial, women whose male partner had ED were asked at initial screening to complete the validated Female Sexual Function Inventory. Significant improvement in the woman's sexual function and sexual satisfaction were observed after their partner was treated with a selective PDE5 inhibitor, vardenafil (Fig. 50-4) versus placebo.

### Effect of the Male Partner Who Has Premature Ejaculation

Because premature ejaculation is the most common male sexual dysfunction, affecting approximately 25% of men, it is likely that many women will experience a sexual relationship with a man with premature ejaculation.<sup>38</sup> Premature ejaculation is objectively determined using a stopwatch to record intravaginal ejaculatory latency time, defined as the time between vaginal intromission and intravaginal ejaculation. It has been suggested that an intravaginal ejaculatory latency time of 2 minutes or less may serve as a criterion for defining premature ejaculation.<sup>39</sup>

Women with men who have premature ejaculation may have significant distress, interpersonal difficulties, and dissatisfaction with sexual intercourse.<sup>40</sup> The woman's distress is a common

**Figure 50-4 A**, At baseline, there was no difference in total Female Sexual Function Index (FSFI) scores of untreated woman whose partners with erectile dysfunction were assigned to placebo versus treatment with vardenafil, a selective phosphodiesterase type 5 (PDE5) inhibitor. At 3 months or last observation carried forward (LOCF), the total FSFI score fell if the woman's partner was assigned to placebo and increased if he was assigned to PDE5 inhibitor treatment. The total FSFI scores were significantly different (*asterisk*) between placebo and active groups by Week 12 and at LOCF. **B**, At 3 months, those untreated women whose male partners with erectile dysfunction received the active PDE5 inhibitor vardenafil had significant increases in all domains of the FSFI except for sexual pain; those whose partners received placebo had significant decreases in all domains of the FSFI except for sexual pain.

reason for the man to consult a clinician about premature ejaculation.

Byers and Grenier investigated the effect of premature ejaculation on the sexual function of 152 couples.<sup>41</sup> Concerning the couple's perceptions of whether the premature ejaculation was a problem, reports of women and men were only moderately correlated. For both the women and the men, having more

premature ejaculation characteristics was related to lower sexual satisfaction. The results suggested that, for most couples, the premature or early timing of ejaculation adversely affects sexual satisfaction.

Patrick and colleagues<sup>40</sup> carefully selected patients with and without premature ejaculation based on stopwatch testing. The mean intravaginal ejaculatory latency time was 1.8 minutes in the 207 men with premature ejaculation. This was significantly lower than the time (7.3 minutes) in the 1380 men without premature ejaculation. Women whose male partner had premature ejaculation had significantly decreased satisfaction with sexual intercourse and significantly increased interpersonal difficulty and distress, compared to women whose partner did not have premature ejaculation ( $P < .0001$ ). They also reported "poor" or "very poor" satisfaction with sexual intercourse (28% versus 2%) and gave worse ratings ("quite a bit" or "extremely") for personal distress (44% versus 3%) and interpersonal difficulty (25% versus 2%), compared to women whose partner did not have premature ejaculation ( $P < .0001$ ).

### Changes in the Female Genitalia with Aging

The structure and function of a woman's genitalia are highly dependent on the sex steroid hormonal milieu.<sup>1,19,42-46</sup> As a woman ages or a young woman is exposed to medicines that interfere with the hormonal milieu (e.g., oral contraceptives, tamoxifene), her supply of sex steroid hormones (estradiol, testosterone, and progesterone) diminishes significantly.<sup>1,19</sup>

Of importance, not all women have absent estradiol synthesis in the menopause. During menopause, ovarian estradiol production ceases in all women. However, estrogen continues to be synthesized in the periphery (e.g., skin, adipose tissue, bone, muscle) in postmenopausal women through conversion of androstenedione to estrone and testosterone to estradiol, but the amount of estradiol synthesized depends, in part, on the enzymatic activity of aromatase.

Estrogens and androgens are required for genital tissue structure and function.<sup>19</sup> These hormones act on estrogen and androgen receptors, respectively, which exist in high numbers in genital tissues, including the epithelial/endothelial cells and smooth muscle cells of the vagina, vulva, vestibule, labia, and urethra. Diminished estrogen production for natural or iatrogenic reasons renders women's genital tissues highly susceptible to atrophy (see Figs. 50-1 and 50-2). Physical examination<sup>7,47</sup> of the postmenopausal woman's genitalia shows clitoral atrophy, phimosis, and nearly absent labia minora (Fig. 50-5). The appearance of a woman's labia minora mirrors her level of estradiol, because these labia are exquisitely sensitive to estradiol. The urogenital area termed the vestibule is very important in female sexual function because it contains organs that are sensitive to both estrogen and androgen. For example, the clitoral tissues and prepuce are androgen sensitive. The minor vestibular glands (Fig. 50-6), which are located in the labial-hymenal junction, are embryologically derived from the glands of Littre, which are also androgen dependent. The glands of Littre are located on the anterior surface of the urethra.

A host of structural changes and cellular dysfunctions occur in women's genital tissues as a result of estrogen deficiency.<sup>7,48-51</sup> For example, estrogen deficiency specifically in the vagina leads to vaginal atrophy. One consequence is an alteration in the normally acidic vaginal pH that discourages the growth of pathogenic bacteria. The change to an alkaline pH value in the atrophic

**Figure 50-5** This is a photograph of a postmenopausal woman with clitoral atrophy, phimosis, and nearly absent labia minora.

**Figure 50-6** This is a photograph of a premenopausal woman with bilateral erythema overlying the minor vestibular glands at the labial-hymenal junction. Note also the clitoral atrophy, phimosis, and nearly absent labia minora.

vagina leads to a shift in the vaginal flora, increasing the likelihood of discharge and odor. In an estrogen-rich environment, glycogen from sloughed epithelial cells is hydrolyzed into glucose and then metabolized to lactic acid by normal vaginal flora. In postmenopausal women, however, epithelial thinning reduces the available glycogen.

In addition to vaginal atrophy and a reduction in organ size, other signs of a decline in sex hormones in women include vaginal dryness, absent secretions or lubrication, pale or inflamed tissue, petechiae, epithelial/mucosal thinning, organ prolapse, changes in external genitalia, decreased tissue elasticity, and loss of smooth muscle. Symptoms of women's sexual health concerns that the clinician may elicit when taking a history in a menopausal woman are include dyspareunia, vaginismus, coital anorgasmia, vaginal and/or urinary tract infections (pH imbalance), and overactive bladder/incontinence.<sup>7,48-52</sup>

### Effects of Sex Steroid Hormones on the Vagina

The human vagina consists of three layers of tissue: the epithelium (composed of squamous cells), the lamina propria, and the muscularis (inner circular and outer longitudinal smooth muscle). The epithelium undergoes mild changes during the menstrual cycle. The lamina propria is replete with tiny blood vessels that become engorged with blood during sexual arousal, leading to lubrication. The smooth muscle of the muscularis enables the vagina to dilate and lengthen during penile penetration. Relaxation of that muscle leads to arousal. These three layers of tissue may function in an interrelated way (Fig. 50-7). It is hypothesized that the blood vessels in the lamina propria that allow for lubrication are dependent on growth factors, and that the growth factors are derived from the muscularis. Postmenopausal atrophy of vaginal tissues may be caused by decreased synthesis these growth factors that results in diminished number of critical blood vessels in the lamina propria.

**Figure 50-7** A grid overlies a histologic section of animal vagina illustrating the epithelium (*left side of section*), the lamina propria (*middle*) and the vaginal muscularis (*right side*). The grid is used to objectively measure the structural changes in the various vaginal layers in response to oophorectomy and then replacement by various doses and combinations of sex steroid hormones.

Controlled studies employing a rat model of vaginal atrophy demonstrated the effects of various dosages of estrogen, progesterin, testosterone, and combinations of these hormones on physiologic and anatomic outcome parameters.<sup>52</sup> These measures included organ wet weight, vaginal blood flow, epithelial height, muscularis thickness, and vaginal innervation. In each study, the effects on the vagina of the hormones being tested were compared between rats that had undergone sham ovariectomies and rats that had actually had both ovaries removed. The hormones (or saline) were delivered through a pump inserted into the back of the neck of each animal. A Doppler probe inserted into the vagina was used to record blood flow after electrical stimulation of a nerve next to the vagina. All animals were then killed, and vaginal tissue was removed for biochemical or histologic studies. Removal of the ovaries was found to reduce the wet weight of the uterus, which rose again with administration of estrogen, because the uterus is a very estrogen-sensitive organ, much more so than the vagina.

Increased vaginal blood flow is an indicator of sexual arousal. Genital swelling and lubrication are responses to increased clitoral and vaginal perfusion; increased length and diameter of the vaginal canal and clitoral corpora cavernosa; engorgement of the vagina wall, clitoris, labia majora, and labia minora; and transudation of lubricating fluid from the vaginal epithelium. In the animal studies just described, blood flow to the vagina was greatly reduced in the oophorectomized rats compared with the intact rats. Contrary to what one might expect, subphysiologic doses of estradiol increased vaginal blood flow in oophorectomized rats more than either physiologic or supraphysiologic doses.<sup>52</sup> Ovariectomy deprived the rats of estradiol, causing the vaginal epithelium to thin down to a single layer. Subphysiologic doses of estradiol increased the thickness of the vaginal epithelium most, because the oophorectomized rats had more estrogen ER $\alpha$  receptors in the epithelium than the intact animals did. A small amount of estradiol delivered to tissue with many estrogen ER $\alpha$  receptors produced a huge response. Thus, estradiol regulates estrogen receptors through a negative feedback system. The more estradiol that is available, the fewer estrogen receptors there are. The muscularis, the muscle that enables the vagina to lengthen and widen during sexual arousal, also atrophies without estrogen. In postmenopausal women who do not take hormone therapy, the vaginal epithelium, lamina propria blood vessels, and muscularis all decrease. Like the epithelium, the muscularis responds to estradiol by increasing in thickness.<sup>52</sup>

### Role of the Pelvic Floor in Women's Sexual Function

Female urologists are familiar with the diagnosis and treatment of disorders of the female pelvic floor, especially bladder/urethra and sexual dysfunction. Normal function of the pelvic floor musculature is essential in maintaining appropriate sexual function. Both "low-tone pelvic floor dysfunction" and "high-tone pelvic floor muscle dysfunction" can be closely associated with women's sexual health concerns.<sup>53-57</sup> Hypotonus of the pelvic floor muscles, resulting from childbirth, trauma, and/or aging, is related to urinary incontinence during orgasm, vaginal laxity, and/or thrusting dyspareunia secondary to pelvic organ prolapse. Hypertonus of the pelvic floor caused by childbirth, postural stressors, microtrauma, infection, adhesions, or surgical trauma and can contribute to symptoms of urinary retention, reduced force of stream, dysuria, urgency, penetrative dyspareunia, and/or vaginismus.<sup>53-61</sup>

The assessment of tone in the pelvic floor is determined by the woman's ability to isolate, contract, and relax the pelvic floor muscles. During a pelvic examination, a digital examination is used to assess pelvic floor tone; light pressure is exerted on the lateral walls of the vagina while the woman is asked to squeeze on the examining finger and to elevate the pelvic floor without simultaneously contracting the abdominal, gluteal, or adductor muscle groups. If the patient is not able to produce sufficient muscle strength to compress the finger or is not able to sustain that pressure for several seconds, she may be exhibiting a low-tone pelvic floor dysfunction pattern. Conversely, if the woman experiences muscle tenderness or pain when pressure is applied to the lateral vaginal wall or during an attempted squeeze against resistance, she may be exhibiting a high-tone pelvic floor dysfunction pattern. A perineometer or an electromyography probe designed to measure muscle activity can verify these physical examination findings.<sup>53-61</sup>

Hypersensitivity disorders involving the genitourinary tract represent a spectrum of symptoms and conditions that include chronic bacterial cystitis, urgency and frequency syndrome, sensory urgency, urethral syndrome, interstitial cystitis, vulvar pain, vaginal pain, perineal pain, and pelvic pain. Hypersensitivity disorders, associated with hypertonus of the pelvic floor musculature, account for some of the concerns of female patients who present for evaluation of sexual health concerns. Sexuality is adversely affected for most women with hypersensitivity disorders of the bladder, bowel, or vulva or high-tone pelvic floor dysfunction. Those that are able to tolerate coitus often suffer a flare of their symptoms for days as a result of sexual activity, and this becomes a negative reinforcement for future sexual activity.<sup>53-61</sup>

Weakness and laxity of the pelvic floor muscles represent a spectrum of symptoms and conditions that include pelvic organ prolapse with or without urinary or fecal incontinence. Risk factors include age, heredity, vaginal birth trauma, previous pelvic/vaginal surgery, history of radiation therapy, menopausal status, lifestyle factors such as strenuous lifting, and chronic medical conditions including obstructive pulmonary disease, obesity, and constipation. Stress incontinence that occurs with increased intra-abdominal pressure and maneuvers such as sneezing, coughing, and straining is related to abnormalities in urethral closure and poor pelvic muscle support. Sexuality is often adversely affected for women with severe low-tone pelvic floor dysfunction, especially for those with severe incontinence and prolapse in whom symptoms are a source of anxiety and interfere with the overall sense of sexual satisfaction. Women who experience incontinence during intercourse express concern about feeling undesirable, fearing embarrassment, and possibly infecting themselves or their partner.<sup>53-61</sup>

### Urethritis, Recurrent Urinary Tract Infections, and Interstitial Cystitis

It is very common for women, especially during transition and in menopause, to complain of irritative voiding symptoms, especially burning, frequency, urgency, and nocturia, which significantly interfere with sexual activity.<sup>62-65</sup> In such women, the vulvovaginal and urinary irritative and burning symptoms are often poorly defined. Patient and physician confusion in this area occurs because the differential diagnosis of irritation and burning in the perineum, especially after coitus, involves multiple different urologic and gynecologic conditions. Urologic conditions

that do not involve the urethral meatus include, for example, recurrent urethritis, recurrent urinary tract infections, urethral diverticula, irritable bladder, cystocele, ureteral stones, and endometriosis of the ureter and/or bladder. Irritative symptoms that occur during voiding, especially after coitus, may also be associated with inflammatory gynecologic conditions. In such situations, the contact of voided urine against the inflamed vestibular, vulvar, and/or vaginal tissues can result in significant perineal burning and stinging. Vaginal yeast infections, vulvar dermatitis conditions, and uterine prolapse with or without rectocele are common gynecologic pathophysiologies. In many cases, expert urologic and gynecologic consultations are required to confirm the multiple diagnoses in the individual patient so that varied specific focused treatments may be initiated.<sup>62-65</sup>

One rare genital sexual pain condition, called “interstitial cystitis,” is confusing and ill-defined; it is associated with severe urogenital and pelvic pain, urgency, frequency, nocturia, and dyspareunia.<sup>53,66</sup> The pathophysiology of interstitial cystitis is unknown but appears to be unrelated to any recognized bacterial pathophysiology. Interstitial cystitis symptoms, including the dyspareunia, often increase with the menses, increase during bladder filling, and decrease with bladder emptying. There is no definitive diagnostic test for interstitial cystitis. History, physical examination, urinalysis, urine culture, and maintenance of a voiding log are mandatory. Specific patient questionnaires are often useful. Other specific testing procedures include potassium sensitivity testing and cystoscopy with or without hydrodistention. Because it relates to the dyspareunia and genital sexual pain component associated with interstitial cystitis, treatment of the underlying condition is important.<sup>53,66</sup>

### Dermatologic Conditions

*Lichen sclerosis* is a chronic genital dermatitis condition that is associated with varying intensity of symptoms including vulvar itch and/or burning and various degrees of vulvar scarring leading to narrowing of the introitus and dyspareunia.<sup>61-64,66</sup> There is a wide variation in presentation symptoms. In some women, especially those not sexually active, there can be minimal symptoms and the patient may be unaware of the condition of lichen sclerosis for years. Alternatively, the burning and itching symptoms can be so intense as to severely interfere with sexual activity, day-to-day activities, and even sleep. If the scarring of lichen sclerosis involves the perianal area, the patient may also complain of perianal fissuring and painful defecation. The diagnosis of lichen sclerosis is suspected by physical examination showing white color genital, vulvar, and vestibular tissue with paleness, loss of pigmentation, and a characteristic “cigarette paper” wrinkling (Fig. 50-8). Classically, the genital tissue changes do not involve the inside of the vagina, and if they involve the perianal area, there is a traditional “figure of eight” extension. The lichen sclerosis condition commonly involves the vestibule with associated labia minora atrophy and the vaginal introitus with loss of elasticity and narrowing.

*Lichen planus*<sup>67</sup> is another chronic genital dermatitis condition that is probably pathophysiologically related to various immunologic disorders. The presenting symptoms vary widely, most likely due to the varied pathophysiologies. Lichen planus may occur secondary to use of drugs such as antihypertensives, diuretics, oral hypoglycemics, and nonsteroidal anti-inflammatory agents, which may rarely induce a lichen planus-like eruption. One type of lichen planus is primarily associated with itching and

**Figure 50-8** This is a photograph of a postmenopausal woman with lichen sclerosis that reveals white color perineal and perianal tissue with characteristic “cigarette paper” wrinkling. There are also classic signs of vaginal atrophy with fusion of the labia minora to the labia majora.

does not result in scarring. Another type is erosive and destructive. Overall, patient complaints may include severe vulvar itching, pain, burning, and irritation. Dyspareunia<sup>61-64,66,67</sup> occurs in sexually active women secondary to vaginal introital scarring. Some types of lichen planus, unlike lichen sclerosis, may involve the vaginal mucosa. If there is vaginal involvement, a purulent, malodorous discharge may be noted. Findings on physical examination of women with lichen planus vary widely. The pruritic type of lichen planus is associated with a purple color and multiple papules and plaques on the vulva and vestibule. The erosive type is associated with vestibular ulcers, scarring, and atrophy of the clitoris and labia minora; destruction of the vagina has been reported. A biopsy and dermatopathologic review may be needed to establish the diagnosis of lichen planus.<sup>67</sup>

### Genital Sexual Pain Disorders

*Generalized vulvodynia*<sup>59,61,62,68,69</sup> refers to a diffuse, constant, burning pain anywhere on the vulva, from mons to anus, which is hyperpathic and greatly out of proportion to the stimulus. Afflicted patients have a constant or sporadic awareness of the vulva with widespread sensation that “everything hurts,” vulvar soreness, rawness, constant irritation, various paresthesias, aching, and/or stinging. Generalized vulvodynia may be considered primary if it occurs with the first penetrative sexual encounter or with a tampon or speculum examination. Generalized vulvodynia may be considered secondary if it occurs after previous nonpainful vaginal penetrations. The diagnosis of generalized vulvodynia<sup>59,61,62,68,69</sup> is made by ruling out, on physical examination and laboratory testing, such diagnoses as candida vaginitis and chronic genital dermatitis conditions. Q-tip testing shows all vulvar areas positive for pain and/or tenderness. The treatment of any genital sexual pain disorder involves a multidisciplinary team approach, and this is especially true for the disabling condition of generalized vulvodynia.

*Vulvar vestibulitis syndrome* is another genital sexual pain disorder. On history, there is severe pain on vestibular touch or attempted vaginal entry. On physical examination, there is ery-

**Figure 50-9** This is a photograph of a premenopausal woman with vulvar vestibulitis syndrome involving minor vestibular glands at the 6- to 7-o'clock position. Cotton swab testing revealed extreme sensitivity and burning to touch.

thema of various degrees within the vestibule. During Q-tip testing, there is tenderness to pressure that is “localized” within the vulvar vestibule. Often, the tender localized region is along the labial-hymenal junction associated with the presence of minor vestibular glands (Fig. 50-9). Vulvar vestibulitis syndrome<sup>59,61,62,68,69</sup> is one of the most likely causes of dyspareunia, especially in women younger than 50 years of age. Afflicted patients with vulvar vestibulitis syndrome complain of severe pain during sexual activity, often described as raw, red burning, feeling like sandpaper, or feeling like burnt tissue being rubbed. Most women experience the pain in the vulvar region with initial penetration. There is another group of women who do not experience pain during initial penetration but experience severe pain on deep penetration when the man’s perineum comes into contact with the woman’s. In this latter group, physicians are misguided to the cervix, when the site of the pain trigger is really within the vulvar region. With vulvar vestibulitis syndrome, genital sexual pain may also be experienced with the use of tampons, during speculum examination, when wearing tight pants, or during straddling while bicycling or horseback riding. Although there is no known pathophysiology, there are several possible pathophysiologic factors, including exposure to human papillomavirus, exposure to the irritant oxalate, abnormal immunologic conditions, psychopathology, and an abnormal sex steroid hormonal milieu.

## DIAGNOSIS OF WOMEN’S SEXUAL HEALTH CONCERNS

### History

There are limited consensus management paradigms for the diagnosis of women with sexual health complaints. The corner-

stone of the physical-based diagnosis of sexual dysfunction is a history and physical examination performed by the biologically focused health care professional. Specifically, obtaining a careful history is crucial, because this aspect of the diagnosis establishes impressions and forms the basis of emphasis on physical examination.<sup>7,47</sup>

The history of a woman with sexual health concerns includes sexual, medical, and psychosocial aspects, in order to characterize the many physical and psychological factors that often contribute to the sexual health difficulty. It is advised that women with sexual health concerns undergo a separate and concomitant psychological interview by a psychologically focused health care professional to broaden the psychosocial information derived during the interview process.<sup>7,47</sup>

### Sexual History

The sexual history should begin with the patient describing the sexual problem. The following questions may be used to help obtain maximal descriptive information.

What is the sexual problem?

When did the sexual problem manifest? How long have you had the sexual problem? Does the sexual problem happen all the time?

Does the sexual problem occur during partner-related sexual activity? Does the sexual problem occur during self-stimulation? In which situations is the sexual problem minimized? In which situations is the sexual problem maximized?

Did you ever experience full capabilities for sexual interest, sexual arousal, and sexual orgasm? How many years were you at peak sexual function? What is your current sexual functioning in terms of interest, arousal, and orgasm compared to when you were at peak sexual function?

Is the sexual problem associated with any degree of discomfort, tenderness, soreness, or pain? If so, can you localize the site of the pain on a schematic diagram of a woman’s genitalia?

What tests have you already had in the evaluation of your sexual health concern? What treatments have you already received, and what have been the outcomes of the various treatments?

How does the sexual problem affect you? How is your partner affected by the sexual problem? Does the sexual problem cause you to withdraw from partner-related sexual activity, from self-stimulated sexual activity, or from the relationship?

How would you feel if the sexual problem were cured?

It is relevant to inquire after the sexual health of the partner. For women with a male partner, there may exist male sexual dysfunctions such as ED, early ejaculation, or an anatomic concern (e.g., Peyronie’s disease). Data on the importance of the male partner to the sexual function of the woman are expanding exponentially. Current knowledge indicates that, in a committed heterosexual relationship, the male partner’s sexual performance is linked to the female partner’s sexual function and sexual satisfaction. Therefore, if the male partner has some form of sexual dysfunction, such as ED, the woman’s desire, arousal, ease of achieving orgasm, and satisfaction are reduced. This information is critical to obtain using history-taking.

The use of validated, reliable, standardized self-rated questionnaires<sup>70-73</sup> is a very helpful clinical starting point to assist in

identification of the presence or absence of a sexual problem and which of the disorders of desire, arousal, orgasm, and/or sexual pain are involved. Such self-report measures are valuable screening tools that are easy to administer and score and have normative values for populations of women with and without sexual dysfunction. Common self-rated questionnaires include the Female Sexual Function Index and the Sexual Function Questionnaire. As in all areas of clinical medicine, the use of screening tools for clinical diagnosis has recognized limitations. The determination of particular psychological contributors or confounds, contextual conditions, and other features and characteristics that cause individual women their unique sexual concerns requires more traditional assessment through structured history and physical examination.

### Medical History

The medical history should include focused questions on any accompanying medical/surgical illnesses or use of medications. Topics of importance in the medical history include

1. Chronic medical illnesses such as diabetes, anemia, or renal failure
2. Neurologic illnesses such as spinal cord injury, multiple sclerosis, or lumbosacral disc disease
3. Endocrinologic illnesses such as hypogonadism, hyperprolactinemia, or thyroid disorders
4. Atherosclerotic vascular risk factor exposure such as hypercholesterolemia, hypertension, diabetes, smoking, or family history
5. Nonhormonal medication or recreational drug use such as antihypertensives, selective serotonin-reuptake inhibitor (SSRI) antidepressants, over-the-counter drugs, street drugs, alcohol, or cocaine
6. Hormonal medication use such as combined oral contraceptives, infertility drugs, or leuprolide acetate
7. Pelvic/perineal/genital trauma such as pelvic fracture or bicycling injury
8. Gynecologic history such as childbirth, abortions, episiotomy, abnormal Papanicolaou (PAP) smears, sexually transmitted diseases, pelvic inflammatory disorder, endometriosis, fibroids, hysterectomy with or without oophorectomy, or menopause
9. Urologic history such as incontinence, frequent urinary tract infections, interstitial cystitis, or pelvic surgeries
10. Surgical history such as laminectomy, colon/anal surgery, or vascular bypass surgery
11. Psychiatric history such as depression, panic, or anxiety

Because sex steroid hormones are critical for genital structure and function, the medical history should routinely probe and evaluate for symptoms of estrogen deficiency, such as vaginal dryness, vaginal bleeding with minimal sexual contact, pain and soreness after sexual activity, hot flashes, and night sweats. Symptoms of androgen deficiency include fatigue, lack of energy, diminished skeletal muscle strength, depressed mood, falling asleep after meals, decreased athletic performance, and lack of interest in sexual activity.

### Psychosocial History

The psychosocial history should assess such issues as social factors, past sexual beliefs, past sexual abuse and trauma, emotional concerns, and interpersonal relationship matters. Any past history of mood or psychiatric disorders should be identified.

There are multiple caveats to history taking in women with sexual health concerns. One is that the health care professional should consider history taking as having more significance than the first diagnostic step toward resolution of the sexual problem. The fact is that history taking may be viewed as actually the beginning of treatment for women with sexual health concerns. Women often feel empowered after this detailed discussion about their sexual health, because they have taken the first step in overcoming their past failures to take action in this area. It is not uncommon for the discussion with the health care provider to become a model of what is possible in conversations about sexual health. Many patients then are able to initiate a sexual health conversation with their partner, a close friend, or a family member.

The second caveat is that the health care professional should be cognizant that, whereas the women may have a specific sexual health complaint (e.g., lack of interest), there may be additional and more complex mind, body, and relationship issues in the overall pathophysiology. For example, a woman may experience sexual pain during intercourse. She may be so psychologically distracted by the discomfort, throbbing, stinging, aching, soreness, burning, and/or tenderness that physiologic desire, arousal, and orgasm responses during sexual stimulation are not able to manifest. This woman may present to the health care provider with a primary sexual complaint, such as lack of interest or orgasm, but a more detailed history and physical examination may yield the concomitant long-standing genital sexual pain problem.

### Physical Examination

The physical examination for a woman with sexual health concerns should be tailored to the sexual medicine complaint obtained on history taking. For example, if during history taking genital itching is found to be a major sexual health problem, a careful assessment would follow for the presence of a genital dermatitis condition. If a woman with sexual health problems is younger than 50 years of age and has sexual pain, a careful physical examination should evaluate for the presence or absence of vulvar vestibulitis syndrome/vestibular adenitis. Similar complaints of sexual pain in a woman older than 50 years of age should lead to assessment for the presence of vaginal atrophy with dryness, loss of rugae, mucosal thinning, pale hue, and lack of shiny vaginal secretions. The physical examination should be performed ideally without menses and without intercourse or douching for 24 hours before the examination. If dysfunction occurs at a specific time, such as midcycle dyspareunia, the physical examination should be scheduled at the time of the sexual problem. Such scheduling may require two visits: one for history taking and one for the physical examination.<sup>7,47</sup>

The genitally focused examination should be considered routine in the diagnosis of women's sexual health problems, but its personal character demands that a rational explanation exist for its inclusion in the diagnostic process. A focused peripheral genital examination is recommended in women with sexual dysfunction for complaints of dyspareunia, vaginismus, genital or combined arousal disorder, orgasmic disorder, pelvic trauma history, and any disease affecting genital health such as herpes or lichen sclerosis. For women with suspected neurologic disorders, the examiner may also assess for anal and vaginal tone, voluntary tightening of anus, and bulbocavernosal reflexes.

It is particularly important that the patient with sexual dysfunction have full communication with the health care provider and have final authority during the physical examination to terminate at any time, to ask questions, to control who is in attendance, and to understand the extent of the assessment. It is vital that the patient be aware of the purpose of the examination. Inclusion of the sexual partner, with permission of the patient, is advantageous and provides needed patient support. Allowing the patient (and the partner) to observe any pathology via mirrors or digital photography is often therapeutic. It allows them, for the first time in many cases, an illustration and connection of a detected physical abnormality with the sexual health problem. If there exists a genital sexual pain history, the patient should point with her finger to the locations of the discomfort during the physical examination.

Independent of the gender of the examining health care provider, it is strongly recommended that a female chaperone health care provider be present in the examination room. The following equipment should be available: examination table, hospital gown, bed sheet, disposable absorbing chucks, patient covering sheet, surgical loupes or magnifying glass, examination light source, examination gloves, gauze, lubricant, Q-tips, speculum, pH paper, glass slides, saline, and microscope. The patient should wear a hospital gown, and a sheet should cover her lower torso. The patient should be placed in the lithotomy position, equipment for magnified vision and a carefully focused light source should be arranged, and the examining health care provider should be seated comfortably.

The first part of the examination involves inspection. If appropriate, lubricant should be placed on the vulva. Gauze can be grasped between thumb and index finger and used to retract the labia majora for a full inspection of the vestibular contents. Two gloved fingers are placed on either side of the clitoral shaft, and, with an upward force in the cephalic direction, the prepuce is retracted to gain full exposure of the glans clitoris, corona, and right and left frenula emanating at 5- and 7-o'clock from the posterior portion of the glans clitoris (Fig. 50-10). With the use of gauze to retract the labia minora, the labial-hymenal junction is identified. A Q-tip cotton swab test is performed, with gentle pressure applied on the minor vestibular glands, to document the quality of the discomfort or pain. The Q-tip cotton swab may also be placed at multiple locations in the vulva and vestibule. Palpation is next performed, using a single-digit examination. This procedure occurs before speculum insertion or bimanual searches for vaginismus. Single-digit palpation is achieved by gently placing a finger into the vaginal opening and depressing the bulbocavernosus muscle. The test is positive if there is hypertonicity and pain.

The goals of the physical examination for a woman with sexual health concerns are to confirm normal architecture, to detect any existing pathology or abnormalities, to educate the woman about normal anatomy and physiology, and, if pain is a feature, to reproduce and localize the pain to potential tender areas of the vulva, vagina, or pelvis or hypertonicity of the pelvic floor.

A bimanual examination and evaluation of the pelvic floor may be performed subsequently if indicated. Two fingers are placed against the lateral walls, and the levators and underlying obturator are assessed for tenderness or taut bands. In addition, a bimanual examination can evaluate the integrity of the fornices, bladder, urethral bases, and pelvic organs. A rectovaginal examination and speculum examination can be performed if indicated. For the speculum examination, a warm, lubricated speculum is

A

B

**Figure 50-10 A**, This is a photograph of a premenopausal woman with clitoral phimosis and a prepuce cyst. This woman experienced discomfort in the clitoral region during sexual activity. **B**, This is an intraoperative photograph of a woman who developed labial redundancy after her third childbirth. The woman complained that the excessive labia occasionally entered the vaginal canal during sexual activity and lead to dyspareunia.

used. The vaginal wall is examined for estrogen milieu integrity, inflammation of the walls, and any vaginal lesions.

The health care physician should also perform a complete physical examination, to rule out other comorbid conditions (e.g., thyroid goiter) that might be causing sexual dysfunction. A general physical examination is highly recommended in women with chronic illnesses and as part of good medical care, including evaluation of blood pressure, heart rate measurement, and a detailed breast examination.<sup>7,47</sup>

## Laboratory Testing

There are no consensus recommended routine laboratory tests for the evaluation of women with sexual health concerns about desire, arousal, and orgasm. Blood testing should be dictated by clinical suspicion, especially the results of the history and physical examination. If appropriate, the health care clinician may assess multiple androgen and estrogen values, such as dehydroepiandrosterone sulphate (DHEAS), androstenedione, total testosterone, free testosterone, sex hormone binding globulin (SHBG), dihydrotestosterone, estradiol, and estrone. Pituitary function may be evaluated by measuring luteinizing hormone (LH), follicle-stimulating hormone (FSH), and prolactin. Thyroid-stimulating hormone (TSH) should be measured to exclude subclinical thyroid disease.<sup>25,26,74,75</sup>

There are many problems with the determination of serum hormone levels. The normal ranges of testosterone concentration values for women of different age groups without sexual dysfunction are not well defined. Testosterone levels reach a nadir during the early follicular phase, with small but less significant variation across the rest of the cycle. Testosterone assays are not uniformly sensitive or reliable enough to accurately measure testosterone at the low serum concentrations typically found in women. Free testosterone is clinically more important than total testosterone in sexual function, because most testosterone is bound to SHBG, and only a small amount of total testosterone is biologically available. The measurement of SHBG is not controversial and is relatively simple to perform with good reproducibility. Equilibrium dialysis is a highly sensitive assay for free testosterone; however, this method is not feasible for clinical practice. Measurement of free testosterone by analogue assays is unreliable. Free androgen may also be calculated using the free androgen index, which is defined as total testosterone divided by SHBG (both measured in nanomols per liter). Calculated free testosterone may be determined and takes into account total testosterone, SHBG, and albumin. A calculator for free testosterone is available online at <http://www.issam.ch/freetesto.htm>.<sup>25,26,74,75</sup>

DHEAS is commonly measured because the half-life is much longer than that of dehydroepiandrosterone (DHEA), resulting in more stable levels. The immunoassay for DHEAS sulphate is relatively robust and simple to perform. DHEAS does not vary in concentration over the phases of the menstrual cycle. Many investigators have shown consistent decline curves for DHEAS with aging.

Although there is a lack of clinical consensus as to the value, specificity, and sensitivity of individual hormone blood tests, there are evidence-based, placebo-controlled, double-blind data supporting the efficacy of exogenous sex steroid hormone treatment in women with sexual health concerns. The prudent physician may wish to discuss with the patient the strategy of serial blood test surveillance testing to address safety concerns during such treatment.

A most common and controversial question concerns the “normal range” for sex steroid blood test values in women with sexual health problems. Guay and colleagues examined androgen values in women who were “without sexual dysfunction” as determined by a validated Sexual Function Questionnaire. Androgen concentrations were highest in women aged 20 to 29 years, decreased at approximately age 30, and remained relatively constant thereafter. The free androgen index in women without sexual dysfunction was approximately 3.7 for women aged 20 to 29 years and 2.0 for women between the ages of 30 and 39 years.<sup>25,26,74,75</sup>

Serum levels of sex steroids can measure only deficiency or excess. Sex steroid hormone actions are quite complex and involve critical enzymes and hormone receptors that also determine tissue exposure, tissue sensitivity, and tissue responsiveness, independent of the blood concentrations. For example, there are interindividual variations in the amount and activity of critical enzymes such as 5 $\alpha$ -reductase and aromatase, as well as variations in individual sex steroid hormone receptor sequencing. More research is needed regarding the blood testing of sex steroid hormones in women with sexual health concerns.

## TREATMENT

This goal of this section to discuss the biologically focused management of sexual health issues in women. The ideal management of sexual health concerns is holistic, engaging both psychological and biologic strategies.

### Hormonal

Sex steroid hormones are critical for sexual structure and function.<sup>19,25,26,45,74,75</sup> A number of studies have demonstrated that hormone therapy using systemic or local preparations improves sexual desire, arousal, orgasm, and frequency of sexual activity. There is no single hormonal intervention that will be effective in all women with desire, arousal, or orgasm sexual health concerns that are secondary, in part, to sex steroid hormone deficiency states.

Studies have consistently reported that androgen sex steroid hormone values decline gradually and estradiol values decline abruptly in menopausal women. Hormone insufficiency states may also be caused by a number of clinical conditions and medications, including the use of oral contraceptive therapy.

The use of systemic testosterone or systemic and/or local estrogen with or without systemic progesterone must be individualized to each patient's desires, wishes, requirements, and expectations.<sup>21</sup> Systemic hormone therapy can successfully improve hot flashes, night sweats, and sleep disturbances that can otherwise markedly diminish afflicted women's body image and mood. Local hormone therapy can successfully improve vaginal lubrication dryness and dyspareunia. Alleviation of hormone deficiency-induced symptoms through the use of systemic and/or localized sex steroid hormones can increase quality of life, desire, arousal, and orgasmic function. Although not yet specifically approved for clinical use in women with sexual health concerns, sex steroid hormones may eventually provide a safe and effective treatment option. However, more research is indicated.

The following paragraphs describe a clinical paradigm currently used in our outpatient sexual health clinic for the evidence-based, biologically focused treatment of women with desire, arousal, and orgasm sexual health concerns. As discussed previously, treatment is holistic and is based on the history, physical examination, and laboratory test results.

#### Phase 1

It is important to emphasize that no single type of hormonal intervention or regimen is effective in all women with desire, arousal, or orgasm sexual health concerns. Women who seek treatment may have symptoms of sexual health problems due in part to the onset of natural menopause or menopause induced

by chemotherapy or surgery. Or, they may be younger women whose labia minora have begun to atrophy because of the adverse effects of oral contraceptives on the sex steroid hormonal milieu. Treatments for infertility or endometriosis may also disturb the sex steroid hormone milieu.

The hormonal abnormalities that are identified determine which of the following four biologic treatment options are offered to women in Phase 1. Based on blood test results, systemic androgen treatment may be achieved with DHEA alone, systemic testosterone alone, or a combination of both. Based on the history and physical examination, local estrogen treatment may be achieved with vestibular estradiol alone, intravaginal estradiol alone, or a combination.

Systemic androgens (DHEA and/or testosterone) have been shown to improve mood, energy, stimulation, sensation, arousal, and orgasm.<sup>76-78</sup> Limited clinical trials have examined the effects of DHEA therapy on sexual function in women. Baulieu and colleagues administered DHEA (50 mg) or placebo to 140 women between the ages of 60 and 79 years for 12 months. DHEA treatment produced approximately a doubling of serum total testosterone concentration and also significantly increased skin hydration and bone density. Libidinal interest was increased after 6 months of treatment, and sexual activity and sexual satisfaction were increased after 12 months.<sup>76-78</sup>

Testosterone has been used to treat women with sexual dysfunction for more than 50 years.<sup>79</sup> Transdermal patches or gels, which are more consistently absorbed and avoid first-pass metabolism in the liver, are currently being studied for their safety and efficacy in reducing sexual symptoms associated with testosterone insufficiency.<sup>80,81</sup> Recently, transdermal testosterone patches were compared with placebo in estrogenized women who had undergone oophorectomy and hysterectomy.<sup>80</sup> The study results showed that the 300- $\mu$ g testosterone patch was significantly more effective than the 150- $\mu$ g patch or placebo in improving frequency of sexual activity, pleasure, and fantasy during a 12-week period. Typically, testosterone is used in gel form (Food and Drug Administration–approved delivery system for men) and is applied to the back of the calf. One tenth of the dose used in men is appropriate for initial therapy in women.

One benefit of administering DHEA and testosterone is that a certain percentage of these hormones will aromatize to an estrogen, thus relieving hot flashes and night sweats without the administration of systemic estrogen.

Local estrogen, whether it is prescribed in the form of vaginal estradiol or a vestibular cream, improves perfusion, lubrication, tissue tone, and elasticity and restores the normal pH and vaginal health.<sup>48,82,83</sup> Vaginal estradiol also relieves dyspareunia, atrophic vaginitis, and vaginismus. Some systemic absorption occurs with all local estrogens, but less so than with oral therapy. Daily application of a film of vestibular estrogen is recommended as well, because it promotes the health of the frenulum (the most sensitive part of the external genitalia), labia minora, urethral meatus, hymenal tissue, and vestibular glands.

Women with sexual dysfunction who are placed on Phase 1 treatment need to undergo surveillance blood tests after 3 months of therapy to monitor the levels of estradiol, progesterone, DHEA, testosterone, androstenedione, dihydrotestosterone, FSH, LH, prolactin, and TSH as indicated.

Women with desire, arousal, or orgasm sexual health concerns whose symptoms of distress are not resolved satisfactorily with phase 1 treatments may consider progressing to phase 2 treatments.

### Phase 2

In phase 2, women receive systemic estrogen and/or systemic testosterone. Several clinical trials have shown that the distressing symptoms of vaginal atrophy associated with low estrogen states are ameliorated after estrogen therapy. Low doses of systemic bioidentical nonsynthetic 17- $\beta$  estradiol reduced vaginal atrophy compared with placebo in healthy menopausal women.<sup>84</sup> Systemic estrogen therapy can also successfully improve hot flashes, night sweats, and sleep disturbances that negatively affect body image, mood, and sexual desire. All efforts are made to keep serum estradiol levels between 30 and 50 pg/mL. Risks of systemic estrogen use include breast cancer, heart attack, and stroke. The concept of maintaining estradiol values at low levels is to reduce the side effect risk while achieving a minimum efficacious dose.

In women with an intact uterus, systemic estrogen should always be opposed by a progestogen. All efforts are made to use a bioidentical nonsynthetic progesterone and to keep values in the range of 1 pg/mL.

### Phase 3

In phase 3, attention is given to the possible role of dopamine agonists in facilitating desire and orgasm sexual responses. Sexual motivation is encouraged, sustained, and ended by a number of central nervous system neurotransmitter and receptor changes induced, in part, by the actions of sex steroids, androgens, estrogens, progestins, and the central neurotransmitter dopamine.<sup>85,86</sup> The activation of dopamine receptors may be a key intermediary in the stimulation of incentive sexual motivation and sexual reward. These neurotransmitter and receptor changes, in turn, activate central sexual arousal and desire. Contemporary animal research has revealed that dopamine neurotransmitter systems may play a critical intermediary role in the central regulation of sexual arousal and excitation, mood, and incentive-related sexual behavior—and in particular, in the motivational responses to conditioned external stimuli. In summary, the complex central neurochemical actions of steroid hormones stimulate sensory awareness, central sexual arousal, mood, and reward and relate them to an individual's relevant sexual experiences involving a partner, a place, and an action.

Bupropion may have a beneficial effect on women with hypoactive sexual desire disorder. In a placebo-controlled trial, bupropion produced an increase in desire and frequency of sexual activity compared with placebo.<sup>85,86</sup> However, frequency was correlated to total testosterone level at baseline and during treatment. A traditional starting dose is 100 mg bupropion per day taken in the morning.

### Vasodilators

Basic science studies investigating the physiology of sexual function using female animal models support the role of nitric oxide–cyclic guanosine monophosphate–PDE5 pathways in the peripheral arousal physiology of the clitoral corpus cavernosum,<sup>88,89</sup> corpus spongiosum, vaginal epithelium, and vaginal lamina propria.

There have been several clinical studies on selective PDE5 inhibitors over the last few years, conducted with either premenopausal or postmenopausal women with arousal sexual health concerns as well as healthy women without sexual dysfunction. Many studies did not take into account the hormonal

milieu of the subjects in the inclusion and exclusion criteria. An important point in treating women with arousal sexual health concerns is that an adequate sex steroid (androgen and estrogen) hormonal milieu is critical for benefits from selective PDE5 inhibitor treatment.<sup>19</sup> Several studies did assess the safety and efficacy of selective PDE5 inhibitors in subjects with a normal hormonal milieu.

A double-blind, crossover, placebo-controlled safety and efficacy study with a selective PDE5 inhibitor was performed in premenopausal women with normal ovulatory cycles and normal levels of steroid hormones who were affected by female sexual arousal disorder without hypoactive sexual desire disorder. Subjects were observed to benefit from treatment with the active selective PDE5 inhibitor versus placebo, showing improvement in sexual arousal, orgasm, frequency, and enjoyment of sexual intercourse.<sup>90</sup>

A double-blind, placebo-controlled safety and efficacy study with a selective PDE5 inhibitor was performed in postmenopausal women with female sexual arousal disorder who had adequate serum estradiol and free testosterone values. Women with female sexual arousal disorder without hypoactive sexual desire disorder assigned the active drug had a significantly greater improvement in sexual arousal, orgasm, intercourse, and overall satisfaction with sexual life compared with placebo. No efficacy was shown for women with concomitant hypoactive sexual desire disorder.<sup>91</sup>

Another study was performed using selective PDE5 inhibitors in women with psychotropic-induced sexual dysfunction. Women who had normal premenopausal sexual function and who had developed sexual dysfunction, particularly anorgasmia with or without other sexual disturbances (i.e., loss of libido), lubrication difficulties, or uncomfortable or painful intercourse, were treated with a selective PDE5 inhibitor. The subjects showed improvement of the presenting condition, usually depression, anxiety, or both, and experienced sexual side effects continuously for more than 4 weeks. Patients took selective PDE5 inhibitors and reported a complete or very significant reversal of their sexual dysfunction. This included return of effective duration and intensity of adequate arousal, lubrication, and orgasmic function.<sup>92</sup>

## SEXUAL PAIN MANAGEMENT

### Medical Therapy for Genital Sexual Pain Disorders

Biologic pathophysiologies resulting in woman's sexual health problems associated with sexual pain may occur in the clitoris, urethra, bladder, vulva, vestibule, vagina, and pelvic floor muscles. It is not within the scope of this chapter to detail all the management of genital sexual pain disorders. If the reader is interested, one option would be to refer to the reference text book entitled *Women's Sexual Function and Dysfunction: Study, Diagnosis and Treatment*.<sup>20</sup>

#### Clitoris, Prepuce, and Frenulae

In women with focused clitoral pain, clitoral itching, or clitoral burning, careful inspection of the glans clitoris should be performed. Failure to visualize the whole glans clitoris with the corona is consistent with some degree (mild, moderate, or severe) of prepuce phimosis, based on the elasticity of the prepuce and its ability to retract on examination.<sup>93</sup> Because it can create a

closed compartment, phimosis is often the underlying pathology in clitoral glans balanitis associated with recurrent fungal infections. Initial treatment may be conservative with topical estrogen and/or testosterone creams to determine whether the prepuce can be made more elastic and retractile.<sup>94</sup> Topical antifungal agents such as nystatin or oral antifungal agents such as fluconazole<sup>95</sup> may be considered. Infections can also be related to herpesvirus infection, and appropriate treatment can be administered (e.g., acyclovir). If conservative treatment fails due to the phimotic prepuce, surgical management by dorsal slit procedure should be considered.

#### Urethral Meatus

Gentle retraction of the labia minora should provide a full view of the urethral meatus. Prolapse of the urethral mucosa out the urethral lumen is highly associated with estrogen deficiency states such as natural menopause, surgical menopause due to bilateral oophorectomy, or deficiency caused by chemotherapy for malignancy. Clinical symptoms include urgency, frequency, and discomfort on urination; also, spotting of blood may be observed on the toilet paper after wiping following voiding. The abnormal voiding history is often accompanied by a unique sexual history. Women with urethral prolapse often have the ability to have full sexual pleasure and satisfaction during self-stimulation of the clitoris, but with a partner or with a mechanical device she experiences pain, urgency to urinate, and/or inability to have orgasm secondary to distracting pain. Conservative treatment options include topical or systemic estrogens, although the risks and benefits of estrogen treatment need to be fully discussed.<sup>64,69</sup>

#### Vulva and Vestibule

Genital sexual pain in the vulva and vestibule may be related to various specific disorders. Generalized vulvodynia<sup>69</sup> refers to genital sexual pain with a nonlocalized, persistent, irritating pain anywhere on the vulva, from mons to anus, that is very sensitive and greatly out of proportion to the stimulus. The treatment of any genital sexual pain disorder involves a multidisciplinary team approach, and this is especially true for the disabling condition of generalized vulvodynia. Patient management includes education and support, especially regarding avoidance of contacts and practice of healthy vulvar hygiene, pelvic floor physical therapy treatment, management of concomitant depression, and management of any associated neurologic, dermatologic, gynecologic, orthopedic, or urologic conditions. Medical management includes amitriptyline and/or gabapentin.

Vulvar vestibulitis syndrome is one of the most common causes of dyspareunia, especially in premenopausal women.<sup>96,97</sup> The treatment of vulvar vestibulitis syndrome also begins with conservative measures including education, support, counseling, physical therapy, and/or biofeedback. Elimination of the pain trigger should be performed. Topical estrogen and topical xylocaine creams or ointments should be considered. Systemic medications include tricyclic antidepressants or gabapentin. Correction of the sex steroid hormonal milieu should be considered. Unlike generalized vulvodynia, in women with vulvar vestibulitis syndrome, if medical management fails surgery (e.g., vestibulectomy) can be considered.

The symptoms of atrophic vaginitis include vaginal dryness, dyspareunia, stinging, bleeding, and dysuria.<sup>98</sup> On physical examination, women with atrophic vaginitis have vaginal mucosal changes. The classic healthy-appearing vagina has a pink hue with vaginal folds and rugae that, when touched with a Q-tip,

**Figure 50-11** Modified vestibulectomy for vulvar vestibulitis syndrome. **A**, Intraoperative photograph. The tip of the surgical instrument has entered into the ostia of the minor vestibular gland. **B**, Intraoperative photograph. Tagging sutures have been placed into the ostia of the minor vestibular glands prior to local excision. **C**, This surgical excision specimen was 2.5 cm long and 0.5 cm deep and wide.

reveal a shiny lubricating substance and, when rubbed with a Q-tip, do not bleed. In atrophic vaginitis, the vagina transforms to an unhealthy pale complexion, with a lack of vaginal folds and rugae, a lack of lubricating substance on the surface, and bleeding of the tissue with minimal contact. On wet mount, the microscopic examination reveals parabasal cells, increased white blood cells, and absent background flora of lactobacilli. The vaginal pH is elevated to 6.0 to 7.0. Conservative treatment involves the use of local topical vestibular and/or intravaginal estrogen. There are multiple products on the market, including intravaginal rings, intravaginal pills, and creams. There are also multiple estrogen alternatives, such as soy, although there are limited double-blind placebo-controlled safety and efficacy trials with these products.

Disorders of the female pelvic floor, especially those involving bladder/urethra and sexual dysfunction, are common. Conservative therapies for hypersensitivity disorders of the pelvic floor are aimed at muscle reeducation. A pelvic floor rehabilitation program aimed at facilitating sexual comfort and pleasure for patients can be designed. Massage of the pelvic floor can be performed to elongate shortened muscles and decrease high-tone spasm. Conservative therapies for low-tone pelvic floor dysfunction

are also aimed at muscle reeducation. Pelvic floor muscle-strengthening exercises, augmented with biofeedback and/or electrical stimulation to the pelvic floor, can be initiated. If this and other conservative treatment options fail, surgical procedures, including sling and tension-free vaginal tape placement, provide cure rates as high as 95% when performed in appropriate candidates.<sup>55,56,59</sup>

### **Surgical Therapy for Genital Sexual Pain Disorders**

#### ***Surgical Treatment for Vulvar Vestibulitis Syndrome***

Surgical intervention for management of vulvar vestibulitis syndrome is offered to those for whom initial conservative medical, psychological, and/or physical therapy treatment has failed. Surgery is based on the hypothesis that the pathophysiology of vulvar vestibulitis syndrome is associated with inflamed, irritated, and hypersensitive vestibular glandular tissue and related increased nerve density in the vestibular mucosa. Surgical success is, therefore, based on excision of this abnormal glandular and nerve tissue in the vestibule.<sup>99,100</sup>

In women with vulvar vestibulitis syndrome, the first surgical and reconstructive procedure consisted of excision of a semicir-

**D**  
**Figure 50-11 D**, Intraoperative photograph of a woman undergoing modified vestibulectomy for vulvar vestibulitis syndrome and dorsal slit for clitoral phimosis. Interrupted 4-0 chromic sutures have been used to reestablish vestibular tissue integrity.

cular segment of perineal skin, the mucosa of the posterior vulvar vestibule, and the posterior hymenal ring. The reconstruction consisted of undermining 3 cm of the vaginal mucosa and approximating this directly to the perineum. Subsequently, variations and modifications have evolved. Specifically, in contemporary vulvar vestibulectomy procedures, the posterior incision extends only to the posterior fourchette and does not include excisions of perineal skin. A “complete vulvar vestibulectomy” includes excision of the vestibular mucosa adjacent to the urethral meatus/Skene’s glands region anteriorly, and excision of vestibular mucosa laterally and posteriorly, with reconstruction including the posterior vaginal flap advancement. A “modified vulvar vestibulectomy” limits the excision of vestibular mucosa to the posterior vestibule. Both procedures are usually performed with the patient under general or regional anesthesia. During vestibulectomy, the vaginal advancement may cover the ostia of the Bartholin glands; however, the risk of postoperative Bartholin gland cysts is only 1%. A vestibuloplasty or excision of vestibular

adenitis consists only of excision of localized painful areas of vestibular mucosa without vaginal advancement and can be performed with local anesthesia. Most surgeons choose the procedure based on the individual needs and symptoms of the patient. The complications of surgery for vulvar vestibulitis syndrome increase with the invasiveness of the procedure performed. Specifically, complications include bleeding, infection, increased pain, hematoma, wound dehiscence, vaginal stenosis, scar tissue formation, and Bartholin duct cyst formation. As always with surgery, the risks of these complications can be reduced with appropriate surgical techniques. Various closure techniques have been described to minimize the risks of postoperative complications. Specifically, the vaginal advancement flap should be anchored by multiple subcutaneous mattress sutures of 3-0 Vicryl placed in an anterior-posterior direction and should be approximated to the perineum with interrupted stitches of 4-0 Vicryl (Fig. 50-11).<sup>99,100</sup>

### *Other Surgical Procedures*

Distressing and disabling clitoral pain may occur secondary to phimosis of the clitoral prepuce and recurrent fungal balanitis of the clitoral glans or frenula. If conservative treatment fails, a dorsal slit procedure of the prepuce may be indicated to relieve the closed compartment that is perpetuating the recurrent fungal clitoral glans infection.<sup>93</sup>

Distressing and disabling vestibular pain, urinary urgency and frequency, and genital sexual pain may occur secondary to urethral prolapse. If conservative treatments fail, surgical excision of the prolapsed urethral mucosa may be indicated.<sup>55</sup>

Distressing vulvar or vestibular discomfort may occur secondary to a Bartholin’s cyst. If conservative treatments fail, marsupialization of the cyst may be indicated to enable drainage of the highly viscous and mucinous cyst fluid.<sup>101</sup>

## CONCLUSIONS

It is entirely appropriate to have a detailed chapter on women’s sexual health concerns in a textbook on female urology. Increasing numbers of health care professionals manage sexual health concerns as part of their goal to maximize the all health care delivery to each patient.

The basic premise of biologically focused management of women’s sexual health concerns is that physiologic processes can be altered by pathology. Understanding how specific medical conditions modulate a woman’s sexual health requires much investment in basic science investigation. From the perspective of biologically focused clinicians, the essential principle guiding medical decision-making is identification of the underlying pathophysiology of the sexual dysfunction. If the biologic basis of the sexual health concern can be diagnosed, management may be successfully directed to the source pathophysiology. Two of the many challenges facing health care professionals today are improving their ability to accurately diagnose sexual health concerns in women and ensuring that they offer women the best available, evidence-based treatment options. To achieve these goals, biologically focused clinicians need to be familiar with evidence-based, state-of-the-art data and current biologically focused management strategies.

# EPIDEMIOLOGY OF PELVIC ORGAN PROLAPSE

*Firouz Daneshgari and Courtenay K. Moore*

## EPIDEMIOLOGY

Although pelvic organ prolapse (POP) is one of the most common indications for gynecologic surgery, little is known about the epidemiology of the condition.<sup>1</sup> Caring for women with pelvic floor disorders has become an increasingly important component of women's health. An analysis of U.S. procedure codes for prolapse surgery estimates that more than a half-million procedures are performed annually accounting for more than 1 billion US health care dollars.<sup>2</sup> It is estimated that women have an 11% lifetime risk of undergoing a single operation for POP and urinary incontinence by age 80 years.<sup>3</sup> Studies have shown that 50% of parous women lose pelvic floor support, with resulting prolapse.<sup>3</sup> Yet, of these women, only 10% to 20% seek medical care. The Oxford Family Planning Association study monitored more than 17,000 women aged 25 to 39 years for 26 years.<sup>4</sup> Whereas the annual incidence of hospital admission for the diagnosis of prolapse was 0.204%, the annual incidence of surgery for prolapse was only 0.162%.<sup>4</sup> This highlights the fact that only a fraction of women with POP seek medical attention. Therefore, incidence and prevalence rates based on surgical intervention significantly underestimate the magnitude of POP.

Given the difficulties in determining the number of women affected by POP, there has been little agreement on the resources needed to serve this population. It is estimated that the proportion of the U.S. population between the ages of 30 and 89 years will grow by 22% over the next 30 years (Fig. 51-1).<sup>5,6</sup> One of the most dramatic features of this population change is the large increase in the number of Americans older than 50 years of age. The population of women aged 50 years and older is expected to increase by 72%. Lubner and colleagues found that women aged

60 years and older are far more likely to seek medical care for pelvic floor disorders than their younger cohorts.<sup>6</sup> They estimated that, over the next 30 years, the demand for services to care for female pelvic floor disorders will increase at twice the rate of growth of the general population (Fig. 51-2). Therefore, at a time when the general population is projected to increase by 22%, there will be a 45% increase in the demand for care for pelvic floor disorders.<sup>6</sup>

One of the reasons that the demographics of POP are so poorly understood is that its prevalence varies widely in different populations, ranging from 30% to 93%. Differences in prevalence and incidence rates may be explained by varying diagnostic criteria, different examination techniques, and the sensitivity of these techniques. Before 1995, one of the main problems in studying the epidemiology of POP was the absence of a standardized tool for evaluating the degree or stage of POP. In 1996, an international committee comprised of members from the International Continence Society (ICS), the American Urogynecologic Society, and the Society of Gynecologic Surgeons met to develop an objective, site-specific system to describe, quantify, and stage female POP.<sup>7</sup> The result was the Pelvic Organ Prolapse Quantification system (POPQ). The creation of this classification system was a major advance in the study of POP, allowing researchers to report findings in a standardized fashion. The POPQ has demonstrated good reliability as well as intraexaminer and interexaminer reproducibility.<sup>8</sup>

A second reason for lack of understanding of the epidemiology of POP is that there have been no epidemiologic studies of

Figure 51-1 Projected U.S. female population.

Figure 51-2 Estimated increase in pelvic floor disorders among women aged 30 to 80 years. (From Lubner KM, Boero S, Choe JY: The demographics of pelvic floor disorders: Current observations and future projections. *Am J Obstet Gynecol* 184:1496, 2001.)

POP in community-based populations.<sup>9</sup> Instead, most studies are based on small, mainly white clinical populations or surgical databases. An additional limitation in understanding the epidemiology of POP is inherent to the condition itself. Studies on POP are wrought with difficulties. Complying with the ICS definition of POP requires an invasive examination that limits the feasibility of large community-based studies. Furthermore, symptoms associated with POP have not been shown to correspond to the severity of prolapse. This inconsistency limits the use of symptoms in the epidemiologic definition of prolapse.

Finally, lack of understanding of the distribution of normal versus abnormal female pelvic organ mobility and support remains another limitation. In a study of young nulligravid women, Dietz and coworkers found a wide range of pelvic organ mobility, concluding that the “range of ‘normality’ in pelvic organ mobility is wider than previously assumed.”<sup>10</sup> In 2000, Swift performed an observational study on the distribution of pelvic organ support of women seen at outpatient gynecology clinics for routine gynecologic care. The distribution of POP was a bell-shaped curve, with most subjects having stage 1 or 2 prolapse.<sup>11</sup> The overall distribution was as follows: stage 0, 6.4%; stage 1, 43.3%; stage 2, 47.7%; and stage 3, 2.6%.<sup>11</sup> The Pelvic Organ Support Study (POSST), a multicenter, cross-sectional observational study of 1004 women undergoing annual gynecologic examinations, found a similar distribution. The prevalence of POP quantification stages was as follows: stage 0, 24%; stage 1, 38%; stage 2, 35%; and stage 3, 2%.<sup>12</sup>

## PREVALENCE

The *prevalence* of a disease refers to the number of affected persons present in the population at a specific time divided by the number of persons in the population at that time.<sup>13</sup> Prevalence also describes the probability of experiencing a symptom or having a condition or a disease within a defined population at a defined time.<sup>9</sup> This is important in establishing the distribution of a condition in the population and projecting the need for future health and medical services.

The data on prevalence of POP is limited and highly variable. Many estimates of the prevalence of POP define prolapse based on symptoms alone or a nonvalidated genital examination, not on the POPQ. To date, only two studies have used the ICS definition of POP. The first, done by Swift in 2000, found that 94% of women aged 18 to 82 years had stage 1 POP or greater; when only women with stage 2 or greater were considered, the prevalence fell to 51%.<sup>11</sup> A second study, also done by Swift and colleagues, found that 22% of women aged 18 to 83 years seeking routine gynecologic care had POP, which was detected on routine examination.<sup>12</sup>

Two other studies have looked at the prevalence of POP using physical examination; however, these studies used nonvalidated genital examination classification systems. Hendrix and associates looked at the prevalence of POP in women aged 50 to 79 years who were enrolled in the Women’s Health Initiative Hormone Replacement Therapy Clinical Trial. Forty-one percent of women with a uterus had some form of prolapse (34.3% cystocele, 14.2% uterine prolapse, 18.6% rectocele), compared to 38% of the women without a uterus (32.9% cystocele, 18.3% rectocele).<sup>14</sup> In the second study, Samuelsson and colleagues examined Swedish women aged 20 to 59 years and found the overall prevalence of genital prolapse to be 30.8%.<sup>15</sup> In compari-

son, the prevalence studies of POP based on symptoms alone tend to report lower rates of POP, ranging from 7% to 25%.<sup>16-18</sup> This discrepancy in prevalence rates highlights the lack of correlation between POPQ and prolapse symptoms.

## INCIDENCE

The *incidence* of a disease is the number of new cases of a disease that occur during a specified period of time in a population at risk of developing the disease or the probability of developing the condition under study during a defined time period.<sup>13</sup> Studies of the incidence of POP come primarily from surgical databases (Table 51-1). Cases are identified by the International Classification of Diseases (ICD) diagnosis and procedures codes. In the United States, the annual incidence of surgery for POP ranges from 1.5 to 4.9 cases per 1000 women.<sup>3,19,20</sup> Olsen and coworkers looked at the incidence of POP surgery in a managed care setting. They found that the age-specific incidence of surgically managed POP increased with age (Fig. 51-3); with the overall lifetime risk of a woman’s undergoing at least one operation for POP being 11.1%.<sup>3</sup>

In 1997, Brown and associates<sup>20</sup> calculated the incidence of surgery for POP from the National Hospital Discharge Survey and National Census records of 225,964 women to be 22.7 per 10,000 women. The rate of prolapse surgery increased with age, peaking at age 60 to 69 years with a rate of 42.1 per 10,000 women. Interestingly, rates for surgery varied significantly by region. Women living in the South had the highest overall rate of surgery for POP (29.3 per 10,000), whereas women living in the Northeast had the lowest overall rate of surgical intervention (16.1 per 10,000; see Fig. 51-1).

Boyles and colleagues<sup>19</sup> looked at the trends in surgery performed for POP from 1979 to 1997 using data from the National Hospital Discharge Survey. During this period, 3,734,000 procedures were performed for POP. The number of POP procedures decreased significantly from 226,000 in 1979 to 205,000 in 1997. The age-adjusted rate of POP procedures decreased from 2.2 per 1000 women in 1979 to 1.3 per 1000 from 1988 to 1992. This number rose slightly to the rate of 1.5 per 1000 in 1997. Overall, the absolute number of prolapse procedures in women younger than 50 years of age decreased from 135,000 in 1979 to 80,000 in 1997. However, the number of prolapse procedures in women older than 50 years rose from 91,000 in 1979 to 125,000 in 1997. Therefore, the age-adjusted rate of prolapse surgery from 1979 to 1997 in women younger than 50 years of age decreased from 1.9 to 0.8 per 1000 women, but it did not change in women older than 50 years.

## RISK FACTORS

POP is a common disorder, accounting for more than a half-million surgical procedures and more than 1 billion health care dollars annually.<sup>2</sup> The ratio of procedures performed for POP to those performed for urinary incontinence is 2 : 1.<sup>1</sup> Despite its commonality, little is known about the pathophysiology of POP. Like urinary incontinence, POP seems to be multifactorial. Age, gender, and parity are established risk factors for POP, and many other factors have been suggested but not rigorously proven. Without identifying the risk factors of POP, efforts at prevention are fruitless and therapy can only be empiric.<sup>21</sup>

**Table 51-1 Summary of Epidemiology of Pelvic Organ Prolapse (POP) Studies**

Study	Design/Study Population	No. Patients	Classification of POP	Results
Hendrix	USA. Cross-sectional study of healthy, postmenopausal women enrolled in Women's Health Initiative Hormone Replacement Clinical Trial	27,342	Nonvalidated gynecologic examination (not POPQ)	Risk of POP increases with age, parity, obesity. Risk of POP varies among ethnic groups: lowest among African Americans, highest among Hispanics
Progetto	Italy. Cross-sectional study of women attending menopausal clinics	21,449	Examination using Baden Walker	Risk of uterine prolapse increased with age, BMI, vaginal deliveries
Swift	USA. Case-control study	368 controls 87 cases	POPQ examination	Factors predictive of severe POP: age, weight largest vaginal delivery, hysterectomy, previous prolapse surgery
Brown	USA. National Hospital Discharge Survey	300,000	Surgical procedure and discharge diagnosis codes	Surgery for POP among Caucasians was three times greater than for African Americans. Regional differences: South highest, Northeast lowest rate of surgery for POP
Mant	UK. Cohort from Oxford Family Planning Study	17,032	Hospital in-patient admission with diagnosis of prolapse (ICD codes)	Risk of POP increased with age, parity, weight, hysterectomy
Moalli	USA. Case-control study. Cases selected from patients who underwent surgery for POP ± UI. Controls patients seen in gynecology for routine examination	80 cases 176 controls	Nonvalidated examination	Development of POP associated with: younger age at first delivery, higher BMI, forceps delivery, prior gynecologic surgery
Nygaard	USA. Cohort of healthy, postmenopausal women enrolled in Women's Health Initiative Hormone Replacement Clinical Trial	270	POPQ examination	Risk of POP increased with less education, higher vaginal parity, larger babies

BMI, body mass index; ICD, International Classification of Diseases; POPQ, Pelvic Organ Prolapse Quantification system.

**Figure 51-3** Lifetime risk of undergoing surgery for urinary incontinence (UI) and pelvic organ prolapse (POP). (From Olsen AL, Smith VJ, Bergstrom JO, et al: Epidemiology of surgically managed pelvic organ prolapse and urinary incontinence. *Obstet Gynecol* 89:501, 1997.)

### Age

Studies have shown a rise in the incidence and prevalence of POP with age. In a cross-sectional analysis of women enrolled in the Women's Health Initiative Hormone Replacement Therapy Clinical Trial, Hendrix and colleagues found that the risk of developing uterine prolapse, rectocele, and cystocele increased with advancing age.<sup>14</sup> Women aged 60 to 69 years had an odds ratio (OR) of 1.16 for uterine prolapse compared to women aged 50 to 59 years; for women aged 70 to 79 years, the OR was 1.36. Similarly, the ORs for both cystocele and rectocele increased with advancing age. In another cross-sectional study of Italian women, a similar rise in uterine prolapse with age was noted. Compared with women aged 51 years or younger, women aged 52 to 55 years and those aged 56 years or older had ORs for uterine prolapse of 1.3 and 1.7, respectively.<sup>22</sup> Swift and coworkers found that the OR of POP increased by 1.38 per 10-year period.<sup>12</sup> Among women with severe prolapse (stage 3 or 4), the odds of having severe prolapse increased 12% with each year of advancing age.<sup>23</sup>

Surgery for POP is uncommon in patients younger than 30 years of age and in those older than 80 years. Surgical rates of

POP increase with age, peaking in the sixth decade.<sup>20</sup> Brown and coworkers found that, whereas African American women have a lower risk of developing POP than white women, the mean age at which African American women undergo surgery for POP is younger than that for their white counterparts (49.3 versus 54.3 years).<sup>20</sup>

### Race

U.S. data suggest a protective effect of African American race compared to white race for POP.<sup>9</sup> Brown found there to be large racial difference in the rates of POP surgery. Compared with African American women, white women have a much higher rate of surgery for POP (6.4 versus 19.6 per 10,000). Hendrix and coworkers<sup>14</sup> also found that, compared with white and Hispanic women, African American women had the lowest rate of uterine prolapse, cystocele, and rectocele. Hispanic women were found to have the highest rate of uterine prolapse and an increased risk for cystocele but not rectocele. American Indian women, although a small sample size, had lower risks than white women for all types of pelvic floor relaxation. Asian women had the greatest risk of all women for cystocele and rectocele. Swift and colleagues found similar results for Hispanic race (OR = 4.29), but black race was not protective (OR = 1.20).<sup>12</sup>

### Parity

Multiple studies have shown a positive association between parity and POP. In the Oxford Family Planning Association study, parity was the strongest risk factor for the development of POP, with an adjusted relative risk of 10.85.<sup>4</sup> Although the risk increased with increasing parity, the rate of increase slowed after two deliveries. Hendrix and associates<sup>14</sup> also found an increase in the risk of uterine prolapse, cystocele, and rectocele with increasing parity. Similarly, the Progetto Study showed an OR of 2.6 when comparing nulliparity to a parity of 1 and an OR of 3.0 when comparing nulliparity to a parity of 3 or greater.<sup>22</sup> Nygaard and associates, in a multivariate analysis of 270 women, found that those women who had had no vaginal deliveries had a marked reduction in risk of POP compared with parous women.<sup>24</sup> Higher vaginal parity was associated with the development of stage 2 or greater POP (OR = 1.61).<sup>24</sup>

Moalli and coauthors, in a case-control study, found an increased likelihood of pelvic floor surgery among women who underwent spontaneous vaginal delivery compared with cesarean section. Compared with cesarean delivery, vaginal delivery was associated with an OR of 2.9 for POP surgery.<sup>25</sup> Forceps delivery carried the greatest risk of pelvic floor surgery, with an OR of 5.4.<sup>25</sup> Swift and coworkers identified not only gravidity, parity, and number of vaginal deliveries as risk factors for POP, but also the weight of vaginally delivered infants.<sup>12</sup>

### Obesity

Both moderate and severe obesity are associated with increased risks of POP. Hendrix and associates found overweight women (body mass index [BMI] = 25 to 30 kg/m<sup>2</sup>) to have an increased risk for the occurrence of uterine prolapse of 31%; for rectocele, 38%; and for cystocele, 39%. Obese women (BMI >30 kg/m<sup>2</sup>) also had increased risks 40%, 75%, and 57%, respectively. Women with a waist circumference of 88 cm or greater had a 17% increased risk of cystocele and rectocele. In the Progetto Italia

Study, the risk of uterine prolapse increased with increasing BMI. In comparison with women with BMI less than 23.8, women with a BMI of 23.8 to 27.2 had an OR of 1.4, and those with a BMI greater than 27.2 had an OR of 1.6. Other studies have found similar associations between BMI and POP.<sup>12</sup>

### Bowel Dysfunction

Chronic constipation with repeated defecatory straining has been linked to POP because of pelvic floor denervation and pudendal neuropathy. In a British case-control study, straining with bowel movements and constipation (fewer than two bowel movements per week) as a young adult were significantly more common in women with uterovaginal prolapse than in controls.<sup>26</sup> Women with uterovaginal prolapse were also noted to have prolonged pudendal nerve terminal motor latency compared with controls, suggesting pudendal neuropathy as a factor involved in the pathogenesis of POP.<sup>26</sup>

### Menopause and Gynecologic Factors

#### Hormonal Status

Swift and colleagues, in 2001, found that postmenopausal women who were not taking hormone replacement therapy (HRT) had a higher rate of prolapse than premenopausal or postmenopausal women taking HRT.<sup>23</sup> Moalli and associates also found that women not taking HRT were at a greater risk of developing POP. Menopausal women who took HRT for 5 or more years had a 90% decreased risk of surgery for POP.<sup>25</sup>

#### Gynecologic Surgery

Several studies have shown that gynecologic surgery, notably hysterectomy and previous prolapse surgery, predispose women to POP. Swift and colleagues, in their study on severe POP, found a previous history of prolapse surgery or hysterectomy to be among the strongest etiologic predictors of severe POP.<sup>23</sup> The odds of having severe POP increased by more than 200% in patients with a previous history of hysterectomy and by 500% in women with a previous history of prolapse surgery (Fig. 51-4).<sup>24</sup> Mant and colleagues found that women who had a hysterectomy for prolapse were 5.5 times more likely to have a surgery for POP than women whose hysterectomy had been done for other reasons.<sup>4</sup> The cumulative risk of repair after hysterectomy increased in a linear fashion, rising from 1% at 3 years to 5% at 15 years.<sup>4</sup>

### Lifestyle

#### Chronic Obstructive Pulmonary Disease and Smoking

Chronic illnesses such as chronic obstructive pulmonary disease (COPD) are often cited as conditions that appear to predispose women to POP because of the increased stress and strain on the pelvic floor. However, the data are mixed and inconclusive.<sup>3,11,12,17,24</sup> Similarly, the data regarding the effect of smoking on POP are also controversial at this time.<sup>4,12,15,24,27</sup>

#### High-Impact Activity and Manual Labor

Strenuous high-impact exercise and heavy physical labor have been implicated in female pelvic floor disorders. In 1996, Davis reported three cases of severe POP after the rigors of airborne training in young nulliparous soldiers who had previously

**Figure 51-4** Lifetime risk of pelvic organ prolapse (POP) after hysterectomy. (From Mant J, Painter R, Vessey M: Epidemiology of genital prolapse: Observations from the Oxford Family Planning Association Study. *Br J Obstet Gynaecol* 104:579, 1997.)

undergone laparoscopic uterine nerve ablation.<sup>28</sup> The Danish National Registry of Hospitalized Patients also looked at the effect of heavy physical activity (heavy lifting) on surgery for POP. The risk of surgery for POP in 28,000 nursing assistants aged 20 to 69 years was compared with the risk in 1.6 million age-matched controls. The OR for POP surgery for nursing assistants compared with controls was 1.6.<sup>1</sup> In a case-control study, Italian housewives were found to be at an increased risk of POP when compared with professional/managerial women (OR = 3.1).<sup>27</sup> On univariate analysis, Swift and colleagues also found an increased risk of POP among laborers versus nonlaborers. However, labor did not remain statistically significant in the multivariate logistic regression analysis.<sup>12</sup> Nygaard and associates reported no overall association with employment history, current exercise, or past history of strenuous exercise among women in the United States; however, women with a history of past heavy, manual labor were more likely to have uterine prolapse than those who did not engage in heavy, manual labor.<sup>24</sup>

### Genetics and Collagen

In a Finnish study, the familial incidence of genital prolapse was 30%.<sup>29</sup> The risk of POP was higher among women who had a

mother or sister with POP. Compared with women whose relatives did not have POP, the OR for these women was 3.2 if their mother had POP and 2.4 if a sister had POP.<sup>27</sup>

It has been suggested that genetic or intrinsic differences in connective tissues may predispose individuals toward urinary incontinence or POP. Ehlers-Danlos syndrome is a connective tissue disorder involving collagen gene defects. Several studies have suggested that women with Ehlers-Danlos syndrome are at an increased risk of POP given these collagen defects. Carley and coworkers looked at women with Ehlers-Danlos syndrome and found that 75% of them had POP.<sup>30</sup> McIntosh and associates also found that women with Ehlers-Danlos syndrome had a higher prevalence of POP than the general population.<sup>31</sup>

It has also been suggested that women with clinical joint hypermobility (a sign of connective tissue laxity) have a higher prevalence of cystocele, rectocele, and uterine prolapse than women with normal joint hypermobility.<sup>32</sup> Al-Rawi and Al-Rawi found that 66% of Iraqi women with POP had clinical joint hypermobility, compared with 18% of controls.<sup>33</sup>

The results on collagen content of vaginal and pelvic tissues in women with prolapse are variable, given inconsistent data. The data vary based on biopsy site, biochemical tests used for analysis, and heterogeneity of the populations studied.<sup>34</sup> Chen and coworkers found women with POP to have an increased rate of collagen breakdown compared with controls.<sup>35</sup> Similarly, Wong and associates found women with POP to have a significantly decreased amount of cervical collagen compared with controls.<sup>36</sup>

### SUMMARY

POP is a common condition among women, with an estimated 11% lifetime risk of undergoing surgery by age 80 years. Yet despite its commonality and its significant cost to the health care system, little is truly known about the epidemiology of POP. Lack of standardized definitions, differing physical examination techniques, difficulty in recruitment, embarrassment surrounding the condition, and coexistence with other pelvic floor disorders have all hindered understanding of POP. Although the POPQ system has facilitated standardization, scientific communication, and epidemiologic and clinical studies of POP, understanding of the epidemiology of POP is still rudimentary. Age, race, parity, obesity, menopause, bowel dysfunction, pelvic surgeries, genetic factors, and lifestyle choices appear to contribute to POP, but further epidemiologic and clinical studies are needed to identify the modifiable risk factors to prevent POP.

# PREGNANCY, CHILDBIRTH, AND PELVIC FLOOR INJURY

*Asnat Groutz*

Pregnancy and childbirth have long been considered risk factors in the genesis of pelvic floor disorders. Mechanical and hormonal changes that occur during pregnancy, as well as the mechanical strain of labor and delivery, may all cause partial denervation of the pelvic floor and direct injury to pelvic muscles and connective tissue. These injuries may further lead to the development of stress urinary incontinence, anal incontinence, pelvic organ prolapse, and/or voiding dysfunction. Although many studies have shown some correlations between various obstetric risk factors and the development of these symptoms, there is no consensus regarding the impact and relative contribution of the various parameters. Moreover, the etiology of pelvic floor disorders is multifactorial. Additional risk factors, other than pregnancy and childbirth, include heredity, collagen abnormalities, obesity, and aging. Reliable antenatal models for the identification of women at risk are not yet available. Further studies are required to establish such risk models and the manner in which labor should be managed to minimize potential childbirth-induced pelvic floor injuries.

### PHYSIOLOGY

#### Functional Changes

The physiology of the lower urinary tract during normal pregnancy has not been thoroughly investigated. Furthermore, significant hemodynamic changes may directly affect urinary tract function throughout the course of pregnancy. Total blood volume increases by up to 40%, and cardiac output is increased by 30% to 50% by the third trimester of pregnancy. Simultaneously, systemic vascular resistance is reduced due to progesterone-induced smooth muscle relaxation. Glomerular filtration rate and renal plasma flow consequently increase by 40% to 50%, and 60% to 80%, respectively.<sup>1</sup> These changes result in increased urine output and, with the pressure effect of the gravid uterus on the bladder, may cause urinary frequency, urgency, and nocturia. Up to 80% of women experience urinary frequency during pregnancy, and the symptom usually appears early (i.e., in the first trimester) and tends to worsen as pregnancy progresses.<sup>2-5</sup>

#### Anatomic Changes

Early radiologic and endoscopic studies showed that the bladder is pressed by the gravid uterus and pushed upward and anteriorly.<sup>2,6,7</sup> More recent studies investigated the mobility of the bladder neck and pelvic floor during pregnancy. Peschers and colleagues<sup>8</sup> reported that bladder neck position at rest is changed at the end of pregnancy, compared with the position in nulligravidas. This finding suggests that mechanical pressure of the

fetal head and uterus and/or hormonal and connective tissue changes may alter the bladder neck position during pregnancy. Similarly, Wijma and associates<sup>9</sup> used perineal ultrasound to study a cohort of 117 pregnant nulliparous and 27 nonpregnant nulliparous women. The angle of the urethrovesical junction at rest and the displacement/pressure coefficient during coughing showed a significant increase during pregnancy. King and Freeman,<sup>10</sup> also using perineal ultrasound, found that women with stress urinary incontinence at 10 to 14 weeks postpartum had significantly greater bladder neck mobility antenatally than those who were continent postpartum. There were no significant differences in obstetric parameters between the postpartum continent and incontinent groups. The authors suggested that collagen susceptibility to changes during pregnancy, measured by changes in bladder neck mobility, could predict postpartum incontinence. Dietz and colleagues<sup>11</sup> investigated pelvic organ mobility in 28 pregnant women, seen at 10 to 17 weeks and again at 32 to 39 weeks of gestation, and 88 nonpregnant controls. Pregnant women showed greater bladder and urethral mobility. The effect was already noticeable in the first trimester, but it was significantly augmented later in pregnancy. Because similar changes were also noted in elbow hyperextension, the authors speculated that pregnancy may adversely affect connective tissue biomechanics. This speculation is further supported by earlier data suggesting that, compared with nonpregnant women, connective tissue in pregnant women contains less collagen and has less tensile strength, greater extensibility under low pressure, and loss of recoil after overstretching.<sup>12</sup>

#### Urodynamic Observations

Only a few urodynamic studies have been performed on pregnant women. Van Geelen and coworkers<sup>13</sup> assessed the urethral pressure profile during pregnancy and after delivery in 42 nulliparas. Lower values of urethral pressure profile parameters were observed in almost all women who experienced stress urinary incontinence during pregnancy and/or after delivery. The investigators concluded that “inherent weakness of the urethral sphincter mechanism plays a key role in the pathogenesis of stress incontinence.”<sup>13</sup> Other urodynamic studies revealed decreased cystometric parameters during pregnancy. Chaliha and colleagues<sup>14</sup> studied 286 nulliparous women during the third trimester of pregnancy, 161 of whom returned for postpartum urodynamic evaluation. The mean urodynamic values in the third trimester and after delivery were lower than the reported normal limits of the nonpregnant population. Antenatally, the prevalence of urodynamically proven stress incontinence was 9% and that of detrusor instability was 8%; after delivery, these values were 5% and 7%, respectively. Similarly, Nel and associates<sup>15</sup>

studied 66 pregnant women, 40 of whom returned for postpartum urodynamic evaluation. A strong desire to void, urgency, maximum cystometric capacity, and maximum and average flow rates were all significantly decreased during pregnancy. Urodynamically proven stress incontinence was present in 12% of the pregnant subjects, and detrusor instability in 23%.

The cystometric capacity of the bladder during pregnancy has been studied by several investigators, but findings are contradictory. An early study by Muellner<sup>16</sup> found that bladder capacity gradually increased from 12 to 32 weeks of gestation, reaching an average capacity of 1300 mL, and was associated with bladder hypotonia. This finding was confirmed by another small urodynamic study<sup>17</sup> but doubted later by Francis,<sup>2</sup> who found a reduced bladder capacity in the third trimester. Francis<sup>2</sup> also found increased detrusor irritability in late pregnancy, rather than bladder hypotonia. More recent studies have confirmed these latter observations.<sup>14,15</sup>

## PATHOPHYSIOLOGY

Labor and delivery have long been known to be the major causes of pelvic floor injury. However, it is unknown whether the insult begins during pregnancy, before the active process of labor and delivery, and whether delivery by elective cesarean section, with no trial of labor, provides any protective effect. Major injury mechanisms include partial denervation of the pelvic floor and direct injury to the pelvic soft tissues.

### Neurologic Damage

Electromyography (EMG) and pudendal nerve terminal motor latency (PNTML) measurements are considered to be useful in detecting denervation of the pelvic floor. Prolonged PNTML is obtained when large myelinated nerve axons have been damaged. Snooks and colleagues<sup>18,19</sup> used electrophysiologic techniques to study 71 women at 48 to 72 hours after delivery and again, in 70% of these women, 2 months later. An increased PNTML was found in 42% of the women 48 to 72 hours after vaginal delivery, but not in any of those who delivered by cesarean section. Multiparity, forceps delivery, increased duration of the second stage of labor (defined as the interval between full cervical dilatation and the delivery of the newborn), third degree perineal tear and high birth weight were all found to be associated with increased risk of pudendal neuropathy. However, by 2 months postpartum, the PNTML had returned to normal in 60% of the women, implying that the denervation injury is usually reversible. Fourteen multiparas of the original cohort underwent repeated neurophysiologic studies 5 years after delivery.<sup>20</sup> Five of these 14 women complained of stress urinary incontinence and were found to have marked pudendal neuropathy. The investigators concluded that childbirth-associated pudendal neuropathy may persist and worsen with time.

Allen and colleagues<sup>21</sup> studied the innervation of the pelvic floor muscles before and 2 months after delivery in 96 nulliparas. Using motor unit potential duration as a sign of reinnervation in response to denervation injury, they found evidence of partial denervation of the pelvic floor with consequent reinnervation in 80% of the women after vaginal delivery. It was unclear whether the EMG changes were due to stretching of the pudendal nerve or to direct pressure of the fetal head on the nerve branches. Furthermore, evidence of partial denervation was also found in women who had undergone cesarean section during labor. This

finding suggests that the denervation process may start during the first stage of labor, before delivery. Women who had a long (>56.7 min) active second stage of labor (defined as the stage of active pushing) and heavier (>3.41 kg) babies showed the most EMG evidence of nerve damage. The investigators concluded that vaginal delivery causes partial denervation of the pelvic floor in the majority of women delivering their first baby. For most women, the degree of denervation is slight, but in some there is severe damage that may be associated with loss of sphincteric control. Of the original study cohort of 96 women, 77 (80%) were available for 7-year and 65 (68%) for 15-year follow up.<sup>22</sup> The motor unit potential durations were found to be increased significantly after delivery, and again at 7 and 15 years; however, no correlation was found between this EMG finding and the symptom of stress incontinence. The investigators concluded that the absence of an adequate marker for pelvic floor denervation makes it difficult to determine the role of denervation/reinnervation after the first delivery in the etiology of stress urinary incontinence.

### Muscular Damage

Relative weakness of the pelvic floor muscles after vaginal delivery was confirmed in several clinical studies. Insult may be secondary to nerve damage, local ischemia, muscle distention, or direct tearing of muscle fibers. Peschers and associates<sup>23</sup> demonstrated that pelvic muscle strength was significantly reduced 3 to 8 days after vaginal delivery but not after cesarean section. In most women, muscle strength was restored to antepartum values 6 to 10 weeks postpartum. However, Sampselle and coauthors<sup>24</sup> reported that recovery of levator ani contractility could take as long as 6 months after delivery.

Advanced imaging techniques have enabled visualization of the pelvic floor structures before and after labor and delivery. Sultan and colleagues<sup>25</sup> used endosonography to assess antenatal and postnatal anal sphincter anatomy. At 6 to 8 weeks postpartum, 35% of the 79 primiparous women studied had occult disruption of the internal or external anal sphincter. None had such sphincter defects before delivery. Of 48 multiparous women, 40% had a sphincter defect before delivery and 44% thereafter. None of the 23 women who underwent cesarean section had a new sphincter defect after delivery. Further analysis revealed that forceps delivery was significantly associated with anatomic damage.

Magnetic resonance imaging (MRI) has been used to detect anatomic and chemical changes, as well as to localize specific injury sites. DeLancey and coworkers<sup>26</sup> used MRI to explore the appearance of the levator ani muscle after vaginal delivery. The study population consisted of 80 nulliparous and 160 primiparous women. The primiparas were all examined 9 to 12 months after vaginal delivery. As many as 20% of the primiparas were found to have levator ani defects on MRI. Most defects were identified in the pubovisceral portion of the levator ani (consists of the pubococcygeus, puborectalis, and puboperineus muscles), and some were in the iliococcygeal portion of the muscle. No levator ani muscle defects were identified in nulliparous women. Moreover, stress-incontinent women were twice as likely to have levator ani defects than continent women. More recently, Lien and colleagues<sup>27</sup> used MRI to create a three-dimensional computer model of the levator ani muscle. This model was used to quantify levator ani muscle stretch during the second stage of labor. The investigators found that the medialmost pubococcygeus muscle is at greater risk for stretch-related injury than any

other levator ani muscle during the second stage of labor. Tissue stretch ratios were also proportional to fetal head size.

### Connective Tissue Damage

Normally, the endopelvic fascia and the anterior vaginal wall form a hammock-like layer in which the bladder and vesical neck rest. During increased intra-abdominal pressure, the urethra is compressed against this supporting hammock, and continence is maintained. Simultaneous contraction of the levator ani and the urethral sphincter muscles must also occur to support the vesical neck and to occlude the urethra.<sup>28</sup> Indirect evidence of the effects of childbirth on this coordinated support mechanism was obtained by sonogram measurements of the vesical neck position before and after delivery. Both transperineal and transvaginal ultrasound were used to facilitate visualization of the vesical neck at rest; then, with the Valsalva maneuver, the relative descent was measured. Several studies showed lower vesical neck position in women who delivered vaginally, compared with those who underwent elective cesarean section and with nulliparous women. Likewise, mobility of the vesical neck during the Valsalva maneuver was found to increase after vaginal delivery. However, it is less clear whether this increased vesical neck mobility is also associated with long-term pelvic floor disorders.<sup>8,10,29-31</sup>

## OBSTETRIC RISK FACTORS

Parity, prolonged labor, instrument-assisted delivery, and increased birth weight have always been considered predisposing factors for pelvic floor injury and subsequent development of long-term pelvic floor dysfunction. However, clear scientific data regarding various obstetric parameters, as well as the possible protective effects of cesarean section, are inconsistent. These conflicting data stress the need for further investigation of the role of pregnancy and delivery in the development of pelvic floor disorders.

### Parity

Several investigators reported a positive correlation between parity and stress urinary incontinence.<sup>32-35</sup> However, data concerning a possible linear correlation versus a certain threshold of parity for the development of urinary incontinence are subject to controversy. Foldspang and colleagues<sup>36</sup> found the prevalence of urinary incontinence in women aged 30 to 44 years to be correlated with parity. However, in women aged 45 years or older, only three or more deliveries were associated with an increased risk of incontinence. Thomas and associates,<sup>37</sup> in a postal questionnaire study of more than 7000 women, reported an increased prevalence of urinary incontinence in women with four or more children. Nulliparous women had a lower prevalence of urinary incontinence than did those who had been delivered of one, two, or three babies, but within the parity range of one to three there were no differences in prevalence. Similarly, Wilson and coworkers<sup>38</sup> reported that the odds ratio for postpartum urinary incontinence increased significantly after four deliveries.

The association between parity and urinary incontinence was also investigated by two large epidemiologic studies, the Norwegian Epidemiology of Incontinence in the County of Nord-Trøndelag (EPINCONT) study<sup>39</sup> and the Nurses' Health Study.<sup>40</sup> The EPINCONT study was a large survey performed in one county in Norway during the years 1995-1997. The association

between parity and urinary incontinence was analyzed in an unselected sample of 27,900 women who answered a detailed questionnaire. Overall, urinary incontinence was reported by 25% of participants. Parity was associated only with stress and mixed types of incontinence, the first delivery being the most significant. The association was strongest in the age group 20 to 34 years, with relative risks of 2.2 and 3.3 for primiparas and grand multiparas, respectively. A weaker association was found in the age group 35 to 64 years (relative risks, 1.4 and 2.0, respectively), and no association was found among women older than 65 years of age. The investigators concluded that all effects of parity seem to disappear in later years. The Nurses' Health Study comprised 83,168 women aged 50 to 75 years. Overall, urinary incontinence was reported by 34% of participants. Similar to the EPINCONT study results, parity was associated with increased prevalence of urinary incontinence; however, the association was weaker among women aged 60 years or older. Results of these two large epidemiologic studies suggest that additional factors, other than childbirth, become more significant in older women, thereby minimizing the effects of parity per se.

### Birth Weight

The importance of specific labor parameters and their etiologic role in the development of pelvic floor disorders remains controversial. Dimpfl and associates<sup>41</sup> found a similar incidence of postpartum stress urinary incontinence among mothers whose neonates weighed 3500 g or more and those with infants weighing less than 3500 g. Viktrup and coworkers<sup>42</sup> reported increased birth weights in infants of mothers who developed stress urinary incontinence after delivery, although statistical significance was not reached. Our group<sup>34</sup> found that the prevalence of postpartum stress incontinence among grand multiparas who had given birth to at least one baby weighing more than 4000 g was significantly higher than in those who had not (29.4% versus 16.7%, respectively). Similarly, Persson and colleagues<sup>35</sup> found that the risk of later surgery for stress incontinence after vaginal delivery correlated with the weight of a woman's largest infant.

The effect of various obstetric parameters and urinary incontinence in later life was also investigated in the Norwegian EPINCONT study.<sup>43</sup> The investigators analyzed data from 11,397 women who had delivered vaginally only and who had no more than five children. Nine obstetric parameters were investigated: birth weight, gestational age, head circumference, functional delivery disorders, injuries/tears, breech, forceps, vacuum deliveries, and epidural anesthesia. Statistically significant associations were found between any incontinence and birth weight of 4000 g or more and between stress urinary incontinence and high birth weight; however, odds ratios were relatively weak (1.1 and 1.2, respectively).

### Dysfunctional Labor

Early electrophysiologic studies showed that prolonged second stage of labor can cause partial denervation of the pelvic floor.<sup>18,19,21</sup> However, clinical studies have presented conflicting data regarding the association between duration of labor and the later risk of sphincteric incontinence.<sup>44-48</sup> The EPINCONT study grouped various disorders, among which were labor duration of more than 24 hours, cervical dystocia, uterine atonia, and attenuation of contraction, into one category entitled "functional delivery disorders."<sup>43</sup> Statistically significant association was observed between this general category and moderate or severe urinary

incontinence; however, the odds ratio (1.3) was relatively weak. No further analysis was undertaken to examine specific parameters, such as duration of the second stage of labor, within this category.

### Instrument-Assisted Delivery

Results regarding the possible role of instrument-assisted vaginal delivery (i.e., vacuum or forceps) in the development of pelvic floor disorders are also conflicting. Dimpfl and colleagues<sup>41</sup> found a higher incidence of incontinence after instrumental-assisted vaginal delivery. However, other studies did not confirm this finding.<sup>38,49,50</sup> Sultan and coworkers<sup>25</sup> used endosonography to assess antenatal and postnatal anal anatomy. Forceps delivery was found to be significantly associated with anatomic damage: sphincter defects developed in 8 of the 10 primiparas who underwent forceps delivery, but not in any of the 5 who had undergone vacuum extraction. In another study of 43 patients who had undergone an instrumental delivery, Sultan's group<sup>50</sup> reported that 81% of forceps deliveries were associated with sonographic anal sphincter damage, compared with 24% of vacuum deliveries. Several other studies also demonstrated an increased risk of pelvic floor injury after forceps compared with vacuum deliveries.<sup>52-55</sup> However, one study reported a higher rate of vacuum rather than forceps deliveries in patients with postpartum fecal incontinence.<sup>56</sup> Differences between obstetricians in their primary choice of instrument delivery (vacuum versus forceps), as well as their clinical skills and experience, may explain some of these results. Furthermore, it is possible that the main cause of pelvic floor damage during instrument deliveries is the obstetric indication for such an intervention, namely a prolonged second stage, rather than the type of instrument used per se. Therefore, avoidance of instrumental intervention may facilitate prolonged distention of the vagina by the fetal head, causing greater damage to the pelvic floor.<sup>57</sup> This speculation may be supported by the recent EPINCONT findings suggesting a tendency for these procedures to protect against urinary incontinence, particularly for vacuum delivery.<sup>43</sup>

### Cesarean Section

Several studies have examined the association between delivery by cesarean section and urinary incontinence. Persson and colleagues,<sup>35</sup> in a large population-based study of 1942 women, studied risk factors for stress urinary incontinence as represented by a history of anti-incontinence surgery. No association was found between anti-incontinence surgery and pregnancy per se. Vaginal delivery was found to be associated with increased risk for anti-incontinence surgery, compared with elective cesarean section. Moreover, the odds ratio for anti-incontinence surgery was similarly decreased for nulliparas and for primiparas delivered by elective cesarean section. Wilson and associates<sup>38</sup> studied the prevalence of urinary incontinence at 3 months after delivery in a heterogeneous group of 1505 primiparous and multiparous women. They found a significantly lower prevalence of urinary incontinence after cesarean section, in particular among primiparas with no previous history of incontinence, compared to normal vaginal delivery. However, the difference between cesarean sections performed before labor and those performed during labor was nonsignificant. A follow-up study, performed 5 to 7 years later,<sup>58</sup> confirmed the lack of difference between elective and emergency cesarean sections; however, no differentiation

was made between the various indications for emergency cesarean section. Farrell and colleagues<sup>59</sup> studied the association between the mode of first delivery and prevalence of urinary incontinence at 6 months postpartum. Vaginal delivery was associated with a higher prevalence of urinary incontinence (relative risk, 2.8) compared with cesarean section. No significant difference was found between cesarean sections performed before and during labor. The authors concluded that cesarean section at any stage of labor reduced postpartum urinary incontinence. Rortveit and coworkers<sup>60</sup> investigated the association between childbirth and urinary incontinence in a large community-based cohort of 15,307 women who were younger than 65 years of age and were either nulliparous, had undergone only cesarean deliveries, or had had only vaginal deliveries. This analysis was part of the EPINCONT study described earlier. The prevalence of stress urinary incontinence was 4.7% in the nulliparous group, 6.9% in the cesarean section group, and 12.2% in the vaginal delivery group. Further classification of cesarean sections into elective versus nonelective, performed in a subgroup of 239 primiparas, failed to reveal a statistically significant difference. However, as in all other aforementioned studies, nonelective cesarean sections were analyzed as one group, with no further differentiation among cesarean sections for obstructed labor, fetal distress, maternal indications, and other obstetric conditions.

Grouping all cesarean section deliveries into one category may be associated with an overestimation bias, because it is possible that, in cases of cesarean section performed for obstructed labor, pelvic floor injury is already too extensive to be prevented by surgical intervention. To investigate this possibility, our group recently studied the prevalence of stress urinary incontinence 1 year postpartum according to the mode of delivery: spontaneous vaginal delivery versus elective cesarean section versus cesarean section performed for obstructed labor.<sup>61</sup> Our results showed a similar prevalence of stress urinary incontinence 1 year after delivery among primiparas who underwent spontaneous vaginal delivery and those who had undergone cesarean section for obstructed labor (10.3% and 12%, respectively;  $P = .7$ ). Conversely, elective cesarean section, with no trial of labor, was associated with a significantly lower prevalence of postpartum stress urinary incontinence (3.4%;  $P = .02$ ). This low prevalence of stress urinary incontinence among primiparas who had elective cesarean sections was similar to that reported for nulliparous women.<sup>34,60</sup>

Whether prevention of pelvic floor injury should be an indication for elective cesarean section is controversial<sup>62</sup> and involves medical, financial, and ethical aspects. It should be borne in mind that cesarean section may expose women to greater morbidity and mortality. Furthermore, the etiology of stress urinary incontinence is multifactorial. Additional risk factors, other than mode of delivery, include heredity, collagen abnormalities, aging, obesity, and parity. Specific labor plans should therefore be based on overall judgment, taking into consideration personal clinical status and risk factors.

## CLINICAL PRESENTATIONS

### Stress Urinary Incontinence

Stress urinary incontinence is an exceedingly common symptom during pregnancy and the puerperium. Viktrup and associates<sup>42</sup> interviewed 305 primiparas in regard to stress urinary inconti-

nence before and during pregnancy and after delivery. Of these, 4% had stress urinary incontinence before pregnancy, 32% during pregnancy, and 7% after delivery. Among those women who reported stress incontinence during pregnancy, fewer than 5% remained symptomatic 12 months after delivery. Of those who developed the condition after delivery, 24% remained symptomatic at 12 months. These observations suggest that pregnancy-associated stress incontinence resolves after delivery in most women. The question of greater interest is whether women with pregnancy-associated stress incontinence are at increased risk for incontinence in later life. Of the original study cohort of 305 primiparous women reported by Viktrup and colleagues,<sup>42</sup> 278 (91%) were available for a 5-year follow-up.<sup>63</sup> The overall prevalence of stress urinary incontinence at 5 years postpartum was 30%. Among those women with pregnancy-associated stress incontinence but full remission at 3 months postpartum, symptoms recurred 5 years later in 42%. Up to 92% of those with stress incontinence at 3 months postpartum developed stress incontinence 5 years later. The investigators concluded that first pregnancy and delivery are important in the development of long-lasting stress incontinence and that the use of vacuum delivery and episiotomy seems to increase the risk.

Schytt and colleagues<sup>64</sup> studied the prevalence and predictors of stress incontinence 1 year after childbirth. The study cohort comprised 2390 Swedish women who completed questionnaires during pregnancy and again at 2 months and 1 year after delivery. One year postpartum, 22% of the women were stress-incontinent, but only 2% considered it a major problem. The strongest predictor for stress incontinence at 1 year, in primiparas as well as multiparas, was urinary incontinence during pregnancy and at 4 to 8 weeks after delivery. Of those who had urinary incontinence during the third trimester, 31% to 41% were stress-incontinent 1 year after delivery. Of those who had urinary incontinence 4 to 8 weeks after delivery, 44% to 59% were stress incontinent 1 year postpartum. Other predictors unrelated to parity were obesity and constipation during pregnancy and after delivery. Several other investigators found that, regardless of the mode of first delivery, new onset of stress urinary incontinence during pregnancy is associated with increased risk of long-lasting stress urinary incontinence.<sup>5,34,35,38,61,65</sup> These observations suggest that the etiology of stress incontinence is more complicated than previously estimated and that the onset of incontinence is also related to the pregnant status, rather than to obstetric trauma per se.

### Anal Incontinence

The true prevalence of anal incontinence is unknown and most probably has been underestimated. Although anal incontinence is more common among elderly patients, many young female patients are also affected. Previous studies reported that 3% to 7% of women experienced anal incontinence several months after delivery.<sup>45,56,66</sup> Pollack and colleagues<sup>67</sup> studied the prevalence of anal incontinence in primiparous women 5 years after their first delivery. The study population included 242 women who completed questionnaires before pregnancy and at 5 months, 9 months, and 5 years after delivery. Among women with no visible sphincter tears at their first delivery, 25% reported anal incontinence at 9 months and 32% at 5 years. Among those with sphincter tears, 44% reported anal incontinence at 9 months and 53% at 5 years. The majority of symptomatic women had infre-

quent incontinence to flatus, whereas frank fecal incontinence was rare. Risk factors for anal incontinence at 5 years were age, sphincter tear, and subsequent childbirth.

The reported incidence of anal sphincter tears after first delivery and subsequent childbirth varies widely. Moreover, sphincter tears may be overt (third- or fourth-degree tears), diagnosed and repaired immediately after delivery, or occult, identified by endoanal ultrasonography after childbirth. The incidence of overt sphincter injury is estimated to be 0.5% to 3.3% in centers where mediolateral episiotomy is practiced or higher, 11% to 28%, in centers where midline episiotomies are used.<sup>68-70</sup> Women with third- and fourth-degree sphincter tears are more likely to develop anal incontinence. Fornell and associates<sup>71</sup> compared 51 women with and 31 women without anal sphincter injury and found that as many as 40% of the affected women reported fecal incontinence 6 months after delivery. Twenty-six of the original study group and 6 of the original controls were objectively and subjectively re-examined 10 years later.<sup>72</sup> Incontinence to flatus and liquid stool was more severe in the study group than in controls. Subjective and objective anal function after sphincter injury was found to deteriorate over time and with subsequent vaginal deliveries. Moreover, 7 of the original 51 women underwent second repair of the sphincter defect (5 before the follow-up study, and 2 more afterward by referral for secondary repair due to fecal incontinence). The investigators indicated that fecal incontinence must be considered a strong marker for unsatisfactory results of primary repair. In view of the disappointing results obtained with secondary repairs, preventive measures and optimal primary repair are strongly recommended.

A relatively high incidence of occult sphincter injury was reported after apparently uneventful vaginal deliveries. Sultan and associates<sup>25</sup> used endosonography to assess antenatal and postnatal anal anatomy. No sphincter defects were demonstrated antenatally among 79 primiparous patients studied. However, at 6 to 8 weeks postpartum, 35% had occult disruption of the internal or external anal sphincter. Of the 48 multiparous women, 40% had a sphincter defect prenatally and 44% postnatally. None of the 23 women who underwent cesarean section had a new sphincter defect after delivery. When the women studied 6 weeks after delivery, anal incontinence or fecal urgency was found in 13% of the primiparas and 23% of the multiparas who delivered vaginally. A strong association was observed between sphincter defects and the development of bowel symptoms. In another study of 43 patients who had had instrumental deliveries, Sultan and colleagues<sup>51</sup> reported that 81% of forceps deliveries were associated with sonographic anal sphincter damage, compared with 24% of vacuum deliveries. A recent meta-analysis of five studies, with overall 717 women who underwent endoanal ultrasonography after childbirth, revealed a 26.9% incidence of anal sphincter defects in primiparous women and an 8.5% incidence of new sphincter defects in multiparous women. About one third of women with occult anal sphincter defects were symptomatic after delivery.<sup>73</sup>

### Pelvic Organ Prolapse

Pelvic organ prolapse is very common and is seen in up to 50% of parous women.<sup>74</sup> Hendrix and associates<sup>75</sup> studied the prevalence of pelvic organ prolapse among 27,342 women (the Women's Health Initiative Study). Among the 16,616 women with a uterus, the rate of uterine prolapse was 14.2%; the rate of

cystocele was 34.3%, and the rate of rectocele was 18.6%. Among the 10,727 women who had undergone hysterectomy, prevalence of cystocele was 32.9% and that of rectocele was 18.3%. In 1997, the rate of pelvic organ prolapse surgery in the United States was 22.7 per 10,000 women, making prolapse one of the most common surgical indications in women.<sup>76</sup> Similarly, the lifetime risk of surgery for prolapse by age 80 years was estimated to be 11%.<sup>77</sup>

Pregnancy and childbirth are major risk factors for pelvic organ prolapse. Both the levator ani muscle and the endopelvic fascia are important in maintaining the pelvic organs in their normal anatomic position. Both may be injured during pregnancy and delivery, thus predisposing to the later development of pelvic organ prolapse. Sze and colleagues<sup>78</sup> found that some degree of pelvic organ prolapse existed in their subjects during the third trimester of pregnancy and that the prevalence of prolapse at 6 weeks after delivery was similar in women who underwent vaginal delivery and those who had emergency cesarean section. Similarly, O'Boyle and associates<sup>79</sup> found that nulliparous pregnant women were more likely to have pelvic organ prolapse than their nulliparous, nonpregnant controls. These findings imply that the prolapse process begins during pregnancy and early labor. The risk is further increased after vaginal deliveries. Mant and colleagues<sup>80</sup> studied a cohort of 17,000 British women. Parity was the strongest variable related to surgery for pelvic organ prolapse. Samuelsson and coworkers<sup>81</sup> studied a cohort of 487 Swedish women. The risk for pelvic organ prolapse was found to increase with parity and age. Parity and obesity were also strongly associated with increased risk for pelvic organ prolapse in the large Women's Health Initiative Study.<sup>75</sup> Women who had had at least one child were twice as likely to have pelvic organ prolapse as were nulliparous controls, after adjusting for age, ethnicity, body mass index, and other factors.

Richardson and colleagues<sup>82</sup> documented breaks in the endopelvic fascia in women with pelvic organ prolapse and stress urinary incontinence. These breaks are considered to be secondary to obstetric trauma. The anatomic injury may be further complicated by childbirth-associated denervation injury. Evidence of such denervation has been detected in up to 50% of women with symptomatic pelvic organ prolapse.<sup>83-85</sup> However, one should bear in mind that, as with sphincteric incontinence, the etiology of pelvic organ prolapse is complex and multifactorial. Possible risk factors, other than pregnancy and childbirth, include connective tissue abnormalities, aging, hysterectomy, menopause, and factors associated with chronically raised intra-abdominal pressure.<sup>86</sup>

### Voiding Difficulties

Data regarding the correlation between obstetric parameters and voiding phase disorders are scarce and controversial. Conceptually, voiding phase dysfunction may be result from bladder and/or urethral causes. Bladder causes include detrusor contraction of inadequate magnitude and/or duration to effect bladder emptying (detrusor underactivity) and the absence of detrusor contraction (detrusor areflexia). Urethral causes consist of bladder outlet obstruction due to urethral overactivity (functional obstruction) or anatomic pathologies (mechanical obstruction). These mechanisms may all be responsible for abnormal voiding during the puerperium. Mechanical bladder outlet obstruction may develop secondary to local hematoma or edema, functional

obstruction may be secondary to pain, and detrusor underactivity may be the end result of pelvic floor denervation or neglected bladder overdistention.

Most previously published studies used postvoid residual urine volume, measured by either ultrasound or transurethral catheterization, to detect postpartum voiding dysfunction. Andolf and colleagues<sup>87</sup> investigated residual urinary volumes on the third postpartum day in 539 women who delivered vaginally. Eight women (1.5%) had a residual volume exceeding 150 mL. Retention was more common after instrument delivery or epidural analgesia. Yip and associates<sup>88,89</sup> reported a 4.9% incidence of acute, symptomatic postpartum urinary retention among 691 women who delivered vaginally. An additional 9.7% of patients had no urinary symptoms, but their postvoid residual urinary volume on the first postpartum day was 150 mL or greater (up to 1000 mL). A significant correlation was found between the duration of the first and second stages of labor and postpartum residual urinary volume. We recently reported that approximately half of 277 consecutive women complained of significant voiding difficulties in the immediate postpartum period. The main risk factors included prolonged first and second stages of labor, vacuum extraction, and birth weight 3800 g or greater.<sup>90</sup>

Most cases of early postpartum voiding difficulties resolve spontaneously within few days. Persistent postpartum urinary retention, beyond the early puerperium, is uncommon. In a study of 8402 consecutive, unselected parturients delivered in a university-affiliated maternity hospital over a 1-year period, only 4 patients (0.05%) developed persistent postpartum urinary retention.<sup>91</sup> Risk factors for persistent postpartum urinary retention included vaginal delivery after cesarean section, prolonged second stage of labor, epidural analgesia, and delayed diagnosis and intervention. Urodynamic evaluation, performed in two of these patients 1 month after removal of the suprapubic catheter, revealed stress incontinence in one and detrusor overactivity in the other. Similarly, Carley and colleagues<sup>92</sup> reported a 0.45% prevalence rate of clinically overt postpartum urinary retention among 11,332 vaginally delivered women. Urinary retention was found to be highly associated with instrument-assisted delivery and epidural analgesia. Most affected women resumed spontaneous voiding within 72 hours, but 13 women (0.1%) developed persistent postpartum urinary retention. These two studies indicate that persistent postpartum urinary retention is rare in modern obstetric practice but may be associated with long-term bladder dysfunction. Early diagnosis of postpartum voiding dysfunction and adequate intervention are therefore required to prevent irreversible bladder damage.

### SUMMARY

Pregnancy and childbirth are associated with anatomic and neuromuscular injuries of the pelvic floor. These injuries predispose for various pelvic organ disorders that may manifest during pregnancy and after delivery or develop in later years. Cesarean section appears to be protective, especially if undertaken electively, with no trial of labor. Whether the prevention of pelvic floor injury should be an indication for elective cesarean section is controversial. It should be borne in mind that cesarean section may expose women to greater morbidity and mortality, and that the etiology of pelvic organ disorders is multifactorial. Additional risk factors, other than pregnancy and childbirth, include hered-

ity, collagen abnormalities, obesity, and aging. Better understanding of pathophysiologic mechanisms associated with pelvic floor dysfunction may provide the possibility of using appropriate preventive measures other than elective cesarean section. Fur-

thermore, as new therapies emerge, it is likely that different pathophysiologies will be treated differently. Exploring these processes and quantifying subjective and objective findings remains a clinical challenge.

# FUNCTIONAL ANATOMY AND PATHOPHYSIOLOGY OF PELVIC ORGAN PROLAPSE

*Yvonne Hsu and John O.L. DeLancey*

Pelvic floor disorders, including pelvic organ prolapse and urinary incontinence, are debilitating conditions that result in surgery in one of nine women.<sup>1</sup> In the United States, the National Center for Health Statistics estimates that 400,000 operations are performed for pelvic floor dysfunction each year, with 300,000 of these occurring in the inpatient setting.<sup>2,3</sup> This is six to eight times more operations than radical prostatectomies performed each year. Although there is wide recognition of urinary incontinence, pelvic organ prolapse is responsible for twice as many operations, yet its causes are largely unknown. Prolapse arises because of injuries and deterioration of the muscles, nerves, and connective tissues that support and control normal pelvic function. This chapter addresses the *functional* anatomy of the pelvic floor in women and specifically focuses on how the pelvic organs are supported by the surrounding muscle and fasciae. It also considers the pathophysiology of pelvic organ prolapse as it relates to changes in these structures.

### SUPPORT OF THE PELVIC ORGANS: CONCEPTUAL OVERVIEW

The pelvic organs rely on their connective tissue attachments to the pelvic walls and on support from the levator ani muscles, which are under neuronal control from the peripheral and central nervous systems. In this chapter, the term *pelvic floor* is used broadly to include all of the structures that support the pelvic cavity rather than just the levator ani group of muscles.

The pelvic floor consists of several components lying between the peritoneum and the vulvar skin. From above downward, these are the peritoneum, pelvic viscera and endopelvic fascia, levator ani muscles, perineal membrane, and superficial genital muscles. The support for all these structures comes from connections to the bony pelvis and its attached muscles. The pelvic organs are often thought of as being supported by the pelvic floor, but they are actually a part of it. The pelvic viscera play an important role in forming the pelvic floor through their connections with structures such as the cardinal and uterosacral ligaments.

In 1934, Bonney pointed out that the vagina is in the same relationship to the abdominal cavity as the in-turned finger of a surgical glove is to the rest of the glove (Fig. 53-1).<sup>4</sup> If the pressure in the glove is increased, it forces the finger to protrude downwards in the same way that increases in abdominal pressure force the vagina to prolapse. Figure 53-2 provides a schematic illustration of this prolapse phenomenon. In Figure 53-2C, the lower end of the vagina is held closed by the pelvic floor muscles, which

prevents prolapse by constricting the base of the invaginated finger. Figure 53-2D shows suspension of the vagina to the pelvic walls. Figure 53-2E demonstrates that spatial relationships are important in the flap-valve closure, in which the suspending fibers hold the vagina in a position against the supporting walls of the pelvis; increases in pressure force the vagina against the wall, thereby pinning it in place. Vaginal support is a combination of constriction, suspension, and structural geometry.

The female pelvis can naturally be divided into anterior and posterior compartments (Fig. 53-3). The genital tract (vagina and uterus) divides these two compartments through lateral connections to the pelvic sidewall and suspension at its apex. The levator ani muscles form the bottom of the pelvis. The organs are attached to the levator ani muscles when they pass through the urogenital hiatus and are supported by these connections.

### Functional Anatomy and Prolapse

The pelvic organ support system is multifaceted and includes the endopelvic fascia, the perineal membrane, and the levator ani muscles, which are controlled by the central and peripheral nervous system. The supports of the uterus and vagina are different in different regions (Fig. 53-4).<sup>5</sup> The cervix (when present) and the upper third of the vagina (level I) have relatively long suspensory fibers that are *vertically* oriented in the standing position, whereas the midportion of the vagina (level II) has a more direct attachment *laterally* to the pelvic wall (Fig. 53-5). In the most caudal region (level III), the vagina is attached directly to the structures that surround it. At this level, the levator ani muscles and the perineal membrane have important supportive functions.

In the upper part of the genital tract, a connective tissue complex attaches all the pelvic viscera to the pelvic sidewall. This endopelvic fascia forms a continuous, sheet-like mesentery, extending from the uterine artery at its cephalic margin to the point at which the vagina fuses with the levator ani muscles below. The fascial region that attaches to the uterus is called the parametrium, and that which attaches to the vagina is the paracolpium. Level I is composed of both parametrium and paracolpium. The uterosacral and cardinal ligaments together form the parametrium and support the uterus and upper third of the vagina. The paracolpium portion of level I consists of a relatively long sheet of tissue that suspends the superior aspect of the vagina by attaching it to the pelvic wall. This is true whether or not the cervix is present. The uterosacral ligaments are important components of this support. At level II, the paracolpium changes configuration and forms more direct lateral attachments of the

**Figure 53-1** Bonney's analogy of vaginal prolapse. The vagina is in the same relationship to the abdominal cavity as the in-turned finger of a surgical glove is to the rest of the glove (*left*). The eversion of an intussuscepted surgical glove finger by increasing pressure within the glove is analogous to prolapse of the vagina (*right*). (© 2002 DeLancey; with permission.)

**Figure 53-2** Diagrammatic display of vaginal support. **A**, Invaginated area in a surrounding compartment. **B**, The prolapse opens when the pressure (*arrow*) is increased. **C**, Closing the bottom of the vagina prevents prolapse by constriction. **D**, Ligament suspension. **E**, With flap-valve closure, suspending fibers hold the vagina in a position against the wall, allowing increases in pressure to pin it in place. (© 2002 DeLancey; with permission.)

**Figure 53-3** Compartments of the pelvis. The vagina, connected laterally to the pelvic walls, divides the pelvis into an anterior and posterior compartment. (© 1998 DELANCEY.)

**Figure 53-4** Attachments of the cervix and vagina to the pelvic walls, demonstrating different regions of support with the uterus in situ. Note that the uterine corpus and the bladder have been removed. (© 2002 DeLancey; with permission.)

**Figure 53-5** Levels of vaginal support after hysterectomy. In *level I* (suspension), the paracolpium suspends the vagina from the lateral pelvic walls. Fibers of *level I* extend both vertically and also posteriorly toward the sacrum. In *level II* (attachment), the vagina is attached to the arcus tendineus fascia pelvis and the superior fascia of levator ani. Sagittal view (*inset*) shows the three regions of support. (© 2002 DeLancey; with permission.)

**Figure 53-6** Close-up diagram of the lower margin of *level II* vaginal support system after a wedge of vagina has been removed (*inset*). Note how the anterior vaginal wall, through its connections to the arcus tendineus fascia pelvis, forms a supportive layer clinically referred to as the pubocervical fascia. (© 2002 DeLancey; with permission.)

midportion of the vagina to the pelvic walls (Fig. 53-6). These lateral attachments have functional significance: they stretch the vagina transversely between the bladder and the rectum. In the distal vagina (*level III*), the vaginal wall is directly attached to surrounding structures without any intervening paracolpium. The vagina fuses anteriorly with the urethra, posteriorly with the perineal body, and laterally with the levator ani muscles.

Damage to *level I* support can result in uterine or vaginal prolapse of the apical segment. Damage to the *level II* and *level III* portions of vaginal support results in anterior and posterior vaginal wall prolapse. The varying combinations of these defects

**Figure 53-7** Uterine prolapse, showing the cervix protruding from the vaginal opening (*left*) and vaginal prolapse where the puckered scar indicates where the cervix used to be (*right*). (© 2002 DeLancey; with permission.)

are responsible for the diversity of clinically encountered problems and are discussed in the following sections.

### Apical Segment

In level I, the cardinal and uterosacral ligaments attach the cervix and the upper third of the vagina to the pelvic walls.<sup>6,7</sup> Neither is a true ligament in the sense of a skeletal ligament that is composed of dense regular connective tissue similar to knee ligaments. Rather, they are “visceral ligaments” that are similar to bowel mesentery. They are made of blood vessels, nerves, smooth muscle, and adipose tissue intermingled with irregular connective tissue. They have a supportive function in limiting the excursion of the pelvic organs, much as the mesentery of the small bowel limits the movement of the intestine. When these structures are placed on tension, they form condensations that surgeons refer to as ligaments.

The uterosacral ligaments are bands of tissue that run under the rectovaginal peritoneum; they are composed of smooth muscle, loose and dense connective tissue, blood vessels, nerves, and lymphatics.<sup>6</sup> They originate from the posterolateral aspect of the cervix at the level of the internal cervical os and from the lateral vaginal fornix.<sup>6</sup> Although macroscopic investigation showed insertion of the ligament to the levator ani, the coccygeus, and the presacral fascia,<sup>8</sup> examination by magnetic resonance imaging (MRI) showed that the uterosacral ligaments overlie the sacrospinous ligament and coccygeus in 82% of the cases and overlie the sacrum in only 7% of the cases.<sup>9</sup> The difference between the appearance of these structures on MRI and on dissection may have to do with the tension placed on the structures during dissection and require further research to clarify.

The cardinal ligament is a mass of retroperitoneal areolar connective tissue in which blood vessels predominate; it also contains nerves and lymphatic channels.<sup>7</sup> It has a configuration similar to

that of “chicken wire” or fishing net in its natural state, but when placed under tension it assumes the appearance of a strong cable as the fibers align along the lines of tension.<sup>7</sup> It originates from the pelvic sidewall and inserts on the uterus, cervix, and upper third of the vagina. Both the uterosacral and cardinal tissues are critical components of level I support and provide support for the vaginal apex after hysterectomy (see Figs. 53-5 and 53-6). The cardinal ligaments are oriented in a relatively vertical axis (in the standing posture), whereas the uterosacral ligaments are more dorsal in their orientation.

The nature of uterine support (Fig. 53-7) can be understood when the cervix is pulled downward with a tenaculum during dilation and curettage. After a certain amount of descent, the level I supports become tight and arrests further cervical descent. Similarly, downward descent of the vaginal apex after hysterectomy is resisted by the paracolpium. Damage to the upper suspensory fibers of the paracolpium (cardinal and uterosacral ligaments) allows uterine or apical segment prolapse (Fig. 53-8).

Although descriptions of uterine support often imply that the uterus is suspended by the cardinal/uterosacral complex, much like a light suspended by a wire from the ceiling, this is not the case. The suspensory ligaments hold the uterus in position over the levator muscles, which in turn reduce the tension on the ligaments and protect them from excessive tension. This concept is discussed later, in the section on interactions between muscles and ligaments.

### Anterior Compartment

Anterior compartment support depends on the connections of the vagina and periurethral tissues to the muscles and fascia of the pelvic wall via the arcus tendineus fascia pelvis (Fig. 53-9). On both sides of the pelvis, the arcus tendineus fascia pelvis is a

**Figure 53-8** Damage to the suspensory ligaments (tears) can lead to eversion of the vaginal apex when subjected to downward forces (arrow). (© 2002 DeLancey; with permission.)

**Figure 53-9** Lateral view in the standing position of the pelvic floor structures related to urethral support. The cut is just lateral to the midline. Note that windows have been cut in the levator ani muscles, vagina, and endopelvic fascia so that the urethra and anterior vaginal walls can be seen. (© 2002 DeLancey; with permission; redrawn after © 1994 DeLancey).

**Figure 53-10** *Left*, Attachment of the arcus tendineus pelvis to the pubic bone, the arcus tendineus pelvis (black arrows). *Right*, A paravaginal defect wherein the cervical fascia has separated from the arcus tendineus (black arrows point to the sides of the split). PS, pubic symphysis. (© 2002 DeLancey; with permission.)

band of connective tissue attached at one end to the lower sixth of the pubic bone, 1 cm lateral to the midline, and at the other end to the ischium, just above the spine.

The anterior wall fascial attachments to the arcus tendineus fascia pelvis have been called the paravaginal fascial attachments

by Richardson.<sup>10</sup> Lateral detachment of the paravaginal fascial connections from the pelvic wall is associated with stress incontinence and anterior prolapse (Fig. 53-10). Further details of the structural mechanics of anterior wall support are provided later. In addition, the upper portions of the anterior vaginal wall are

**Figure 53-11** *Left*, Displacement “cystocele”: the intact anterior vaginal wall has prolapsed downward due to paravaginal defect. Note that the right side of the patient’s vagina and cervix has descended more than the left because of a larger defect on that side. *Right*, Distention “cystocele”: the anterior vaginal wall fascia has failed, and the bladder is distending the mucosa. (© 2002 DeLancey; with permission.)

affected by the suspensory actions of level I. If the cardinal and uterosacral ligaments fail, the upper vaginal wall prolapses downward while the lower vagina (levels II and III) remains supported.

Anterior vaginal wall prolapse can occur either because of lateral detachment of the anterior vaginal wall at the pelvic side wall, referred to as a displacement “cystocele,” or as a central failure of the vaginal wall itself that results in distention “cystocele” (Fig. 53-11). Although various grading schemes have been described for anterior vaginal prolapse, they are often focused on the degree of prolapse rather than the anatomic perturbation that results in descent; therefore, it is important to describe anterior prolapse with regard to the location of the fascial failure (lateral detachment versus central failure). At present, although a number of investigators have described techniques to distinguish central from lateral detachment, validation of these techniques remains elusive.

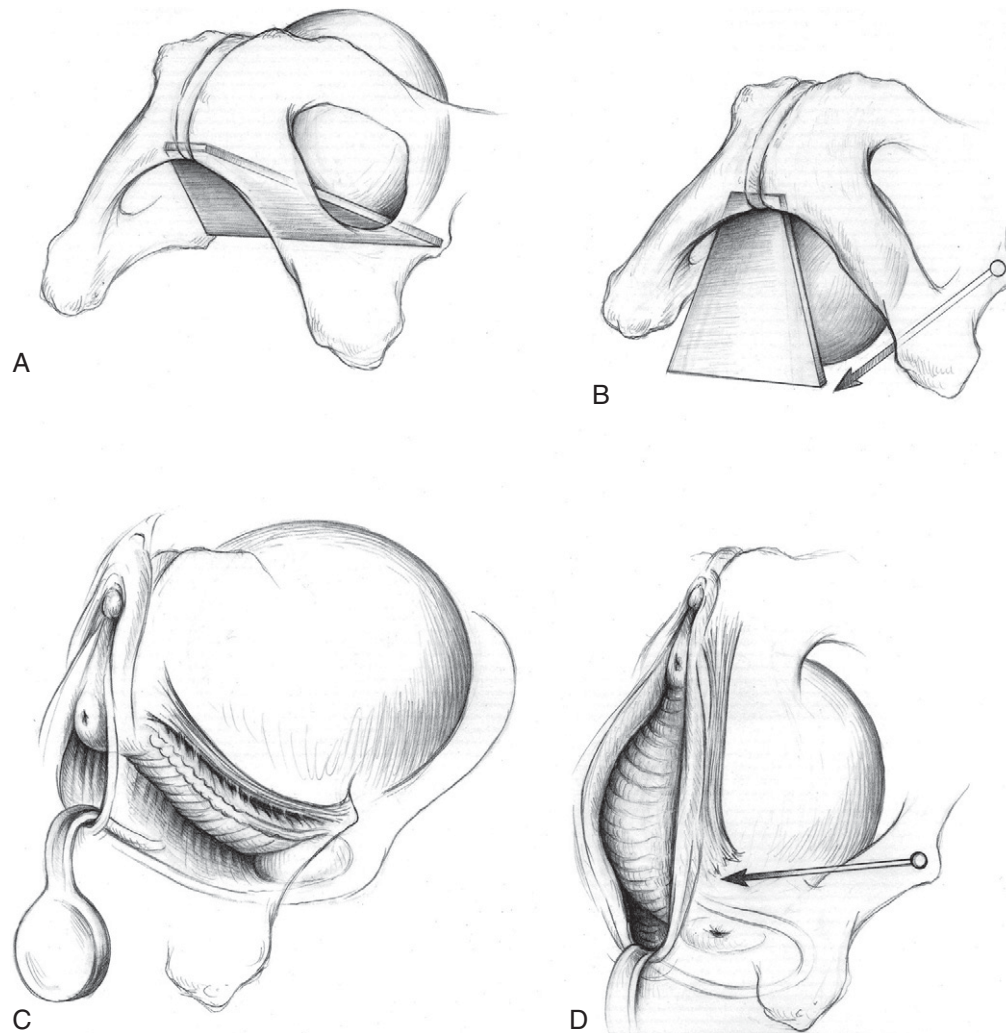

Cystocele caused by defects of the midline fascia is easy to understand, but understanding how lateral detachment results in cystocele is not as obvious. The fact that lateral detachment is associated with cystourethrocele was first established by Richardson and colleagues<sup>10</sup> (see Fig. 53-10). A study of 71 women with anterior compartment prolapse showed that paravaginal defect usually results from a detachment of the arcus tendineus fascia pelvis from the ischial spine, and rarely from the pubic bone.<sup>11</sup> A visual analogy is that of a swinging trapezoid (Fig. 53-12). The mechanical effect of this detachment allows the trapezoid to rotate downward. When this happens, the anterior vaginal wall protrudes through the introitus. Upward support of the trapezoid is also provided by the cardinal and uterosacral ligaments in level I. For this reason, resuspension of the vaginal apex at the

time of surgery, in addition to paravaginal or anterior colporrhaphy, helps to return the anterior wall to a more normal position.

Anatomically, the term *endopelvic fascia* refers to the areolar connective tissue surrounding the vagina. It continues down the length of the vagina as loose areolar tissue surrounding the pelvic viscera (Fig. 53-13). The term “fascia” is often used by surgeons to refer to the strong tissue that they sew together during anterior repairs. This has led to confusion and misunderstanding of the anatomy. Histologic examination has shown that the vagina is made up of three layers: epithelium, muscularis, and adventitia (Fig. 53-14).<sup>12-14</sup> The adventitial layer is loose areolar connective tissue made up of collagen and elastin. These layers form the vaginal tube. The tissue that surgeons plicate during repairs is not what an anatomist would refer to as endopelvic fascia; rather, it is the vaginal muscularis and the adventitial layer of the vaginal tube. Also, many basic science studies that are addressed later in this chapter have used biopsies from the vaginal tube and not from the endopelvic fascia that connects the vaginal wall to the pelvic sidewalls.

### **Perineal Membrane (Urogenital Diaphragm)**

Spanning the anterior part of the pelvic outlet, below the levator ani muscles, there is a dense triangular membrane called the perineal membrane. The term *perineal membrane* replaces the old term, urogenital diaphragm, reflecting the fact that this layer is not a single muscle layer with a double layer of fascia (i.e., a “diaphragm”) but rather a set of connective tissues that surround the urethra.<sup>15</sup> The orientation consists of a single connective tissue membrane, with muscle lying immediately above. The

The attachments to the pubis and the ischial spines are intact. **B**, The connection to the spine has been lost, allowing the fascial plane to swing downward. **C**, Normal anterior vaginal wall as seen with a weighted speculum in place. **D**, The effect of dorsal detachment of the arcus from the ischial spine. (© 2002 DeLancey; with permission.)

perineal membrane lies at the level of the hymen and attaches the urethra, vagina, and perineal body to the ischiopubic rami (Fig. 53-15). The compressor urethrae and urethrovaginal sphincter muscles are associated with the cranial surface of the perineal membrane.

### Posterior Compartment and Perineal Membrane

The posterior vagina is supported by connections between the vagina, the bony pelvis, and the levator ani muscles.<sup>16</sup> The lower third of the vagina is fused with the perineal body (level III), (Fig. 53-16) which connects the perineal membranes on either side. The midposterior vagina (level II) is connected to the inside of the levator ani muscles by sheets of endopelvic fascia (Fig. 53-17). These connections prevent vaginal descent during increases in abdominal pressure. The most medial aspects of these paired sheets are the rectal pillars. In its upper third, the posterior vagina is connected laterally by the paracolpium of level I. Separate

systems for anterior and posterior vaginal support do not exist at level I.

The fibers of the perineal membrane connect through the perineal body, thereby providing a layer that resists downward descent of the rectum. If this attachment becomes broken, then the resistance to downward descent is lost (see Fig. 53-16B). This situation is somewhat like an incisional hernia seen after disruption of a vertical incision, in which the bowel protrudes through a defect between the rectus abdominus muscles if the hernia is due to a defect in the rectus sheath. In the same way, protrusion of the rectum between the levator ani muscles can be seen if a disruption of the perineal body and connections of the perineal membrane occurs (Fig. 53-18). Reattachment of the separated structures during perineorrhaphy corrects this defect and is a mainstay of reconstructive surgery. Because the levator ani muscles are intimately connected with the cranial surface of the perineal membranes, this reattachment also restores the muscles to a more normal position under the pelvic organs, in a location where they can provide support.

**Figure 53-14** Higher magnification of a section of vaginal wall. Note the lack of a fascial layer. The endopelvic fascia is not seen at this magnification. (© 2005 DeLancey; with permission.)

### Levator Ani Muscles

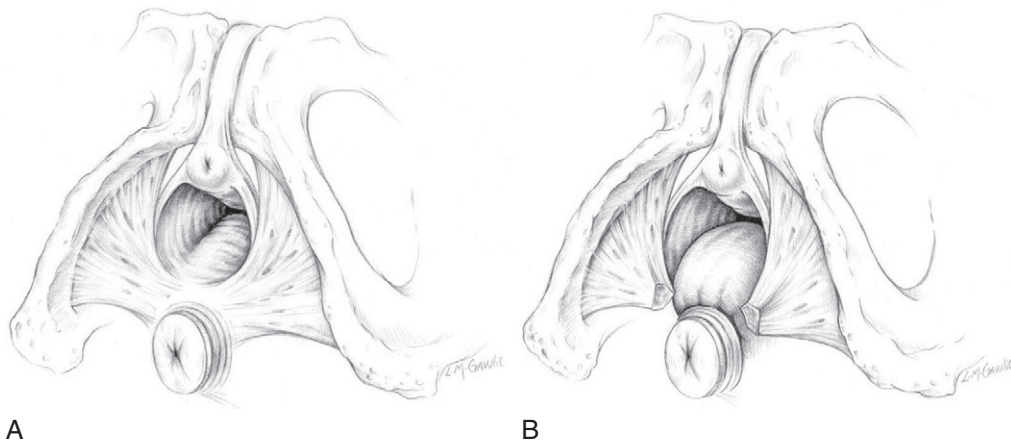

Below and surrounding the pelvic organs are the levator ani muscles (Fig. 53-19).<sup>17</sup> When these muscles and their covering fascia are considered together, the combined structures are referred to as the *pelvic diaphragm* (not to be confused with the so-called urogenital diaphragm, discussed in the previous section).

There are three components of the levator ani muscle. The iliococcygeal portion forms a thin, relatively flat, horizontal shelf that spans the potential gap from one pelvic sidewall to the other. The pubovisceral muscle (also known as the pubococcygeus muscle) attaches the pelvic organs to the pubic bone, and the puborectal muscle forms a sling behind the rectum. The origins and insertions of these muscles as well as their characteristic anatomic relations are shown in Table 53-1 and Figure 53-19.<sup>18</sup>

The opening between the levator ani muscles through which the urethra, vagina, and rectum pass is the levator hiatus. The portion of the levator hiatus that lies ventral to the perineal body

**Figure 53-15** Position of the perineal membrane and its associated components of the striated urogenital sphincter, the compressor urethrae, and the urethrovaginal sphincter (© DeLancey; with permission.)

**Figure 53-16** **A**, The perineal membrane spans the arch between the ischiopubic rami, with each side attached to the other through their connection in the perineal body. **B**, Note that separation of the fibers in this area leaves the rectum unsupported and results in a low posterior prolapse. (© 1999 DeLancey; with permission.)

is referred to as the urogenital hiatus, and it is through this opening that prolapse of the vagina, uterus, urethra, and bladder occurs. The urogenital hiatus is bounded anteriorly by the pubic bones, laterally by levator ani muscles, and posteriorly by the perineal body and external anal sphincter. The baseline tonic activity of the levator ani muscle keeps the hiatus closed by compressing the urethra, vagina, and rectum against the pubic bone, pulling the pelvic floor and organs in a cephalic direction.<sup>19</sup> This continuous muscle action closes the lumen of the vagina, much as the anal sphincter closes the anus. This constant action eliminates any opening within the pelvic floor through which prolapse could occur and forms a relatively horizontal shelf on which the pelvic organs are supported.<sup>20</sup> Damage to the levators resulting from nerve or connective tissue injury leaves the urogenital hiatus open and results in prolapse.

### Endopelvic Fascia and Levator Ani Interactions

The interaction between the levator ani muscles and the endopelvic fascia is one of the most important biomechanical features of pelvic organ support. As long as the muscles maintain their constant tone closing the pelvic floor, the ligaments of the endopelvic fascia have very little tension on them even with increases

**Figure 53-17** Lateral view of the pelvis showing the relationships of the puborectalis, iliococcygeus, and pelvic floor structures after removal of the ischium below the spine and sacrospinous ligament (SSL). EAS, external anal sphincter. The bladder and vagina have been cut in the midline, with the rectum left intact. Note how the endopelvic fascial “pillars” hold the vaginal wall dorsally, preventing its downward protrusion. (© 1999 DeLancey; with permission.)

in abdominal pressure. If the muscles become damaged so that the pelvic floor sags downward, the organs are pushed through the urogenital hiatus. Once they have fallen below the level of the hymenal ring, they are unsupported by the levator ani muscles, and the ligaments must carry the entire load. Although the endopelvic fascia can sustain these loads for short periods, if the pelvic muscles do not close the urogenital hiatus, the connective tissue

**Figure 53-18** Posterior prolapse due to separation of the perineal body. Note the end of the hymenal ring that lies laterally on the side of the vagina, no longer united with its companion on the other side. (© DeLancey; with permission.)

**Table 53-1 International Standardized Terminology: Divisions of the Levator Ani Muscles**

Nomina Terminologica	Origin	Insertion
Pubovisceral muscle (pubococcygeus)		
Puboperinealis (PPM)	Pubis	Perineal body
Pubovaginalis (PVM)	Pubis	Vaginal wall at the level of the mid-urethra
Puboanalis (PAM)	Pubis	Intersphincteric groove between internal and external anal sphincter to end in the anal skin
Puborectalis (PRM)	Pubis	Forms sling behind the rectum
Iliococcygeus (ICM)	Tendinous arch of the levator ani	The two sides fuse in the iliococcygeal raphe

**Figure 53-19** **A**, Schematic view of the levator ani muscles from below after the vulvar structures and perineal membrane have been removed, showing the arcus tendineus levator ani (ATLA); external sphincter (EAS); puboanal muscle (PAM); perineal body (PB) uniting the two ends of the puboperineal muscle (PPM); iliococcygeal muscle (ICM); and puborectal muscle (PRM). Note that the urethra and vagina have been transected just above the hymenal ring. **B**, The levator ani muscle seen from above, looking over the sacral promontory (SAC), showing the pubovaginal muscle (PVM). The urethra, vagina, and rectum have been transected just above the pelvic floor. (The internal obturator muscles have been removed to clarify levator muscle origins.) (© 2003 DeLancey; with permission.)

eventually fails, resulting in prolapse. The support of the vagina has been likened to a ship in its berth, floating on the water and attached by ropes on either side to a dock.<sup>21</sup> The ship is analogous to the vagina, the ropes to the ligaments, and the water to the supportive layer formed by the pelvic muscles. The ropes' function to hold the ship (pelvic organs) in the center of its berth as it rests on the water (pelvic muscles). However, if the water level were to fall far enough that the ropes would be required to hold the entire weight of the ship, the ropes would all break.

Once the pelvic musculature becomes damaged and no longer holds the organs in place, the ligaments are subjected to excessive forces. These forces may be enough to cause ligament failure over the course of time. A woman who sustains an injury to her pelvic floor muscles when she is young must depend to a greater extent on strength of her ligaments to prevent pelvic organ prolapse over the subsequent years of her life. An woman with injured muscles may have strong connective tissue that compensates and therefore may never develop prolapse, whereas another woman, who has the same degree of muscular damage but was born with weaker connective tissue, may experience prolapse as she ages.

In addition, the interaction between the pelvic floor muscles and the endopelvic fascia is responsible for maintaining the flap-valve configuration in the pelvic floor that lessens ligament tension because of the supportive nature of the levator plate (see Fig. 53-2E). The flap-valve requires the dorsal traction of the uterosacral ligaments, and to some extent the cardinal ligaments, to hold the cervix back in the hollow of the sacrum. It also requires the ventral pull of the pubovisceral portions of the levator ani muscle to swing the levator plate more horizontally to close the urogenital hiatus. It is this interaction between the two forces that is so critical in maintaining the normal structural relationships that lessen the tension on ligaments and muscles.

### Nerves

There are two main nerves that supply the pelvic floor relative to pelvic organ prolapse. One is the pudendal nerve, which supplies the urethral and anal sphincters and perineal muscles, and the other is the nerve to the levator ani, which innervates the major musculature that supports the pelvic floor. These are distinct nerves with differing origins, courses, and insertions. The nerve to the levator originates from S3 to S5 foramina, runs inside the pelvis on the cranial surface of the levator ani muscle, and provides the innervation to all the subdivisions of the muscle.<sup>22</sup> The pudendal nerve originates from S2 to S4 foramina and runs through Alcock's canal, which is caudal to the levator ani muscles. The pudendal nerve has three branches—the clitoral, perineal, and inferior hemorrhoidal—which innervate the clitoris, the perineal musculature and inner perineal skin, and the external anal sphincter, respectively.<sup>22</sup>

### PATHOPHYSIOLOGY

The previous section described how different structures work together to provide pelvic organ support; this section explores the current scientific literature regarding possible causes of structural failure leading to prolapse. The discussion has been divided based on the components that are thought to be important in pelvic support: connective tissue supports and vaginal wall, levator ani muscles, and nerves. At the end of each component section, we discuss the challenges and questions that confront future research. In addition to the three components, we also briefly discuss the pathophysiologic effects of vaginal delivery, because of its special importance in the natural history of prolapse. Finally, we have devoted a section to biomechanical research on prolapse, an area of increasing clinical and research interest.

## Connective Tissue Supports and Vaginal Wall

The adventitial layer of the vagina, referred to as the endopelvic fascia, is composed of collagen and elastin that separates the muscular wall of the vagina and the paravaginal tissues. Investigators have studied the biology of pelvic connective tissue. Its structural support comes from its composition, which includes collagen and elastin arranged in different fiber orientations and embedded in a dynamic ground substance. Much of the distensibility of collagen and connective tissues comes from rearrangement of the fibers. A collagen fiber by itself is relatively inelastic, able to stretch only 4% longitudinally, whereas an elastin fiber can stretch up to 70%.<sup>23</sup> Therefore, if the fibers were arranged longitudinally, the tissue would not be able to stretch much before rupture. Instead, collagen and elastin fibers are arranged in different directions, so that, when placed under strain, they can stretch much more before being subject to rupture. An analogy can be made in comparing a cotton ball to a cotton dress shirt. When you pull on a cotton ball, there is a great deal of stretch that occurs until all the individual fibers become aligned in the same direction. After fiber alignment occurs, there is little stretch before rupture as the mechanical properties of the individual fiber come into play. In a cotton dress shirt, the individual fibers are already in alignment, and not much stretch can occur before rupture.

Several studies have explored whether differences in the vaginal tissues of women with prolapse and normal support explain the pathophysiology of prolapse. Researchers have focused on collagen, elastin, smooth muscle, and hormone receptors as the major factors in vaginal support.

### Collagen

Collagen provides much of the tensile strength for the endopelvic fascia and vaginal epithelium. Over the years, collagen studies have yielded varying, and at times conflicting, results. Women with prolapse had just as much if not greater rates of collagen synthesis than women without prolapse in earlier histochemical studies using fibroblast cultures.<sup>24</sup> In contrast, Jackson and colleagues found that women with prolapse had a 25% reduction in total collagen compared to controls.<sup>25</sup> Types I and III are the most common collagen fibers in vaginal tissues. Type I fibers are the more abundant, and type III contributes more of the elastic properties of the tissue.<sup>26</sup> Liapis and associates found a modest reduction in collagen type III in women with prolapse and a more significant decrease in women with stress incontinence, suggesting that an altered ratio could lead to pelvic floor dysfunction.<sup>26</sup> However, other researchers found no difference in the collagen ratios.<sup>25</sup>

Recently, attention has turned toward collagen metabolism and turnover as markers of prolapse. There does seem to be consistent evidence that collagen metabolism is significantly altered in the pelvic tissues of women with prolapse. Collagen fibers are stabilized by intermolecular covalent cross-links. The formation of cross-links and glycation lead to maturation and inhibit turnover. Degradation depends on the activity of proteinases secreted from connective tissue cells.<sup>25</sup> Whereas women with prolapse have collagen with more cross-links and other signs of maturation, they also have increased synthesis of new collagen, which is degraded in preference to older material because it has fewer cross-links.<sup>25</sup> Chen and coworkers found increased expression of matrix metalloproteinase messenger RNA, which is

responsible for collagen breakdown, and decreased expression of inhibitors of metalloproteinases in women with stress incontinence and prolapse.<sup>27</sup>

### Elastin

Elastin provides much of the elastic properties of the pelvic connective tissue.<sup>23</sup> Compared with collagen, fewer studies have examined the role of elastin in the development of prolapse. Jackson and colleagues did not find a difference in elastin content between premenopausal women with prolapse and controls.<sup>25</sup> Chen and coworkers examined elastolytic activity in women with both stress incontinence and prolapse compared with controls. They found little difference in elastolytic activity but a decrease in  $\alpha_1$ -antitrypsin, an inhibitor of elastin turnover, in women with prolapse, suggesting that there may be higher elastin turnover in prolapse.<sup>28</sup>

### Smooth Muscle

Smooth muscle is another important aspect of the endopelvic fascia, because it is a major component of the vaginal wall. Smooth muscle analysis of anterior vaginal wall sections from the urethrovesical junction of fresh cadavers showed quantifiable variations in thickness and densities.<sup>29</sup> Morphometric analysis of the anterior and posterior vaginal walls showed decreased fraction of smooth muscle in the muscularis of women with pelvic organ prolapse compared with controls.<sup>30,31</sup> Other markers suggest that women with prolapse have less smooth muscle contractility and force maintenance.<sup>32</sup>

### Hormone Receptors

It has long been assumed that pelvic floor dysfunction is related to changes in menopause and is influenced by hormones. Untangling loss of hormonal action from age-related changes is extremely difficult. In blinded, randomized, placebo-controlled studies, two selective estrogen receptor modulators (SERMs), idoxifene and levormeloxifene, were thought to be associated with an increased incidence of pelvic organ prolapse in postmenopausal women participating in clinical trials of osteoporosis.<sup>33</sup> In contrast, neither amoxifen nor toremifene, two clinically available SERMs, was associated with pelvic floor relaxation.<sup>34,35</sup> More recently, there has been evidence that raloxifene reduces the likelihood or need for prolapse surgery by 50%.<sup>36</sup> Paradoxically, Vardy and coauthors suggested that there was an increase in prolapse in women receiving raloxifene and tamoxifen, but the status of support in the population was not given, and most changes were small (1 cm), with only one individual having a change in prolapse stage.<sup>37</sup> This finding might be a result of minor differences in vaginal pliability and might not reflect structural changes, such as connective tissue rupture and muscle damage, that go with actual prolapse.

Several studies have looked at the presence or absence of hormone receptors in tissues that are involved in pelvic organ support.<sup>38,39</sup> Other studies have examined the effects of estrogen on biologic markers such as collagen.<sup>40-42</sup> Estrogen receptors are present throughout the body, and yet there are important differential effects. For example, endometrium is highly sensitive to fluctuations in estrogen, but skin is much less responsive. Any supposition that hormones play a major role in pelvic organ prolapse must be based on human studies that actually prove differences in prolapse occurring in those with and without

hormonal supplementation or administration of hormonal antagonists.

### Challenges

There has been a significant body of basic science research regarding the components of the vaginal wall (vaginal tube). However, relatively little has been done to investigate the connections of the vagina to the pelvic walls (e.g., endopelvic fascia). Most of the studies reviewed used either partial- or full-thickness vaginal biopsies. It is difficult to make any assumptions about the endopelvic fascia, because it is not included in samples of the vaginal wall (see Fig. 53-13). Therefore, the question of whether it is the connection between the vagina to the pelvic sidewall that fails, as suggested by Richardson,<sup>10</sup> or whether it is the vaginal wall itself that is involved in prolapse remains scientifically unresolved. Also, although some of the differences found in women with prolapse suggest that biochemical changes in the connective tissue may play an important role in prolapse, these studies were unable to explain the sequence of prolapse progression. In other words, we are left to wonder whether the alterations in connective tissue led to the prolapse or were a response to the mechanical effects of prolapse.

### Levator Ani

MRI has been established as a technique for examination of the levator ani muscle.<sup>43,44</sup> Using MRI, visible levator ani defects are beginning to be linked to the development of prolapse. Up to 20% of primiparous women have a visible defect in the levator ani muscle, probably as a result of birth injury.<sup>45</sup> Also, computer-generated birth models using MRI have found that the medial puboviseral muscle is at greatest risk for stretch-induced injury.<sup>46</sup> A few investigations have found that the levator ani muscles of women with prolapse have different morphologic characteristics than those of controls.<sup>47-49</sup> The changes in morphology are beginning to be quantified. Investigators have found that women with prolapse have smaller overall levator volume,<sup>47,48</sup> larger levator symphysis gap, and wider levator hiatus.<sup>49</sup> Aside from these MRI findings, histologic evidence of muscle damage has been found as well<sup>50</sup> and is associated with operative failure.<sup>51</sup>

### Challenges

Quantification of levator ani differences or defects in prolapse have so far been limited to measurements of volume or thickness.<sup>47,48,52</sup> The maximal force that a muscle generates depends on the cross-sectional area of the muscle perpendicular to its fiber direction.<sup>53</sup> Measurement of this force is challenging because of the complex shape of the levator ani muscles, with different sections having differing fiber directions. Continued advances in imaging may make it possible to relate levator ani appearance to function.

### Nerves

A unifying neurogenic hypothesis has been well established as a contributor to pelvic floor dysfunction. Although there is a significant body of literature regarding neurogenic causes of fecal incontinence and urinary incontinence, there is comparatively little exploring the relation between nerve damage and prolapse. Prospective study of perineal descent on defecography and pudendal nerve terminal motor latency failed to show any rela-

tionship between pudendal nerve damage and increased degree of perineal descent.<sup>54</sup> Two studies in which patients with prolapse were included did not show a difference in pudendal nerve terminal motor latencies in patients with prolapse.<sup>55,56</sup> However, electromyographic studies of women with pelvic floor dysfunction, including prolapse and incontinence, found changes consistent with motor unit loss or failure of central activation.<sup>57</sup> More electromyographic and nerve studies are needed to tie neurogenic injury and pelvic organ prolapse.

### Vaginal Birth

Although it is clear that incontinence and prolapse increase with age,<sup>1</sup> there is no time during a woman's life when these structures are more vulnerable than during childbirth. Vaginal delivery confers a fourfold to 11-fold higher risk of prolapse that increases with parity.<sup>58</sup> Increased descent of vaginal wall points after vaginal delivery has been found in studies using a combined method of clinical examination and functional cine-MRI.<sup>59</sup> Two studies suggested that pregnancy alone may be a risk factor for worsening prolapse; however, both of these studies used definitions of prolapse that many would consider clinically normal.<sup>60,61</sup>

### Biomechanics

Biologic specimens exhibit a mixture of elastic, viscous, and plastic properties. Elasticity is the ability of a tissue to return to its original shape after loading. Viscosity refers to the elongation of the tissue over time. Plasticity is the residual deformation that remains after loading is complete. There is a paucity of biomechanical studies of pelvic organ supports. Previous biomechanical research was performed using constant elongation to induce failure or rupture.<sup>62-64</sup> This does not provide accurate information about the physiologic function of the tissue, because it does not account for the viscoelastic and plastic properties of connective tissues. Ettema and colleagues proposed a more accurate way of measuring the elastic properties of vaginal tissue, using a slow-rate, linear elongation method.<sup>65</sup> This method is able to discriminate small changes in a tissue's elastic properties at lower stress levels and therefore is functionally more meaningful. Using this method, Goh and coworkers compared the biomechanical properties of premenopausal and postmenopausal women with prolapse and found little difference between the groups.<sup>66</sup>

### CONCLUSION

Understanding the functional anatomy of prolapse lays the necessary groundwork for understanding the mechanisms of pelvic organ prolapse. When the components of pelvic support and how they relate to each other have been identified, we will be able to understand how disruptions result in failure. Compared to stress incontinence, prolapse has received relatively little scientific attention. Although basic science research concerning the vaginal connective tissue and levator ani muscles has been performed, little has been done on other vital structures, such as the endopelvic fascia. In addition, investigations into the biomechanical processes of prolapse are lacking. Although this chapter provides an overview of existing knowledge on pelvic organ prolapse, it also looks ahead to the many unanswered scientific questions.

# PELVIC ORGAN PROLAPSE: CLINICAL DIAGNOSIS AND PRESENTATION

*Chi Chiung Grace Chen and Mark D. Walters*

Pelvic organ prolapse (POP) is a heterogeneous condition in which weaknesses of the pelvic floor musculature and connective tissue result in herniation of pelvic organs into the vaginal lumen. In more severe cases, this herniation can protrude through the vaginal introitus and beyond the hymenal ring. Organs that may potentially herniate into the vaginal canal include the bladder with or without involvement of the urethra, resulting in cystourethroceles and cystoceles, respectively. Patients may have uterine prolapse, or, after hysterectomy, the vaginal cuff may herniate resulting in apical vaginal prolapse. The rectum, small bowel, and sigmoid colon may also herniate, resulting in rectoceles, enteroceles, and sigmoidoceles, respectively. This chapter focuses on the definition, diagnosis, and classification of POP.

### DEFINITION AND EPIDEMIOLOGY

It is estimated that more than 300,000 surgeries are performed to correct POP annually, at a cost of greater than \$1 billion.<sup>1</sup> Furthermore, the number of patients seeking care for these disorders is expected to increase by 45% in the future.<sup>2</sup> Despite this high prevalence, POP is a poorly understood condition, and many of the accepted definitions are based on expert opinion and consensus rather than epidemiologic or clinical data. The American College of Obstetrics and Gynecology (ACOG) defines POP as the protrusion of pelvic organs into the vaginal canal.<sup>3</sup> More specifically, in a terminology workshop convened by the National Institutes of Health (NIH) for researchers in female pelvic floor disorders, POP was defined as the descent of vaginal segments to within 1 cm of the hymen or lower.<sup>4</sup> POP encompasses anterior and posterior vaginal prolapse as well as apical or uterine prolapse. Terms such as “cystocele” and “rectocele” are intentionally not used because they imply an unrealistic certainty as to the specific organs behind the vaginal wall at the time of physical examination.

It is important to note that, although most clinicians can recognize the extremes of normal support versus severe prolapse, most cannot objectively state at what point vaginal laxity becomes pathologic and requires intervention. There are limited data concerning the normal distribution of POP in the population and the correlations between symptoms and physical findings. In a study of 497 women, Swift demonstrated that the distribution of prolapse in a population exhibited a bell-shaped curve, with most women having stage I or II prolapse by the Pelvic Organ Prolapse Quantification (POPQ) classification system (discussed later) and only 3% having stage III prolapse.<sup>5</sup> This signifies that, at baseline, most women have some degree of pelvic relaxation. However, these women are typically asymptomatic and develop symptoms only as their prolapse increases in severity.<sup>6</sup> Therefore,

even if POP is found on physical examination by the definition given, it may not be clinically relevant and may not require intervention if the patient is asymptomatic.

### HISTORY

Although it has been shown previously that patients' histories cannot be used alone to differentiate or diagnose different types of urinary incontinence,<sup>7,8</sup> less is known about the reliability of patients' symptoms for diagnosing POP. Patients with POP may present with a plethora of symptoms relating to voiding, defecatory, and sexual dysfunction as well as symptoms directly associated with the prolapse, such as vaginal pressure and discomfort. Despite the few studies specifically addressing the association between reported symptoms and POP, the consensus in the literature seems to be that the severity of the prolapse is not necessarily associated with increased visceral symptomatology.

Vaginal prolapse in any compartment—anterior, apical, or posterior—can manifest as vaginal fullness, pain, and/or protruding mass. In a recent study by Tan and associates, the feeling of “a bulge or that something is falling outside the vagina” had a positive predictive value of 81% for POP, and the lack of this symptom had a negative predictive value of 76%.<sup>9</sup> Not surprisingly, increased degree of prolapse, especially beyond the hymen, is associated with increased pelvic discomfort and visualization of a protrusion.<sup>10</sup>

Stress urinary incontinence and voiding difficulties can occur in association with anterior and apical vaginal prolapse. However, women with advanced degrees of prolapse may not have overt symptoms of stress incontinence, because the prolapse may cause a mechanical obstruction of the urethra, leading to a higher urethral closure pressure and thereby preventing urinary leakage.<sup>11</sup> Instead, these women may require vaginal pressure or manual replacement of the prolapse in order to accomplish voiding. They are therefore at risk for incomplete bladder emptying and recurrent or persistent urinary tract infections, and for the development of de novo stress incontinence after the prolapse is repaired. Patients who require digital assistance to void in general have more advanced degrees of prolapse.<sup>12</sup>

In addition to difficulty voiding, other urinary symptoms such as urgency, frequency, and urge incontinence, are found in women with POP.<sup>13</sup> However, it is not clear whether the severity of prolapse is associated with more irritative voiding symptoms or bladder pain.<sup>10,12</sup>

POP, especially in the apical and posterior compartments, can be associated with defecatory dysfunction, such as pain with defecation, the need for manual assistance with defecation, and anal incontinence of flatus, liquid or solid stool. These patients

often have outlet-type constipation secondary to the trapping of stool within the rectal hernia, necessitating splinting or application of manual pressure in the vagina, rectum, or perineum to reduce the hernia and aid in defecation. Although defecatory dysfunction remains the area that is least understood in patients with POP, clinical and radiographic studies have shown that the severity of prolapse is not strongly correlated with increased symptomatology.<sup>9,10,12,14</sup>

Although women with isolated posterior prolapse (e.g., rectocele, enterocele, perineal body defect) may also have the sensation of vaginal bulge and pressure, these women are often asymptomatic and the prolapse is recognized only on physical examination. Once a posterior vaginal defect is identified, questions regarding defecatory dysfunction must be elicited.

Although the relationship between sexual function and POP is not clearly defined, questions regarding sexual dysfunction must be included in the evaluation of any patient with POP. Patients may report symptoms of dyspareunia, decreased libido and orgasm, and increased embarrassment with altered anatomy that affects body image. Some studies have reported that prolapse adversely affects sexual functioning, with subsequent improvement in sexual function after repair of prolapse.<sup>15-17</sup> However, other studies have shown little correlation between the extent of prolapse and sexual dysfunction.<sup>12</sup> It is important to note that the evaluation of sexual function may be especially difficult in this patient population because the hindrances to sexual function may include factors other than POP, such as partner limitations and functional deficits.

## PHYSICAL EXAMINATION

The physical examination for POP should be conducted with the patient in dorsal lithotomy position, as for a routine pelvic examination. If physical findings do not correspond to symptoms, or if the maximum extent of the prolapse cannot be confirmed, the woman can be reexamined in the standing position.

Initially, the external genitalia are inspected; if no displacement is apparent, the labia are gently spread to expose the vestibule and hymen. The integrity of the perineal body is evaluated, and the extent of all prolapsed parts is assessed. A retractor, a Sims speculum, or the posterior blade of a bivalve speculum may be used to depress the posterior vagina to aid in visualizing the anterior vagina, and vice versa for the posterior vagina. Because most patients with POP are postmenopausal, the vaginal mucosa should be examined for atrophy and thinning, which may affect management. Healthy, estrogenized tissue without significant evidence of prolapse, is well perfused and exhibits rugations and physiologic moisture. Atrophic vaginal tissue appears pale and thin, is without rugation, and can be friable.

After the resting vaginal examination, the patient is instructed to perform a Valsalva maneuver or to cough vigorously. During this maneuver, the order of descent of the pelvic organs is noted, as is the relationship of the pelvic organs at the peak of increased intra-abdominal pressure. A rectovaginal examination is also required to fully evaluate prolapse of the posterior vaginal wall and perineal body. Digital assessment of the contents of the rectovaginal septum during straining examination can differentiate between a “traction” enterocele (in which the posterior cul-de-sac is pulled down by the prolapsing cervix or vaginal cuff but is not distended by intestines) and a “pulsion” enterocele (in which the intestinal contents of the enterocele distend the rectovaginal

septum and produce a protruding mass). Other clinical observations and tests to help delineate POP include cotton swab (Q-tip) testing for the measurement of urethral axis mobility; measurement of perineal descent; measurement of the transverse diameter of the genital hiatus or of the protruding prolapse; measurement of vaginal volume; description and measurement of posterior prolapse; and examination techniques differentiating among various types of defects (e.g., central versus paravaginal defects of the anterior vaginal wall). Inspection should also be made of the anal sphincter because fecal incontinence is often associated with posterior vaginal support defects. Grossly, women with a torn external sphincter may have scarring or a “dovetail” sign on the perineal body.

Anterior vaginal wall descent usually represents bladder descent with or without concomitant urethral hypermobility. However, in 1.6% of women with anterior vaginal prolapse, an anterior enterocele can mimic a cystocele on physical examination.<sup>18</sup> Furthermore, lateral paravaginal defects, identified as detachment of the lateral vaginal sulci, may be distinguished from central defects, seen as a midline protrusion with preservation of the lateral sulci. This is done with the use of a curved forceps placed in the anterolateral vaginal sulcus and directed toward the ischial spine. Bulging of the anterior vaginal wall in the midline between the forcep blades implies a midline defect; blunting or descent of the vaginal fornices on either side with straining suggests lateral paravaginal defects. However, researchers have shown that the physical examination technique used to detect paravaginal defects is not particularly reliable or accurate. In a study by Barber and colleagues of 117 women with prolapse, the sensitivity of clinical examination to detect paravaginal defects was good (92%), yet the specificity was poor (52%).<sup>19</sup> Despite a high prevalence of paravaginal defects, the positive predictive value was only 61%. Fewer than two thirds of the women believed to have a paravaginal defect on physical examination were confirmed to possess the same at surgery. Another study by Whiteside and associates, demonstrated poor reproducibility of clinical examination to detect anterior vaginal wall defects.<sup>20</sup> Therefore, the clinical value of determining the location of midline, apical, and lateral paravaginal defects remains unknown.

In regard to posterior defects, it has previously been demonstrated that preoperative clinical examinations do not always accurately differentiate between rectoceles and enteroceles.<sup>21,22</sup> Some investigators have advocated performing imaging studies to further delineate the exact nature of the posterior wall prolapse. Traditionally, most clinicians believe they are able to detect the presence or absence of these defects without anatomically localizing them. However, little is known regarding the accuracy or utility of clinical examinations in evaluating the anatomic locations of posterior vaginal defects. Burrows and colleagues found that clinical examinations often did not accurately predict the specific location of defects in the rectovaginal septum subsequently found intraoperatively.<sup>23</sup> Clinical findings corresponded with intraoperative observations in 59% of patients and differed in 41%; sensitivities and positive predictive values of clinical examinations were less than 40% for all posterior defects. However, what remains unclear is the clinical consequence of not detecting these defects preoperatively.

Clinical evaluation for POP also should include a lumbosacral neurologic evaluation consisting of strength, sensory, and reflex examinations. First, the strength of the pelvic floor musculature is assessed by palpating the levator ani muscle complex in the posterior vaginal wall approximately 2 to 4 cm cephalad to the

hymen. The patient is then asked to squeeze around the examiner's fingers. Weakness in this muscle can be a result of neurologic deficits or direct trauma during childbirth. Internal and external anal sphincter tone is assessed by placing a finger in the rectum and noting the initial resistance to entry and then the resistance after the patient maximally squeezes her anal sphincter. Sensory function is assessed with the use of pinprick and light-touch of the mons pubis, perineum/perianal area, and labia majora. Cystometry and anal manometry can be used to evaluate the visceral sensation of the bladder and rectum, respectively. Lastly, anal and bulbocavernosus reflexes can be elicited by lightly stroking the perianal skin and observing or palpating the contraction of the anal sphincter, and by lightly tapping the clitoris and observing the contraction of the bulbocavernosus muscle and/or anal sphincter.

### CLASSIFICATION OF PELVIC ORGAN PROLAPSE

Presently, there are two widely accepted classification systems for assessing the severity of POP: the Baden-Walker "half-way" vaginal profile and the POPQ, which was established by the International Continence Society (ICS) in 1996.<sup>24</sup> The purpose of any classification system is to facilitate understanding of the etiology and pathophysiology of disease, to establish and standardize treatment and research guidelines, and to aid precision and avoid confusion among practitioners.

For many years, POP has been described using criteria modified from the Baden-Walker "half-way" vaginal profile.<sup>25-27</sup> This grading system is simple to use; it is widely understood among gynecologic surgeons and has been found to have reasonable inter-examiner reliability for all segments of the vagina and for uterine support.<sup>28</sup> The most dependent position of the pelvic organs during maximum straining or standing is used and graded as normal or first-, second-, or third-degree prolapse. First-degree prolapse refers to vaginal segments that descend halfway (but not to) the hymen; second-degree is descent to the hymen; and third-degree is prolapse beyond the hymen. A rectovaginal examination can also be used to better delineate the severity of rectoceles. This classification system, although popular, is slowly being replaced by the more precise and standardized POPQ system.

In the POPQ system, the pelvic organ anatomy is described during physical examination of the external genitalia and vaginal canal.<sup>24</sup> Segments of the lower reproductive tract replace the terms cystocele, enterocele, rectocele, and urethrovesical junction, because these terms imply an unrealistic certainty as to the structures on the other side of the vaginal bulge, particularly in women who have had previous prolapse surgery. The examiner sees and describes the maximum protrusion noted by the patient during her daily activities. The details of the examination, including criteria for the end point of the examination and full development of the prolapse, should be specified. Suggested criteria for demonstration of maximum prolapse include any or all of the following: any protrusion of the vaginal wall that has become tight during straining by the patient; traction on the prolapse causes no further descent; the subject confirms that the size of the prolapse and the extent of the protrusion seen by the examiner are as extensive as the most severe protrusion she has had (a small hand-held mirror to visualize the protrusion may be helpful); and a standing/straining examination confirms that the full extent of the prolapse was observed in the other positions.

**Figure 54-1** Six sites (points Aa, Ba, C, D, Bp, and Ap), genital hiatus (gh), perineal body (pb), and total vaginal length (tvl) are used for pelvic organ support quantitation. (From Bump RC, Mattiasson A, Bø K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10, 1996.)

Details about patient position, types of vaginal specula or retractors, type and intensity of straining used to develop the prolapse maximally, and fullness of the bladder should be stated.

This descriptive system contains a series of site-specific measurements of the woman's pelvic organ support. It can be easily learned and taught by means of a video tutorial.<sup>29</sup> Prolapse in each segment is evaluated and measured relative to the hymen (not introitus), which is a fixed anatomic landmark that can be identified consistently and precisely. The anatomic position of the six defined points for measurement should be in centimeters above or proximal to the hymen (negative number) or centimeters below or distal to the hymen (positive number), with the plane of the hymen being defined as zero. For example, a cervix that protrudes 3 cm distal to (beyond) the hymen should be described as +3 cm.

Six points (two on the anterior vaginal wall, two in the superior vagina, and two on the posterior vaginal wall) are located with reference to the plane of the hymen (Fig. 54-1). In describing the anterior vaginal wall, the term *anterior vaginal wall prolapse* is preferable to *cystocele* or *anterior enterocele* unless the organs involved are identified by ancillary tests. There are two anterior sites:

**Point Aa:** A point located in the midline of the anterior vaginal wall 3 cm proximal to the external urethral meatus, corresponding to the proximal location of the urethrovesical crease. By definition, the range of position of point Aa relative to the hymen is -3 to +3 cm.

**Point Ba:** A point that represents the most distal (i.e., most dependent) position of any part of the upper anterior vaginal wall from the vaginal cuff or anterior vaginal fornix to point Aa. By definition, point Ba is at -3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff in women with total posthysterectomy vaginal eversion.

Two points are on the superior vagina. These points represent the most proximal locations of the normally positioned lower reproductive tract.

**Point C:** A point that represents either the most distal (i.e., most dependent) edge of the cervix or the leading edge of the vaginal cuff (hysterectomy scar) after total hysterectomy.

**Point D:** A point that represents a location of the posterior fornix in a woman who still has a cervix. It represents the level of uterosacral ligament attachment to the proximal posterior cervix. It is included as a point of measurement to differentiate suspensory failure of the uterosacral—cardinal ligament complex from cervical elongation. Point D is omitted in the absence of the cervix.

Two points are located on the posterior vaginal wall. Analogous to anterior prolapse, posterior prolapse should be discussed in terms of segments of the vaginal wall rather than the organs that lie behind it. Thus, the term *posterior vaginal wall prolapse* is preferable to *rectocele* or *enterocele* unless the organs involved are identified by ancillary tests. If small bowel appears to be present in the rectovaginal space, the examiner should comment on this fact and clearly describe the basis for this clinical impression (e.g., by observation of peristaltic activity in the distended posterior vagina or palpation of loops of small bowel between an examining finger in the rectum and one in the vagina).

**Point Ap:** A point located in the midline of the posterior vaginal wall 3 cm proximal to the hymen. By definition, the range of position of point Ap relative to the hymen is  $-3$  to  $+3$  cm.

**Point Bp:** A point that represents the most distal (i.e., most dependent) position of any part or the upper posterior vaginal wall from the vaginal cuff or posterior vaginal fornix to point Ap. By definition, point Bp is at  $-3$  cm in the absence of prolapse and would have a positive value equal to the position of the cuff in a woman with total posthysterectomy vaginal eversion.

Other landmarks include the genital hiatus, which is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening. The total vaginal length is the greatest depth of the vagina in centimeters when point C or D is reduced to its full normal position. The points and measurements are presented in Figure 54-1.

The positions of points Aa, Ba, Ap, Bp, C, and (if applicable) D with reference to the hymen are measured and recorded. Positions are expressed as centimeters proximal to (above) the hymen (negative number) or centimeters distal to (below) the hymen (positive number), with the plane of the hymen defined as zero. Measurements may be recorded as a simple line of numbers (e.g.,  $-3$ ,  $-3$ ,  $-7$ ,  $-9$ ,  $-3$ ,  $-3$ ,  $9$ ,  $2$ , and  $2$  for points Aa, Ba, C, D, Bp, Ap, total vaginal length, genital hiatus, and perineal body, respectively). Alternatively, a  $3 \times 3$  grid can be used to concisely organize the measurements, as shown in Figure 54-2, or a line diagram of a configuration can be drawn, as shown in Figures 54-3 and 54-4. Figure 54-3 is a grid and line diagram contrasting measurements that indicate normal support with those of complete posthysterectomy vaginal eversion. Figure 54-4 is a grid and line diagram representing predominant anterior and posterior vaginal wall prolapse with partial apical descent.

<b>anterior wall</b> <b>Aa</b>	<b>anterior wall</b> <b>Ba</b>	<b>cervix or cuff</b> <b>C</b>
<b>genital hiatus</b> <b>gh</b>	<b>perineal body</b> <b>pb</b>	<b>total vaginal length</b> <b>tvL</b>
<b>posterior wall</b> <b>Ap</b>	<b>posterior wall</b> <b>Bp</b>	<b>posterior fornix</b> <b>D</b>

**Figure 54-2** Three-by-three grid for recording quantitative description of pelvic organ support. (From Bump RC, Mattiasson A, Bø K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10, 1996.)

The profile for quantifying prolapse provides a precise description of anatomy for individual patients. An ordinal staging system of pelvic organ prolapse is suggested using these measurements and can be useful for the description of populations and for research comparisons. Stages are assigned according to the most severe portion of the prolapse when the full extent of the protrusion has been demonstrated. For a stage to be assigned to an individual subject, it is essential that her quantitative description be completed first. The five stages of pelvic organ support (0 through IV) are described in Table 54-1. Because precise characterization of pelvic floor muscle strength and description of functional symptoms are of vital importance, the reader is referred to the ICS committee document for further details.<sup>24</sup>

Studies have demonstrated excellent interexaminer and intraexaminer reliability for the POPQ system in quantifying POP.<sup>28,30</sup> Steele and associates showed that the system can be taught effectively to residents and medical students using a 17-minute video.<sup>29</sup> Furthermore, the measurements can be obtained quickly by both experienced and nonexperienced clinicians (2.1 and 3.7 minutes, respectively).<sup>30</sup> The POPQ system does not take into account lateral defects and perineal body prolapse, but these can be added in descriptive terms. Despite its limitations, the POPQ system is currently the classification system used in most research studies and NIH trials, and it is gaining popularity in clinic practice.

## DIAGNOSTIC TESTS

After a careful history and physical examination, few diagnostic tests are needed to further evaluate patients with POP if there is no concomitant voiding or defecatory dysfunction. For example, hydronephrosis does occur in a small proportion of women with prolapse, but even if it is identified, it usually does not change management in the women for whom surgical repair is planned.

**Figure 54-3 A**, Grid and line diagram of complete eversion of vagina. The most distal point of the anterior wall (point Ba), vaginal cuff scar (point C), and the most distal point of the posterior wall (point Bp) are all at same position (+8), and points Aa and Ap are maximally distal (both at +3). Because total vaginal length equals maximum protrusion, this is stage IV prolapse. **B**, Normal support. Points Aa and Ba and points Ap and Bp are all -3 because there is no anterior or posterior wall descent. The lowest point of the cervix is 8 cm above the hymen (-8), and the posterior fornix is 2 cm above this (-10). The vaginal length is 10 cm, the genital hiatus is 2 cm, and the perineal body measures 3 cm. This represents stage 0 prolapse. (From Bump RC, Mattiasson A, Bø K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10, 1996.)

**Table 54-1 Stages of Pelvic Organ Prolapse**

Stage	Description
0	No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at -3 cm, and either point C or point D is between -TVL cm and -(TVL-2) cm; that is, the quantitation value for point C or D is $\leq$ -(TVL-2) cm. In <b>Fig. 54-3, B</b> represents stage 0.
I	The criteria for stage 0 are not met, but the most distal portion of the prolapse is >1 cm above the level of the hymen (i.e., its quantitation value is $<$ -1 cm).
II	The most distal portion of the prolapse is $\leq$ 1 cm proximal to or distal to the plane of the hymen (i.e., its quantitation value is $\geq$ -1 cm but $\leq$ +1 cm).
III	The most distal portion of the prolapse is >1 cm below (distal to) the plane of the hymen but protrudes no further than 2 cm less than the TVL (i.e., its quantitation value is $>$ +1 cm but $<$ +[TVL-2] cm). In <b>Fig. 54-4, A</b> represents stage III anterior and <b>B</b> represents stage III posterior prolapse.
IV	Essentially complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least (TVL-2) cm (i.e., its quantitation value is $\geq$ +[TVL-2] cm). In most instances, the leading edge of stage IV prolapse is the cervix or vaginal cuff scar. In <b>Fig. 54-3, A</b> represents stage IV C prolapse.

TVL, total vaginal length.

From Bump RC, Mattiasson A, Bø K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10, 1996.

Therefore, routine imaging of the kidneys and ureters is not necessary.

Because patients with anterior, apical, or posterior prolapse may have voiding dysfunction due to obstruction of the urethra, the completeness of bladder emptying should be assessed with timed and measured voids followed by either catheterization or

bladder ultrasound to measure postvoid residual urine volumes. Kinking of the urethra may also obscure any indication of urinary incontinence that may be present.<sup>11,31</sup> Therefore, it is important to assess for evidence of incontinence after reduction of the prolapse. This can be done with a pessary, vaginal packing, or ring forceps at the time of the office bladder filling or urodynamic

**Figure 54-4** **A**, Grid and line diagram of predominant anterior support defect. The leading point of prolapse is the upper anterior vaginal wall, point Ba (+6). There is significant elongation of the bulging anterior wall. Point Aa is maximally distal (+3), and the vaginal cuff scar is 2 cm above the hymen ( $C = -2$ ). The cuff scar has undergone 4 cm of descent, because it would be at  $-6$  (total vaginal length) if it were perfectly supported. In this example, total vaginal length is measure not as the maximum depth with the elongated anterior vaginal wall maximally reduced but rather as the depth of the vagina at cuff with point C reduced to its normal full extent, as specified in the text. This represents stage III anterior prolapse. **B**, Predominant posterior support defect. The leading point of prolapse is the upper posterior vaginal wall, point Bp (+5). Point Ap is 2 cm distal to the hymen (+2), and the vaginal cuff scar is 6 cm above the hymen ( $-6$ ). The cuff has undergone only 2 cm of descent, because it would be at  $-8$  (total vaginal length) if it were perfectly supported. This represents stage III posterior prolapse. (From Bump RC, Mattiasson A, Bø K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10, 1996.)

testing. If urinary leakage occurs with coughing or Valsalva maneuvers after reduction of the prolapse, the urethral sphincter is probably incompetent, even if the patient is normally continent. This can occur in up to half of women with stage III or IV prolapse. In this situation, the surgeon should choose a sling procedure in conjunction with the prolapse repair.<sup>32</sup> If sphincteric incompetence is not present even after reduction of the prolapse, an anti-incontinence procedure may not be indicated.

As discussed in previous sections, preoperative clinical assessments of specific support defects involved in POP often do not correspond to subsequent intraoperative findings. Therefore, some investigators have advocated using imaging procedures such as ultrasonography, contrast radiography, and magnetic resonance imaging (MRI) to further describe the exact nature of the support defects before attempting surgical repairs. For example, some practitioners have used contrast ultrasonography to evaluate for paravaginal defects by placing a water-filled condom in the vaginal canal to better delineate the paravaginal spaces.<sup>33</sup> Others have used MRI to better characterize the soft tissue and viscera of the pelvis.<sup>34</sup> However, there is a lack of standardized radiologic criteria for diagnosing POP. Therefore, the clinical utility of imaging studies remains unknown, and they are currently used mostly for research purposes.

Similar to patients with POP who are without voiding dysfunction, patients with POP who are without symptoms of defecatory dysfunction generally do not warrant ancillary bowel testing. For example, although defecating proctography can provide additional information regarding rectal emptying, studies have demonstrated that it is no more sensitive at detecting rectoceles than physical examination alone.<sup>35</sup> However, patients

with concomitant defecatory dysfunction or motility disorders do merit further evaluation.

In patients with defecatory dysfunction, it is necessary to differentiate between those with colonic motility disorders and those with pelvic outlet symptoms. Useful ancillary tests include anoscopy and proctosigmoidoscopy to evaluate for prolapsing hemorrhoids and intrarectal prolapse. Motility disorders can be assessed with colonic transit studies, which involve a series of radiographs that document the passage of ingested radiopaque markers. Depending on the specific protocol used, passage of less than 80% of the ingested markers could indicate the presence of a motility disorder, whereas collection of markers in the sigmoid colon could indicate the presence of an outlet obstruction.<sup>36</sup>

In patients with apical and posterior vaginal prolapse who also complain of difficult or incomplete bowel emptying, it is important to evaluate for pelvic floor dyssynergia. During the physical examination, patients with pelvic floor dyssynergia often have hypercontracted and tender puborectalis muscles that may not relax on command. Tests for diagnosing pelvic floor dyssynergia include electromyography and the balloon expulsion test, which demonstrates a paradoxical contraction of the puborectalis muscle during defecation. Defecating proctography, which involves dynamic and still images of patients at rest, during defecation, and while contracting the anal sphincter, can also be used for diagnosis. Defecography has the added advantage of providing radiographic evidence of the specific organ that is herniating into the posterior vaginal wall, and it is the gold standard for measuring perineal descent.<sup>37</sup>

Dynamic MRI defecography can also be used to provide information regarding defecation and anatomic soft tissue defects. It

has the advantages of being noninvasive and not requiring ionizing radiation, and it is unrivaled in its depictions of pelvic soft tissue. However, the clinical utility of this costly imaging modality is debatable, because it has not been shown to alter clinical decision-making.<sup>38</sup>

## CONCLUSIONS

POP is a heterogeneous group of conditions that has wide medical and social implications for the current aging female population. Many fundamental concepts such as epidemiology, natural

disease progression, and associations with urinary, bowel, and sexual dysfunction have yet to be fully established and are consequently areas of active research. In this chapter, we have discussed the basic evaluation of patients with POP, from pertinent history to physical findings, classification systems, and ancillary studies. We have also addressed some of the controversies inherent in this emerging field. Because this is an area of active research, we did not attempt to provide an all-encompassing view of POP. Rather, we have provided a foundation from which the reader can extrapolate for patient care as well as for understanding of the current literature.

# IMAGING IN THE DIAGNOSIS OF PELVIC ORGAN PROLAPSE

*Steven S. Raman and Lousine Boyadzhyan*

Pelvic organ prolapse and pelvic floor relaxation are two related and often coexistent conditions. *Prolapse* refers to an abnormal and noticeable protrusion of bladder, urethra, vagina, or rectum through fascial and hiatal defects typically involving the perineum. Pelvic floor *relaxation*, which typically accompanies prolapse, refers to a weakening of the suspensory fascia, ligaments, and muscles of the pelvic sling. Patients typically do not present with an isolated organ defect; instead, these often complex disorders typically comprise a combination of abnormalities such as a rectocele, an enterocele, or a cystocele. These disorders often occur in middle-aged to elderly women. Symptoms may include urinary incontinence, pain, pressure, perineal herniation, and bulging. On physical examination, findings are often equivocal, because the pelvic anatomy may be distorted due to prior pelvic surgery or severe abnormalities. Clinicians rely on a combination of imaging modalities and functional testing (e.g., urodynamics, anorectal manometry) to help describe the anatomic and functional defects.<sup>1,2</sup> Currently, both fluoroscopy and magnetic resonance imaging (MRI) are widely used and complementary techniques to evaluate disorders of the bladder, vagina, and rectum.<sup>3</sup>

### IMAGING MODALITIES FOR EVALUATION OF PELVIC FLOOR DISORDERS

#### Fluoroscopy

Fluoroscopic evaluation of either voiding or defecation may be performed with the patient in the upright position after opacification with contrast material (Fig. 55-1). Some believe that the upright position most closely resembles the physiologic condition reproducing symptoms, and it has been used as a natural extension of the physical examination.<sup>4</sup> Disorders of the posterior pelvic compartment, which typically include constipation and incomplete defecation, may be studied by instilling a barium paste into the rectum and performing a dynamic fluoroscopic evacuation proctogram or defecogram. Similarly, the bladder may be instilled with a water-soluble iodinated contrast agent during dynamic evaluation of filling and voiding by the traditional voiding cystourethrogram (VCUG). Also, the vagina may be similarly studied by dynamic vaginography.<sup>5</sup> With the “four-contrast” defecogram (in which the bowel, rectum, vagina, and bladder are opacified), the relationships among these compartments may be studied simultaneously.<sup>1</sup>

#### Defecography

Defecography, or evacuation proctography, is a simple radiologic technique that is used to image the rectal voiding process of a barium-based paste enema. During the examination, the patient

sits on a special defecography radiolucent commode while fluoroscopic images are recorded in the lateral projection. Although exact protocols vary, in general, one obtains views at rest, at maximal contraction of the voluntary anal sphincter and pelvic floor musculature without actual defecation, while coughing, while emptying the rectum as completely as possible, and while straining maximally after the evacuation is complete (Figs. 55-2 and 55-3).<sup>5</sup> In addition to using barium-based enemas, many urogenital imagers also administer an oral barium suspension with Gastrografin 30 to 60 minutes before the examination to opacify the bowel and thus facilitate the identification of enteroceles. One can also use contrast gel injected into the vaginal apex and look for rectovaginal separation on the images as an indication of an enterocele.<sup>6</sup> The recording process varies from obtaining spot films to videotaping the entire process during so-called dynamic proctography.

The most essential part of the examination is the assessment of evacuation rate and completeness.<sup>7</sup> Defecography yields both morphologic and functional information, because it provides imaging of the rectal configuration throughout all of the phases of evacuation and allows assessment of whether the latter process is normal or prolonged.<sup>6</sup> Such factors of pelvic floor function as rectal emptying and volume, anal sphincter competency, and perineal and pelvic floor musculature can be evaluated with this technique. It is possible to identify the prolapsed organs, to evaluate the morphology of the bladder neck, and to identify the axis of the bladder and the vagina. However, defecography does not assess fine mucosal abnormalities.<sup>6</sup>

There is an important caveat that pertains to the interpretation of defecographic findings by clinicians. Given that there is a rather wide overlap between standard defecographic measurements and findings among normal asymptomatic patients and those with significant symptomatology, radiographic findings obtained during defecography are not to be used as reliable diagnostic criteria of pelvic floor abnormalities.<sup>8-10</sup> They must be combined with clinical measurements and subjective symptoms reported by the patient for interpretation. Many experts agree that defecography alone is of limited value in clinical decision-making and should be interpreted with the results of complementary testing such as anorectal manometry and pelvic MRI.<sup>6</sup>

#### Colpocystodefecography

Colpocystodefecography (CCD) or dynamic cystoproctography (DCP) combines voiding cystography, vaginal opacification, and defecography (discussed in the previous section). The imaging study itself is very similar to that described for defecography. The patient is either upright or seated in a special defecography stool-chair, depending on the phase of the examination, with the images being taken during the static and the dynamic phases of

**Figure 55-1** Defecography or evacuation proctography suite (A) and commode (B) used to image patients during various phases of defecation or micturition in lateral projection.

the examination. During the former phase, the patient is either resting, performing a Valsalva maneuver, or maximally contracting her anal sphincter; the latter phase of the study involves micturition and defecation.<sup>11</sup> Therefore, information obtained during a single CCD study is a combination of voiding cystography and defecography.

CCD has been shown to be more sensitive than physical examination in the detection of various forms of female pelvic organ prolapse, and it was developed to complement the physical examination.<sup>12</sup> It has the advantage of examining the patient under the force of gravity in either upright or seated position, thus revealing pelvic floor weakness during physiologic activities as well as rest. However, it does include exposure of the patient to the effects of ionizing radiation, and it puts a time-constraint on both the examiner and the examinee. In addition, it is a rather intrusive technique and requires a great deal of cooperation from the patient as well as patience from the examiner.

### Ultrasonography

Ultrasonography is popular because it is an inexpensive, noninvasive imaging technique that does not involve the use of ionizing radiation. It is currently best reserved for evaluation of pelvic organs and bladder volume. The main disadvantages of this technique are its operator dependence and suboptimal ability for comprehensive visualization of tissue planes.<sup>5</sup> Because of these

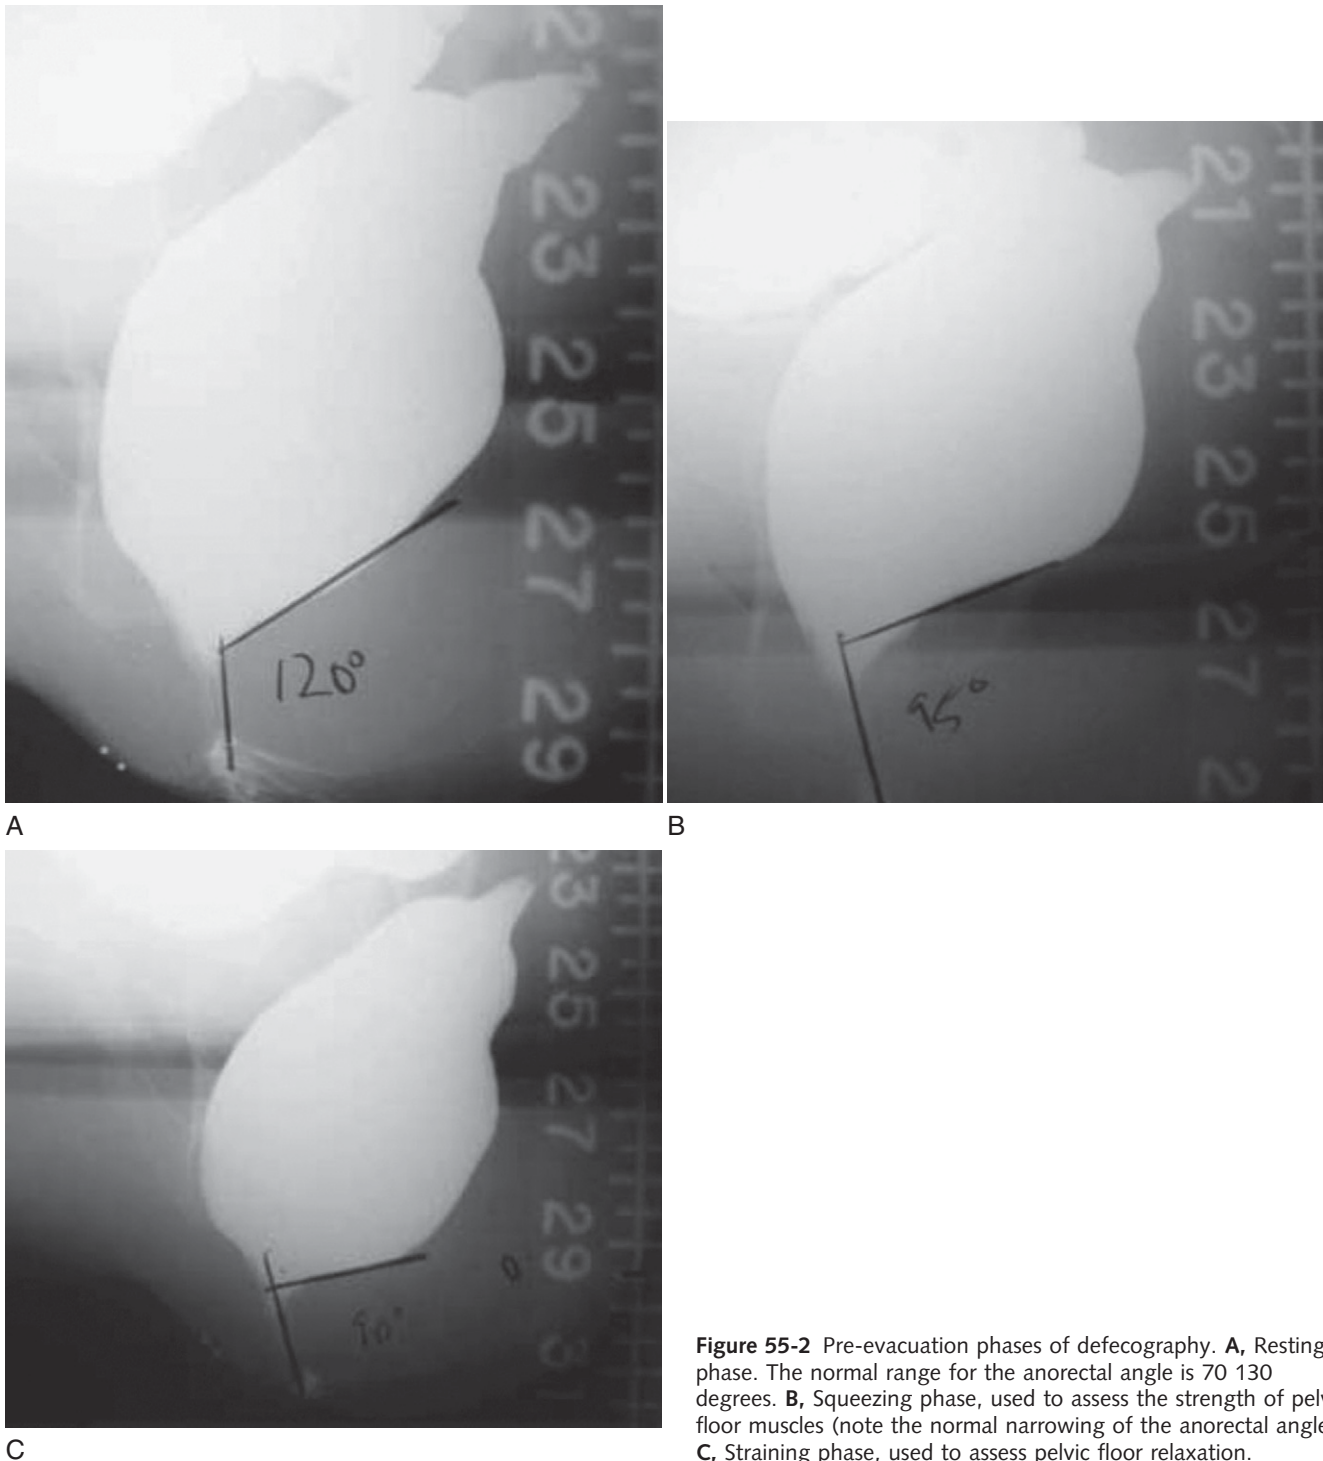

drawbacks, pelvic floor prolapse has been graded by physical examination far more often than by either transvaginal, transrectal, or transperineal ultrasound.<sup>4</sup>

### Endoanal Approach

Endoanal ultrasound is used to assess the anorectal junction in patients with incontinence, because other approaches such as abdominal, perineal, or transvaginal scanning are not capable of visualizing the anal sphincter muscles as adequately as the endoanal approach.<sup>13</sup> Although the anal sphincter and even, to a certain extent, upper anal canal defects can be visualized, there is a very wide range of normal findings owing to differences in methodology and reproducibility of measurements with fibers that lie oblique to the plane of the imaging probe.<sup>5</sup> Positioning of the patient is also important and somewhat gender specific. Whereas in men the left lateral position is adequate, female patients should be imaged either prone or in lithotomy position so as to not disturb the anterior anatomy and to increase the diagnostic accuracy of the study.<sup>14</sup> In general, series of images are taken at several levels of depth as the probe is being withdrawn from the anal canal, with detailed examination of any abnormality encountered along the way.

### Transvaginal Approach

Female anatomy is unique in that it allows a transvaginal approach to imaging of anal sphincter abnormalities. It is possible to obtain

**Figure 55-2** Pre-evacuation phases of defecography. **A**, Resting phase. The normal range for the anorectal angle is 70–130 degrees. **B**, Squeezing phase, used to assess the strength of pelvic floor muscles (note the normal narrowing of the anorectal angle). **C**, Straining phase, used to assess pelvic floor relaxation.

a unique view of the sphincter in its closed state during this study when the probe placed in the distal vagina/perineum is angled backward. Perineal body thickness, the subepithelial thickness, anal cushions, and sphincter damage can be assessed.<sup>15</sup> However, even though the transvaginal approach allows for assessment of the anal sphincters, the endoanal approach is superior for defining the extent of sphincter tears and confirming their intactness

throughout their length.<sup>13,15</sup> In addition to assessing the anal sphincter, transvaginal sonography allows assessment of the urethra and bladder in supine or sitting positions as well as during dynamic studies in the assessment of urinary continence mechanisms.<sup>16</sup> In some cases of enteroceles, it is possible to visualize bowel loops extending down into the rectovaginal space during this examination.<sup>17</sup>

**Figure 55-3** A through F, Dynamic phases of defecography, in which the patient is asked to initiate evacuation rapidly. The latest images (E, F) show near-complete evacuation.

### Perineal Approach

In the perineal approach, the pelvic floor is imaged while the ultrasound probe is placed on the perineum. It is also possible to obtain good images of the bladder neck and pubic symphysis at rest and during Valsalva maneuvers in the sagittal plane with the probe placed over the vulva. Although the relationship of dynamic transperineal ultrasound to other, more established imaging modalities remains to be fully assessed, it has a great potential as a simple, cheap, and relatively noninvasive technique. With the perineal approach the position of the bladder neck, the puborectalis, and the anorectal angle can be measured. In addition, during straining phases, it is sometimes possible to visualize rectoceles, cystoceles, enteroceles, and rectal intussusceptions.<sup>15</sup> Some investigators recommend using rectal and vaginal opacification with ultrasound coupling gel during dynamic transperineal ultrasound studies. With the patient in the left lateral position and a full bladder, movement of the pelvic floor muscles is observed in the sagittal and coronal planes during straining and squeezing.<sup>18</sup>

### Magnetic Resonance Imaging

MRI offers a myriad of advantages over other imaging modalities: lack of ionizing radiation, ease of performance, reproducibility, excellent depiction of pelvic floor soft tissues, multiplanar imaging, and, perhaps most important, its dynamic rapid acquisition capabilities.<sup>19-23</sup> Because MRI is capable of superior differentiation between soft tissues and fluid-filled viscera, the musculofascial support structures of the pelvic organs can be visualized.<sup>24</sup> By using different imaging systems, it is possible to tailor the imaging examination to the needs of the patient and the clinician. Whereas endoanal coils yield the highest-resolution images of the anal sphincter, with somewhat limited visualization of other pelvic floor structures, a body coil permits greater flexibility during the examination, because it results in a more global view of the perineum and the pelvic floor.<sup>5</sup> In addition, most cases of pelvic floor dysfunction involve several pelvic compartments, and MRI is an invaluable technique because it is ideally suited for simultaneous multicompartamental anatomic assessment during a given imaging study.<sup>2,25</sup>

The patient's prone position inside the magnet during the study is the only obvious disadvantage of using MRI, because it naturally eliminates the gravity component from the pelvic prolapse, which may be more pronounced while standing or sitting.<sup>26</sup> However, practically speaking, most clinical physical examinations by urologists and gynecologists are performed with the patient in the prone position. In addition, at least one study designed to compare MRI findings in the upright and supine positions found no significant differences, although the small sample size of this study could have contributed to the statistical insignificance reported by the authors.<sup>25,27</sup> More important, this study described a vertically open-configuration magnet system, which, albeit with artifacts, demonstrated the potential feasibility of eventually being able to conduct dynamic MRI studies with patients in upright and seated positions.<sup>27</sup>

Yet another group described dynamic magnetic resonance defecography with a superconducting open-configuration magnet system with the patients studied in the sitting position. The authors showed that magnetic resonance defecography is superior to fluoroscopic defecography and is a superb method for the detection of clinically relevant pelvic floor pathology.<sup>26</sup> Once

again, this study used a small number of patients, so the findings remain to be further confirmed by larger trials. Because open MRI configuration systems still remain in the experimental stages and are not widely available, clinicians should be well aware of this potential drawback of MRI and rely on the entire clinical picture, complemented with other studies and physical examination findings, in making their final decisions. Another potential disadvantage of MRI is its unsuitability for claustrophobic patients and those with cardiac pacemakers.<sup>24</sup>

Given the numerous advantages of MRI in the study of pelvic organ prolapse and pelvic floor relaxation, there is a rather wide spectrum of methods used by several investigators, as opposed to a single optimal protocol. Some patients may be imaged at rest, whereas others are studied while straining or during dynamic voiding or evacuation in the MRI scanner. In addition, MRI studies have been done without contrast material, with catheters to identify the urethra, with vaginal and rectal markers, and with vaginal, urethral, rectal, and bladder contrast material.<sup>19,28</sup> In general, whereas classic T2-weighted static sequences with correspondingly high spatial resolution are used to assess the anatomy (e.g., levator ani trophicity), fast dynamic sequences are used to study morphologic changes during rest and contraction, straining, and evacuation phases.<sup>4,25</sup> The entire imaging study is usually accomplished in 20 to 25 minutes. Information obtained about peritoneal and digestive compartments is especially useful, because it allows evaluation of complex multicompartamental cases of pelvic prolapse in which physical examination appears grossly inadequate. MRI is also very useful in the assessment of postsurgical recurrences.<sup>25</sup>

The development of dynamic rapid T2 sequences (e.g., single-shot fast spin-echo [SSFSE], half-Fourier acquisition turbo spin-echo [HASTE], true fast imaging with steady-state precision [True FISP]) allows acquisition of superb anatomic detail during brief periods of breath-holds. Of note, no patient preparation or instrumentation is needed to complete these studies. In fact, the ureters, bladder, uterus, vagina, rectum, bowel, ovaries, and even abnormally dilated ureters may be visualized without the use of any contrast agents. More important, data obtained from dynamic MRI are more accurate than physical examination in diagnosing enteroceles, cystoceles, vaginal vault prolapse, and uterine hypermobility.<sup>24</sup> From a surgical point of view, MRI clearly identifies the ovaries, which greatly aids in the decision to perform oophorectomy at the time of hysterectomy if certain abnormalities are present during the preoperative imaging workup of patients. In addition, one is able to visualize other important pelvic pathology, such as uterine leiomyomas, ureteral dilatation, and other pelvic masses.<sup>29</sup>

Opponents of MRI bring up the issue of the costliness of this diagnostic modality. Some investigators concluded in their studies of the economic aspects of MRI that there is a paucity of evidence in the literature to guide such decisions. Yet others have reported that dynamic MRI of the pelvis may be designed to be significantly less expensive than pelvic ultrasound and VCUG. An MRI time of 15 minutes or less may help decrease cost.<sup>4</sup> Most likely, it is these latter factors that will eventually lead to greater cost-effectiveness of MRI for pelvic floor disorders across numerous medical centers in the country.

### Data Analysis Using Magnetic Resonance Imaging Data

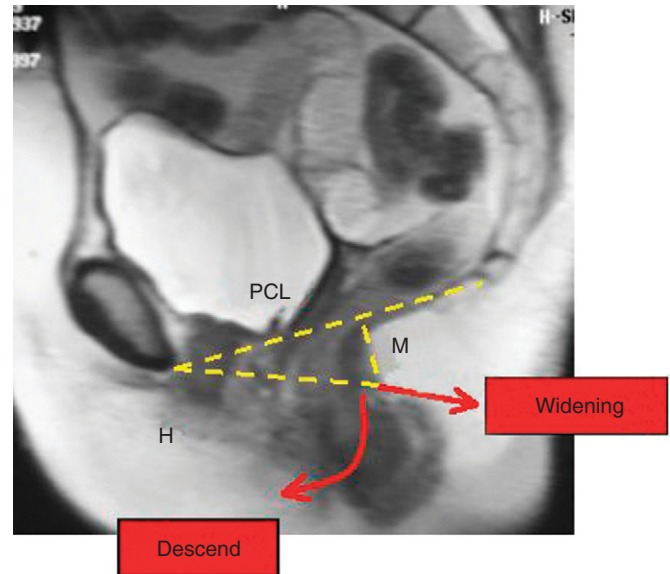

Results of the MRI are analyzed with respect to pelvic organ position at rest and during contraction and straining phases relative to anatomic landmarks.<sup>29</sup> The latter are in turn divided into fixed

and mobile landmarks. The so-called pubococcygeal line (PCL) comprises the fixed landmark, and although there are slight variations among various investigators as to the exact manner of its delineation, it essentially extends from the inferior aspect of the pubis to the sacrococcygeal joint. Mobile landmarks consist of the bladder neck, urethra, uterine cervix (or vaginal vault in cases of hysterectomy), the lowest point of the peritoneum, and the rectoanal junction for the posterior compartment. By measuring the distance between the mobile landmarks and the PCL during the straining phases of the study, one is able to comment on the presence and degree of corresponding pelvic floor prolapse and the organs involved.<sup>25,29</sup>

A rather simple and objective grading system, called the HMO system, has been proposed to quantify pelvic floor relaxation and prolapse and to differentiate between organ prolapse and pelvic floor descent by using MRI images.<sup>24,29</sup> These two terms are often used synonymously, but they are not interchangeable and should be differentiated. Pelvic floor relaxation is composed of hiatal enlargement and pelvic floor descent, two entities defined clearly by the HMO classification system (Fig. 55-4). The so-called H-line (Levator hiatus width) measures the width of the levator hiatus and refers to the distance from the pubis to the posterior anal canal; it represents the hiatal enlargement. The M-line (muscular pelvic floor relaxation) represents the descent of the levator plate from the PCL and measures the muscular pelvic floor relaxation. With significant pelvic floor relaxation, one is able to demonstrate levator hiatal widening and levator plate descent, as indicated by corresponding increases in the H and M lines on MRI data (Fig. 55-5).

Whereas the H and M measurements are used to demonstrate pelvic floor descent, the so-called O-component of the HMO system gives a grading to the visceral (organ) prolapse. For all of the pelvic organs involved (i.e., cystocele, urethrocele, rectocele,

enterocele, or uterine descent), the prolapse is defined as the degree of visceral descent beyond the H-line.<sup>24,29</sup> By obtaining these measurements on dynamic MRI obtained with very fast MRI sequences, one can readily differentiate between pelvic organ descent and pelvic floor prolapse and grade the degree of

**Figure 55-4** Reference lines drawn on a resting sagittal magnetic resonance image demonstrating two components of pelvic floor prolapse (descend and widening) in the HMO classification system. Descent is measured by descent of the H-line relative to the pubococcygeal line (PCL) and thus an increasing M, whereas widening is seen by increase in the anteroposterior dimension of the hiatus and thus lengthening of the H line. See text for details.

**Figure 55-5** **A**, Resting phase magnetic resonance image (MRI). **B**, A severe perineal hernia is appreciated on the MRI in the dynamic phase. The reference lines are drawn on the image to illustrate the accompanying pelvic floor prolapse, with a tremendous increase in the M-line (yellow).

pelvic floor abnormalities (Tables 55-1 and 55-2). In addition to being rather simple and reproducible, the HMO grading system allows better definition and understanding of the pathology involved by enabling differentiation between pelvic organ descent and pelvic organ prolapse.<sup>29</sup>

**Table 55-1 Proposed Pelvic Organ Prolapse Grading System Using Dynamic Magnetic Resonance Imaging Data**

Grade	Organ Location
0 (no prolapse)	Above H-line
1 (mild, small)	0-2 cm below H-line
2 (moderate)	2-4 cm below H-line
3 (severe, large)	>4 cm below H-line
4 (procidentia)	Only for cystourethrocele

**Table 55-2 Proposed Pelvic Floor Descent (Length of the M-Line) Grading System Using Dynamic Magnetic Resonance Imaging Data**

Grade	Pelvic Floor Descent (cm)
0 (normal)	0-2
1 (mild)	2-4
2 (moderate)	4-6
3 (severe)	>6

From Barbaric ZL, Marumoto AK, Raz S: Magnetic resonance imaging of the perineum and pelvic floor. *Topics Magn Res Imaging* 12:83-92, 2001.

Regardless of the exact classification system used to interpret the MRI data, the standard radiologic report includes information on the presence of any incidental lesions (ovarian, uterine, gastrointestinal tract); the morphology of the levator ani muscles; pelvic organ position at rest, during contraction, and during maximum straining; the degree of prolapse; and any coexisting masked prolapse in addition to the main prominent prolapse.<sup>25</sup> According to current studies, MRI appears to be at least equivalent to physical examination for prolapse detection in the anterior pelvic compartments such as the bladder and uterus, and it is superior to the clinical examination in cases of posterior compartment prolapse such as peritoneal and gastrointestinal organs.<sup>30-33</sup> Yet another advantage of MRI over some of the other methods, such as conventional defecography, is lower interobserver variability in the interpretation of the imaging studies.<sup>28</sup>

### Three-dimensional Magnetic Resonance Imaging

Three-dimensional MRI represents an advanced method of presentation and interpretation of data obtained during MRI studies (Fig. 55-6). It has been gaining popularity among investigators in the field, because it enables volumetric analysis of the data and demonstrates with remarkable clarity the spatial relationships among the anatomic structures of interest.<sup>34</sup> For instance, this method has been applied to better define the levator ani morphology and to demonstrate, not only qualitatively but also quantitatively, the pathologic changes involved in various grades of pelvic prolapse.<sup>35-37</sup> Although these findings have not been applied to clinical practice as yet, they could potentially be important in generating treatment plans for patients, predicting the course of progression of prolapse severity, and even predicting the likelihood of recurrence after corrective surgery.<sup>34</sup>

## Computed Tomography

Computed tomography (CT) scanning allows multiplanar visualization of anatomy and becomes especially useful for patients who are unable to tolerate MRI due to the presence of medical devices such as pacemakers, general debilitation, or claustrophobia. However, even though CT is a well-established axial imaging modality, it has limited application in the field of female pelvic prolapse simply because of anatomic limitations. The urogenital diaphragm and levator ani are mostly situated in the axial plane, they are best assessed by coronal imaging. However, with traditional CT, one is able to obtain coronal images only by reformatting the axial images, resulting in loss of spatial resolution during the process and inevitable degradation of the image quality.<sup>3</sup> Because of these factors, very little attention has been paid in the field of radiology to CT scanning as a possible imaging modality for female pelvic floor dysfunction.

A preliminary study using a small number of patients explored the use of CT scanning in the diagnosis of prolapse of female pelvic organs and commented on its potential role in patients intolerant of MRI.<sup>38</sup> Despite the fact that the soft tissue contrast on CT is far inferior to that of MRI, it was possible to identify the bladder, uterus, small bowel, peritoneal fat, and rectum, as well as changes in position with straining, if CT was performed adequately. Another possible advantage of CT scanning is its ability to assess the contour of the levator ani muscles and obtain pelvic images in multiple planes. Both modalities image the patient while supine, thus introducing the possibility of suboptimal results in this nonphysiologic position, especially if the patient's straining is suboptimal.<sup>38</sup> With further evolution of CT technology, such as availability of multiple-detector-row CT scanners and lower image acquisition times, it might be possible to obtain dynamic images almost in real time. In addition, the possibility of acquiring thinner slices will potentially lead to decreased artifacts during volume rendering. However, as with fluoroscopy, radiation exposure will always remain a major concern with CT scanning.

## CLINICAL APPLICATIONS

### Cystoceles

In an ideal world, imaging studies used in the evaluation of cystoceles should yield information on the presence or absence of urinary retention, ureteral obstruction, urethral hypermobility, and other forms of pelvic floor prolapse, as well as evaluation for stress urinary incontinence, in the least invasive manner to the patient.<sup>3</sup> Radiographically, a cystocele usually appears during the maximal straining phase of the imaging study as descent of the normally horizontal bladder base below the inferior margin of the pubic symphysis and as a concave impression on the superior aspect of the vagina.<sup>5</sup> Traditionally, a VCUG and videourodynamics with the patient standing in both straining and relaxed states have been performed as part of the workup for cystoceles. Although these studies are helpful in the evaluation of cystocele severity, postvoid residual volume, stress urinary incontinence, and urethral hypermobility, they fail to comment on the presence of related pelvic floor dysfunction.<sup>3</sup> Because of this drawback of the technique, fluoroscopic cystocolpoproctography or dynamic contrast roentgenography with pelvic organ opacification have been used to determine the presence of related pelvic floor pro-

lapse. However, these studies fail to detect up to 20 % of enteroceles, are time-consuming, and expose the patient to ionizing radiation.<sup>1,11,30-32,39,40</sup>

Even though ultrasonography does not have the drawback of radiation exposure to the patient, it fails to provide optimal visualization of soft tissue planes and is extremely operator dependent.<sup>41</sup>

MRI lacks most of these shortcomings and has numerous advantages previously mentioned.<sup>4,19,24</sup> Studies have shown a very high degree of correlation between dynamic MRI and lateral cystourethrography.<sup>42</sup> The only possible disadvantage of MRI is the fact that, because it is performed with the patient in the supine position, the physiologic effect of gravity cannot be studied.<sup>3</sup> With dynamic MRI, one is able to both quantitate the degree of a cystocele present and diagnose any coexisting pelvic floor descent (Figs. 55-7 and 55-8).

### Enteroceles

Before the introduction of MRI to the study of female pelvic prolapse, defecography was the primary modality in the diagnostic workup of enteroceles (Figs. 55-9 and 55-10). In order to visualize the small bowel loops between the rectum and the vagina, indicative of an enterocele, the patient is asked to strain repeatedly after evacuation. Very often, opacification of the vagina is also necessary to better visualize the pathology.<sup>5</sup> In some cases, voiding cystograms were performed to rule out a cystocele. Later, fluoroscopic cystocolpoproctography or dynamic contrast roentgenography gained popularity. These studies involve opacification of the bladder, vagina, small bowel, and rectum in order to visualize pelvic prolapse. Even though triphasic opacification is more time-consuming, it has been shown to improve recognition of enteroceles during the examination.

In addition to performing the imaging study with all organs opacified at the same time, one can also choose to opacify each organ individually before each straining phase.<sup>1,31,32,39</sup> The diagnosis of an enterocele is made by comparing the images obtained during the straining phase of the study with those recorded during relaxation. Here, an increase in the distance between the vagina and the rectum, which are delineated by the contrast material, is suggestive of an enterocele. Occasionally, physiologic bowel gas bubbles in the contents of this herniated small bowel may be seen to further identify it as such.<sup>30</sup> Unfortunately, in addition to being rather time-consuming and invasive, defecography and cystocolpoproctography fail to detect enteroceles in up to 20% of cases.<sup>3,11,30,40</sup>

Before the introduction of MRI into the field, many considered multiphasic cystocolpoproctography to be the best-suited imaging modality for detection of female organ prolapse (Fig. 55-11). However, many experts now believe that dynamic MRI is a superior radiographic technique in the diagnosis of enteroceles and that the invasiveness of organ opacification is not justified in the light of the very minimal yield of additional information, if any.<sup>3,4,30,32</sup> Studies have shown repeatedly that MRI is far more sensitive than physical examination and dynamic cystocolpoproctography in the diagnosis of enteroceles.<sup>4,30</sup> The diagnosis of an enterocele on an MRI study is made by measuring the distance between the lowest point of the peritoneal borderline and the H (hiatal) anteroposterior reference line obtained during the dynamic (straining) phases of the study. In fact, magnetic resonance colpocystorectography, which utilizes sonography gel to opacify the vagina and the rectum, is the only method available

**Figure 55-7** Magnetic resonance images showing a cystocele in resting position (A) and with pelvic floor descent appreciated on straining (B).

**Figure 55-8** Magnetic resonance images in resting (A) and dynamic (B) phases, demonstrating pelvic floor prolapse and severe cystocele in a 52-year-old woman with complaints of vaginal prolapse and frequency.

B

**Figure 55-9** A and B, Enteroceles shown on dynamic evacuation proctography images.

that can precisely visualize the parietal peritoneum, thus allowing one to make the diagnosis of an enterocele with utmost confidence.<sup>30</sup> An isolated enterocele can be differentiated from one present as part of a combined organ prolapse, and any other coexisting conditions can be diagnosed as well (Fig. 55-12). More importantly, MRI enables the differentiation of contents of enteroceles, revealing such entities as mesenteric fat, rectosigmoidoceles, and small and large bowel. In fact, by taking into account the axial turbo spin echo sequences, often one is able to differentiate sigmoid colon from small bowel loops. On the contrary, hernias containing mostly fluid and components of the mesenteric tissue give a homogenous intense signal on the T2-

A

B

**Figure 55-10** A and B, Enterocele with pelvic floor prolapse demonstrated on dynamic defecography study.

weighted images. In addition, this method of visualization of the herniated contents does not require prior additional measures (e.g., small bowel opacification) to be taken.

Many urologists find MRI particularly useful in differentiating high rectoceles from enteroceles, which is an important distinction as far as safe and efficient surgical planning is concerned.<sup>3-4,30</sup> Because it does not expose patients to ionizing radiation, MRI also has the advantage of no time pressure constraints and gives patients more flexibility and control during repeated phases of straining which often needed to visualize pelvic floor defects.

For completeness, comments should be made about the utility of ultrasonography and defecoperitoneography in the diagnosis

**Figure 55-11** A, Sagittal magnetic resonance image showing an enterocele on dynamic phase. B, Corresponding operating room findings.

**Figure 55-12** Large cystocele and an enterocele in a patient with chronic frequency, nocturia, urgency, urge incontinence, and history of urine leaks with standing appreciated on a dynamic sagittal magnetic resonance image.

of enteroceles. It is possible to indirectly visualize the intestinal loops in the herniated sack as a dorsal attenuation with endovaginal sonography. However, this examination is rather difficult, because it requires a firm and stable contact between the ultrasound probe and the vaginal wall, even during repeated straining phases of the examination.<sup>17</sup>

Defecoperitoneography is a combination of a small-bowel enteroclysm, evacuation proctography, and intra-abdominal puncture.<sup>43,44</sup> Even though magnetic resonance colpocystorectography is comparable to defecoperitoneography in its time-consuming aspects, the latter is a much more invasive procedure associated with several rather morbid complications (e.g., perforation).<sup>45</sup> In addition, defecoperitoneography misses many cases of enteroceles, because the radiation dose with this technique forbids more than one round of straining, and several rounds of repeated straining and defecation are often required to induce and visualize organ prolapse during a given study.<sup>30,46</sup> Therefore, MRI is a superior technique in the diagnosis of enteroceles or peritoneoceles, because it is highly specific, sensitive, versatile, noninvasive, radiation-free, and relatively safe.

### Rectoceles

Because physical examination has a wide range of sensitivities for diagnosis of rectoceles and is unreliable in differentiating enteroceles from high rectoceles, imaging modalities are very helpful in the diagnostic workup of suspected rectoceles.<sup>3</sup> Defecography has

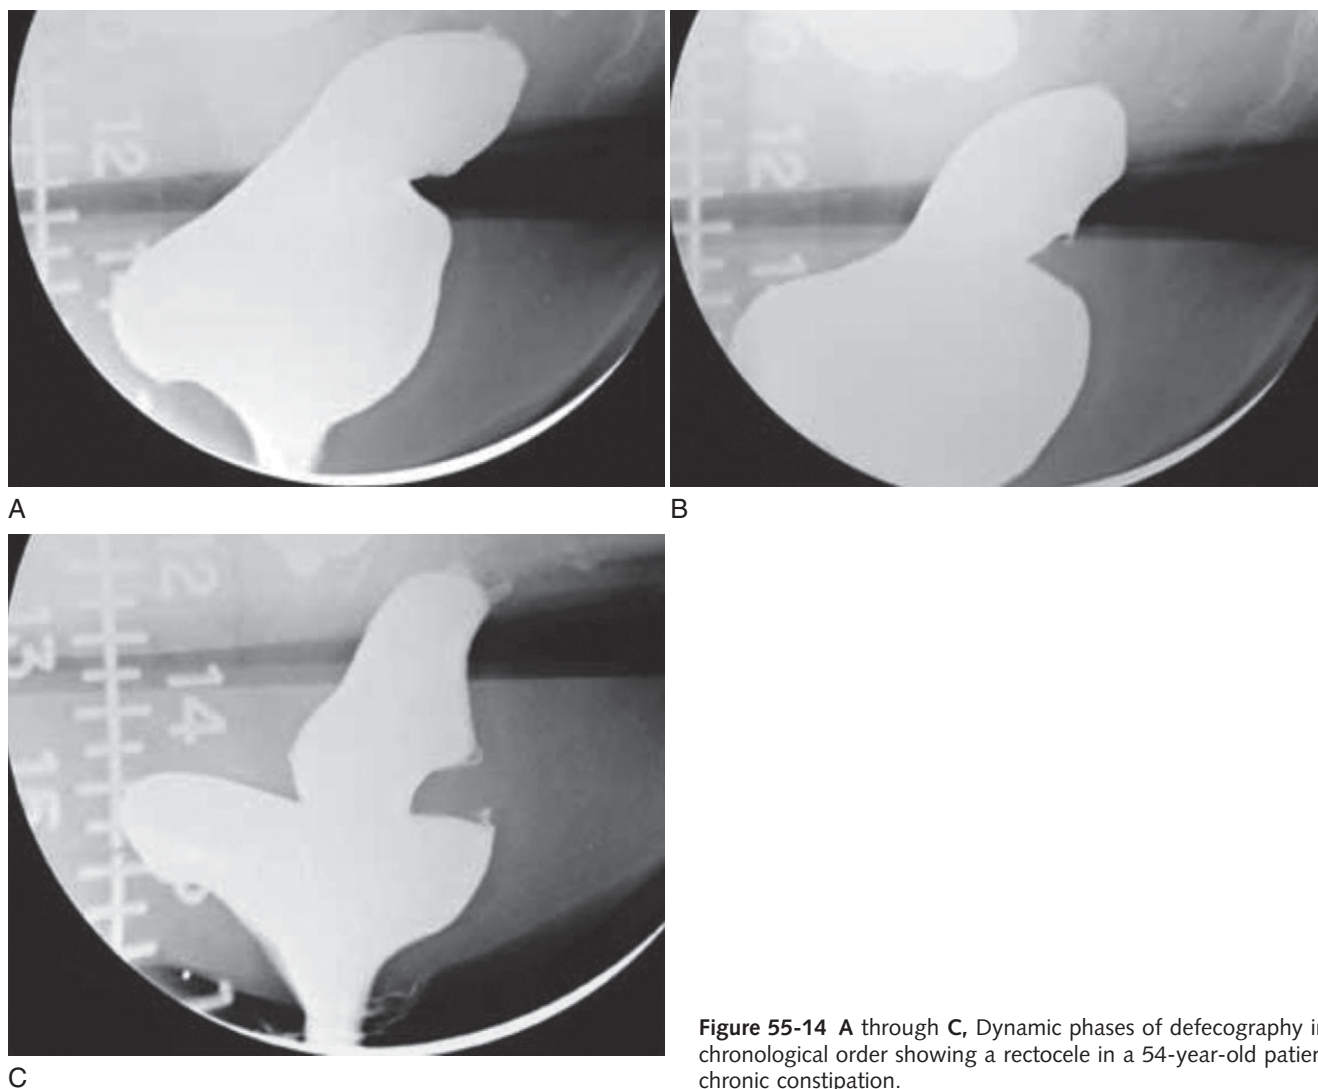

**Figure 55-13** Resting (A), squeezing (B), and straining (C) phases of a defecography study.

been traditionally the study of choice for rectoceles (Fig. 55-13). A rectocele usually appears as an anterior bulge in the extrapolated line of the normal rectal wall that appears with evacuation or strain and is measured as the maximum extent of that bulge (Fig. 55-14).<sup>10</sup> It should be noted that, because rectoceles quite often appear as transient findings during defecography, many prefer to obtain and review the videotape of the evacuation process.<sup>5</sup> To evaluate for other concurrent forms of pelvic prolapse, dynamic contrast roentgenography or fluoroscopic cystocolpoproctography has been used by various investigators.<sup>1,3,31,32,39</sup> However, all of these techniques have the disadvantage of significant radiation exposure and poor visualization of soft tissues in the evaluation of the pelvic floor. MRI eliminates all of these flaws and allows superb visualization of soft tissue structures and concurrent pelvic floor pathology (Fig. 55-15). Studies seem to indicate that rectal opacification should be used to increase the detection rates of rectoceles with MRI. This usually entails the

introduction of sonographic transmission gel into the rectum, which yields a high signal on T2-weighted MRI sequences. Some radiologists prefer to mix it with diluted gadolinium contrast medium for easier visualization. The only caveat to this method is the fact that it can introduce air bubbles and thus image artifacts.<sup>4,25,32</sup> It has been theorized that MRI fails to detect small rectoceles due to collapse of the walls of the empty rectum during the imaging study.<sup>3,4</sup>

### Uterine Prolapse

From a surgical perspective, while evaluating high grade uterine prolapse, it is critical to rule out any kind of uterine or ovarian malignancy, in order to decide on the kind of hysterectomy to be performed. MRI is an ideal imaging modality, because it allows evaluation for all forms of pelvic pathology preoperatively (Fig. 55-16).<sup>3</sup>

# DYNAMIC MAGNETIC RESONANCE IMAGING IN THE DIAGNOSIS OF PELVIC ORGAN PROLAPSE

*Craig V. Comiter and Joel T. Funk*

Weakness and subsequent dysfunction of the pelvic floor is common in parous women of middle or advanced age. Pelvic organ prolapse (POP) and pelvic floor relaxation are caused by anatomic abnormalities, including weakness of the muscles of the pelvic floor and the fascial attachments of the pelvic viscera. The prevalence of POP has been reported to be as high as 16% of women aged 40 to 56 years.<sup>1</sup> Approximately 500,000 surgeries for POP are performed in the United States each year.<sup>2</sup>

Women with POP present not only to the gynecologist but also to the urologist, as up to one third of patients with prolapse also suffer from urinary incontinence. POP is also associated with fecal incontinence, incomplete voiding, and constipation. A detailed knowledge of pelvic anatomy is paramount for the proper evaluation and management of such conditions. Pelvic support defects result from both neurophysiologic and anatomic changes<sup>3</sup> and often occur as a constellation of abnormal findings. Symptomatic individuals often have multifocal pelvic floor defects, not always evident on physical examination.<sup>4</sup>

Even experienced clinicians may be misled by the physical findings, having difficulty differentiating among cystocele, enterocele, and high rectocele by physical examination alone. Depending on the position of the patient, the strength of the Valsalva maneuver, and modesty of the patient, the examiner may be limited in his or her ability to accurately diagnose the various components of pelvic prolapse. Furthermore, with uterine prolapse, the cervix and uterus may fill the entire introitus, making the diagnosis of concomitant anterior or posterior compartmental prolapse even more difficult. Regardless of the etiology of the support defect, the surgeon must identify all aspects of vaginal prolapse and pelvic floor relaxation for proper surgical planning. Incorrect diagnosis of these defects may lead to inadequate surgical treatment.<sup>5</sup> Accurate preoperative staging should reduce the risk of recurrent prolapse, which can occur in up to 34% of patients after surgery.<sup>6</sup>

## RADIOGRAPHIC EVALUATION

Radiographic evaluation plays an important role in the identification of these defects and should be used as an extension of the physical examination. Various methods have been used to visualize the pelvic structures and lower urinary tract, including fluoroscopy, sonography, computed tomography (CT), and, most recently, magnetic resonance imaging (MRI).

### Levator Myography

Levator myography is an outdated method of visualizing the pubococcygeus and iliococcygeus via direct injection of contrast solution into the levator muscles. Originally described in 1953, this technique allows visualization of the position and supportive role of these muscle groups.<sup>7</sup> Widening of the levator hiatus, which often occurs after traumatic childbirth and predisposes to pelvic floor relaxation and to visceral prolapse, can be demonstrated with levator myography. Today, this information may be obtained noninvasively with CT<sup>8</sup> and MRI.<sup>9,10</sup>

### Voiding Cystourethrography

Voiding cystourethrography (VCUG) is mainly used for demonstrating a cystocele, evaluating bladder neck hypermobility, and demonstrating an open bladder neck at rest (sphincteric incompetence). Dynamic lateral cystography at rest and during straining is an important adjunct to the urodynamic evaluation; it is useful for demonstrating the presence of and degree of urethra-vesical hypermobility and cystocele formation (Fig. 56-1).<sup>11</sup> In addition, dynamic fluoroscopy has been shown to be more accurate than physical examination in demonstrating an enterocele.<sup>12,13</sup> Other pathologic conditions detected by VCUG include

**Figure 56-1** Lateral cystogram, with patient relaxed (*left*) and straining (*right*).

vesicoureteral reflux, vesicovaginal fistula, and urethral diverticular disease.

### Dynamic Proctography

Dynamic proctography, in the cooperative patient, allows precise identification and quantification of a rectocele, measured as the maximum extent of an anterior rectal bulge beyond the expected line of the rectum.<sup>14,15</sup> Limitations of this examination include the cumbersome and potentially painful instillation of rectal barium paste and lack of correlation between the viscosity of the paste and the individual patient's stool. Modesty makes this a difficult technique for many patients, because they are unable to defecate on command.

### Colpocystourethrography

The colpocystourethrogram was first described in France in 1965 and combines opacification of the bladder, urethra, and vagina.<sup>16</sup> Modified and made popular in the mid 1970s, the colpocystourethrogram is a dynamic study of pelvic support and function.<sup>17</sup> The anatomic relationships among the bladder, urethra, and vagina may be demonstrated, and, when the study is combined with proctography, it may be even more useful in outlining the anatomy of the normal pelvis and of complex POP.

An enterocele, defined as a herniation of the peritoneum and its contents at the level of the vaginal apex, may be appreciated via straining or defecation during colpocystoproctography. This is demonstrated by a widening of the rectovaginal space.<sup>18</sup> The accuracy of dynamic colpocystoproctography is even further enhanced by opacification of the small bowel. The patient drinks oral barium 2 hours before the examination. With the vagina, bladder, small intestine, and rectum opacified, the vaginal axis may be measured at rest and with straining, and prolapse of the anterior, middle, and/or posterior vaginal compartment should become evident.

### Sonography

Sonography offers a convenient, painless, and radiation-free technique. As with fluoroscopy, a dynamic component may be added to sonography. In particular, dynamic ultrasound allows identification of an enterocele during straining maneuver, evidenced by widening of the rectovaginal septum, diminution of the peritoneal-anal distance, and herniation of bowel contents into the cul-de-sac.<sup>19</sup> Ultrasonography using an abdominal, rectal, vaginal, or perineal transducer is also useful for demonstrating vesicourethral anatomy,<sup>20-23</sup> So-called contrast sonography uses echogenic material instilled into the bladder or vagina and is able to identify bladder neck funneling with straining<sup>24</sup> as well as paravaginal defects.<sup>25</sup>

### Computed Tomography

CT pelvimetry is an accurate and reproducible method for measuring pelvic dimensions and the capacity of the maternal birth canal.<sup>26,27</sup> However, CT has not been shown to be particularly useful in the evaluation of pelvic visceral prolapse. The components of the levator plate and urogenital diaphragm are better seen in the coronal plane or sagittal view, but CT images are routinely presented in the axial plane. Although CT images can

be reconstructed into a coronal view with the use of cumbersome and expensive computer software, poor image quality and distorted spatial resolution has limited the utility of this presentation technique.<sup>8</sup>

### Magnetic Resonance Imaging

Most recently, MRI has emerged as an important diagnostic tool, both for evaluating the functional relationships among the pelvic floor viscera and supporting structures and for assessing pelvic pathology. MRI offers the advantages of being noninvasiveness, lack of exposure of the patient and examiner to ionizing radiation, and superior soft tissue contrast and multiplanar imaging without superimposition of structures. Axial images provide information about the urogenital hiatus and its contents, whereas sagittal images more easily demonstrate visceral prolapse. Because static images alone do not demonstrate relevant pelvic floor changes with activity, dynamic MRI has been used to reveal the structural functional changes that occur during stress maneuvers. Those established criteria for abnormality derived from fluoroscopy (colpocystoproctography) are directly applicable to MRI.<sup>28</sup>

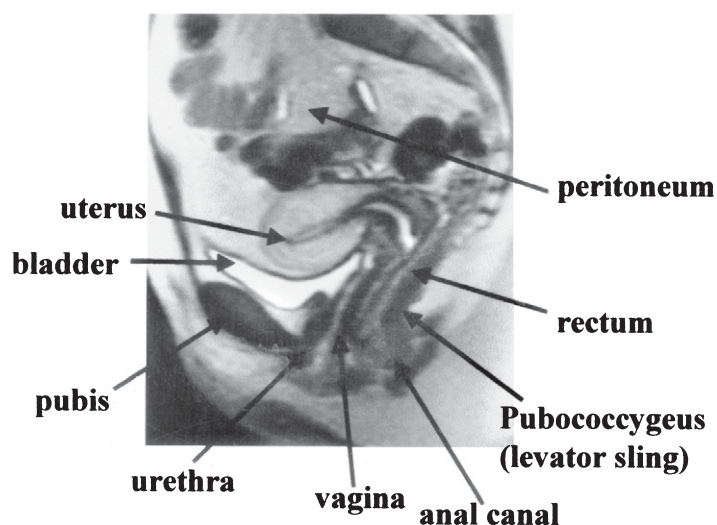

The development of fast-scanning MRI techniques has greatly improved the ability to describe and quantify anatomic changes that have a causative role in pelvic floor relaxation. Fast-scan Valsalva imaging formatted in a pseudokinematic cine-loop provides a dynamic method to study the anatomic changes that occur with straining. Additionally, MRI offers a noninvasive method to evaluate the female pelvis without exposure to the ionizing radiation that is integral to prior modalities such as CT, colpocystoproctography, and fluoroscopy.

MRI also allows evaluation of all three pelvic compartments simultaneously for organ descent. Kelvin's group used "triphasic" dynamic MRI, consisting of a cystographic, a proctographic, and a post-toilet phase to facilitate the recognition of prolapsed organs that may be obscured by other organs that remain unemptied.<sup>29</sup> Fielding showed that MRI is useful for measuring levator muscle thickness,<sup>30</sup> demonstrating focal levator ani eventrations (outpouching) not visible with levator myography,<sup>31</sup> and measuring urethral length and the thickness and integrity of periurethral muscle ring.<sup>9</sup> Hoyte and colleagues<sup>48</sup> demonstrated that the anterior portion of the levator (puborectalis) is typically thinner in women with POP and/or stress incontinence compared with asymptomatic controls—possibly due to muscle atrophy caused by denervation from childbirth injuries or muscle wasting secondary to loss of insertion points for the puborectalis.

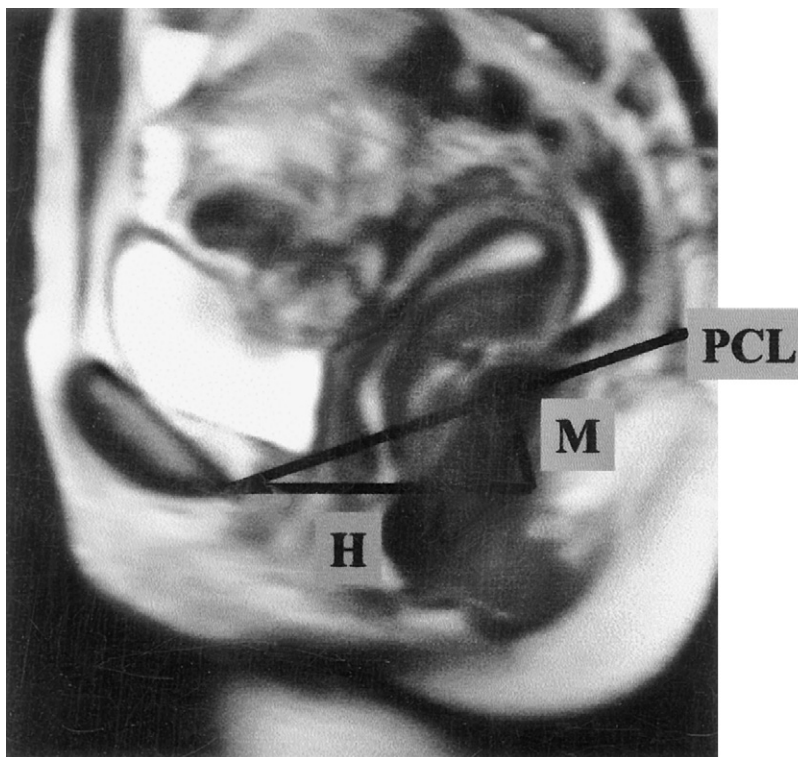

Yang and associates were the first to popularize dynamic fast MRI for the evaluation of POP,<sup>9</sup> using T1-weighted gradient recalled acquisition in a steady-state pulse (GRASS) sequence, with acquisition times between 6 and 12 seconds. Since then, other investigators have shown that MRI is more sensitive than physical examination for defining pelvic prolapse.<sup>5,10,32</sup> Whereas some advocate the use of contrast opacification of the bladder, vagina, and rectum,<sup>29,33</sup> others have shown that the vagina, rectum, bladder, urethra, and peritoneum are adequately visualized without any contrast administration.<sup>5</sup> By avoiding instrumentation of the vagina or urethra, iatrogenic alteration of the anatomy is minimized.<sup>10</sup>

Several years ago, Comiter and coworkers published their experience with dynamic half-Fourier acquisition, single-shot turbo spin-echo (HASTE sequence) T2-weighted MRI using a 1.5-Tesla magnet with phased array coils (Siemens) or single-

**Figure 56-2** Lateral magnetic resonance image denoting normal pelvic structures.

**Figure 56-3** The H-line (levator hiatus width) measures the distance from the pubis to the posterior anal canal. The M-line (muscular pelvic floor relaxation) measures the descent of the levator plate from the fixed pubococcygeal line (PCL).

shot fast spin-echo (SSFSE, General Electric) for evaluating the female pelvis.<sup>5</sup> Midsagittal and parasagittal resting and straining supine views were obtained for the purpose of identifying the midline and for evaluating the anterior pelvic compartment (anterior vaginal wall, bladder, urethra), posterior compartment (rectum), and middle compartment (uterus, vaginal cuff), as well as the pelvic floor muscles, adnexal organs, and intraperitoneal organs (Fig. 56-2). Images were looped for viewing on a digital station as a cine stack and for measuring the relationship of pelvic organs to fixed anatomic landmarks. The first set of images comprised volumetric sagittal cuts from left to right, used to locate the midsagittal plane and to survey the pelvic anatomy. The second set of images was obtained with four cycles of repeated

relaxation and Valsalva maneuver.<sup>5,8</sup> Total image acquisition time was 2.5 minutes, and total room time was 10 minutes per study.

This dynamic MRI technique, known as the HMO classification system, has been shown to be useful for grading pelvic visceral prolapse and pelvic floor relaxation in a simple and objective manner.<sup>5</sup> The size of the levator hiatus and the degree of muscular pelvic floor relaxation and organ prolapse were measured. The “H-line” (levator hiatus width) measures the distance from the pubis to the posterior anal canal. The “M-line” (muscular pelvic floor relaxation) measures the descent of the levator plate from the fixed pubococcygeal line (PCL). The PCL spans the distance from the pubis to the sacrococcygeal joint (Fig. 56-3). The “O”

**Figure 56-4** Organ prolapse. **A**, Cystocele. **B**, Rectocele. **C**, Enterocele.

classification (organ prolapse) describes the degree of visceral prolapse beyond the H-line. The degrees of cystocele, rectocele, enterocele, and uterine descent are graded as 0, 1, 2, or 3, corresponding to none, mild, moderate, or severe (Fig. 56-4).

In a group of women with symptomatic prolapse, the levator hiatus width (H-line) was significantly wider than in a control group ( $7.5 \pm 1.5$  cm versus  $5.2 \pm 1.1$  cm;  $P < .001$ ). Similarly, the levator muscular descent (M-line) was greater in the prolapse group than in the control group ( $4.1 \pm 1.5$  cm versus  $1.9 \pm 1.2$  cm;  $P < .001$ ).<sup>5</sup> These objective findings fit well with our knowledge of the pathophysiology of pelvic prolapse. Trauma to the pubococcygeus and iliococcygeus, usually from childbirth, results in widening of the levator hiatus and laxity of the musculofascial

support structures.<sup>34</sup> This results in a sloping levator plate, with the more vertically oriented vagina and rectum tending to slide down through the widened hiatus. Therefore, the H and M lines both increase with pelvic floor relaxation. This in turn leads to organ prolapse (O classification). Because of the excellent visualization of fluid-filled viscera and soft tissues, MRI can differentiate among cystocele, enterocele, and high rectocele, which may be difficult by physical examination alone.

MRI findings were compared to physical examination and intraoperative findings. HASTE-sequence MRI was more accurate than physical examination in identifying cystocele, enterocele, vault prolapse, and pelvic organ pathology such as uterine fibroids, urethral diverticula, ovarian cysts, and Nabothian and

**Figure 56-5** Magnetic resonance urography demonstrates hydronephrosis secondary to pelvic organ prolapse obstructing the ureters.

Bartholin gland cysts.<sup>32</sup> Comiter and colleagues found that, with dynamic MRI, surgical planning was altered in more than 30% of cases, most often because of occult enterocele not appreciated on physical examination.<sup>35</sup>

In patients with severe prolapse, especially if renal insufficiency is present, the surgeon must rule out obstructive hydro-ureteronephrosis. This may be accomplished by magnetic resonance urography, which adds only 30 seconds of examination time and no additional morbidity (Fig. 56-5). MRI may also be useful for the radiographic evaluation of stress incontinence. Hypermobility of the proximal urethra and bladder neck descent are important pathophysiologic features in the diagnosis of genuine stress urinary incontinence.<sup>36,37</sup> Measurement data on dynamic MRI for the bladder neck position and the extension of cystocele at maximal pelvic strain are comparable with data obtained by lateral cystourethrography (Fig. 56-6).<sup>38</sup>

Recent urogynecologic and radiologic publications have validated MRI as a reliable alternative to colposystoproctography.<sup>29,38,39</sup> The information obtained via MRI is often superior to that obtained via colposystoproctography, because the former allows for direct visualization of the pelvic organs and their fluid content, whereas the latter presents a silhouetted view of contrast-filled organs (complete opacification is not usually achieved). Gufler and associates demonstrated that dynamic MRI is helpful in the evaluation of persistent patient complaints after surgery for POP and is, in fact, more sensitive than physical examination.<sup>40</sup> Dynamic MRI is particularly sensitive for diagnosing enteroceles and is superior to colposystoproctography or physical examination.<sup>41</sup> A minority of studies have shown that MRI

**Figure 56-6** Lateral magnetic resonance image demonstrating stress urinary incontinence secondary to urethral hypermobility.

may not be as accurate for the identification of vaginal vault prolapse or for rectocele as is colposystoproctography.<sup>42</sup> Gousse's group from the University of Miami postulated that the anterior rectal wall is not well differentiated from the posterior wall on rapid-sequence MRI when the rectum is empty, because the rectal walls are collapsed.<sup>32,43</sup> At our institution intravaginal, intravesical, or intrarectal contrast is not instilled, but others have shown that such "triphase dynamic" studies may even further improve the diagnostic accuracy of MRI.<sup>29,34</sup>

The disadvantage of MRI is that the study often must be performed with the patient in the supine position, because upright MRI scanners are not yet universally available. Colposystoproctography is clearly more amenable to performance in a sitting position than is MRI. However, dynamic MRI with relaxing and straining views has been shown to adequately demonstrate POP during straining in the supine position.<sup>44</sup> Additionally, in those institutions that have access to an upright MRI scanner, sitting MRI was not shown to be superior to supine MRI for demonstrating POP. Although patients undergoing sitting MR imaging demonstrated a greater degree of visceral descent, supine studies were not inferior for demonstrating *clinically relevant* prolapse.<sup>45</sup>

Competition among prolapsing organs filling a finite introital space may also limit MRI, just as it may limit physical examination and dynamic fluoroscopy. This is especially true for identification of a rectocele. Additionally, claustrophobic patients and those with cardiac pacemakers or sacral nerve stimulators cannot enter the enclosed magnet. Despite these limitations, dynamic MRI has become the study of choice at our institution for evaluating POP and pelvic floor relaxation.

Alternative MRI sequences have recently been demonstrated to be as good or better than the HASTE sequence. Lienemann and colleagues recommended a true fast imaging with steady-state precession (True FISP) sequence, because it may be associated with superior image quality compared to the HASTE sequence.<sup>41,45</sup> Gousse's group from Miami demonstrated the utility of extended-phase conjugate-symmetry rapid spin-echo sequence (EXPRESS) as a novel and very rapid scanning technique; individual images are obtained in 0.8 seconds with the use of half-Fourier reconstruction and fast gradients with sophisticated recently available software.<sup>43</sup> Both the True FISP and EXPRESS dynamic MRI examinations were superior to physical examination in accuracy and completeness for the preoperative evaluation of POP.

Over the last decade, there has been an increasing interest in use of elective cesarean delivery to reduce maternal birth trauma and decrease long-term morbidity,<sup>46,47</sup> but reliable prepartum criteria have not been established to identify those women most likely to develop pelvic floor injuries during childbirth. Fielding's group at Harvard recently published their experience with MRI pelvimetry as a potentially important research tool.<sup>48</sup> Their protocol is easily performed with the patient in the supine position using a pelvic coil, fast spin-echo T2-weighted sequences, 2-mm cuts, and a 1.5-T system. Pelvimetry measurements are obtained from coronal, axial, and midsagittal images. Significant differences in mean pelvimetry measurements were demonstrated between women with and without pelvic visceral prolapse and pelvic floor relaxation. With multivariate analysis, POP patients had a wider transverse inlet diameter, and a trend toward a wider interspinous diameter. Recent CT studies have demonstrated that women with wider transverse inlet diameters have a higher prevalence of prolapse after childbirth,<sup>26</sup> and perhaps MRI pelvimetry may contribute to the identification of such risk factors.

## SUMMARY

Most cases of incontinence and minimal pelvic floor weakness can be treated based on physical examination with or without urodynamic evaluation. On the other hand, in women with complex or recurrent POP and pelvic floor relaxation, radiographic evaluation is recommended as an extension of the physical examination. A detailed working knowledge of normal and abnormal female pelvic anatomy is necessary for the proper evaluation of pelvic visceral prolapse. However, even the most experienced gynecologist or urologist may have difficulty distinguishing among prolapsing organs competing for introital space. Accurate identification of all aspects of vaginal prolapse and pelvic floor relaxation are vital, not only to permit adequate surgical planning but also to reduce the risk of recurrent prolapse. Urography, voiding cystography, dynamic colpocystodefecography, sonography, and MRI are each useful for the evaluation of pelvic prolapse and pelvic floor relaxation.

MRI can demonstrate the levator muscles in three-dimensional fashion, providing details about herniation during straining, muscle thickness, and asymmetry. MRI allows complete analysis of the anterior, middle, and posterior pelvic compartments in a single procedure without the use of ionizing radiation. Differentiation among soft tissues is excellent, anatomic information is accurate, and no contrast agent is needed. The advent of rapid sequencing with cine stacking has enabled MRI to replace dynamic colpocystoproctography at many institutions, providing not only superb differentiation among fluid-filled, air-filled, and solid pelvic viscera but also a functional demonstration of all three pelvic compartments during relaxation and straining. As dynamic MRI becomes more widespread, standardization of the technique will become more important.

# URODYNAMIC EVALUATION OF THE PATIENT WITH PROLAPSE

Sender Herschorn

Symptoms caused by pelvic organ prolapse may or may not be specific to the prolapsing compartment or compartments, and the correlation of many pelvic symptoms with the extent of prolapse is weak.<sup>1,2</sup> Many women with pelvic organ prolapse have no symptoms, especially if the prolapse remains inside the vagina.<sup>3</sup> Others present with symptoms in addition to the vaginal bulge, as a result of the associated organ dysfunction. It is recommended that symptoms be elucidated in four primary areas: lower urinary tract, bowel, sexual symptoms, and other local symptoms.<sup>4</sup> Documentation of symptoms not only serves as a guide to treatment but also permits an accurate assessment of post-treatment results.

There is general agreement that the aim of urodynamic testing is to reproduce symptoms of the patient under controlled and measurable conditions. Ideally, this allows diagnosis, helps with informed treatment choice, and improves treatment outcome. Specifically, the testing identifies or excludes contributing factors to incontinence or voiding dysfunction and assesses their relative importance.<sup>5</sup> However, the role of urodynamics in the evaluation of symptoms related to prolapse is not yet fully established. A recent Cochrane review attempted to test the hypotheses that urodynamic testing improves the clinical outcome of incontinence management, that it alters clinical decision-making, and that one type of test is better than another in these areas.<sup>6</sup> Only two trials were found, but the numbers of patients were too small to determine whether clinical outcomes were affected by the urodynamics. This chapter reviews the various tests that are available and may be helpful in patient evaluation.<sup>6</sup>

### LOWER URINARY TRACT SYMPTOMS

Urinary incontinence is one of the most common symptoms associated with prolapse. Blaivas and Groutz<sup>7</sup> described the clinical evaluation in detail. However, the specific symptoms and their impact on the patient's quality of life should be elucidated in each case.

Urinary symptoms may include stress incontinence; symptoms of bladder overactivity, such as frequency, nocturia, urgency, and urgency incontinence; and voiding symptoms such as difficulty with bladder emptying. The mechanisms for stress incontinence include hypermobility and intrinsic sphincter deficiency. It is not unusual for patients to present with a combination of urge and stress incontinence.<sup>8,9</sup> If both symptoms are present, the patient has *mixed incontinence*.<sup>10</sup> Mixed incontinence is especially common in older women. Often, however, one symptom (urge or stress) is more bothersome to the patient than the other.

Identifying the most bothersome symptom is important in targeting diagnostic and therapeutic interventions.

Many women with severe prolapse recall that, as the prolapse worsened, their stress incontinence symptoms improved. Reducing the vaginal prolapse with a pessary or a speculum during the examination by the clinician can produce stress incontinence in up to 80% of clinically continent patients with severe prolapse.<sup>11-14</sup> This phenomenon has been termed *latent, masked, occult, or potential* stress incontinence, and it should be elicited when considering therapy. Although the clinical experience reported refers primarily to cystocele, occult incontinence may also be unmasked in a similar manner in patients with severe middle or posterior compartment prolapse. The postulated mechanism for continence may be urethral kinking by the cystocele or external compression of the urethra.<sup>15</sup>

Other storage symptoms, such as frequency, nocturia, and urgency, have been listed as symptoms of prolapse,<sup>16</sup> although the mechanism is unknown and there are frequently other associated factors. Urge incontinence may also be present. However, urge incontinence is a common complaint in patients without organ prolapse, may or may not be the result of detrusor overactivity,<sup>17</sup> and becomes more prevalent with aging. Patients with advanced organ prolapse and urge incontinence have also been shown to have detrusor overactivity<sup>15</sup> that may resolve after surgical correction of the prolapse.<sup>13,18</sup> The mechanism is unclear; however, many of those patients may have outflow obstruction caused by the prolapse that is alleviated after repair. Nguyen and Bhatia reported resolution of urgency incontinence after pelvic prolapse repair in patients who had no obstruction preoperatively.<sup>18</sup>

A number of tools are now available to aid the clinician in elucidating the symptoms and their impact on quality of life, to gain as accurate a picture as possible. These tools include questionnaires, voiding diaries, and pad tests, which are also used to evaluate treatment outcomes.<sup>19</sup>

Difficult voiding symptoms are common with severe prolapse and should be elicited. Patients with prolapse may have urethral kinking or external pressure on the urethra that not only prevents incontinence but also may cause difficult voiding.<sup>15</sup> They occasionally have to digitally reduce the prolapse to void (splinting) or need to assume unusual positions to initiate or complete micturition.<sup>4</sup> Urinary splinting has been reported to be 97% specific for severe anterior prolapse.<sup>20</sup>

Urodynamic abnormalities with decreased uroflow, increased postvoid residual urine,<sup>21</sup> and bladder outlet obstruction have been reported.<sup>15,22,23</sup> The degree of obstruction may be related to the severity of the prolapse.<sup>15</sup> Acute urinary retention secondary to the prolapse is rarely seen.<sup>24</sup>

## INITIAL EVALUATION OF URINARY SYMPTOMS

The initial evaluation includes a history, physical examination, urinalysis, and measurement of postvoid residual urine.<sup>25</sup> The basic evaluation may be satisfactory for proceeding with treatment, including surgery, for patients with straightforward stress incontinence associated with hypermobility and normal postvoid residual volume.<sup>10</sup> However, the International Scientific Committee of the Third International Consultation on Urinary Incontinence advised that urodynamic testing is highly recommended for women who desire interventional treatment,<sup>25</sup> although the specific chapter indicates the lack of evidenced-based medicine for this recommendation.<sup>5</sup> Furthermore, Diokno and coworkers<sup>26</sup> showed that a systematic history, vaginal speculum examination and postvoid residual measurement were 100% accurate in identifying patients who had pure type II stress incontinence on urodynamic studies. Other groups have shown a positive correlation of symptoms and urodynamic findings,<sup>27,28</sup> potentially bypassing the need for urodynamic studies in many patients.<sup>29,30</sup> Investigators have also shown that symptoms are not always related to the actual dysfunction causing the incontinence demonstrated on urodynamics.<sup>31-35</sup> As mentioned previously, the actual role of urodynamics in case selection and in predicting the continence outcome of surgery is still unknown.<sup>36</sup>

There are many instances in which a basic clinical evaluation is insufficient. The Agency for Health Care Research and Quality (formerly the Agency for Health Care Policy and Research) published guidelines in 1996 that are still relevant.<sup>10</sup> Criteria for further evaluation of incontinence include

- uncertain diagnosis and inability to develop a reasonable treatment plan based on the basic diagnostic evaluation
- uncertainty in diagnosis when there is lack of correlation between symptoms and clinical findings
- failure to respond or patient dissatisfaction with an adequate therapeutic trial and patient desire to pursue further therapy
- consideration of surgical intervention, particularly if previous surgery failed or the patient is a high surgical risk
- hematuria without infection
- the presence of other comorbid conditions, such as incontinence associated with recurrent symptomatic urinary tract infection
- persistent symptoms of difficult bladder emptying
- history of previous anti-incontinence surgery or radical pelvic surgery
- symptomatic pelvic prolapse beyond the hymen
- abnormal postvoid residual urine volume
- a neurologic condition, such as multiple sclerosis or spinal cord lesions or injury.

Additional testing includes urodynamics but may also include cystoscopy and imaging.

## Urodynamics in the Patient with Prolapse

For good urodynamic practices, the reader is referred to the International Continence Society (ICS) publication that reviews current standards for carrying out uroflowmetry, filling cystometry, and pressure-flow studies.<sup>37</sup>

## Urinary Flow Rate

A urinary flow rate is a simple urodynamic test that can provide objective and quantitative measures on both storage and voiding symptoms.<sup>37</sup> The curve is either continuous or intermittent. The continuous flow curve is smooth and arc-shaped or a fluctuating (if there are multiple peaks during a period of continuous urine flow). The precise shape of the curve is determined by detrusor contractility, the presence of abdominal straining, and the bladder outlet.<sup>38</sup>

The parameters of uroflowmetry include the following<sup>38</sup>:

- *Flow rate* is defined as the volume of fluid expelled via the urethra per unit time (mL/sec).
- *Voided volume* is the total volume expelled via the urethra.
- *Maximum flow rate* ( $Q_{max}$ ) is the maximum measured value of the flow rate after correction for artefacts.
- *Voiding time* is the total duration of micturition (i.e., including interruptions). If voiding is completed without interruption, voiding time is equal to flow time.
- *Flow time* is the time over which measurable flow actually occurs.
- *Average flow rate* ( $Q_{ave}$ ) is voided volume divided by the flow time. The average flow should be interpreted with caution if flow is interrupted or if there is a terminal dribble.
- *Time to maximum flow* is the elapsed time from onset of flow to maximum flow.

The Liverpool Nomogram (Fig. 57-1) was created in 1989 by Haylen and colleagues, who plotted voided volume against peak flow ( $Q_{max}$ ) in 249 normal women.<sup>39</sup> Normal peak flow ranges between 12 and 30 mL/sec, depending on the voided volume (Fig. 57-2). Average flow rates vary from 6 to 25 mL/sec, with a substantial overlap between normal and abnormal individuals.<sup>40</sup> Voiding time varies, from 10 to 20 seconds for a volume of 100 mL to 25 to 35 seconds for a volume of 400 mL. The first half of the urinary volume is rapidly evacuated in the first one third of the total voiding time, and the rest in the remaining two thirds of the voiding period.<sup>41</sup> Arbitrary criteria have been set by a number of authors to diagnose voiding difficulty, including peak flow less than 15 mL/sec and residual urine greater than 50 mL with a minimum total bladder volume of 150 mL before the void (volume voided + residual).<sup>15,42</sup> The 10th percentile curve of the Liverpool Nomogram has also been identified as a useful discriminant in the diagnosis of voiding difficulties.<sup>43</sup>

Bottacini and colleagues<sup>44</sup> reported that women with stress incontinence void with a lower flow rate than healthy women; however, other investigators have demonstrated the opposite: women with stress incontinence void with a higher flow rate because of the reduced outlet resistance.<sup>44</sup>

Uroflowmetry findings (peak flow rate, average flow rate, and voided volume) in prolapse have been described to be significantly lower than in normal controls.<sup>29</sup> Cystocele is significantly more frequent in patients with voiding difficulties and abnormal uroflowmetry.<sup>35</sup> Valentini and colleagues<sup>26</sup> demonstrated a constrictive effect on outflow in women with varying degrees of cystocele. A poor flow rate and elevated residual urine may be associated with large cystoceles.<sup>41</sup>

In general, an abnormal pattern is generated in the presence of a weak detrusor, abdominal straining, or bladder outlet obstruction. Although urodynamic catheters have less effect on voiding patterns in females than in males, it is still useful to obtain a urinary flow rate on arrival of the patient, to compare

**Figure 57-1** The Liverpool Nomogram showing maximum (*Top*) and average (*Bottom*) flow for women.<sup>39</sup>

**Figure 57-2** Normal flow curve for a voided volume of 350 mL with maximum flow ( $Q_{\max}$ ) of 27 mL/sec. (Modified from Lose G: Urethral pressure measurements. In Cardozo L, Staskin D [eds]: Textbook of Female Urology and Urogynaecology. London: Isis Medical Media, 2001, pp 215-226.)

**Figure 57-3** Commode chair for uroflow measurement.

with flow data generated during the subsequent urodynamic study. After the initial flow is completed, a postvoid residual can also be determined on introduction of the urodynamic catheters.

#### Urine Flow Meters

Flow meters are commonly of one of three types: weight, electronic dipstick, or rotating disc.<sup>45</sup> The first measures the weight of the collected urine; the second measures the changes in electrical capacitance of a dipstick mounted in the collecting chamber; and the third measures the power required to keep a disc rotating at a constant speed while the urine, which tends to slow it down, is directed toward it. All three can provide high sensitivity and reproducibility of data. A commode chair with uroflow measuring apparatus is shown in Figure 57-3.

#### Cystometry

The first part of the filling study is cystometry, the method by which the pressure-volume relationship of the bladder is measured.<sup>38</sup> It is used to assess detrusor sensation, capacity, and activity. The detrusor pressure ( $P_{\det}$ ) is calculated by subtraction of the abdominal pressure ( $P_{\text{abd}}$ ), as measured by a balloon in the rectum, vagina, or bowel stoma, from the total intravesical pressure ( $P_{\text{ves}}$ ), as measured by the intravesical catheter. The resulting detrusor pressure reflects the activity and pressure generated by the detrusor muscle alone. Artifacts in the  $P_{\det}$  may be produced by intrinsic rectal contractions.<sup>46</sup>

Filling rates in the past were described as slow, medium, or fast. Currently, the filling rate is classified as physiologic or non-physiologic, and the actual rate should be specified.<sup>38</sup> Most studies in non-neurologic patients are done with medium fill rates of 50 to 100 mL/min.

Bladder storage function should be noted with bladder sensation (normal; first sensation of filling; first and strong desire to void; increased, reduced, or absent bladder sensation; bladder pain; and urgency), detrusor overactivity, bladder compliance, and capacity.<sup>38</sup> The terminology to describe detrusor activity has been standardized by the ICS.<sup>38</sup> *Detrusor overactivity* is characterized by spontaneous or provoked involuntary detrusor contractions during filling. Although an involuntary contraction was originally defined as a minimum pressure rise of 15 cm  $H_2O$ ,<sup>47</sup>

there is presently no lower limit for the amplitude of an involuntary contraction (Fig. 57-4).<sup>38</sup> If leakage is detected in association with an involuntary detrusor contraction, it is termed *detrusor overactivity incontinence*. Detrusor overactivity can be further characterized into idiopathic and neurogenic detrusor overactivity. *Idiopathic detrusor overactivity* describes involuntary detrusor contractions of unknown etiology and has replaced the term “detrusor instability.” An involuntary detrusor contraction secondary to an underlying neurologic condition is *neurogenic detrusor overactivity*, which has replaced “detrusor hyperreflexia.”<sup>38</sup>

Another type of overactive bladder dysfunction is reduced compliance. *Bladder compliance* is defined as the change in pressure for a given change in volume. It is calculated by dividing the volume change by the change in detrusor pressure during that change in bladder volume, and it is expressed as milliliters per centimeters of water pressure (see Fig. 57-4B).<sup>38</sup> Normal bladder compliance is high, and in the laboratory the normal pressure rise is less than 6 to 10 cm H<sub>2</sub>O.<sup>48</sup> Low bladder compliance implies a poorly distensible bladder. The actual numeric values to indicate normal, high, or low compliance have yet to be defined.<sup>38</sup>

The finding of detrusor overactivity on cystometry is important if it correlates with the clinical condition of the patient. Idiopathic detrusor overactivity has been reported in 30% to 35% of patients with stress incontinence undergoing surgery. It resolves in most such patients after repair and may not have a significant impact on outcome.<sup>49,50</sup> Alternatively, if the patient's symptoms are primarily from bladder overactivity, or other factors predisposing to abnormal bladder behavior are present, the cystometric findings will influence treatment. These predisposing factors include a history of radiation, chronic bladder inflammation, indwelling catheter, chronic infection, chemotherapy, voiding dysfunction after pelvic surgery, and other neurologic conditions.

### Urethral Function Tests

The normal urethral closure mechanism maintains a positive urethral closing pressure during bladder filling, even in the presence of increased abdominal pressure. An incompetent mechanism allows leakage in the absence of a detrusor contraction.<sup>38</sup> Two urodynamic tests have been used to depict urethral competence: the Valsalva or abdominal leak point pressure (VLPP or ALPP) and the urethral pressure profile (UPP).

### Leak Point Pressures

The VLPP is the intravesical pressure that exceeds the continence mechanism resulting in a leakage of urine in the absence of a detrusor contraction.<sup>38</sup> The test is performed by a progressive Valsalva maneuver or cough.<sup>51</sup> VLPP tests the strength of the urethra. The study is performed with the patient in the sitting or standing position with at least 150 to 200 mL of fluid in the bladder. Historically, a VLPP of less than 60 cm H<sub>2</sub>O was evidence of significant intrinsic sphincter deficiency (ISD), between 60 and 90 cm H<sub>2</sub>O suggested a component of ISD, and greater than 90 cm H<sub>2</sub>O suggested minimal ISD with leakage mainly due to hypermobility.<sup>48</sup> Currently, no prospective studies have shown that VLPP less than 60 cm H<sub>2</sub>O can accurately diagnose ISD. Although the VLPP may be reproducible,<sup>52</sup> it has not yet been standardized.<sup>5</sup>

There are limitations to a VLPP. If the patient's Valsalva effort is inadequate, urinary leakage may not be seen, and a VLPP

measurement cannot be determined. The presence of a catheter in the urethra may prevent incontinence.<sup>53</sup> Furthermore, a cystocele or other prolapsing segment may produce inferior pressure on an incompetent urethra that prevents incontinence or falsely elevates the VLPP. If a cystocele is present, the VLPP should be repeated with the prolapse reduced by insertion of a vaginal pack or pessary.

The detrusor or bladder leak point pressure (DLPP) is the lowest detrusor pressure ( $P_{det}$ ) on cystometry at which urinary leakage occurs during bladder filling in the absence of a detrusor contraction or increased abdominal pressure.<sup>38</sup> This parameter is used to investigate and monitor patients with neurogenic and low-compliance bladders. In general, patients with a DLPP greater than approximately 25 to 30 cm H<sub>2</sub>O are at risk for upper tract deterioration from reflux or obstruction.<sup>54,55</sup> In these patients, it is necessary to assess compliance as well. A high DLPP indicates poor compliance with urethral obstruction, whereas a low DLPP is seen in patients with incompetent urethras. In order to demonstrate poor compliance in these patients, filling may be done with a Foley catheter to obstruct the outlet.<sup>56</sup>

### Urethral Pressure Profile

Urethral pressure is defined as the fluid pressure needed to just open a closed urethra. The urethral pressure measurements recorded are<sup>38</sup>

- *urethral pressure profile* (UPP), a graph indicating the intraluminal pressure along the length of the urethra
- *maximum urethral closure pressure* (MUCP), the maximum difference between the urethral pressure and the intravesical pressure
- *functional profile length*, the length of the urethra along which the urethral pressure exceeds intravesical pressure in women
- *pressure transmission ratio*, the increment in urethral pressure on stress as a percentage of the simultaneously recorded increase in intravesical pressure

Intraluminal urethral pressure may be measured with the subject at rest, with the bladder at any given volume; during coughing or straining; and during voiding.<sup>57</sup> Measurements can be made at one point in the urethra over a period of time (continuous urethral pressure recording) or as a UPP. A mechanical retracting puller that is synchronized with the chart or digital recorder allows measurement of anatomic distances in the profile.

Two types of UPP may be measured: Resting UPP (Fig. 57-5A), with the bladder and subject at rest, and stress UPP (see Fig. 57-5B), with a defined applied stress (e.g., cough, strain, Valsalva maneuver).

The simultaneous recording of both intra-urethral ( $P_{ura}$ ) and intravesical ( $P_{ves}$ ) pressure enables calculation of urethral closure pressure (i.e.,  $P_{ura} - P_{ves}$ ). The three main methods for UPP measurement are perfused catheters with side holes, catheter-tip transducer catheters, and balloon catheters. Recordings of profile parameters must be repeated several times to verify reproducibility.<sup>58</sup>

An MUCP of less than 20 cm H<sub>2</sub>O (“low-pressure urethra”) has been reported to be predictive of poor outcome of conventional bladder neck suspension procedures<sup>59</sup> and has been called a predictor of ISD.<sup>58</sup> However, the MUCP alone does not provide any information about the integrity of the bladder neck or proximal urethra, and it can be highly variable as a result of involuntary contractions of the smooth and striated muscles of the

**Figure 57-4 A**, Detrusor overactivity. The uninhibited contraction at the end of the filling phase leads to leakage (detrusor overactivity incontinence). EMG, electromyographic tracing; P<sub>abd</sub>, abdominal pressure; P<sub>det</sub>, detrusor pressure; P<sub>ves</sub>, intravesical pressure. **B**, Reduced bladder compliance. As the bladder is filled, the detrusor pressure rises by 50 cm H<sub>2</sub>O (ΔP<sub>det</sub>) while the increase in bladder volume (ΔV) is 150 mL. The compliance (ΔV/ΔP<sub>det</sub>) is 3 mL/cm H<sub>2</sub>O, which is much lower than the normal range of at least 30 mL/cm H<sub>2</sub>O. Griffiths D, Kondo A, Bauer S, et al: Dynamic testing. In Abrams P, Khoury S, Wein A (eds): Incontinence: Third International Consultation. Paris, France: Health Publications, 2005, pp 585-673.

A

B

urethral sphincter, possibly provoked by the catheter itself. Furthermore, the size, stiffness and type of catheter, rate of perfusion, patient position, and bladder volume affect the pressure readings.<sup>5</sup>

A variety of values of MUCP have been obtained by different authors in normal and abnormal female populations.<sup>5</sup> They have several notable features. The first is the intercenter variability in the values reported, with mean MUCP varying from 36 to 101 cm H<sub>2</sub>O in subjects without stress incontinence. The second is the large intersubject standard deviation in most studies (from

**Figure 57-5 A**, Resting urethral pressure profile. (Modified from Lose G: Urethral pressure measurements. In Cardozo L, Staskin D [eds]: Textbook of Female Urology and Urogynaecology. London: Isis Medical Media, 2001, pp 215-226.) **B**, Urethral pressure profile during coughs in a continent woman. The bottom trace shows the bladder response to a series of coughs ( $P_{ves}$ ). The middle trace shows the corresponding urethral responses ( $P_{ura}$ ) while the measuring catheter is slowly withdrawn out of the bladder and through the urethra. The top trace shows the difference between the middle and the bottom traces. The pressure transmission ratio (PTR) is the increment in urethral pressure on stress as a percentage of the simultaneously recorded increase in intravesical pressure:  $(\Delta P_{ura}/\Delta P_{ves} \times 100\%)$ . (Modified from Lose G: Urethral pressure measurements. In Cardozo L, Staskin D [eds]: Textbook of Female Urology and Urogynaecology. London: Isis Medical Media, 2001, pp 215-226.)

10 to 52 cm H<sub>2</sub>O). However, despite this variability, the mean MUCP was less in stress-incontinent patients than in non-stress-incontinent women, sometimes significantly so and sometimes not. Some of the variations are the result of different patient populations, and others are the result of technical errors. A weighted averaging of the mean values suggests that a normal ( $\pm$ SD) MUCP is about  $54 \pm 25$  cm H<sub>2</sub>O. In stress-incontinent women, the corresponding figure is  $39 \pm 24$  cm H<sub>2</sub>O. Clearly, there is so much overlap that it has been impossible to define a cutoff level that allows differentiation between women with and without stress incontinence.<sup>5</sup>

Stress profiles show greater variability than static variables do. The within-subject standard deviation for the pressure transmission ratio varies between 13% and 18.5% (95% confidence limits up to  $\pm 37\%$ ) in published reports. The coefficient of variation has been estimated to be 20% (95% confidence limits,  $\pm 39\%$ ).

Maximum urethral pressure (MUP), like MUCP, also declines with aging.<sup>60</sup>

There clearly are limitations to the test that prevent it from providing reliable pathophysiologic information.<sup>5</sup>

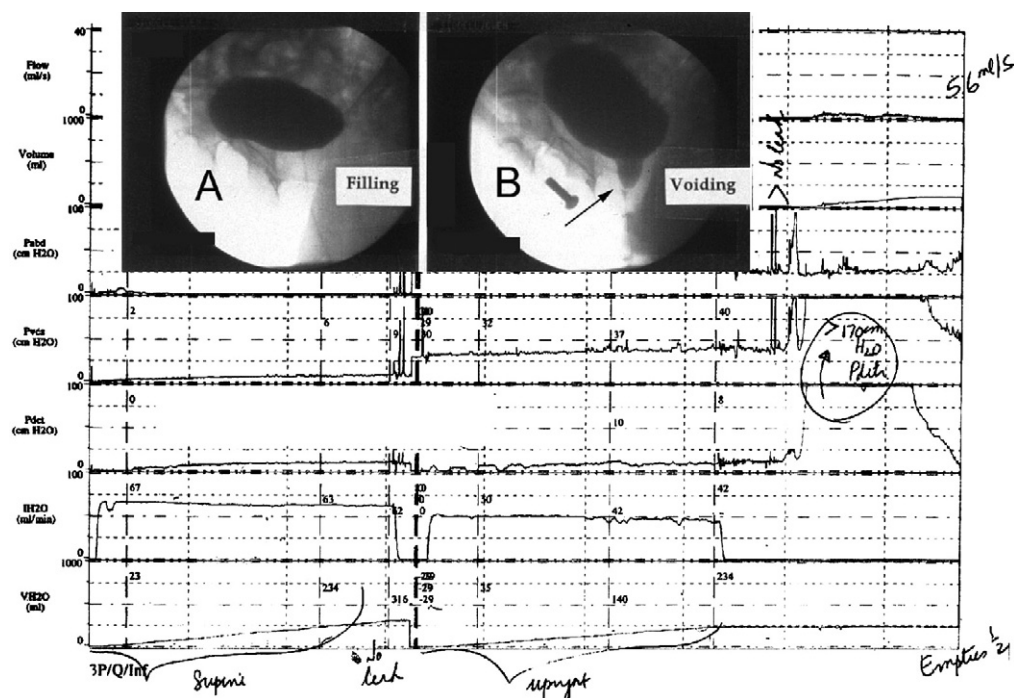

In summary, although the VLPP under ideal circumstances may indicate the severity of stress urinary incontinence, it is not clear whether it is more useful than clinical grading,<sup>5</sup> and, although UPP measurements may be interesting as a research tool, their practical applicability is still to be determined.

### Pressure-Flow Studies

Pressure-flow studies are designed to provide dynamic information on the emptying phase of lower urinary tract function. Obstruction is not common in women<sup>61</sup> but may be found after surgical correction of stress urinary incontinence or, less commonly, with detrusor sphincter dyssynergia, non-neurogenic voiding dysfunction, and, rarely, stricture disease. Interference with voiding may also be associated with pelvic organ prolapse. There are no established nomograms to depict pressure-flow relationships in women as there are in men (although one has been proposed<sup>62</sup>), but the pattern of high detrusor pressure and low urinary flow indicates obstruction (Fig. 57-6). Simultaneous cystography can demonstrate the level of obstruction.

Detrusor pressure during voiding is characteristically low in women. A preoperative study that demonstrates a low detrusor pressure with a low flow rate may aid in counseling the patient about postoperative urinary retention after stress incontinence surgery. The urodynamic definition of obstruction in women is

**Figure 57-6** A and B, Videourodynamic study of a 62-year-old woman with urgency, frequency, and slow stream after multiple urethral dilations. The study shows a normal bladder on filling, with no overactivity. Her voiding pressure exceeds 170 cm H<sub>2</sub>O, and her flow rate is low. There is a urethral stricture visible (arrow in B) with proximal urethral dilatation.

different than in men. A cutoff value of 12 mL/sec or less maximum flow rate and a detrusor pressure at maximum flow of 25 cm H<sub>2</sub>O or more, in conjunction with high clinical suspicion, provides good predictive value.<sup>63</sup>

### Electromyography

Sphincter electromyography (EMG) during videourodynamics is used to examine striated sphincter activity during filling and voiding. These are termed *kinesiologic* studies, and they can be performed with surface electrodes, vaginal or anal probes, or needles. Normal sphincter EMG activity has characteristic audio quality that may be monitored simultaneously. Its most important role is the identification of abnormal sphincter activity in patients with neurogenic bladder dysfunction and in those with behavioral voiding dysfunction.<sup>64</sup> The fluoroscopy component, however, can demonstrate detrusor external sphincter dyssynergia in patients with suprasacral lesions and can show urethral obstruction in patients with dysfunctional voiding. EMG recordings are not usually necessary in routine videourodynamics for incontinence in women who have no neurologic abnormalities. Artifacts can occur secondary to room appliances, fluorescent lights, defective insulation, and patient movement.<sup>48</sup>

### Videourodynamics

Videourodynamics is a diagnostic tool that incorporates urodynamics with simultaneous imaging of the lower urinary tract. The incorporation of radiologic visualization of the lower urinary tract during bladder filling and voiding is useful for determining the site of bladder outlet obstruction, the integrity of the sphincter mechanism, and the presence of vesicoureteral reflux, bladder diverticula, fistulas, and trabeculation.<sup>40</sup> Urodynamics was first

synchronized with cineradiography in the early 1950s through the pioneering efforts of E. R. Miller.<sup>65,66</sup> The initial goal was to minimize the radiation exposure to the patient during cystourethrography. Originally, patient exposure to radiation was high when movies were taken, but with the advent of image intensifiers, video transduction, and, later, videotape recording, the patient exposure was reduced. This permitted bursts of continuous activity to be recorded during critical phases of lower urinary tract activity without overexposing the patient. Today, most studies can be done with less than 1 minute of fluoroscopy time.<sup>48</sup> These developments have contributed to the wealth of information about lower urinary tract function and dysfunction. Modern videourodynamic techniques incorporate fluoroscopy, and the urodynamic machine has evolved from a strip chart recorder to a microcomputer.

Videourodynamic studies are not necessary in every patient, and simpler studies frequently provide enough information to adequately delineate and treat the dysfunction. Videourodynamic studies are beneficial if simultaneous evaluation of function and anatomy is needed to provide detailed information about the whole or parts of the storage and emptying phases. Common indications well suited for videourodynamic evaluation include complex incontinence, in which the history does not fit with the findings on preliminary investigations; incontinence in women with previous anti-incontinence surgery; and incontinence in the face of a neurologic abnormality.

Aside from the minimal radiation exposure to the patient, the only disadvantage of videourodynamics is its cost. This is a result of the time and effort of the personnel required and the expense of the equipment, which may limit its utility to larger centers with larger patient populations. The cost can, however, be justified by the utility of videourodynamics in solving complicated problems.

**Figure 57-7** Diagram of a videourodynamic suite. The patient is in the upright position after the filling catheter has been removed. She will be asked to cough and strain to demonstrate stress incontinence and then to void. The *left arrow* indicates the multichannel recorder, and the *right arrow* indicates the transducers.

**Figure 57-8** Schematic diagram of videourodynamic setup.

### Components of Videourodynamic

A typical arrangement for videourodynamic studies includes a multichannel recorder, a fluoroscopy unit with a table that can be positioned in the supine and upright positions, and a flow meter (Figs. 57-7 and 57-8). A commode seat attachment facilitates fluoroscopic screening of voiding in the seated position, which is ideal for women. Most modern systems are computer based, which allows for complex analysis to be performed.

#### Multichannel Recorder

Because the procedure involves measuring simultaneous pressures during both phases of lower urinary tract function and flow during the voiding phase, a multichannel recorder is necessary. Many systems are available,<sup>67</sup> most of which have dispensed with a strip chart output in favor of television monitor display of the procedure.

The choice of components of the study is up to the individual clinician. Figure 57-8 illustrates possible inclusions. The channels demonstrating volume of fluid instilled and volume voided are

helpful but not essential, as these values can be measured manually. The sphincter EMG channel is not necessary for routine clinical practice but can be helpful in patients with neurologic disease; its inclusion introduces another level of complexity and sophistication.

For a review of the currently recommended urodynamic technique of pressure measurements the reader is referred to the article of Schaeffer and colleagues describing "Good Urodynamic Practices."<sup>37</sup>

#### Fluoroscopy

A good-quality fluoroscopy unit with a high-resolution image intensifier and a table that can function in both the supine and the erect position is required. Fluoroscopic images are obtained selectively during the filling and voiding study and are either superimposed on the pressure-flow tracing or displayed on a separate screen. The fluoroscopic images can be stored and reproduced individually or as continuous clips during key parts of the study. A recording of the procedure can be made for subsequent review.

Because the contrast medium instilled into bladder is unlikely to be absorbed, we use the less expensive high-osmolality contrast media. A dilute solution of 1 L of Hypaque is prepared by the pharmacy and supplied in sterile intravenous bags.

#### Videourodynamic Technique

The patient reports for the study with a full bladder, and a flow rate is obtained. The equipment is zeroed, and the transducer is placed at a height adjacent to the upper edge of the patient's symphysis pubis. Either a double-lumen catheter or two 8-Fr feeding tubes (one for filling, which is removed before the voiding study, and one for pressure measurements) are inserted into the bladder. Residual urine is measured. The rectal catheter is a 42-cm 14-Fr tube with a balloon over the tip. If desired, EMG recording devices may be applied to the patient.

The study is conducted by a uroynamics specialist who is present in the room, communicates with the patient throughout the procedure, and records the findings manually and electronically. A supine or semioblique filling study is carried out, various measurements are taken during the study, and responses to actions such as Credé, cough, and Valsalva maneuvers are recorded. The filling rate is no longer divided into slow, medium, or fast but rather is described as physiologic or nonphysiologic.<sup>38</sup> In practice, most clinicians use a medium fill rate of 50 to 75 mL/min.<sup>46</sup> A commonly used method is to fill the bladder supine and then stand the patient up for provocative manoeuvres.

During the study, recordings are made of bladder images in the filling phase in the supine and/or upright position (see Fig. 57-8). Anteroposterior (AP) and oblique views are obtained. The AP position permits documentation of reflux and its extent, and in the oblique position the course of the urethra can be seen separate from a cystocele. Notation is made of the bladder outline, the appearance of the bladder neck at rest, and its position relative to the inferior margin of the symphysis at rest and with straining and coughing. Leakage of urine with overactivity, decreased compliance, or leakage with various stress maneuvers is recorded. In the upright position, the presence of a cystocele and its relationship to the urethra are also noted. If the patient is able to void in front of the camera, the voiding phase (or parts of it) are recorded, along with the pressures and flow tracings. If the patient is unable to void with the catheters in place, they are removed, and a flow rate and voided volume are measured. Total fluoroscopy time is usually less than 1 minute.

**Table 57-1 Radiologic Type of Stress Incontinence**

Type	Description
0	Vesical neck and proximal urethra closed at rest and situated at or above the lower end of the symphysis pubis. They descend during stress, but incontinence is not seen.
I	Vesical neck closed at rest and well above the inferior margin of the symphysis. During stress, the vesical neck and proximal urethra are open and descend less than 2 cm. Incontinence is seen.
IIa	Vesical neck closed at rest and above the inferior margin of the symphysis. During stress, the vesical neck and proximal urethra open and descend more than 2 cm. Incontinence is seen.
IIb	Vesical neck closed at rest and at or below the inferior margin of the symphysis. During stress, there may or may not be further descent but as the proximal urethra opens incontinence is seen.
III	Vesical neck and proximal urethra are open at rest. The proximal urethra no longer functions as a sphincter. There is obvious urinary leakage with minimal increases in intravesical pressure.

From Blaivas JG, Olsson CA: Stress incontinence: Classification and surgical approach. *J Urol* 139:727-731, 1988.

The recorded study provides an opportunity for the case to be reviewed and discussed. All of the events of the study are recorded and displayed on the monitor during the study. The urodynamics machine is usually equipped with the capability of compressing the study so that it can be viewed on an ordinary letter-size sheet of paper.

### Urinary Incontinence

The main advantage of fluoroscopic imaging during the urodynamic study is to obtain an anatomic view of the function or dysfunction. The technique is ideally suited to the evaluation of incontinence. A useful anatomic/radiologic classification of female incontinence, devised by Blaivas,<sup>68</sup> is described in Table 57-1 and illustrated in Figure 57-9. We use this classification to determine the radiologic abnormality and add to it the information from the VLPP and the position of the urethra in relation to the cystocele to describe the functional problem. Each of the urodynamic tracings in the figures described in the next few paragraphs is shown in full with annotations made during the study. The video recordings depicting parts of the studies were obtained from a video printer connected to the fluoroscopy equipment.

Type I abnormalities are illustrated in Figure 57-10; the patient had a VLPP of 62 cm H<sub>2</sub>O and minimal hypermobility. The patient in Figure 57-11 had a VLPP of more than 120 cm H<sub>2</sub>O on straining during upright filling. At the end of filling, a cough caused a large leak without much hypermobility and appeared to be accompanied by a small bladder contraction. This indicated that the patient had stress incontinence as well as cough-induced overactivity.

Figures 57-12 thru 57-14 demonstrate type IIa abnormalities. The patient in Figure 57-12 has a high VLPP without any appreciable cystocele. In Figure 57-13, the patient has an involuntary detrusor contraction with incontinence in the upright position and a high VLPP. The patient shown in Figure 57-14 has a grade

II cystocele that appears with straining; she probably has mainly a lateral defect.

Type IIb abnormalities are shown in Figures 57-15 thru 57-17. The bladder neck in Figure 57-15 is seen well below the lower margin of the symphysis and is associated with a grade II cystocele. Because the bladder neck is above the base of the cystocele but below the lower margin of the symphysis, the patient most likely has a combined central and lateral defect. In Figure 57-16, the large cystocele is not associated with demonstrable stress incontinence, despite coughing and straining pressures greater than 100 cm H<sub>2</sub>O. It appears to be primarily a central defect. Clinical examination must include reducing the cystocele and checking for stress incontinence. The patient in Figure 57-17 has a combined central and lateral defect. She has marked detrusor overactivity with leakage, but stress incontinence is not demonstrated, most likely because of the compressive effect of the cystocele.

Type III incontinence or pure ISD is demonstrated by the patient in Figure 57-18. Her bladder neck is open at rest, no appreciable descent is seen with coughing or straining, and her VLPP is low at 59 cm H<sub>2</sub>O.

Videourodynamic and fluoroscopic studies, in addition to demonstrating incontinence and degree of hypermobility, may also allow characterization of the type of cystocele (see Fig. 57-15).

### Obstruction

Although outflow obstruction is uncommon in females, it is occasionally seen. The patient in Figure 57-6 had an iatrogenic and functionally significant urethral obstruction that was treated with a visual internal urethrotomy and subsequent long-term self-dilation.

### Pitfalls of Videourodynamics

Patient cooperation, comfort, and compliance are necessary to obtain a meaningful and relevant study. Occasionally, an apprehensive patient has a vasovagal reflex and faint when the table is moved from the supine to the upright position, and the study cannot be completed. Moreover, stress incontinence may not be demonstrated in an anxious patient.

Of 2259 studies that we reviewed in our laboratory for neurologically normal women whose chief complaint was stress incontinence, we were unable to demonstrate stress incontinence on fluoroscopy in 630 (28%). It is also difficult for many patients to void in front of the camera with catheters in the bladder and rectum and observers watching them. In our series, only 1348 patients (59.7%) were able to void, and some of these did so with abdominal straining. The others were unable to void during the procedure, and the voiding data was obtained from the uroflow measurements.

To optimize visibility of the lower urinary tract on fluoroscopy, patient positioning must be correct. However, visibility may be poor or absent with very obese patients. The clinician must also maintain a dialogue with the patient to image crucial events, because the patient must relay changes in sensation during filling and may be the first to sense incontinence.

The radiation equipment must be well maintained and undergo regular maintenance and safety inspections. The failure to maintain equipment may lead to inaccurate results. Because fluoroscopy time is short, radiation exposure to the patient is inconsequential; however, the clinician should use radiation protection, including aprons and thyroid shields.

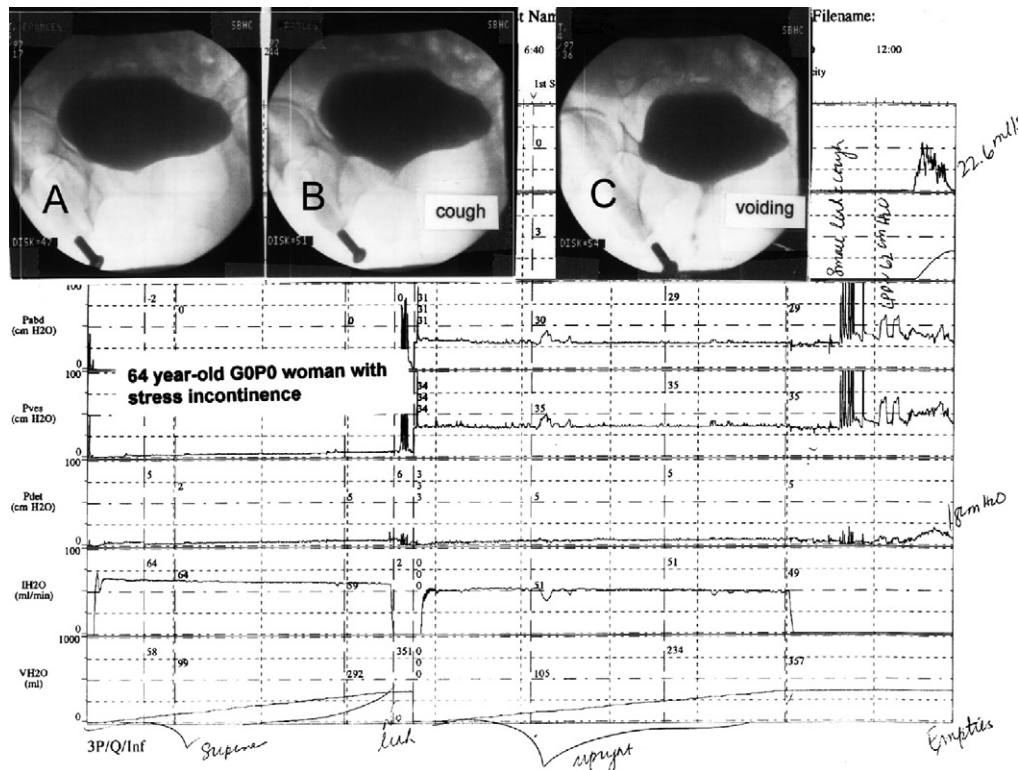

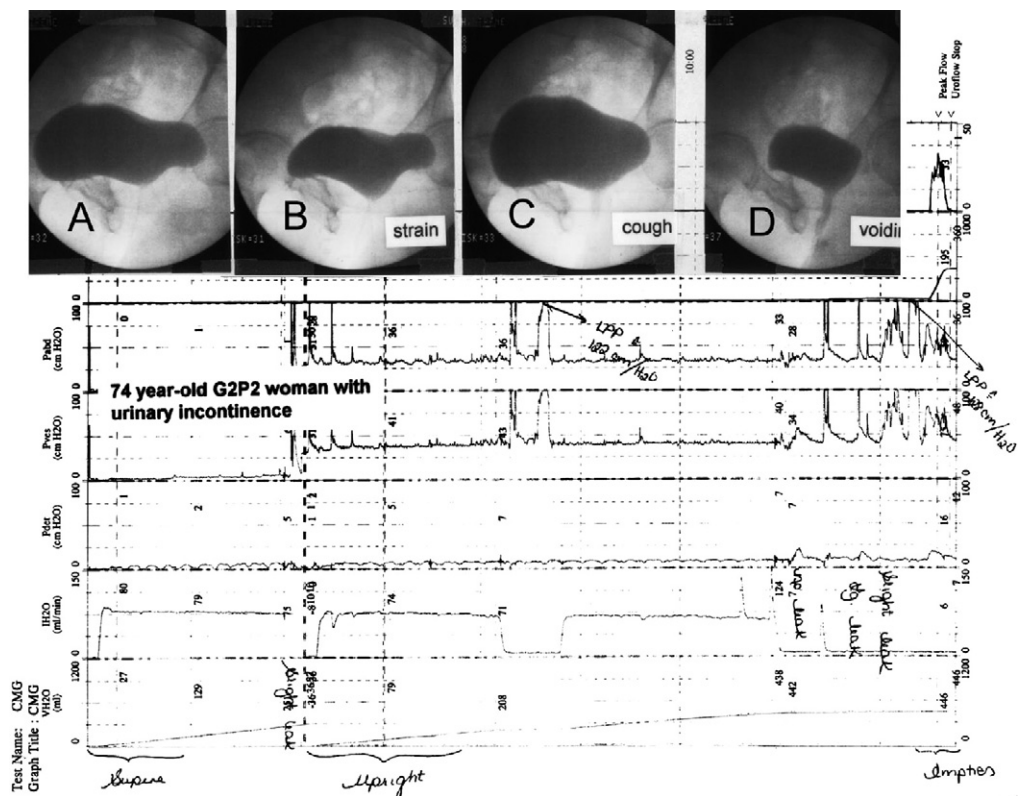

**Figure 57-9** Schematic diagrams of the radiologic images obtained from women with the various types of female stress urinary incontinence. **A**, Type I. The bladder neck is closed at rest and is well above the inferior margin of the symphysis. During stress, the bladder neck and proximal urethra open and descend less than 2 cm, and incontinence is seen. **B**, Type IIa. The bladder neck is closed at rest and is above the inferior margin of the symphysis. During stress, the bladder neck and proximal urethra open and descend more than 2 cm. Incontinence is seen. **C**, Type IIb. The bladder neck is closed at rest and is at or below the inferior margin of the symphysis. During stress, there may or may not be further descent, but as the proximal urethra opens, incontinence is seen. **D**, Type III. The bladder neck and proximal urethra are open at rest. The proximal urethra no longer functions as a sphincter. There is obvious urinary leakage with minimal increases in intravesical pressure. (From Blaivas JG, Groutz A: Urinary incontinence: Pathophysiology, evaluation, and management overview. In Walsh PC, RetikAB, Vaughan ED Jr, Wein AJ [eds]: *Campbell's Urology*, 8th ed. Philadelphia: Saunders, 2000, pp 1027-1052.)

Other pitfalls relate to the urodynamic aspects and are similar to those previously outlined by O'Donnell.<sup>69</sup> Standardized terminology to communicate results and concepts should always be used.<sup>38</sup> The testing procedures and equipment should be compatible with commonly accepted methodologies. The value and limitations of each measurement must be realized; for example, the VLPP may not be useful in the presence of a large prolapsing cystocele. To confirm reliability within a particular laboratory, it is necessary to have a high test-retest

correlation of studies. The validity of a test refers to its ability to measure what it is supposed to measure. The clinician must always be aware of the how the test in question compares to a "gold standard" test, which in urodynamics may be difficult to establish. The urodynamic studies should correlate with other clinical data. The voiding history, physical examination, endoscopic examination, and videourodynamic evaluation should serve to validate one another and strengthen the clinical assessment.

**Figure 57-10** A through C, Videourodynamic study of a 64-year-old gravida 0, para 0 woman with type I stress incontinence. She had a bladder capacity of more than 300 mL. The bladder neck was slightly open at rest (A). With coughing, there was a small amount of descent and Valsalva leak point pressure was 62 cm H<sub>2</sub>O. She had no apparent cystocele, and her voiding phase was normal.

**Figure 57-11** A through D, Videourodynamic study of a 74-year-old gravida 2, para 2 woman with type I stress incontinence. The bladder neck is slightly open at rest (A). In the upright position (B), leaks occur with straining and a Valsalva leak point pressure of 122 cm H<sub>2</sub>O is recorded. On coughing (C), leaking is followed by a detrusor contraction (arrow). Voiding is normal (D).

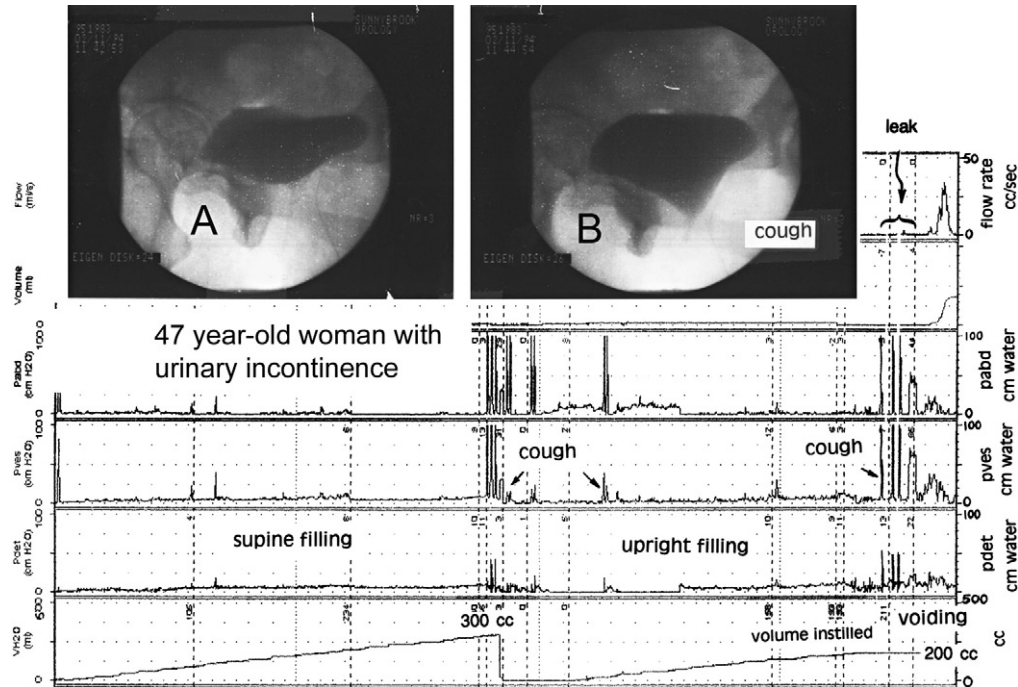

Figure 57-12 A and B, Videourodynamic study of a 47-year-old gravida 1, para 1 woman with type IIa stress incontinence. Her bladder neck is open at rest (A). Leakage and hypermobility are seen with coughing (B).

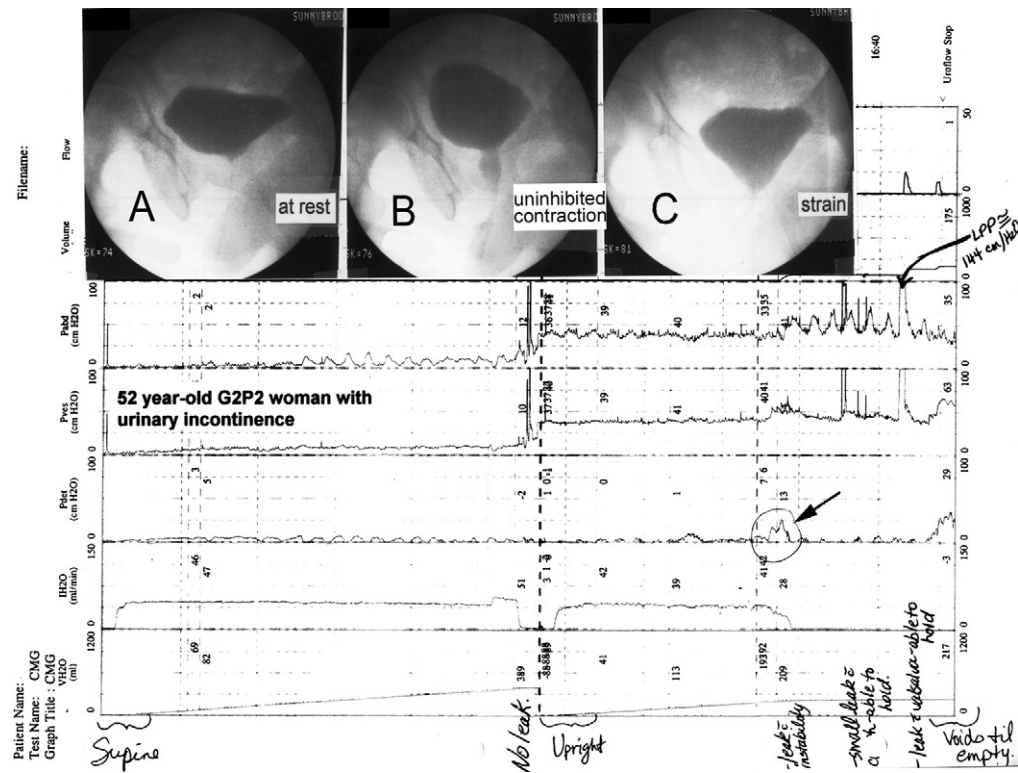

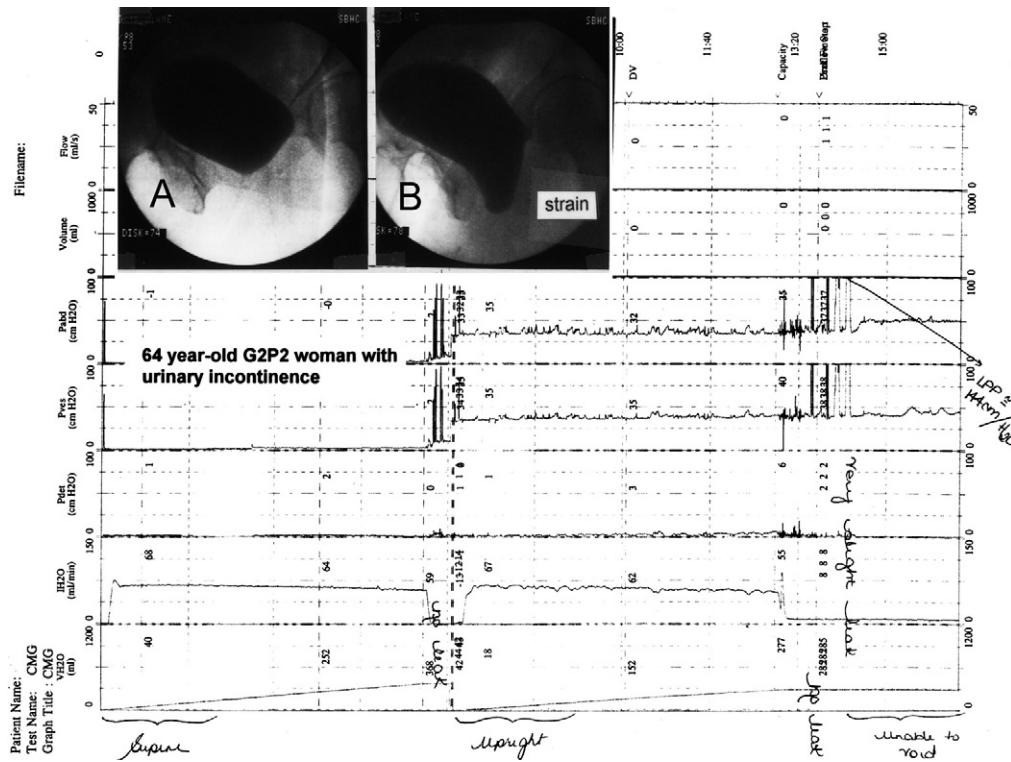

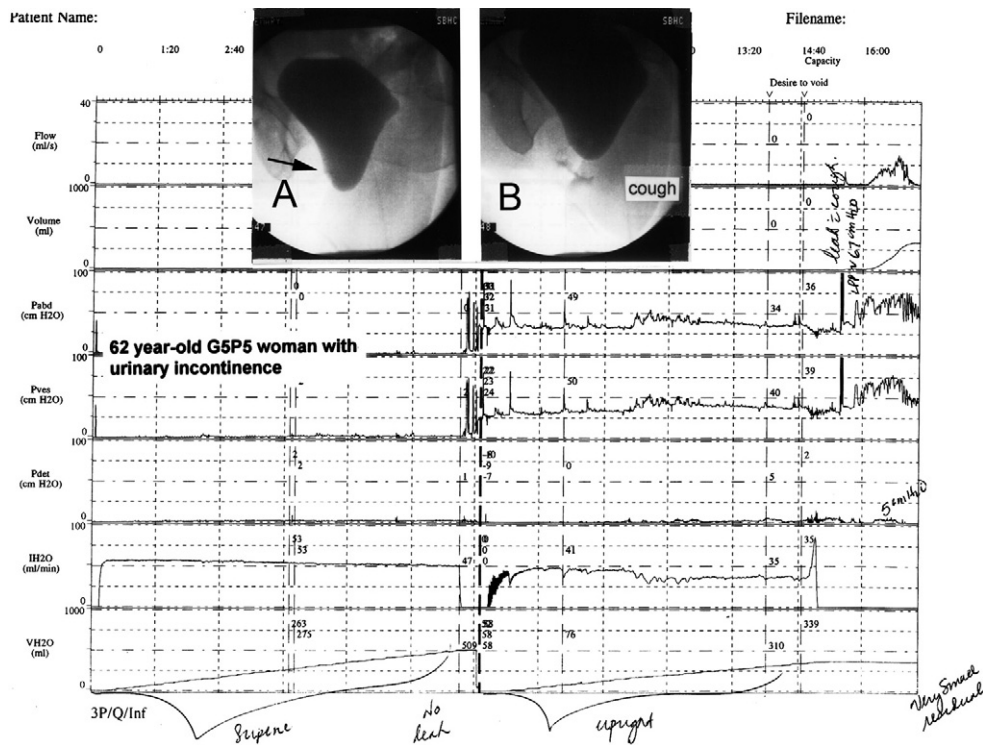

Figure 57-13 A through C, Videourodynamic study of a 52-year-old gravida 2, para 2 woman with a type IIa abnormality who complained of both stress and urgency incontinence. The bladder neck is slightly open at rest (A). She has an involuntary detrusor contraction (arrow) on upright filling that results in incontinence (B). With straining, leaking occurred, with a Valsalva leak point pressure of more than 140 cm H<sub>2</sub>O (C).

**Figure 57-14** A and B, Videourodynamic study of a 64-year-old gravida 2, para 2 woman with type IIa stress incontinence. Her bladder neck is well supported on upright filling (A). With straining, leaking occurs with a Valsalva leak point pressure of 144 cm H<sub>2</sub>O, and a cystocele is demonstrated (B). She most likely has mainly a lateral defect.

**Figure 57-15** A and B, Videourodynamic study of a 62-year-old gravida 5, para 5 woman with type IIb stress incontinence. Her bladder neck (arrow) on filling (A) is below the lower margin of the inferior symphysis, and a cystocele is seen. She most likely has a combined central and lateral defect. She has leakage with coughing (B) and a Valsalva leak point pressure of 62 cm H<sub>2</sub>O on straining.

**Figure 57-16** Videourodynamic study of a 75-year-old gravida 1, para 1 woman with a large cystocele. Although she complained of stress incontinence, it is not visible on this study. The bladder neck (arrow) is at the lower margin of the symphysis. The cystocele appears primarily to be a central defect. Clinical evaluation must include reducing the cystocele and testing for stress incontinence.

**Figure 57-17** Videourodynamic study of an 81-year-old gravida 1, para 1 woman with a central and lateral defect. The bladder neck is below the symphysis (arrow on image). She has marked detrusor overactivity on supine and upright filling (arrows on graph). Although she complained of stress incontinence in addition to urge incontinence, it is not demonstrated on this study.

residual urine measurement are good screening tests for voiding dysfunction. More invasive testing may be helpful in many cases, including those involving complex or recurrent symptoms. Although there are benefits of urodynamic studies, in that the

lower urinary tract problem may be more clearly elucidated, overall there still exists a lack of evidence of reproducibility and predictive value in assigning treatments and determining outcomes.

# NONSURGICAL TREATMENT OF VAGINAL PROLAPSE: DEVICES FOR PROLAPSE AND INCONTINENCE

Peggy A. Norton

### NONSURGICAL TREATMENT OF VAGINAL PROLAPSE

Surgery for pelvic floor disorders such as stress urinary incontinence and pelvic organ prolapse (POP) is aimed at restoring or improving the function of the pelvic organs. By its nature, such functional surgery cannot be guaranteed to restore continence and support to its original state. Up to one third of surgeries for pelvic floor disorders fail.<sup>1</sup> Given these facts, many women are interested in nonsurgical options for vaginal prolapse that offer less risk and expense. Once fitted, patients are immediately aware of whether the device is comfortable and whether it is effective in treating the condition. Although use of these devices should not be viewed as a permanent solution for prolapse, many women successfully use them for many years without much bother. Such devices are widely available but require some professional intervention to determine correct use and fit, similar to fitting a contraceptive diaphragm. Little has been published on the use of vaginal devices for prolapse, possibly because there is no industry support for (or profit from) conducting properly controlled clinical trials.

### Indications for Pessary Use

Indications for a pessary in the management of POP include patient desire for nonsurgical management of the condition. Traditionally, this group of patients has included those few women who are unable to undergo surgical management because of medical problems. But there are many women who might be interested in a pessary, because it manages the prolapse without the need to undergo surgery. In our practice, pessaries are used successfully in women who cannot take time off for surgery, such as mothers with small children at home and women with busy careers outside the home.

Willingness to use a vaginal device may be cultural, especially in areas where contraceptive diaphragms are used. Prashar and colleagues<sup>2</sup> found that only a fifth of 104 women who presented to a community continence clinic in Australia felt very comfortable about inserting a device into the vagina (and half felt uncomfortable). In our practice at the University of Utah, most women who are believed to be good candidates for a pessary trial are readily fitted and can demonstrate removal and replacement of the device. Clemons and colleagues<sup>3</sup> successfully fitted three-quarters of patients with POP with a pessary. It has even been suggested that use of a pessary longer than 1 year may have some therapeutic effect, in that a minority of users have an improvement in prolapse stage.<sup>4</sup>

### Patient Selection

In addition to a patient's interest in nonsurgical management, there are physical factors that favor use of a pessary. The best clinical situation is an anterior and/or apical defect (cystocele, uterine prolapse, vaginal vault prolapse) in a woman with adequate vaginal capacity, a narrow pubic arch, and good pelvic floor strength. This is because the ventral edge of a pessary is held behind the pubic rami, and a wide arch would allow extrusion of the device. Likewise, the dorsal edge of the pessary is braced by the pelvic floor muscles. In the absence of these factors, one must consider the use of pessaries that utilize suction or inflation (see later discussion). An isolated posterior wall defect (rectocele) is more difficult to manage with a pessary, because the force vectors act to extrude the pessary. If the vaginal capacity is reduced after surgery, a narrower pessary may be needed (e.g., oval, Hodge, cube). Other reported risk factors for pessary failure include a shortened vagina and a wide levator hiatus.<sup>3</sup>

### Selection of a Pessary

Vaginal pessaries have been used for many centuries, but improvements in materials and design have increased the usefulness of these devices for prolapse. Most are made of silicone (latex-free), are flexible to allow easier placement and removal, and should last for several years with proper care. Sources for vaginal pessaries are listed in Table 58-1.

### Supportive Pessaries

Supportive pessaries (which depend on some levator muscle support to stay in place) include the Gehrung, Hodge, and Schatz designs, as well as rings and ovals with support. Although individual practices may vary, flexible ring pessaries and Gelhorn pessaries are used most commonly. Members of the American Urogynecologic Society (AUGS) were surveyed by Cundiff and colleagues,<sup>5</sup> and more than three quarters of respondents reported that they tailored the pessary to the defect. A ring pessary was more common for anterior and apical defects, a Gelhorn was more common for large Stage III and IV prolapse, and a donut pessary was used for posterior defects. Twenty-two percent of respondents used the same pessary, usually a ring pessary, for all support defects. One questionnaire study of gynecologists reported that ring and donut pessaries were the types most commonly used.<sup>6</sup> In a tertiary referral practice in Texas, Sulak and colleagues<sup>7</sup> used a Gelhorn pessary in 96 of 107 women with symptomatic POP. Because many of the women desiring pessary use have stage II prolapse, the pessary we use most at the

Information on pelvic floor muscle training (Kegel exercises) is also available.

University of Utah is the ring with support in sizes 3 and 4 (size refers to diameter in centimeters.)

Supportive pessaries are the easiest pessaries to use because they fold to a smaller dimension for insertion. Many of them, because they are similar to a contraceptive diaphragm, permit coitus while wearing the device. Perhaps because they are easier to manage, supportive pessaries may not be sufficient to support large prolapses. Pessaries are easiest to insert lying down, easiest to remove standing up, and may require digital bracing *per vaginam* during bowel movements. Some women have difficulty removing the pessary, and in the past some pessaries came with removal strings that became malodorous over time. Instead, we recommend tying a strand of dental floss around the ring, so that the pessary can be pulled out by the floss, and renewing the floss each time.

### Space-Occupying Pessaries

Space-occupying pessaries include the cube, donut, Gelhorn, and inflatable. These pessaries are more difficult to insert and remove, but they work in situations in which other devices would be extruded: with larger prolapse, poor pelvic floor strength, or wider pubic arch. Of these, we use the donut and the Gelhorn with the most frequency. The donut is simply pushed into the vagina quickly, and it is easiest to use in women without significant atrophy or scarring. The Gelhorn is held by the knob, aligned along an almost vertical axis (but sparing the urethra) and rapidly inserted, then adjusted so that the knob faces the introitus or posterior distal vagina. We have not found that pinching the flexible disk of the Gelhorn makes much difference to the relative discomfort with which this pessary is placed. To remove the Gelhorn, an index finger should be inserted to break the slight suction seal of the disk in the vagina, and the thumb and index finger of the other hand may grasp and pull the knob. Occasionally, we use a ring forceps to grasp the knob and bring it to the introitus. Although insertion and removal of the Gelhorn sounds daunting, it is a highly successful pessary for large prolapses, and with practice this pessary is inserted and removed on a regular basis in many patients. The cube has a relative suction effect and may be effective in cases of lax vaginal walls, but it generates significant discharge and in our experience is more prone to excoriation and ulceration than other pessaries. The inflatable is

pumped up with a small bulb and is similarly prone to excoriation unless care is taken.

### Care and Long-Term Use of a Vaginal Pessary

Postmenopausal women may benefit from vaginal estrogen. This has little systemic absorption, may increase vaginal skin thickness and tolerance of the device, and is best given as a vaginal pill (Vagifem 25 µg, Novo Nordisk, Princeton, NJ) once nightly for 10 nights, then twice weekly thereafter. After an initial follow-up examination to demonstrate efficacy and self-management, women who manage their own pessary without difficulty may be seen annually. Women may need to brace the device digitally during straining for bowel movements to prevent extrusion. A device that is easily dislodged or uncomfortable is not satisfactory and should be removed and replaced.

Care of a vaginal pessary depends on the type used. Because it is easy to remove and reinsert, we recommend that women remove the ring pessary at least weekly, wash it with soap and water, leave it out overnight, and then reinsert in the morning. In our experience, women rarely encounter excessive or malodorous vaginal discharge using this approach and therefore have little use for creams other than estrogen. Space-occupying pessaries are sometimes difficult for a woman to remove on her own. In such cases, we try to individualize the intervals between insertions. We may ask a patient with a donut or Gelhorn device to return for reexamination within a few weeks. If discharge is minimal and no erosions are present, we examine next at 4 weeks and then at increased intervals. The appropriate pessary interval is either a maximum of 3 months or the interval at which foul-smelling discharge or early erosions appear.

For women who can remove and replace their own pessaries, we schedule a follow-up evaluation within 1 month of placement and then monitor the patient annually, depending on her comfort level. For women who retain the pessary for several months at a time, we believe that a visual inspection of the vagina should occur at least twice yearly. It is important to examine the anterior and posterior vaginal walls during the examination (by turning the speculum 90 degrees), as well as the obvious lateral walls that are visible when the speculum is placed in the usual fashion. This

vaginal inspection is not only important in preventing erosions from the pessary, but it can offset the poor compensation for pessary placement in individual practices. If an area of redness or erosion is seen, the patient is asked to remove the device more often, use vaginal estrogen, and even consider leaving the device out for a week or two.

### Clinical Outcomes

Several series have demonstrated that POP can be managed with pessary use. In one study by Wu and colleagues,<sup>8</sup> of the 62 women that used a pessary for more than 1 month, 66% were still using it after 12 months. In Sulak's series,<sup>7</sup> half of women continued to use the pessary at the time of manuscript preparation (average duration of use, 16 months).

Clemons and coworkers<sup>9</sup> (2004) prospectively evaluated women with symptomatic POP, and 73 of 100 women were satisfied with their pessary at 1 week. At 2 months, only 3% of women endorsed feeling a bulge, compared to 90% at baseline. Other symptoms that improved included pressure, discharge, and splinting. One third of women had urge incontinence at baseline; this improved in 54%. Twenty-three percent had voiding difficulty at baseline, which improved in half. At 2 months, 92% were either very or somewhat satisfied with their pessary. Ring pessaries were used more with stage II and III prolapse (100% and 71%, respectively), whereas Gelhorn pessaries were used more with stage IV prolapse (64%,  $P < .001$ ). Factors associated with long-term pessary use included older age (76 versus 61 years;  $P < .001$ ) and poor surgical risk (26% versus 0%;  $P = .03$ ). Characteristics that were associated with women going on to surgery were sexual activity, the presence of stress incontinence (a coexisting problem that may not be helped by a vaginal pessary for prolapse), and desire for surgery at the first visit. Age 65 years was the best cutoff value for continued pessary use, with a sensitivity of 95% (95% confidence interval [CI], 84% to 99%) and a positive predictive value of 87% (95% CI, 74% to 94%). Logistic regression demonstrated that age greater than or equal to 65 years ( $P < .001$ ), stage III-IV posterior vaginal wall prolapse ( $P = .007$ ), and desire for surgery ( $P = .04$ ) were independent predictors

In contrast, other researchers have found that pessary use is acceptable to women who are sexually active. Brincat and colleagues<sup>10</sup> reviewed 136 women who initiated pessary treatment for POP or urinary incontinence over a 2-year period. Of the 60% of women who became long-term pessary users, those who were more likely to continue pessary use were those who were using

the pessary for treatment of prolapse and those who were sexually active.

### Recommendations for Initiating Pessary Use

Wu and colleagues<sup>8</sup> recommended a simple management strategy in which a flexible ring pessary with support was the first pessary tried, and 70% of patients were successfully fitted with a size 3, 4, or 5 ring. In Utah, many urologists and gynecologists keep a few simple pessaries in their practice for fitting. A number 3 or 4 ring pessary with support can be inserted, and, if appropriate, a prescription can be written and the pessary ordered through a pharmacy. The fitting pessary can then be sterilized for refitting. Alternatively, a few high-volume urogynecologic practices keep large numbers of pessary types and sizes. Once fitted, patients return to their clinician for long-term management. This practice is more feasible for pessaries such as the Gelhorn. If the patient is postmenopausal, a 2- to 3-week course of vaginal estrogen is recommended, and a pessary may be ordered in the interval for placement in the office.

## NONSURGICAL TREATMENT OF URINARY INCONTINENCE

In women, treatment of urge urinary incontinence (overactive bladder) is primarily pharmacologic and behavioral. Although stress urinary incontinence can be treated surgically, many women choose nonsurgical options such as intravaginal devices and new pharmacologic treatments. Both types of urinary incontinence may benefit from lifestyle interventions, physical therapy, biofeedback, bladder retraining, and behavioral modifications. Mixed urge and stress incontinence is sometimes treated as two separate entities, although there is increasing evidence that both components of mixed incontinence may respond to treatments aimed at a single type of incontinence, such as anticholinergics/antimuscarinics and combination selective serotonin/norepinephrine reuptake inhibitors (SSRI/NERIs). A consensus conference on urinary incontinence was sponsored by the World Health Organization in 2001, and levels of evidence for many of nonsurgical treatments were summarized by Wilson and associates<sup>11</sup> (Table 57-2). We consider here the use of devices for stress urinary incontinence.

Intravaginal devices work by creating a "backstop" at the level of the bladder neck. Devices that have been studied include a short super tampon inserted just inside the vagina, a Hodge pessary placed backward and upside down, and a variety of

**Table 58-2 Device and Pharmacologic Treatments for Urinary Incontinence**

Device or Treatment	Efficacy	Effort	Evidence
<b>Continence devices</b>			
Intravaginal (pessary-like) devices	Moderate to high	Low to moderate	Scant 1-2
Occlusive urethral devices (not currently marketed)	Moderate	Low to moderate	Level 3-4
Intraurethral devices (not currently marketed)	High	Moderate	Level 2-3
<b>Pharmacologic treatments</b>			
Of overactive bladder	Moderate	Low but expensive	Level 1
Of stress urinary incontinence	Moderate	Low, no cost estimates	Level 1
Of mixed urinary incontinence	Moderate	Low	Level 1

**Table 58-3 Studies of Devices for Stress Urinary Incontinence**

Device and Ref. No.	N	Indication	Follow-up	Outcome
Smith-Hodge pessary <sup>12</sup>	30	Stress incontinence	None	Cough pressure profile; 24/30 patients continent
RCT of super tampon and Hodge pessary <sup>13</sup>	18	Exercise-induced stress incontinence	None	36% of pessary users continent; 58% of tampon users continent
Bladder neck support prosthesis <sup>15</sup> (no current distributor)	77	Stress and mixed Incontinence	12 wk	On subjective pad test, 29% continent, 51% decreased severity by more than half; 81% had combined subjective/objective some or maximum benefit
Bladder neck support prosthesis <sup>16</sup> (no current distributor)	70	Stress or mixed incontinence	4 wk	53/70 completed trial; significant improvement on pad tests, diaries; high subjective improvement and quality of life
Continence ring pessary <sup>17</sup>	38	Stress incontinence	1 yr	6/38 continued device use long term; improved scores on pad test, voiding diary
Variable continence pessaries <sup>18</sup>	100	Stress and mixed incontinence, prolapse	11 mo	59% continued use long term, with significant reduction in incontinence
Continence dish <sup>14</sup>	119	Stress Incontinence	6 mo	89% successful device fitting; >50% continued use for 6 mo

RCT, randomized controlled trial.

Summarized and updated from Wilson et al., 2001.

continence devices manufactured by several companies who also manufacture pessaries for prolapse (Table 57-3). Additionally, there are several disposable intravaginal devices that are not yet available for use in the United States. These devices are easy to use and seem to have moderately good efficacy, especially for the woman with predictable stress incontinence, who may use such devices when exercising or for that week of coughing from a bad cold. Use among urogynecologic and urology practices is variable: some specialists offer these devices to all women with stress incontinence, whereas others do not include intravaginal devices in their practice. The devices have not been well studied. These are low-cost devices sold in modest volumes whose manufacturers do not have research funds, and there are no sham devices for randomized controlled trials.

## Types of Devices

### Nonpessary Devices

Many women report use of their contraceptive diaphragm as being effective. Its mechanism is probably similar to that of other continence devices: creation of a “backstop” against which the urethra is briefly compressed during increased abdominal pressure. A short menstrual tampon may be inserted just comfortably inside the introitus; patients need to be instructed to use the tampon under dry conditions, which improves the adherence of the tampon. We instruct patients to use this “tampon trick” with a super tampon, and only on an occasional basis. The Conveen Continence Guard is a polyurethane foam cushion that is folded on its long axis and placed in the vagina. When moistened and partially unfolded, it acts as a backstop under the bladder neck. The device is available in three sizes and is worn for up to 18 hours and then discarded. It is not yet available in the United

States. Several studies have documented good tolerance and significant reductions in urine loss with use.<sup>19,20</sup>

### Supportive (Modified Pessary) Devices

The majority of continence devices have been modified from vaginal pessaries used for POP, and all recreate the supportive “backstop” effect for the urethra. These include rings with knobs placed at the bladder neck, the Hodge pessary inserted backward and upside down, the incontinence dish with support, the PelvX ring, and the Suarez ring.

### Nonsupportive Devices

Nonsupportive devices include a urethral insert (Rochester Medical, Inc., Rochester, MN) and urethral suction caps (Uromed; not currently available.) Such urethral plugs and caps have been studied with some success but do not seem to be popular in clinical practice. Some women may wear these devices for activities only, whereas others need to wear them on a daily basis. Care of these pessaries is similar to that for supportive pessaries.

### Clinical Use

Although use of a short super tampon may be suggested on a temporary basis, we use the incontinence dish as our main incontinence pessary. Patients can immediately see the advantages (effective, no surgery) and disadvantages (small amount of bother with insertion, need for continued use) associated with these devices. Although most women wear these devices on an as-needed basis, some patients who have daily stress incontinence prefer to wear the device on a continual basis.

Once an appropriate candidate for a supportive device has been identified, we prefer to fit the device in a separate session,

often after several weeks of vaginal estrogen in postmenopausal women. It is helpful to demonstrate leakage with a standing cough stress test, then to demonstrate continence after a device is fitted. A comfortable bladder volume does not seem to impair fitting of the device. In supine lithotomy, the capacity of the vagina laterally is assessed; this may be limited in women who have had vaginal surgery. We begin with a continence dish of a similar diameter, squeezing the device to narrow its entry into the vagina. All of these devices are placed with the knob just inside the introitus, creating the support for the urethra. The best fit is that which leaves a fingerbreadth or two between the device and the pubic symphysis, is comfortable, and does not readily extrude with straining. Women with a narrow pubic arch and good pelvic floor strength are the best candidates for a supportive device, because the pessary is more easily retained. For a narrow vagina with limited capacity, a Hodge pessary (placed so that the arch is directed at the bladder neck) or a knobbed device may be preferable.

We recommend that women remove the intravaginal supportive device at least weekly, leave it out overnight, and then reinsert it in the morning. The device can be washed with simple soap and water, rinsed, and air-dried. In our experience, women rarely encounter vaginal excoriations or excessive or malodorous vaginal discharge using this approach. Postmenopausal women may benefit from vaginal estrogen. This has little systemic absorption, may increase vaginal skin thickness and tolerance of the device, and is best given as a vaginal pill (Vagifem 25 µg, Novo Nordisk) once nightly for 10 nights, then twice weekly thereafter. After an initial follow-up examination to demonstrate efficacy and self-management, women who manage their own pessary without difficulty can be seen annually. Women may need to brace the device digitally during straining for bowel movements to prevent extrusion. A device that is easily dislodged or uncomfortable is not satisfactory and should be removed and replaced.

Most studies evaluating the effectiveness of devices for stress incontinence are small in numbers and short in duration. In a prospective, randomized study by Nygaard,<sup>13</sup> 6 of 14 women were cured and an additional 2 improved during exercise while wearing a super-sized tampon in the vagina. Nine of 12 women had resolution of stress incontinence while wearing a contraceptive diaphragm during urodynamic testing, and 4 of 10 women wearing a contraceptive diaphragm for 1 week had improved continence.

Of 190 women presenting to a tertiary care center with symptoms of stress or mixed urinary incontinence who were offered pessary management, 63% chose to undergo fitting and 89% achieved a successful fit in the office. Of the 106 women who took a pessary home, follow-up was available on 100. Fifty-five women used the pessary for at least 6 months as their primary method of managing urinary incontinence (median duration, 13 months). Of the remaining 45 women who discontinued use before 6 months, most did so by 1 month.<sup>14</sup>

Intraurethral devices work through occlusion of the urethra. They are removed for voiding, and most cannot be reinserted. Several trials of several products have been conducted with favorable efficacy and low risk of side effects, but the intraurethral devices are less comfortable than the intravaginal ones. Studies of intraurethral inserts showed that most women who used them (66% to 95%) were dry or improved while the device was in place. It is not surprising that urinary tract infections may occur with these devices; however, the incidence of infection decreases after the first several months of use. These intraurethral devices have failed to gain popularity with patients and physicians. Although few women choose an intraurethral device as a first option, an occasional patient is highly satisfied with long-term use of an intraurethral device.

Use of occlusive (extra)urethral devices or patches have been reported with similar results: the devices seem to work in many patients, but acceptance by physicians and patients has been poor, and the devices are not currently marketed in the United States.

## CONCLUSION

Pessaries and other devices are an important part of the treatment scheme for stress urinary incontinence. Although some patient effort is required for removal and maintenance of the devices, the risk and costs are minimal with moderate efficacy. Further research is needed to determine which women are most likely to respond to the various types of devices, and to evaluate both effectiveness and adverse events associated with these devices compared to surgery. Nevertheless, the risk-benefit ratio seems quite favorable with these devices for stress urinary incontinence.

# USE OF SYNTHETICS AND BIOMATERIALS IN VAGINAL RECONSTRUCTIVE SURGERY

*Fred E. Govier, Kathleen C. Kobashi, and Ken Hsiao*

The surgical field encompassing vaginal reconstructive surgery and urinary incontinence is extensive and extremely complex. As opposed to many surgical disciplines that focus on a single isolated organ, we are dealing with multiple organs that interact with multiple complex supporting structures that must function as a single unit to be maximally effective. The trauma of childbirth, the ever-present effect of gravity, and the inevitable deterioration of these organs and their supporting structures with age and hormone deficiency continuously stress this intricate system. Deficiency in one or more of these components can lead to urinary incontinence, dyspareunia, pelvic pressure, or any of a multitude of other symptoms associated with pelvic floor descent and/or prolapse.

Over the last century, a variety of autologous tissues, absorbable and nonabsorbable synthetic materials, and, more recently, allografts and xenografts have been used in attempts to reconstruct the pelvic floor and its supporting structures. This chapter focuses on the relative strengths and weaknesses of each of these materials, realizing that in 2005 we still lack the perfect material for vaginal reconstructive surgery. We address urethral support, support of the anterior compartment, and support of the vaginal apex as somewhat separate topics, as well as autologous materials, allografts, xenografts, and synthetic mesh products as separate groups. Although this chapter's focus is on the materials themselves, it must be realized that failure is not limited only to the materials. Surgical technique, points of attachment, and methods of attachment can all play a crucial role in the ultimate success or failure of the operative intervention. Because the use of these materials is relatively new in reconstruction of the anterior compartment and apex, we will use our experience with urethral slings to further highlight the relative strengths and weaknesses of these materials. Even then, teasing out the exact cause of a surgical failure or a complication in this setting is challenging and at the present time there are still many unanswered questions.

### PREVALENCE OF URINARY INCONTINENCE AND PELVIC FLOOR RELAXATION

Interest in women's health care issues and public awareness of stress urinary incontinence (SUI) and pelvic floor relaxation have increased substantially over the past several years. In 2000, an estimated 17 million community-dwelling individuals had daily urinary incontinence in the United States, and an additional 34 million had symptoms of overactive bladder. The costs of urinary incontinence in the United States were recently estimated at \$19.5 billion, with an additional \$12.6 billion for overactive bladder.<sup>1</sup>

A postal survey regarding urinary incontinence involving 29,500 community-dwelling women aged 18 years or older in France, Germany, Spain, and the United Kingdom was recently reported.<sup>2</sup> Of the women responding, 35% reported involuntary loss of urine in the proceeding 30 days, with SUI being the most prevalent type. Only 25% of the women had consulted a physician, and fewer than 5% had undergone surgery for their condition.

It is estimated that a woman's lifetime risk of needing a single prolapse surgery by 80 years of age is 11.1%, and the risk of needing reoperation for recurrent prolapse is 29.2%.<sup>3</sup> Undoubtedly, as the population ages, life expectancy increases, and the stigma of incontinence and pelvic prolapse is replaced by education, these numbers and their associated costs will rise.

### HISTORY OF THE URINARY SLING WITH AUTOLOGOUS FASCIA

In 1907, Van Girodano introduced the concept of the urinary sling for the treatment of urinary incontinence, when he wrapped a gracilis graft around the urethra.<sup>4</sup> Credit for the first pubo-vaginal sling (PVS) goes to Goebell, who, in 1910, rotated the pyramidalis muscles beneath the urethra and joined them in the midline.<sup>5</sup> In 1942, Aldridge described the first fascial sling. He used rectus fascia, without muscle, passed through the retro-pubic space to support the proximal urethra and bladder neck.<sup>6</sup> Variations on this procedure over the following decades involved attempts to minimize morbidity and obtain suitable fascia from patients with multiple previous abdominal procedures and/or pelvic radiation. Ridley<sup>7</sup> described the use of fascia lata in 1955, followed by reports from Williams and Telinde,<sup>8</sup> Moir,<sup>9</sup> Morgan,<sup>10</sup> and Stanton and associates<sup>11</sup> involving the use of synthetic materials with variations on the approach or on anchoring sutures. Using autologous fascia and synthetic materials, these original investigators showed encouraging results, but the outcomes were plagued with urethral obstruction, erosion, fistula formation, and infections.

McGuire and Lytton revived the PVS in 1978 with their series showing an 80% success rate for intrinsic sphincter deficiency (ISD) using rectus fascia tensioned loosely around the urethra.<sup>12</sup> Blaivas and Jacobs modified the procedure by penetrating the endopelvic fascia, as described by Peyrera,<sup>13</sup> and completely detaching the rectus fascia from the abdominal wall.<sup>14</sup> They also stressed the importance of minimizing tension on the sling and stated that, "in the majority of patients the sling should be placed under no tension at all." Subsequent studies showed no difference in histologic or performance characteristics between free and pedicle fascia flaps for sling surgery.<sup>15</sup>

As the PVS was gaining acceptance, the first reports of poor long-term results from needle suspension procedures were being published. In a landmark study published in 1995, Trockman and Leach's group monitored 125 patients for a mean of 10 years after a modified Peyrera needle suspension. By questionnaire data, 51% reported that they had SUI, and only 20% reported no incontinence of any kind.<sup>16</sup> The American Urological Association guidelines panel for the surgical management of SUI was published in 1997 and concluded, based on cure/dry rates, that retropubic suspensions and slings were the most efficacious procedures for long-term success.<sup>17</sup>

Since these early reports, many authors have published long-term data that attest to the durability of the autologous fascial sling. Morgan and colleagues observed 247 patients with type II and III SUI for a mean of 51 months after autologous rectus sling placement. They reported an overall continence rate of 88% to 91% for type II and 84% for type III SUI. Among those patients with at least 5 years of follow-up, the continence rate was very durable at 85%.<sup>18</sup> Chaiken and coworkers reported on 251 patients with all types of anatomic incontinence treated with an autologous rectus PVS.<sup>19</sup> At a median follow-up of 3.1 years, 73% of patients were cured and 19% were improved. Among the 20 patients with a minimum of 10 years' follow-up, the cure rate was 95%. Brown and Govier, using autologous fascia lata, monitored 46 patients for a mean of 44 months; 90% reported overall cure of their anatomic component, and 73% described no or minimal leakage requiring no pads.<sup>20</sup>

The two greatest advantages of the autologous PVS were that all types of anatomic incontinence could be addressed and, if a good result were achieved at 1 year, the result would be durable. Because of these attributes, by the late 1990s most authorities agreed that the PVS using autologous fascia was the gold standard for the surgical management of anatomic incontinence. Unfortunately, harvesting this fascia from the abdominal wall or thigh adds operative time and incurs a risk of hematoma formation, wound infection, and/or hernia formation. Only relatively narrow strips of fascia can be harvested, and even then the patient requires several weeks of recovery time to achieve a normal activity level. In an effort to minimize patient morbidity and yet further improve surgical results, a variety of biomaterials (allografts, xenografts) and synthetic products (absorbable and permanent) have been introduced and are currently being used for the construction of urinary slings and vaginal reconstructions.

## HISTORY AND CHARACTERISTICS OF BIOMATERIALS IN PELVIC RECONSTRUCTION

### Allografts

Allografts are harvested from a human donor, usually a cadaver, and transplanted into a human recipient. The most common tissues used for pelvic floor reconstruction are fascia lata, dermis, and dura matter. Table 59-1 lists some of the companies supplying these components and their trade names. There are many advantages to the use of allografts or xenografts for pelvic floor reconstruction. Several studies have documented decreased recovery time, length of hospitalization, and postoperative pain using these materials.<sup>21-23</sup> Compared with permanent synthetic materials, allografts carry a lower risk of vaginal extrusion, and, if extrusion does occur, in general the graft does not require removal. Finally, larger-sized grafts for pelvic reconstructive procedures can be obtained easily without incurring additional patient morbidity.

All cadaveric donor materials in the United States are processed by licensed tissue banks regulated by the Food and Drug Administration.<sup>24</sup> Cadaveric donors are carefully screened by review of their medical and social history with the family, partners, and friends. Donors are excluded if the cause of death is unknown or the medical history suggests any of the following: hepatitis, bacterial sepsis, syphilis, intravenous drug abuse, cancer, collagen vascular disease, rabies, Creutzfeldt-Jakob's disease (CJD), or significant risk factors for human immunodeficiency virus (HIV) infection.<sup>25</sup> Serologic testing is performed for HIV-1 and HIV-2 antibodies, hepatitis B surface antigen, and hepatitis C antibodies. One of the most significant problems with serologic testing is that false-negative results can occur, because it takes time after the initial infection before the immunologic response is sufficient for serologic detection. The delay can be up to 6 weeks in the case of hepatitis B, and up to 6 months for HIV.<sup>26,27</sup>

Tissue processing allows for the removal of most of the cellular content, along with the associated antigens, making donor and recipient tissue matching unnecessary. Additionally, tissue sterilization, while preserving the inherent collagen matrix, is required to eliminate infectious complications and ensure satisfactory graft assimilation. Although the American Association of Tissue Banks has made recommendations, no federally mandated

**Table 59-1 Allografts and Xenografts**

Type	Component	Trade Name (Manufacturer)
Autologous	Rectus fascia Fascia lata Vaginal wall	
Allograft	Fascia lata  Dermis	Tutoplast (Mentor, Santa Barbara, CA) Faslata (Bard, Covington, GA) Repliform (LifeCell Corporation, The Woodlands, TX) Duraderm (CR Bard, Inc., Murray Hill, NJ)
Xenograft	Dura mater (no longer used) Porcine small intestine submucosa Porcine dermis  Bovine pericardium	Stratasis (Cook, West Lafayette, IN) Pelvicol (Bard, Covington, GA) IneXen (American Medical Systems, Minnetonka, MN) (Braille Biomedical Industria, Brazil)

processing techniques for all tissue banks exist. Currently, allografts are prepared using a variety of proprietary processing techniques that vary depending on the vendor.

Various mechanisms are used for cellular destruction and include hypertonic solutions that osmotically rupture cells and destroy bacteria and viruses; oxidative destruction with hydrogen peroxide, which oxidatively destroys most proteins; and isopropyl alcohol to destroy cells, bacteria, and viruses by dissolving the lipids in their cell walls.<sup>28,29</sup> An additional method used for tissue sterilization is gamma irradiation, which kills bacteria by disrupting nucleic acids but does not guarantee sterilization of viruses or prions, even at the American Association of Tissue Banks recommended level of 1500 Gy (1.5 megarads).<sup>27,30</sup>

Options for long-term preservation include cryopreservation, freeze-drying (lyophilization), and solvent dehydration. Controversy exists with regards to tissue processing and how it affects tissue strength. Most of the concern regarding processing and storage revolves around two issues. The first is irradiation and how it affects the tensile strength of collagen, and the second is the ice crystal formation that occurs with cryopreservation and the freeze-drying processes and whether they adversely affect the collagen microstructure.<sup>28,31,32</sup>

Thomas and Gresham found no significant difference in tensile strength among fresh, frozen and freeze-dried fascia lata specimens.<sup>33</sup> Sutaria and Staskin found no significant difference in the tensile strength of fascias that were freeze-dried and gamma-irradiated, freeze-dried alone, or solvent-dehydrated and gamma-irradiated.<sup>34</sup> In contrast, Hinton and colleagues found solvent-dehydrated, irradiated fascia lata to be significantly stiffer, with a higher tensile strength than freeze-dried fascia.<sup>32</sup> Two studies reported that tissue irradiated after dehydration resulted in significant loss of tensile strength, and the investigators recommended that irradiation be performed before dehydration.<sup>28,35</sup> In an excellent review, Gallentine and Cespedes concluded that “a number of processing techniques are available that may have different adverse affects on the mechanical properties of allografts, but currently no definitive evidence is available that one technique is superior to another.”<sup>25</sup>

With current federal regulations in place to obtain, process, and store cadaveric materials, the risk of infectious disease transmission is extremely small. As of 1995, approximately 220,000 soft tissue transplants were being performed annually in the United States, and no cases of a transmitted infectious disease had been reported for processed cadaveric fascia lata (CFL) or dermal grafts.<sup>24</sup>

The risk of acquiring HIV-infected tissue from a properly screened donor is reported to be between 1 in 1,667,600 and 1 in 8 million from banked cadaveric fascia.<sup>36-38</sup> Seroconversion was reported in recipients of solid organs (4 of 4) and unprocessed fresh-frozen bone (3 of 3); however, 0 of 34 patients receiving other tissues, including 3 who received lyophilized tissue, became infected with HIV.<sup>26</sup> Still, it is alarming that intact genetic material (DNA segments) was isolated from four commercial sources of processed human cadaveric allografts.<sup>39</sup>

Prion transmission has gained increasing attention because of the neurodegenerative symptoms that occur in the recipient but not in the host. Prions are proteinaceous pathogens that use a novel mechanism of amino acid transposition to change the protein configuration to a that of a neurotoxic prion protein peptide, leading to cases of neurodegenerative Creutzfeldt-Jakob Disease. Iatrogenic cases have been reported after many types of procedures, including corneal transplants and dura mater graft-

ing.<sup>40</sup> It has been described in 43 patients receiving cadaveric dural grafts after neurosurgical or orthopedic procedures, and, for this reason, dura mater is no longer being used as a biomaterial.<sup>41</sup> However, prion transmission has not been described with the use of cadaveric fascia or dermis for anti-incontinence or prolapse procedures. Even though no transmission has been documented in our field, the potential for infectious transmission with these allografts does exist, and all patients need to be informed of the risk before their use.

### Xenografts

The most popular xenograft materials used for sling surgery are derived from porcine and bovine sources (see Table 59-1). Being from an animal source, xenografts are readily available and are devoid of the potential ethical issues associated with use of human tissue. The types most frequently used for pelvic reconstruction are porcine dermis and small intestinal submucosa (SIS) or bovine pericardium. The Food and Drug Administration has strict guidelines controlling all phases of their production.<sup>42</sup>

### Fate of Autologous Tissue and Biomaterials

The most significant controversy involving biomaterials is the ultimate fate of the graft material itself, within the host. When autologous rectus fascia or fascia lata is used to construct a urinary sling, the results of these procedures in terms of durability are uniformly excellent.<sup>17-20</sup> Three studies in the literature examined the fate of autologous fascia in the host. In 1969, Crawford evaluated autologous and frozen fascia lata in rabbits by attaching strips of each from the flank to the posterior abdominal wall.<sup>43</sup> After killing the animals and examining the tissue, he concluded that “fresh fascia is living sutures and cadaveric tissue merely provides a bridge for host fibroblasts.” A more recent paper, in 1997, looked at free versus pedicled fascial flaps again in rabbits.<sup>44</sup> Strips of 7 and 15 mm of each were obtained from the abdominal wall and used to create a urethral sling. The rabbits were killed at 3 months, and all slings were found to be viable with the original histology preserved. The authors surmised that the fascia survives in the early postoperative period by diffusion. Later, neovascularization from the loose connective tissue around the flaps provides long-term vascularity. FitzGerald and colleagues evaluated the histologic appearance of autologous rectus fascial slings that were examined at revision at 3, 5, and 8 weeks for urinary retention and at 17 and 208 weeks for persistent SUI.<sup>45</sup> They concluded that autologous fascial slings remain viable after implantation. They did note fibroblast proliferation, neovascularization, and some remodeling of the graft, but no evidence of graft degeneration was detected. A linear orientation of the connective tissue and fibroblasts was seen in some areas, whereas other areas had remodeled to form tissue similar to noninflammatory scar.

In contrast, cadaveric fascial allografts have been extensively studied in multiple human models in the orthopedic literature as well as animal models.<sup>43,46,47</sup> With the use of serial biopsies, it was found that there is an initial donor fibrocyte death, which is followed by neovascularization of the graft. Fibroblast migration into the implant is then followed by remodeling and eventually by maturation of the graft.<sup>48,49</sup>

The maturation of xenografts is similar to that described for allografts. The processed material serves as an acellular mesh or

scaffolding, which requires remodeling by the host to end up as a viable graft.

It is this need to “remodel” the graft that appears to be the Achilles heel for many or all of the allograft and xenograft products on the market today. As one examines the surgical results with these materials, it is evident that some patients quickly remodel this material to a strong durable structure. In others, it appears that the scaffolding entirely disappears. Authors have theorized that increasing age, poor vascularity, excessive scarring, diabetes, or the use of steroids can adversely affect the remodeling process; however, studies are lacking, and at this time the discrepancies in outcome are largely unexplained.

## SURGICAL RESULTS OF BIOMATERIALS FOR URINARY SLINGS

### Allografts

Hanada and associates,<sup>50</sup> in 1996, and Labasky and Soper,<sup>51</sup> in 1997, were the first to report on the use of cadaveric products for urinary slings. In 1998, Wright and colleagues published the first paper comparing cadaveric allograft fascia lata to autologous rectus fascia.<sup>52</sup> This series reported on a group of 92 patients undergoing sling procedures over a 28-month period. Fifty-nine patients received a 13 × 2 cm portion of freeze-dried allograft fascia lata, and 33 patients received autologous rectus fascia. With a mean follow-up of 9.6 months for the allograft and 16 months for the autologous fascia, no differences in surgical outcome were found. Chaikin and Blauvas described an early failure of a freeze-dried cadaveric fascia sling in which the holding sutures pulled through.<sup>53</sup> In 1999, FitzGerald and associates reported 35 patients who underwent PVS placement using freeze-dried irradiated CFL.<sup>54</sup> At the time of re-exploration in seven of the failures, “histopathologic analysis revealed areas of disorganized remodeling and graft degeneration, as well as complete absence of the graft in some patients.”

In 2000, Brown and Govier compared 121 consecutive patients undergoing slings constructed with fresh-frozen CFL with 46 earlier patients undergoing the same surgical procedure with autologous fascia lata.<sup>20</sup> Although the mean follow-up was longer in the autologous group (44 versus 12 months), questionnaire data demonstrated no significant difference in surgical outcomes. Elliott and Boone, in 2001, reported 12-month follow-up using solvent-dehydrated CFL in 26 patients. Ninety-six percent of patients reported improvement.<sup>55</sup>

In 2001, Carbone and Raz’s group reported on a series of irradiated freeze-dried cadaveric fascial sling procedures with a 40% failure rate and a reoperation rate of 16.9%. At the time of reoperation in 26 patients, they found the allografts to be “fragmented, attenuated or simply absent.”<sup>56</sup> On the basis of these findings, they abandoned the use of allografts for sling construction. In 2002, O’Reilly and Govier re-examined a group of 121 patients who had slings constructed with fresh-frozen CFL; these patients had been reported earlier to have similar results to those treated with autologous slings.<sup>57</sup> They identified 8 patients who experienced intermediate-term failure at 4 to 13 months after they had initially been dry. This development was not noted in the autologous sling group, and, on the basis of these findings, they too abandoned the use of fresh-frozen CFL for slings.

In 2005, the debate over biografts continues, but the pendulum clearly appears to be heading away from the use of biografts

for construction of urinary slings. Crivellaro and colleagues published a prospective series of 253 patients with 18-month follow-up using human dermal allografts for slings.<sup>58</sup> They found that 78% of the patients were improved or cured of their incontinence and were happy with their experience. Owens and Winters also looked at human dermal allografts in slings in 25 patients.<sup>59</sup> At a mean follow-up of 6 months, 68% of the patients were dry, but this rate fell to 32% at a mean follow-up of 14.8 months. They concluded that graft degeneration was the most likely cause of the failures. FitzGerald and coworkers looked at a longer-term follow-up in patients from a previously reported group who had undergone abdominal sacrocolpopexies (67) and/or urinary slings (35) with freeze-dried, irradiated fascia lata. They found that 83% of the sacrocolpopexy patients experienced failure at a mean follow-up of 12 months, and, at the time of reoperation in 16 patients, the graft was still present in only 3 patients.<sup>60</sup> In 2005, Frederick and Leach reported on 251 patients who had undergone a combined anterior repair/sling procedure for SUI using solvent-dehydrated fascia lata. They found a cure/dry rate of 56% with a cure/improved rate of 76% at a mean follow-up of 24 months. They did note that, of the failures, 56% occurred after 12 months. They concluded the late failures were of concern and are continuing to monitor this group.<sup>61</sup>

### Xenografts

The two most commonly used xenografts in reconstructive urology are porcine dermis and porcine small intestinal submucosa (SIS). As with allografts, the results for urinary slings are controversial, and there are even fewer published reports, or fewer publications with shorter follow-up.

Porcine SIS gained increased attention after being successfully implanted in a canine model for bladder augmentation without evidence of rejection or shrinkage.<sup>62</sup> Histologically, the SIS-regenerated bladders demonstrated three separate layers, indicating that a regenerative healing process was occurring rather than a simple replacement with fibroblasts. During the manufacturing process, the serosa, tunica muscularis, and mucosa are removed mechanically from porcine jejunum. Intestinal submucosa is transferred into an acellular collagen matrix which, once implanted, induces local host tissue cell infiltration and is subsequently remodeled within 90 to 120 days. The biomatrix in SIS lacks cellular elements; however, collagen and other growth factors with activities similar to those of transforming growth factor- $\beta$  and fibroblast growth factor 2 are present. These growth factors may act as signals for local epithelial cells to proliferate, thereby colonizing the graft and leading to tissue healing without scarring.<sup>63</sup>

Several groups have employed porcine SIS with good short-term results. Palma and colleagues reported that 92% of 50 patients were cured of SUI at a mean follow-up of 13 months without any serious postoperative complications.<sup>64</sup> Rutner and associates reported on a series of 152 patients undergoing placement of an SIS sling fixed to the pubic bone without bone anchors. Of those patients, 142 (93.4%) remained dry at a median follow-up of 2.3 years.<sup>65</sup> Intermediate-term failures at 9 and 11 months occurred in 2 patients.

Histopathologic studies in which porcine SIS grafts were biopsied and removed have suggested variable levels of biocompatibility. Implant site biopsies under the vaginal mucosa were taken in three cases of recurrent SUI after PVS using SIS. In all three cases, exceptional biocompatibility was demonstrated, with

minimal foreign body or inflammatory reaction.<sup>66</sup> Ho and colleagues were less enthusiastic about the biocompatibility of porcine SIS.<sup>67</sup> They noted postoperative inflammatory reactions consisting of erythema and pain in 6 of 10 patients undergoing eight-ply SIS tension-free sling placement. SIS is an attractive material because of its theoretical ability to stimulate local tissue in-growth. Whether this will translate into long-term efficacy and durability remains to be seen.

As for porcine dermis, Arunkalaivanan and Barrington reported a prospective randomized trial of tension-free vaginal tape ( $n = 74$ ) versus porcine dermis ( $n = 68$ ).<sup>68</sup> With a mean follow-up of 12 months (range, 6 to 24 months), they found no difference in success for correcting SUI. In another prospective randomized trial of porcine dermis ( $n = 34$ ) versus autologous rectus fascia ( $n = 31$ ), Giri and colleagues demonstrated similar rates of cure and improvement between the two groups but noted significantly less morbidity for the xenograft group.<sup>69</sup>

In contrast, Gandhi and colleagues performed histopathologic analysis of porcine dermis sling specimens in eight patients with urinary retention and two failures.<sup>70</sup> Variable tissue reactions were seen, suggestive of a vigorous foreign body reaction. In cases of retention, the original graft was mostly intact, with minimal remodeling and tissue in-growth. However, surgical failures revealed minimal graft remnants left within the resected suburethral tissue.

Encapsulation of porcine dermis slings with poor tissue in-growth was also observed by Cole and coworkers.<sup>71</sup> They found no tissue remodeling or incorporation of porcine dermis into the host tissue at 4 months in a patient operated on for retention. This tendency of porcine dermis to encapsulate might retard host tissue infiltration and, ultimately, graft integration.

In a recent attempt to look at time-dependent variations in biomechanical properties of several types of grafts implanted into rabbits, Dora and colleagues found that cadaveric fascia, porcine dermis, and porcine SIS had a reduction in tensile strength of 60% to 89% at 2 to 6 weeks.<sup>72</sup> Polypropylene mesh and autologous fascia did not differ in strength from baseline over the same period.

Although the use of xenografts is appealing, the variable biocompatibility and tissue responses, combined with unpredictable clinical outcomes observed, clearly require further investigation.

## HISTORY AND CHARACTERISTICS OF SYNTHETIC MATERIALS

Synthetic materials include both absorbable and nonabsorbable (permanent) materials. Other than for historical interest, all of the synthetics discussed here are mesh products, most of which are permanent. Synthetic materials have long been an attractive option for pelvic reconstruction and have many desirable attributes. The permanent mesh products are stronger than native tissue, are available in any size, and are free of any potentially infectious agents. No harvesting is necessary, limiting patient morbidity and enabling outpatient surgery under minimal anesthesia. Drawbacks include difficulty with tissue integration, infection, erosion (vaginal or other structures), and the potential for foreign body reactions.

The first use of synthetic material for construction of a female urethral sling was reported by Williams and Te Linde in 1962; they used Mersilene in 12 patients.<sup>73</sup> Ridley,<sup>74</sup> in 1966, and

Morgan,<sup>75</sup> in 1970, reported their results using Mersilene ribbon and Marlex to construct slings. In 1985, Morgan and colleagues reported on 208 consecutive patients who had undergone Marlex sling placement with a minimum 5-year follow-up.<sup>76</sup> Although these early investigators showed encouraging results for control of incontinence using synthetic materials, these materials and surgical techniques were plagued with problems of erosion, infection, and fistula formation.

Silicone was introduced in 1985 and was thought to be superior to Marlex or Mersilene due to its smooth surface and its ability to promote formation of a fibrous sheath.<sup>77</sup> Again, initial success was good, but a high rate of sinus formation and rejection due to foreign body reaction limited its use.<sup>78</sup>

Ulmsten and associates were first to report the use of a polypropylene mesh around the mid-urethra, in 1996.<sup>79</sup> They used a loosely woven mesh placed with vaginal trocars under no tension around the midportion of the urethra. Although this procedure was controversial when first introduced, Ulmsten and many others have confirmed the incidence of infection, erosion, and extrusion of the material itself to be extremely low when used for the construction of a sling.<sup>80-86</sup>

Cumberland<sup>87</sup> and Scales<sup>88</sup> delineated a series of ideal properties for a synthetic biocompatible material. This material should be clinically and physically inert, noncarcinogenic, and mechanically strong and should cause no allergic or inflammatory reaction. It should be easily sterilized, must not be physically modified by body tissues, and should be available in a convenient and affordable format for clinical use. None of the synthetic meshes currently in use meet all of these criteria.

It appears that three of the most important components for a mesh product used in reconstructive urology are pore size, fiber type, and stiffness.<sup>89</sup> Pore size and fiber type have been used to classify the most common synthetic meshes into four types (Table 59-2; Figs. 59-1 through 59-4). Type I meshes, such as soft Prolene (Ethicon, Endosurgery Inc., Summerville, NJ) and Marlex, contain large pores ( $>75 \mu\text{g}$ ) and are usually constructed from polypropylene. This large pore size allows the admission of macrophages and in-growth of fibroblasts (fibroplasia), blood vessels (angiogenesis), and collagen, which helps prevent infection and forms fibrous connections to the surrounding tissue.<sup>90</sup> Type II mesh, such as Gore-Tex (WL Gore & Associates, Inc., Flagstaff, AZ), has a pore size of less than  $10 \mu\text{g}$  in at least one of three dimensions (microporous). Type III meshes, such as Mersilene, are macroporous in nature but have microporous components that often include braided and/or multifilamentous materials. Type IV materials have submicronic pore size and are not used for sling surgery.

A second important property is the composition of the fibers. Polypropylene meshes are monofilament materials, whereas many other commonly used meshes are multifilament materials. The monofilament materials have a distinct advantage in terms of pore size. Most of the multifilamentous meshes have interstices less than  $10 \mu\text{g}$  wide, which allows small bacteria to infiltrate and proliferate. Theoretically, these small interstices do not allow the entry of macrophages ( $16$  to  $20 \mu\text{g}$ ) or leukocytes ( $9$  to  $15 \mu\text{g}$ ) to eliminate the bacteria, resulting in the potential for a higher infection rate.

Flexibility, or stiffness, is another important property that appears to be related to pore size. Marlex has a higher flexural rigidity (stiffness) than Mersilene or Teflon. Prolene is composed of knitted filaments of polypropylene, as is Marlex. However, Prolene has a pore size twice as large as Marlex ( $1500$  versus

**Table 59-2 Synthetic Fiber Types and Pore Size**

Type	Component	Fiber Type	Pore Size
I	Polypropylene	Monofilament	Macro
	Gynemesh PS (Ethicon, Summerville, NJ)	Mono/multifilament	Macro
	Prolene Soft (Ethicon, Johnson & Johnson, Summerville, NJ)	Multifilament	Macro
	Marlex (Bard, Covington, GA)		
	ProLite (Atrium, Hudson, NH)		
	Polypropylene/Polyglactin 910		
II	Vypro (Ethicon)		
	Polyglactin 910		
	Vicryl (Ethicon)		
	Expanded PTFE	Multifilament	Micro
III	Gore-Tex (Gore, Flagstaff, AZ)		
	Polyethylene	Multifilament	Micro/macro
IV	Mersilene (Ethicon)		
	Polypropylene sheet	Monofilament	Submicro
	Cellgard (not used for slings)		

Macro, >75  $\mu\text{m}$ ; Micro, <75  $\mu\text{m}$ ; PTFE, polytetrafluoroethylene.

**Table 59-3 Surgical Results for Selected Synthetics**

Study (Ref. No.)	Sling Material	N	Follow-up (Mo)	Results
Duckett & Constantine, 2000 (93)	Solid silicone, reinforced with polyethylene	7	3-16	100% success SUI; 71% erosion rate
Govier et al, 2005 (94)	Silicone-coated polyester (mesh)	31 prospective 20 retrospective	6-22	Prospective: 95% success SUI; 29% vaginal erosion Retrospective: 94% success SUI; 40% vaginal erosion
Barbaliás et al, 1997 (95)	Gore-Tex	16	30	87.5% success SUI; 12.5% erosion
Kobashi et al, 1999 (96)	Polyester (ProtoGen)	35 (five centers)	N/A	35 erosions
Nilsson et al, 2005 (98)	Polypropylene (TVT)	90	51	81.3% objective and subjective cure of SUI; 0% erosion
Abouassaly et al, 2004 (99)	Polypropylene (TVT)	241 (six centers)	5 (range, 2-16)	5.8% bladder perforations; 4.1% reoperation for retention; 2.5% blood loss >500 mL; 1.9% pelvic hematoma; 1.0% vaginal erosion
Kobashi & Govier, 2003 (82)	Polypropylene (SPARC)	140	Not stated	1 bowel injury; 4 transfusions; 0% erosion
Delorme et al, 2004 (100)	Polypropylene, UroTape (TOT)	32	17	91% cured; 3.1% urinary retention; 0% erosion

SUI, stress urinary incontinence; TOT, transobturator tape; TVT, tension-free vaginal tape.

600 µg) and is therefore more flexible.<sup>91</sup> Because of this property, Prolene theoretically may have a lower erosion rate through the vagina and adjacent viscera.

### SURGICAL RESULTS OF SYNTHETIC MATERIALS FOR SLINGS

In contrast to biomaterials, whose success appears to rest on the ability of the host to repopulate and remodel an acellular scaffolding, nonabsorbable synthetic mesh products are strong and permanent at the time they are placed. Assuming they are placed in the proper position, under minimal or no tension, and the fixation points are secure, the issues we should focus on are the complications of infection, erosion, and/or extrusion. As discussed earlier, it appears that the specific characteristics of the materials themselves may have a significant impact on the complication rate. Table 59-3 lists surgical success and complication rates for several synthetic materials used to construct slings. The highest rates of erosion/extrusion have been associated with polymeric silicone (Silastic),<sup>92,93</sup> silicone mesh,<sup>94</sup> polytetrafluoroethylene (Gore-Tex)<sup>95</sup> and polyester (ProteGen)<sup>96</sup> and range from 12.5% to 71%. Although this has not always been accomplished in the past, authors should either specify the structure through which the material has eroded (vagina, urethra, bladder) or use the terms “erosion” and “extrusion,” with extrusion signifying vaginal exposure.

A multifactorial etiology appears to be involved in the development of erosions and extrusions. They may occur because of subclinical or delayed infection that eventually leads to separation of the vaginal incision. Excess sling tension or unrecognized urethral injury at the time of surgery may predispose to urethral erosion. As mentioned earlier, the degree of tissue in-growth and host reaction may vary according to pore size and fiber type. Mesh flexibility may also play a role, with stiffer, smaller pore materials more prone to erode or extrude. The smooth surface

of silicone slings may prevent tissue in-growth, leading to poor integration into the surrounding tissues.<sup>94</sup>

Ulmsten and colleagues introduced tension-free vaginal tape (TVT)<sup>79</sup> in 1996, and it was estimated to have been used in more than 600,000 cases worldwide over the first 8 years.<sup>97</sup> TVT uses a large-pore, type I, monofilament, polypropylene sling placed at the mid-urethra in a tension-free manner to reconstitute the continence mechanism. SPARC (American Medical Systems, Minnetonka, MN) represents a modification of the original delivery system by directing the needles antegrade from two suprapubic incisions to the vaginal incision. Transobturator tape (TOT) delivery, the newest method of placement, leaves the mesh in a more transverse, broad-based position under the urethra from one obturator foramen to the other, completely avoiding the retropubic space.

Nilsson and associates presented 7-year follow-up data on 90 women undergoing primary TVT placement for SUI (see Table 59-3).<sup>98</sup> Of the patients available for evaluation, 81.3% met criteria for objective and subjective cure. No change in continence status was reported between 5- and 7-year follow-up visits in 87.5% of the patients. There was no evidence of tape erosion or tissue reaction indicative of material rejection in any of the patients. Abouassaly and coworkers performed a retrospective review of 241 patients undergoing TVT sling procedures and identified 48 (5.8%) intraoperative bladder perforations, with only 2 patients (1%) having vaginal mesh erosions.<sup>99</sup> Early data on the SPARC polypropylene procedure revealed one bowel injury but no mesh erosions in the first 140 patients.<sup>82</sup> The earliest data for polypropylene TOT demonstrated little difference in subjective and objective end points compared with TVT.<sup>100,101</sup> At 1-year follow-up, no sling-related complications were observed.

As shown in Table 59-3, the erosion rates of the newer polypropylene type I mesh slings have fallen dramatically, to between 0% and 1% in these four series. This was also illustrated in a recent review by Bhargava and Chapple, who looked at six centers

that published data from 2002 to 2004 and found a vaginal erosion rate of only 0.6% in 2709 patients undergoing polypropylene mesh sling placement.<sup>102</sup>

Management of erosion or extrusion depends on the type of material, the location, and whether the patient has an erosion or an extrusion. Management varies from observation and antibiotics, to partial excision and closure, to complete removal of all synthetic materials.<sup>95,96,103-105</sup>

The decreased erosion rate seen with modern synthetics is most likely due to a combination of the improved biocompatibility of large-pore, monofilament mesh products; a greater emphasis on surgical technique (specifically tension-free placement); and maintenance of strict aseptic conditions. In 2005, many authorities contend that the type I, monofilament, polypropylene midurethral sling, under minimal to no tension, is the new “gold standard” for the treatment of anatomic urinary incontinence.

### HISTORY OF BIOMATERIALS AND SYNTHETICS FOR THE ANTERIOR COMPARTMENT

Compromise of the structural integrity of the pelvic floor allows herniation or descent of the normally well-contained abdominal-pelvic organs. Recognition that the native tissue may no longer assume the position, strength, or functionality to repair the prolapse by simple reapproximation has prompted investigators to evaluate various techniques and materials to overcome the problem. Furthermore, recognition of the complex interplay of components of the pelvic floor has prompted investigators to view any one intervention for pelvic prolapse as a potential risk factor for further pelvic support problems. Consequently, clinicians now view the manifestations of pelvic prolapse, such as a cystocele or apical prolapse, not as an isolated defect but in a more global context and with a better understanding of what surgery a patient may require.

Although early techniques to repair anterior vaginal prolapse were theoretically sound, it quickly became clear that the use of a patient's inherently weak tissue did not provide the durability necessary to prevent recurrence. Recurrence rates after standard anterior colporrhaphy have been reported to range from 20% to 40%.<sup>106-108</sup> This high recurrence rate has given rise to consideration of graft reinforcement for prolapse repair.

The use of Tantalum mesh in the anterior compartment was reported in 1955 and abandoned after 4 of 10 patients had vaginal extrusion of the mesh.<sup>109</sup> In 1996, Julian reported vaginal extrusions in 3 of 12 patients with Marlex mesh and did not recommend its use.<sup>110</sup> Nicita, in 1998, reported using polypropylene mesh anchored to the arcus tendineus to correct urinary incontinence and anterior prolapse in 44 patients.<sup>111</sup> With a mean follow-up of 14 months, there were no recurrences and only one vaginal extrusion managed by partial excision. Also in 1998, Flood and colleagues reported on 142 patients who had anterior colporrhaphies reinforced with Marlex mesh.<sup>112</sup> With a mean follow-up of 3.2 years, no recurrent cystoceles were noted, and only three patients had vaginal extrusions, requiring partial excision of the mesh at 3 months, 4 years, and 7 years. The authors were enthusiastic about the use of Marlex in the anterior compartment.

In 2000, Kobashi and associates described the cadaveric prolapse repair with sling (CaPS) technique, a combined cystocele/sling procedure using a single piece of solvent-dehydrated CFL.<sup>113</sup>

A 6 × 8 cm fascial graft was cut into a “T” configuration and attached to the vaginal apex superiorly and the levators laterally with the wings of the T, constituting the sling, secured to the pubic bone anteriorly with transvaginal bone anchors. Although this was a technique paper, follow-up at an interval of 1 to 6 months revealed no failures or allograft complications of any kind.

Since these early reports, there has been an ever-increasing number of reports of the use of allografts, xenografts, and a variety of permanent and absorbable synthetic mesh products to reinforce the anterior compartment. In addition to a myriad of materials, some authors have advocated this repair for grade 4 relaxation, and others advocate repairs for any grade 2 through 4 relaxation. Some advocate for lateral attachment directly to the arcus tendineus, the obturator fascia, or the levators, whereas others do not attach the graft to any structures at all. There are fixation techniques using absorbable sutures, permanent sutures, and bone anchors. There are centers advocating a concomitant sling in all patients and centers that continue to try to determine preoperatively who requires additional urethral support. There are those performing the combined repair through a single incision and those who advocate two separate incisions. Some authors advocate the sling and anterior repair with two separate portions of material, using separate attachment points, and some use a single piece of material to construct both, with combined attachment points. In most series, the numbers are small and the follow-up is short.

As opposed to failure of an incontinence procedure, which often prompts a return visit or can be picked up with questionnaires, mild or moderate recurrent pelvic relaxation is often largely asymptomatic and is often discovered only by repeated physical examination.

When all of these variables are combined, it is virtually impossible at this point to determine which material, if any, should be used to resupport the anterior compartment. At best, one can take what has been learned from the sling experience and make some broad generalizations.

Tables 59-4 and 59-5 summarize much of the experience to date with biomaterials and synthetics used to reconstruct the anterior compartment. For biomaterials, we would highlight the series by Kobashi and colleagues in 2000<sup>113</sup> and 2002<sup>114</sup> and by Frederick and Leach in 2005.<sup>61</sup> These three series used a combined cystocele/sling repair with a 6 × 8 cm portion of solvent-dehydrated CFL. The attachment points were described earlier. This is by far the largest group of allograft repairs of the anterior compartment to date and involves two separate institutions with follow-up out to 5 years in the most recent series. In the latest series, it is concerning that, in terms of continence, 56% (33 patients) of failures were initially dry and failed after 1 year. Although there are multiple possible causes, one has to consider that these patients failed to adequately remodel the allograft. On the positive side, the recurrence rate of the anterior compartment was very low, especially for symptomatic relaxation (7% at a mean follow-up of 20 months), and were no complications from the graft material itself. Perhaps even a partial remodeling of the graft supporting the anterior compartment can provide enough additional support in the most of these patients.

Among the synthetic series in Table 59-5, we would highlight the series by Sand<sup>115</sup> and Weber<sup>116</sup> and their colleagues with absorbable Vicryl mesh. If successful, the Vicryl mesh would be much less expensive than biomaterials, would put the recipient at no risk from a transmittable disease, and would have virtually

**Table 59-4 Anterior Prolapse Repair Using Allograft or Xenograft Techniques**

Study (Ref. No.)	N	Graft Material and Technique	Follow-up (Mo)	Outcome

no risk of erosion. Unfortunately, one group found a substantial improvement with the mesh and one group found no difference at all.

On review of the abstracts of studies using permanent mesh products, it is clear that most authors have learned from our sling experience and have used a type I, monofilament, polypropylene mesh. Although the use of permanent mesh products clearly seems to provide a durable repair, the most significant concerns are the risk of vaginal extrusion and dyspareunia. Even with relatively short-term follow-up, the vaginal extrusion rate in these

abstracts ranged from 2% to 25%, with several using polypropylene in the midrange at 8%, 8.3%, and 13%.<sup>104,117,118</sup> The abstract published by Milani and colleagues in 2005 showed that, in addition to a high erosion rate, 20% of the anterior repairs and 60% of the posterior repairs exhibited an increased incidence of dyspareunia.<sup>117</sup>

In our institution, 46 patients have undergone mesh reinforcement of the anterior compartment with polypropylene (Prolene Soft) for grade 3 and 4 defects. We are monitoring one patient who has experienced a vaginal extrusion, and we have

**Table 59-5 Anterior Prolapse Repair with Synthetic Mesh Reinforcement**

reoperated on two additional patients who failed to re-epithelialize with vaginal estrogens. All three of these patients appeared to be well healed at their 6-week examination, and extrusion occurred at a later date. Based on this early experience, we have stopped using synthetic mesh for the anterior compartment and are continuing to monitor this group.

The question we must ask ourselves as pelvic surgeons, is how much risk are we willing to accept now and for many years down the line as the patients we treat age and experience worsening atrophic vaginitis? All permanent synthetic mesh products are going to carry some risk of extrusion. Staskin and Plzak theorized that use of mesh with a higher cross-sectional area would carry

**Table 59-6 Synthetic and Biomaterials for Apical Support**

Study (Ref. No.)	N	Graft Material and Technique	Follow-up (Mo)	Outcome
Snyder et al, 1991 (137)	147	OASC: 65 Dacron, 78 polytetrafluoroethylene	43 (range, 1-204)	93% success; 2.7% graft erosion
Kohli, 1998 (133)	57	OASC: double-thickness synthetic mesh (?), nonabsorbable braided sutures	14 (range, 14-24)	12% vaginal erosion (5 mesh, 2 suture); switched to cadaveric fascia lata
Costantini et al, 1998 (138)	21	OASC: Gore-Tex	31.6 (range, 12-68)	90% (19/21) success; 2 pulmonary emboli; 0 erosions
Culligan et al, 2002 (140)	245	OASC: synthetic mesh (unspecified)	13.3 yr	Follow-up by questionnaire or physical examination; no apical failure; 15.1% failure (most anterior compartment); 2.4% vaginal mesh erosion

Elneil et al, 2005 (141)	128	OASC and LASC: polypropylene (J&J mesh)	19 (range, 1.5-62)	Mesh not retroperitonealized; 0% bowel complication; 10% apical failure; 2.3% vaginal erosion

ASC, abdominal sacrocolpopexy; LASC, laparoscopic abdominal sacrocolpopexy; OASC, open abdominal sacrocolpopexy; SUI, stress urinary incontinence.

a higher risk of vaginal extrusion, and examination of these series appears to support that supposition.<sup>119</sup> Most pelvic surgeons seem to believe that the risk of vaginal extrusion with a narrow piece of a type I monofilament mesh placed around the mid-urethra under minimal to no tension is acceptable in most patients to prevent urinary incontinence. Whether to use a larger portion of the same mesh, which appears to carry a significantly higher risk of vaginal extrusion, for repair of the anterior compartment in an effort to prevent a recurrence (especially with a grade 2 or 3 defect), which is often minimally symptomatic, is something that pelvic surgeons need to consider very carefully.

#### MATERIALS USED FOR APICAL SUPPORT

A variety of surgical repairs have been described to resupport the vaginal apex. With one exception, these reports are primarily transvaginal procedures using the patient's own tissues for

support and abdominal sacrocolpopexies (open or laparoscopic) that attach the apex of the vagina to the hollow of the sacrum with some type of graft. The exception is the transvaginal approach of Drs. Raz and Rodriguez, in which the arms of a type I polypropylene mesh are attached to the origin of the sacrouterine ligaments. The body of the mesh is carried down to the perineum via the posterior vaginal wall.<sup>128</sup> With that notable exception, we will concentrate on the open abdominal sacrocolpopexies (OASC) and laparoscopic abdominal sacrocolpopexies (LASC) for the remainder of this section.

As we have seen in the anterior compartment, there are a large number of variations in how one may perform an abdominal sacrocolpopexy (ASC). These variations, along with the reporting methodologies, make it very difficult to compare series and isolate any differences made by the materials themselves. Table 59-6 summarizes several publications looking at a variety of materials used for support. As with slings and in the anterior compartment, most of the more recent series are now using a large pore, type I polypropylene mesh. At least for the more

recent series, we have to assume that a meticulous vaginal and abdominal preparation and intraoperative antibiotics were used. Most of the synthetic series used a “Y” configuration with the anterior and posterior leaflets attached to the respective portions of the vaginal wall and the main body of the graft attached to the longitudinal ligament of the sacrum or directly to the sacral bone with bone anchors. Where possible, we have tried to report the type of graft material used, whether the sutures used to attach the graft to the vaginal wall were permanent or absorbable, and whether failures occurred at the apex or involved other compartments.

The only recent report using autologous products was that of Latini and colleagues, who performed OASC on 10 patients with a mean follow-up of 30.8 months using autologous fascia lata.<sup>129</sup> They described harvesting adequate-size grafts through a 3-cm thigh incision and reported no vaginal erosions, apical failures, or graft complications as determined by chart review and questionnaires.

There are no published reports for biomaterials using xenografts and only a small number using allografts. The largest series to date is that of FitzGerald and associates, who recently updated their series of OASC using freeze-dried, irradiated CFL.<sup>60</sup> Of 54 patients undergoing OASC, 83% had experienced failure at a mean follow-up of 12 months. At the time of exploration in 16 patients, viable graft could be found in only 3 patients.

The use of synthetic materials for ASC was first reported in 1970 when Soichet reported the use of Silastic grafts in two patients.<sup>130</sup> Feldman and Birnbaum<sup>131</sup> reported on the use of Teflon in 1979, and Dewhurst and coworkers<sup>132</sup> used Marlex mesh in 1980. Since these early reports, a variety of synthetic products have been used. In addition to the materials themselves, there are several other controversial areas regarding the use of synthetics for ASC. The first is the type of sutures used to attach the graft to the vagina. In the past, many authors have used a permanent braided suture to minimize the risk of failure and to provide a suture that the patient and her partner would not feel. In 1998, Kohli and colleagues reported a 12% vaginal erosion rate using an unspecified type of double-thickness mesh and braided sutures.<sup>133</sup> Begley's group, in 2005, reported a 19% erosion rate in 21 patients using a silicone polyester mesh attached to the vagina with braided permanent suture.<sup>134</sup> However, most of the abstracts do not specify the type of suture used. A braided suture that is placed or erodes into the vagina is a theoretical source of infection for the graft. If that graft material has any characteristics that do not allow it to resist infection, this could be a cause of graft failure.

A second controversy is the effect of a simultaneous hysterectomy at the time of ASC. This could potentially increase the risk of infection from vaginal microbes, and, with a fresh suture line in the vagina against the graft, it could also theoretically increase the risk of vaginal extrusion. In an excellent review of ASCs published in 2004, Nygaard and coauthors found the data inconclusive but recommended that the mesh should be attached as far from the suture lines in the vaginal apex as possible.<sup>135</sup>

Addressing the apical failure rate in Table 59-6, one can see that, with the exception of the allograft report by FitzGerald's group, it is less than or equal to 10%; the anterior compartment appears to be an increasing concern, especially as duration of follow-up increases.

As for as longevity, a more recent abstract of a study by Hilger and colleagues using Marlex is significant.<sup>136</sup> Thirty-eight patients underwent OASC and had a mean follow-up of 13.7 years. By

questionnaire data and chart review, there was a 26% overall failure rate, including 10% undergoing reoperation for prolapse and 16% who responded that they had “prolapsing” tissue from the vagina. It is not noted how many of these failures were apical and how many involving other compartments. The vaginal erosion rate in this series was 2.6%.

Regarding the vaginal extrusion rate, Begley and coworkers examined the use of silicone-coated mesh.<sup>134</sup> After noticing several vaginal erosions, with a new commercially available silicone-covered polyester mesh (AMS Triangle), they reviewed a series of 93 patients undergoing OASC or LASC with various materials. Details are shown in Table 59-6, but their vaginal erosion rates with the silicone product, Gore-Tex, polypropylene, and autologous fascia were 19%, 9%, 0%, and 0%, respectively. Among those with the silicone mesh erosions, transvaginal attempts at repair were unsuccessful in all patients, who eventually required open explorations with removal of all mesh. In contrast the Gore-Tex erosions were successfully managed by partial excision of the mesh via a transvaginal approach in most patients.

As to the vaginal extrusion rates in Table 59-6, the rates for the specific materials ranged from 0% for autologous grafts and biografts,<sup>60,129,134,139</sup> to 19% with the silicone coated polyester,<sup>134</sup> to 2.3% and 2.6% with the polypropylene (Prolene and Marlex, respectively).<sup>136,141</sup> In the previously mentioned review by Nygaard and associates,<sup>135</sup> the following vaginal erosion rates for specific materials were found: cadaveric fascia or dura mater, 0% (0/88); polypropylene (Prolene), 0.5% (1/211); polyethylene (Mersilene, Johnson & Johnson), 3.1% (25/811); Gore-Tex, 3.4% (12/350); and Teflon (EI Dupont, deMours, and Co.), 5.5% (6/119).

In conclusion, it would appear that the risk of vaginal extrusion, from an ASC using a type I polypropylene mesh lies somewhere between that of the sling and that of anterior repair. Because it is a formidable procedure for the patient to undergo, even laparoscopically, we do not believe that most practitioners will accept the high failure rate of biomaterials. Additionally, regardless of the approach, the morbidity from harvesting autologous tissue of these dimensions is concerning. At this time, most surgeons performing this operation appear to believe that the current vaginal extrusion rates with the newer mesh products are acceptable in view of the high success rates in terms of apical support. Theoretically, there is a small risk to using a braided permanent suture to attach this graft material to the vaginal wall, and, in a case of a concomitant hysterectomy, it is prudent to keep the graft as far from the suture line in the vaginal apex as possible.

#### CONCLUSIONS CONCERNING THE USE OF SYNTHETICS AND BIOMATERIALS IN VAGINAL RECONSTRUCTIVE SURGERY

Tissue engineering and/or stem cell research may one day render the controversies discussed in this chapter obsolete. When that day arrives, we will have an unlimited supply of biocompatible, healthy, living fascia to use in pelvic reconstruction. Until then, it remains incumbent on pelvic surgeons to closely follow the literature, to provide informed consent, and to carefully weigh the risks and benefits of the use of these materials in our patients.

# MANAGEMENT OF THE URETHRA IN VAGINAL PROLAPSE

*Connie S. DiMarco and Nancy B. Itano*

One of the greatest challenges to the reconstructive pelvic floor surgeon is the approach to pelvic organ prolapse (POP) in the clinically continent woman. It is controversial whether the urethra should be surgically addressed at the time of vaginal prolapse repair. It has been proposed that a prophylactic anti-incontinence procedure be performed concomitantly due to the risk of developing stress urinary incontinence (SUI) once the vaginal axis has been restored. The counterargument suggests that, because only a small percentage of continent women with POP develop SUI postoperatively, many patients would undergo an unnecessary procedure with this approach. Even the most minimally invasive anti-incontinence procedures carry a potential risk of morbidity to the patient.

## EFFECT OF PELVIC ORGAN PROLAPSE ON URINARY SYMPTOMS

Moderate and severe pelvic floor relaxation can present with a variety of lower urinary tract symptoms. Many urinary symptoms can be attributed to obstructive voiding. These symptoms may include frequency, urgency, nocturia, hesitancy, double-voiding, sense of inadequate emptying, stranguria, flow intermittency, and suprapubic discomfort. Elevated postvoid residual volumes can also lead to recurrent or persistent urinary tract infections. Hypothetical causes include urethral kinking, urethral compression, bladder neck elongation, and detrusor hypocontractility/dysfunction. When severe prolapse involves the bladder, patients can also present with ureteral obstruction and hydronephrosis.<sup>1,2</sup>

Patients with POP may be continent or incontinent. Mechanisms for continence in prolapse include urethral obstruction, anatomic urethral kinking with descent of the bladder base, and abdominal pressure dissipation.<sup>3</sup> These mechanisms may also contribute to obstructive voiding symptoms. Bergman and colleagues<sup>4</sup> proposed that, in prolapse, a large cystocele provides a “cushion effect” that absorbs some of the intraabdominal pressure, effectively lowering the abdominal pressure placed on the continence mechanism (urethral complex). Ghoniem and associates<sup>3</sup> proposed that the only fixed portion of the lower urinary tract in large cystoceles is the distal urethra, supported by the pubourethral ligament. They hypothesized that the pubourethral ligament may be the only supporting structure that maintains its

strength in the setting of severe prolapse, allowing for urinary continence.

There are many theories on the cause of stress urinary incontinence (SUI), which are beyond the scope of this chapter. However, POP is a common coexisting condition, and prolapse reduction (surgical or manual) may reveal an underlying incompetent urethral continence mechanism.

## Pelvic Organ Prolapse

Dietz and coworkers<sup>5</sup> reported on 223 vaginal prolapse patients with symptoms of lower urinary tract symptoms presenting in two urogynecology clinics. Urinary symptoms included SUI in 64% (142 patients), urge incontinence in 61% (134), frequency in 38% (84), nocturia in 38% (84), and obstructive symptoms (including stranguria, sense of incomplete emptying, intermittency, and hesitancy) in 56% (124).

## Cystocele

Romanzi and colleagues<sup>6</sup> prospectively evaluated 60 women with various degrees of cystocele and found the following urinary complaints (patients could have more than one symptom): frequency/urgency, 35%; urge incontinence, 15%; stress incontinence, 60%; and difficult voiding 23%. Women with higher stages of anterior prolapse had a statistically greater likelihood of obstructive voiding than did those with lower stages of prolapse (70% in grades 3/4 versus 3% in grades 1/2). Obstruction was defined as a maximum detrusor pressure at maximum flow ( $P_{\text{det}Q_{\text{max}}}$ ) of greater than 25 cm H<sub>2</sub>O and a maximum flow of less than 15 mL/sec.

## Uterovaginal Prolapse

Patients with uterovaginal prolapse may also present with lower urinary tract symptoms. The group at Kaohsiung Medical University<sup>7</sup> studied 38 clinically continent and 20 incontinent women with stage III/IV complete uterovaginal prolapse. Incontinent women were more likely to report urinary frequency, urgency, and nocturia. However, the continent women had a higher incidence of voiding hesitancy. Urodynamic parameters between the two groups were compared. The women without stress incontinence had significantly higher ( $P_{\text{det}Q_{\text{max}}}$ ), maximum urethral closure pressures (MUCP), and urethral-abdominal pressure

**Table 60-1 Urodynamic Comparison of Continent and Incontinent Women with Stage III/IV Uterovaginal Prolapse**

Parameter	Continent Patients (n = 20)	Incontinent Patients (n = 38)	P Value
P <sub>det</sub> Q <sub>max</sub> (mean, cm H <sub>2</sub> O)	38	24	.01
MUCP (mean, cm H <sub>2</sub> O)	84	63	.03
Urethral-abdominal pressure transmission ratio	1.02	0.66	.02

MUCP, maximum urethral closing pressure; P<sub>det</sub>Q<sub>max</sub>, detrusor pressure at maximum flow.

From Long CY, Hsu SC, Wu TP, et al: Urodynamic comparison of continent and incontinent women with severe uterovaginal prolapse. *J Reprod Med* 49:33-37, 2004.

transmission ratios (Table 60-1). The pressure transmission ratio should be 1.0 (ideal) when increases in abdominal pressure are transmitted equally to the abdominal transducer (usually rectal or vaginal) and the urethral transducer. With rotation of the urethra, compressive forces from the abdominal cavity are incompletely transmitted to the urethral complex, creating a ratio of less than 1.0.

### Posthysterectomy Vault Prolapse and Enterocele

Wall and Hewitt<sup>8</sup> described urinary characteristics in 19 women with complete posthysterectomy vaginal vault prolapse. Symptoms of urgency was present in 79% (15 patients) and urge incontinence in 63% (12 patients). Occult SUI was demonstrated by prolapse reduction with a single-bladed speculum in 47% (9 patients). Urodynamic parameters included peak flow rate (Q<sub>max</sub>) and P<sub>det</sub>Q<sub>max</sub>. The mean Q<sub>max</sub> was 11 mL/sec, and P<sub>det</sub>Q<sub>max</sub> was 50 cm H<sub>2</sub>O, meeting the pressure-flow parameters for female outlet obstruction outlined by Massey and Abrams.<sup>9</sup>

### Rectocele

Even patients with isolated posterior wall support defects can have masked SUI. Myers and colleagues<sup>10</sup> evaluated 90 patients with isolated posterior compartment prolapse, including 28 with grade III+ rectoceles. Fourteen percent (n = 4/28) demonstrated SUI when their prolapse was reduced with a split Pederson speculum that was not present without prolapse reduction. The mean decrease in MUCP with rectocele reduction was 7.0 cm H<sub>2</sub>O. The authors theorized that severe posterior wall defects act to compress and support the anterior wall, artificially raising the MUCP, increasing functional length, and masking SUI.

Women with POP can present with a myriad of urinary symptoms. A thorough history must include extensive details of voiding habits, including a previous history of incontinence that improved with worsening prolapse. As with staging of prolapse severity, physical examination findings can vary with bladder volume, rectal contents, and position. The Pelvic Floor Disorders Network recently published their findings on technique modifications that can result in intraobserver variability.<sup>11</sup> Prolapse was graded as more severe in the standing position compared with the lithotomy supine position. The type of speculum was not standardized. Prolapse severity was consistent using either a split speculum or a manual (two-digit) reduction method. Urinalysis should be performed to rule out urinary tract infection, and a culture with sensitivities can be sent if necessary. A screening postvoid residual volume measurement, either by catheterization or by bladder ultrasound, is a simple means to identify patients with urinary retention.

### OCCULT STRESS INCONTINENCE IN PROLAPSE

Many patients with significant POP are continent and demonstrate SUI only when their prolapse is reduced. There is no “gold standard” method for determining whether a patient has occult SUI. The incidence of “masked” incontinence varies with the method of prolapse reduction, with rates of 25% to 80% reported in the literature.<sup>12-15</sup>

The goal of prolapse reduction is to simulate surgical repair and determine whether the patient will be at risk for development of postoperative de novo SUI. Potential pitfalls include obstructing the urethra, which would lower the SUI detection rate, and mechanically widening the levator hiatus, which would falsely elevate the SUI detection rate (Table 60-2).

Several methods of prolapse reduction to detect occult SUI have been described. A positive cough stress test (CST) is determined by objective urethral leakage with increased intra-abdominal pressure. Bladder volumes vary but are commonly reported between 150 and 250 mL. Urodynamics can be employed to ensure that urinary leakage is not the result of bladder compliance abnormalities or detrusor instability. Fluoroscopy may also contribute additional anatomic information.

### Pessary

The primary objective of a pessary is to reduce symptomatic vaginal prolapse. A pessary can be used temporarily to assess for underlying SUI, as described later. Patient satisfaction is also high when these devices are used for nonoperative management of prolapse. Clemons and associates<sup>16</sup> recently studied patient satisfaction and changes in urinary symptoms among women using either a ring or a Gellhorn pessary after 2 months. Of the initial 100 patients, 73% were successfully fitted with a pessary. SUI improved in 45% of the patients who had incontinence symptoms at baseline. Among women without incontinence at baseline, de novo SUI developed in 21%. Pessaries may be employed both in the office setting and in long-term home use to unmask SUI.

Placement of a pessary to reduce prolapse requires appropriate sizing. There should be one fingerbreadth of room around the pessary circumferentially, to prevent compression. Similarly, if the pessary is too small, the patient may extrude it when attempting to cough or perform a Valsalva maneuver. Some pessaries are designed to prevent stress incontinence (e.g., a shelf pessary) and should be avoided in this scenario. This requires a health care provider who is facile in pessary fitting and an inventory of pessaries of various shapes and sizes on hand.

In one of the earliest studies, Richardson and colleagues<sup>13</sup> found that 8 (80%) of 10 continent patients with uterine prolapse were incontinent after reduction with an *inflatable pessary*.

**Table 60-2 Detection Rate of Occult SUI after Anti-incontinence Surgery According to Preoperative Status**

Study & Ref. No.	Year	Surgery Type	N	Detection of Occult SUI (% [No.])	SUI after Surgery (% [No.])		
					Incontinent Preoperatively	Occult SUI Preoperatively	Continent Preoperatively (No Occult SUI)*
Stanton et al <sup>21</sup>	1982	Anterior plication	73		69 (20/29)	11 (5/44)

PVS, bladder neck pubovaginal sling; SUI, stress urinary incontinence; TVT, tension-free vaginal tape.

\*Negative cough stress test for occult SUI.

Bergman and coauthors<sup>4</sup> described the use of a *Smith-Hodge pessary* (size 2 or 3) to reduce prolapse in 67 women without symptoms of SUI. Twenty-four patients had a drop in abdominal pressure transmission to the urethra (<1.0) with pessary insertion. These patients were identified as having a “high likelihood” of developing SUI due to “sphincter weakness.” Seventy-one percent (17/24 patients) had objective loss of urine with pessary placement. Straining Q-tip urethral angles were similar for pessary-supported patients with and without declines in pressure transmission. Urethral hypermobility did not seemingly contribute to pressure transmission.

Versi and associates,<sup>12</sup> using a Gehrung pessary, reported on 49 patients with stage II/III anterior wall relaxation. The radiopaque edge of the Gehrung pessary allowed visualization of pessary position during videourodynamics, ensuring that the bladder neck and urethra were not compressed. One of the 49 patients (2%) could not retain the pessary and was excluded from the study. Occult “genuine” SUI was diagnosed if there was fluoroscopic leakage of contrast into the urethra in the absence of detrusor activity. Of the 22 patients without symptoms of stress incontinence, 26% (7 patients) demonstrated genuine SUI.

A *ring pessary* may be also be used. Hextall and associates<sup>14</sup> demonstrated that 27% (19/70) of their subjects had objective loss of urine only when the ring pessary was placed. Patients underwent urodynamics to ensure that detrusor instability was not the cause of the incontinence.

Klutke and Ramos published their series on patients who had their prolapse reduced with a *Gellhorn pessary*.<sup>17</sup> A positive CST was defined as urethral leakage in the absence of detrusor instability on cystometry. All patients with a positive CST underwent a concomitant Burch colposuspension or combined needle suspension/culposuspension at the time of anterior-posterior repair. Four percent (1/23) of patients in the colposuspension group developed de novo SUI, and 30% (7/23) developed de novo detrusor instability. In the group with reconstruction only, no patients developed de novo SUI, and only 5% (1/20) developed de novo detrusor instability.

These studies show that pessaries are an effective means to reduce vaginal prolapse in the evaluation of occult SUI. A negative pessary test can predict which patients may be incontinent after prolapse repair.

### Vaginal Packing

Vaginal packing does not require special equipment. Adequate packing should reduce prolapse without forcing the levator hiatus open and without obstructing the urethra. Ghoniem and associates<sup>3</sup> described a method using two rolls of 4 × 4 inch gauze. Fluoroscopy confirmed that the urethra was not compressed. Urodynamics confirmed that leakage was not caused by an uninhibited detrusor contraction. Vaginal packing was placed in two groups: patients with significant cystoceles ( $n = 16$ ) and a control group of patients without prolapse ( $n = 10$ ). In the control group, vaginal packing did not change MUCP or the proximal urethral closing pressure. Packing revealed objective urine loss in 69% (11/16) of the patients with prolapse. There was no difference in MUCP between those with occult SUI and those without SUI. The only difference was a lower proximal urethral closing pressure in those with occult SUI compared to those without SUI. The authors concluded that their technique of vaginal packing did not alter urethral pressure dynamics.

### Split Speculum

The split speculum (posterior speculum blade) is also used as part of the physical examination to measure the degree of prolapse, as recommended by the International Continence Society.<sup>18</sup> This is easily performed when the patient is in the supine position. A split speculum can be used to reduce prolapse while asking the patient to cough or bear down. Urethral leakage can be readily visualized. Using a speculum with the patient seated or standing is technically more difficult. The handle of the split speculum may be secured on the perineum (for apical or posterior prolapse) or near the mons pubis (for anterior prolapse). Patients are often sitting or standing during urodynamic studies to recreate the conditions (i.e., positioning) during which urinary symptoms occur. If a Graves speculum (no handle) is used, it may need to be held in place manually.

Gallentine and Cespedes<sup>19</sup> used gauze packing in conjunction with a split speculum to detect occult SUI in patients with posthysterectomy vault prolapse. The frequency of occult SUI was 50% (6/12 patients). The mean decrease in abdominal leak point pressure was 59 cm H<sub>2</sub>O.

### Cotton Swabs

A swab (such as a Scopette or Procto-swab) may be placed at the cuff or in the posterior fornix to reduce prolapse. The non-swab end may be taped to the patient's thigh.

Veronikis, Nichols and Wakamatsu<sup>15</sup> prospectively evaluated the three techniques of prolapse reduction in 30 patients with massive POP. They used an intravaginal swab, a Gellhorn pessary, and the posterior blade of a Graves speculum in each patient. The pessary was dislodged in five patients and expelled completely in three patients during cystometry. The Scopette technique detected the highest rate of occult SUI (83%, 25/30). The mean MUCP was lower with the Scopette technique compared with use of a speculum or pessary and with unreduced prolapse. The swab technique diagnosed patients with a low-pressure urethra that would have been missed by the other techniques.

### OUTCOME STUDIES

All of the techniques described previously attempt to predict which patients (among those without stress incontinence symptoms) might benefit from a preemptive anti-incontinence procedure. It is distressing to both the patient and the physician when a successful vaginal prolapse surgery is complicated by the development of de novo SUI. But this must be tempered by the potential urinary complications that can result from unnecessary procedures, such as de novo urge incontinence, urinary retention, and mesh erosion.

In addition to the presence of occult SUI, consideration should be given to baseline detrusor function. Many patients void by means of pelvic floor relaxation and/or Valsalva maneuvers, instead of a true detrusor contraction. Miller and colleagues<sup>20</sup> showed that lack of a detrusor contraction was a significant risk factor for development of urinary retention after cadaveric fascia lata bladder neck pubovaginal sling surgery. Patients with prolapse can have complicated voiding patterns. It is possible to void without detrusor activity, have incomplete emptying due to urethral kinking, and have occult intrinsic deficiency simultaneously.

### Anterior Repairs

In 1982, Stanton and coworkers<sup>21</sup> published their prospective series of 73 patients who underwent anterior colporrhaphy and vaginal hysterectomy for a variety of reasons (prolapse, menstrual problems, elective sterilization). Eleven percent of patients (5/44) who were continent preoperatively developed objective evidence of SUI postoperatively, despite undergoing an anterior colporrhaphy; 69% (20/29) with SUI symptoms preoperatively continued to have SUI symptoms.

Another study, published in 2002,<sup>22</sup> sought to evaluate patients before and after vaginal hysterectomy combined with a Kelly-Kennedy anterior plication. Twenty-three of the 33 postmenopausal patients had objective loss of urine preoperatively (69%). Three months postoperatively, 14 (61%) continued to show objective SUI. The authors concluded that a Kelly-Kennedy repair was not indicated in the treatment of SUI.

### Traditional Pubovaginal Sling at the Bladder Neck

Chaikin and colleagues<sup>23</sup> prospectively evaluated continent women undergoing surgical repair of severe urogenital prolapse.

Pessary testing was performed to unmask sphincteric incontinence. Occult incontinence was discovered in 58% (14/24) of the patients. All of these patients underwent a pubovaginal sling procedure at the bladder neck in addition to anterior colporrhaphy. With a mean follow-up of 44 months, 14% (2/14) remained incontinent. The authors believed that the pubovaginal sling did not increase the risk of de novo urge incontinence. Only one woman developed urge incontinence postoperatively. None of the patients who remained continent with pessary reduction developed SUI. The authors concluded that the pessary test was a useful way to unmask clinically relevant SUI.

Barnes and associates<sup>24</sup> also reported on the placement of a traditional pubovaginal sling tied over the rectus fascia using autologous rectus fascia, cadaveric fascia lata, or free vaginal wall graft in 38 patients. All patients had occult SUI unmasked by vaginal packing or pessary reduction. Concomitant transvaginal site-specific repairs were performed: cystocele in 100% (38 patients), rectocele in 50% (19), enterocele in 45% (17), vault fixation in 39% (15), and vaginal hysterectomy in 21% (8). With 15 months' mean follow-up, 5% (2/38) of the patients had developed SUI. De novo urge incontinence occurred in only 9.5% (2/38). No patients developed permanent urinary retention, and mean the postoperative postvoid residual volume was 25 mL. There was only one perioperative complication, which was a wound infection. The authors concluded that the performance of a simultaneous pubovaginal sling did not cause excessive voiding dysfunction or prolonged urinary retention and should be considered as a prophylactic anti-incontinence procedure in women with occult SUI and severe urogenital prolapse.

### Suburethral Synthetic Sling

In a contemporary study from de Tairac and colleagues,<sup>25</sup> tension-free vaginal tape (TVT) placement was performed at the time of transvaginal prolapse repair. Prolapse was reduced (although the method of reduction was not stated), and a CST was done with a full bladder (300 to 500 mL). Forty percent of patients (19/48) had occult SUI once prolapse was reduced; 60% (29/48) had complaints of SUI at baseline. Among the patients with a positive CST ( $n = 19$ ), 11 patients underwent TVT plus prolapse repair, and 8 had the prolapse repair only. No patient (0/11) with occult incontinence developed SUI after TVT. Almost one third (27%,  $n = 3$ ) developed voiding dysfunction. Among the 8 patients with a positive CST who did not receive a TVT, only 1 developed stress incontinence, and none developed voiding dysfunction. Among those patients with baseline symptomatic SUI ( $n = 29$ ), 15 received TVT and 14 did not. Postoperative SUI occurred in 1/15 of the TVT group (7%) versus 5/14 (36%) of the non-TVT group. Voiding dysfunction occurred in 2 (13%) of 15 patients in the TVT group 0 of 14 in the control group.

Researchers from the University of Milan<sup>26</sup> randomized patients with occult SUI to receive either bladder neck fascia plication or TVT in addition to prolapse repair. Occult incontinence was detected by a split Sims speculum and a CST. Clinical SUI developed in 1 patient with TVT (4%) and in 9 of 25 women with fascial plication (36%). The addition of TVT resulted in two surgical complications: a recognized bladder perforation and a retropubic hematoma. The series was not sufficiently powered to detect a significant difference in de novo urge incontinence, although the rate was higher in the TVT group than in the control group (12% versus 4%,  $P = .66$ ). The authors recommended prolapse reduction by split speculum technique to detect patients

at risk for development of SUI postoperatively, because 36% of their patients developed clinically significant SUI.

Gordon and colleagues<sup>27</sup> performed a prophylactic TVT in a series of 30 consecutive women diagnosed with occult SUI and severe prolapse. No patients developed symptomatic SUI, but 10% (3/30) had positive objective findings of SUI on CST. There was a 13% rate of de novo urge incontinence, which is within the range reported after TVT in the literature. These patients also underwent significant prolapse surgery.

The experience with suburethral slings performed via a trans-obturator approach is still limited. Published outcomes after transobturator sling placement are currently limited to the treatment of clinically significant SUI and do not include occult SUI in severe urogenital prolapse.

## DISCUSSION

Patients with vaginal prolapse can present with a myriad of urinary symptoms. A thorough history, physical examination, and method for identifying occult SUI and detrusor function are suggested before surgical treatment of vaginal prolapse. Patients should still be counseled on the potential risks and benefits of choosing a concomitant anti-incontinence surgery. Compared with traditional procedures (e.g., Burch colposuspension, bladder neck pubovaginal slings), newer, minimally invasive midurethral slings may have the advantage of less voiding dysfunction with no added recovery time when performed along with vaginal prolapse repair.

# CADAVERIC FASCIAL REPAIR OF CYSTOCELE

Gary E. Leach and Sarah A. Rueff

Traditional anterior colporrhaphy and paravaginal repair of cystoceles are associated with recurrence rates as high as 33% and 71%, respectively.<sup>1,2</sup> The fascial defects responsible for anterior wall prolapse have been previously described.<sup>3</sup> Lateral defects, which involve detachment of the endopelvic fascia from the arcus tendineus fascia, are more common. Central defects result from a break in the pubocervical fascia, the supportive layer between the bladder and the vaginal wall. These defects are not mutually exclusive; both may be present simultaneously.

Multiple inherent problems exist with anterior colporrhaphy and paravaginal repair for anterior vaginal wall prolapse. First, as each is described, only one of the potential areas of defect, central or lateral, is addressed. Second, each involves reapproximation or plication of the patient's own tissue, which has already shown a propensity for weakness. Inevitably, reapproximation of tissue occurs under tension and can result in varying degrees of vaginal narrowing and unacceptable recurrence rates.

Cystocele repair with nonfrozen cadaveric fascia lata offers several advantages. In the technique described here, both central and lateral defects are addressed and repaired simultaneously. The repair is performed transvaginally and secured without the tension that is often necessary in traditional repairs. Avoidance of tissue plication results in minimal vaginal narrowing, which is especially important for patients who are sexually active. We use solvent-dehydrated, nonfrozen cadaveric fascia (Tutoplast, Mentor Corp., Santa Barbara, CA) and avoid the use of the patient's inherently weak tissue. Studies have shown that the tensile strength and tissue stiffness maintained by the five-step preparation process are comparable to those of native autologous rectus fascia.<sup>4</sup> On the other hand, freeze-dried cadaveric fascia has been shown to have less tensile strength and more tissue inconsistencies.<sup>5</sup>

The technique described, cadaveric prolapse repair with sling (CaPS), involves prolapse repair and simultaneous placement of a transvaginal sling to support the proximal urethra and bladder neck. The procedure is performed both in patients who complain of preoperative SUI and in those with occult SUI demonstrated with prolapse reduction. Controversy has existed in the literature regarding the need for prophylactic placement of slings at the time of prolapse repair in women who do not complain of SUI. However, studies have shown that repairing a cystocele without simultaneously supporting the urethra/bladder neck results in unacceptable rates of postoperative SUI.<sup>6</sup> In addition, clinically continent women with genitourinary prolapse and occult SUI are considered to be at high risk of developing symptomatic SUI once the prolapse is repaired.<sup>7,8</sup> Although one may worry that the prophylactic placement of a pubovaginal sling at the time of prolapse repair in women who do not complain of SUI could result in higher rates of postoperative retention, our previous published results on the CaPS have not shown this to be the case.<sup>9-11</sup>

## PREOPERATIVE EVALUATION

Before repair of prolapse, a thorough history is obtained, which should include a gynecologic history, number of vaginal deliveries, and prior anti-incontinence procedures. The severity of a patient's symptoms is ascertained through subjective SEAPI scores (Table 61-1),<sup>12</sup> and the effect of the incontinence and prolapse symptoms on the patient's quality of life is measured by a validated questionnaire.<sup>13</sup>

A careful physical examination is performed to determine the degree of prolapse.

The patient is examined in both the dorsal lithotomy and the standing position with a full bladder. The vaginal mucosa is inspected for signs of atrophy. The posterior blade of a Graves speculum is used to retract the posterior vaginal wall, and the patient is asked to cough and to perform Valsalva maneuvers. The urethra is examined for hypermobility and stress incontinence, and descensus of the anterior vaginal wall is graded using the Baden-Walker classification (Table 61-2).<sup>14</sup> Incidental

**Table 61-1 SEAPI Incontinence Score**

Stress-related leakage ("S")	0 = No urine loss 1 = Loss with strenuous activity 2 = Loss with moderate activity 3 = Loss with minimal activity
Emptying ability ("E")	0 = No obstructive symptoms 1 = Minimal symptoms 2 = Significant symptoms 3 = Only dribbles or retention
Anatomy ("A")	0 = No descent with strain 1 = Descent, not to introitus 2 = Through introitus with strain 3 = Through introitus at rest
Protection ("P")	0 = Never used 1 = Certain occasions 2 = Daily, occasional accidents 3 = Continually, frequent accidents or constant leakage
Inhibition ("I")	0 = No urge symptoms 1 = Rare urge urinary incontinence (UUI) 2 = UUI once/week 3 = UUI at least once/day

**Table 61-2** Baden-Walker Prolapse Classification

Rights were not granted to include this table in electronic media.  
Please refer to the printed publication.

grade 1 cystoceles found in patients who present with other complaints are not routinely repaired. The posterior and apical compartments are examined systematically for associated prolapse. Apical prolapse may not be evident with the patient in the lithotomy position, so it is important to also examine the patient standing with two fingers in the vagina to evaluate for uterine/vaginal cuff descensus. A focused neurologic examination is performed to assess for the presence of neurologic deficits.

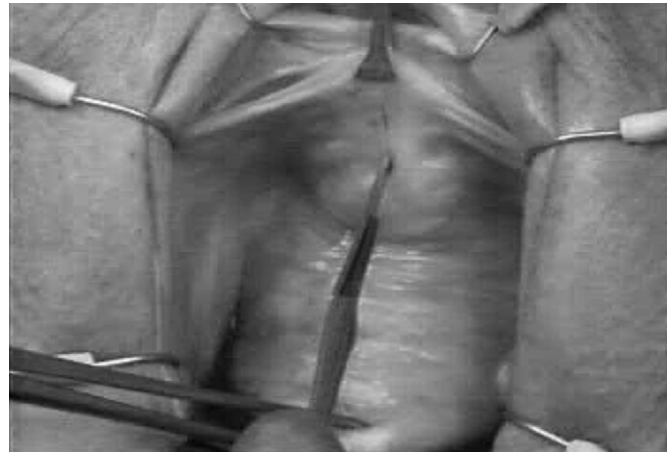

Urodynamic evaluation is performed in all patients before surgical repair. Evaluation of SUI is performed both with and without prolapse reduction. Assessment of underlying bladder dysfunction, such as detrusor overactivity, sensory instability, poor compliance, or incomplete emptying, is important for documentation purposes. Patients with elevated postvoid residuals are counseled regarding the possible need for intermittent catheterization postoperatively.

An upper urinary tract evaluation with renal ultrasound is performed before prolapse repair. This provides a baseline study should the patient develop postoperative flank pain, and it also evaluates for preexisting hydronephrosis secondary to kinking of the distal ureters from prolapse.

### PREOPERATIVE PREPARATION

Before prolapse repair is performed, the urine is confirmed to be sterile. Patients are taught self-catheterization preoperatively. In the event that a patient is unable to learn self-catheterization or has documented incomplete emptying preoperatively, consideration of placing a suprapubic tube intraoperatively should be made. Preferably, patients with vaginal wall atrophy should use estrogen vaginal cream for 4 to 6 weeks before surgery. Patients are instructed to use one third of an applicator of estrogen three times a week to improve the quality of vaginal tissue and postoperative healing properties. A povidone-iodine vaginal douche is performed the night before and on the morning of surgery. Perioperative antibiotics are given. We prefer to use a first-generation cephalosporin, ampicillin, or vancomycin (if the patient is allergic to penicillin) combined with an aminoglycoside.

Transvaginal repair of associated apical or posterior prolapse is performed with the CaPS procedure. A thorough discussion of the risks and complications of prolapse surgery is undertaken before the operation. Patients are counseled regarding the possibility of prolonged or permanent urinary retention, occult or recurrent SUI, recurrent anterior prolapse, and recurrent or de novo prolapse apically or posteriorly. All patients are counseled about the risk of persistent or de novo urgency symptoms and that either of these may require treatment in the future.

**Figure 61-1** A midline incision is made from the mid-urethra to the cervix or vaginal cuff.

**Figure 61-2** The cystocele is dissected off of the anterior vaginal wall laterally to expose the levator complex bilaterally.

### OPERATIVE PROCEDURE

The procedure is performed with the patient in the dorsal lithotomy position. A Foley catheter is placed, and a Scott retractor (Lonestar, Houston, TX) is secured to the medial buttocks with towel clamps. If there is question of an enterocele within the anterior prolapse, an iodine-soaked packing is placed within the rectum before preparation and draping for the procedure. The anterior vaginal wall is infiltrated with saline, and the Foley balloon is palpated at the bladder neck. A midline incision is made from the mid-urethra to the cervix or vaginal cuff (Fig. 61-1). With the use of Metzenbaum scissors, the cystocele is dissected off of the anterior vaginal wall via dissection on the white, shiny layer of the inside of the vaginal wall. In the proper plane, there should be little or no need for use of bovie cauterization. Dissection is continued until the levator complex, consisting of the levator ani musculature and pubocervical fascia, is exposed bilaterally (Fig. 61-2).

Dissection at the level of the bladder neck is performed for sling placement. For the CaPS procedure, the pubic bone is cleared bilaterally to allow placement of transvaginal bone anchors. In patients with urethral fixation or scarring from prior

**Figure 61-3** A transvaginal drill is used to place bone anchors into the pubic bone.

**Figure 61-4** The transvaginal drill is placed on the undersurface of bone and activated until a change in tone signifies firm placement of the bone anchor.

procedures, urethrolysis is performed to free the urethra and allow the sling to apply adequate urethral compression.<sup>15</sup> Bone anchors with polypropylene sutures attached are then placed with the use of a transvaginal drill (InFast, American Medical Systems, Minneapolis, MN) (Fig. 61-3). The bladder is placed on drainage, and the drill is positioned flush on the undersurface of the pubic bone. The drill is activated, and a change in tone signifies firm placement of the anchor into the bone (Fig. 61-4). The drill is removed, and a firm pull on the suture should confirm secure anchor placement. Bone anchor placement is repeated on the opposite side. Then, 4-0 polydioxanone sutures (two on each side) are placed into the levator complex and tagged for the cystocele repair. A fifth suture is placed into the vaginal cuff or cervix for proximal support (Fig. 61-5).

A 6 × 8 cm piece of nonfrozen cadaveric fascia lata (Tutoplast), presoaked in antibiotic solution, is cut along the line of its fibers in a “T” configuration. The top portion serves as a 2-cm wide sling (Fig. 61-6). The edges of the sling portion are folded

**Figure 61-5** Size 1-0 polydioxanone sutures are placed into the levator complex bilaterally and the cervix or vaginal cuff proximally to provide support for the fascial patch.

**Figure 61-6** A 6 × 8 cm piece of cadaveric fascia is cut into a “T” configuration along the line of its fibers. The top portion serves as a 2-cm wide sling.

over, because cross-hatching of the fibers minimizes chances of pull through.<sup>16</sup> An 18-gauge needle is used to pass the bone anchor sutures on one side through the folded edge. The bladder neck suture is placed more medially than the distal suture to keep the fascia tight against the bladder neck (Fig. 61-7). The sutures are tied and secured in place up to the bone. The distal edge of the sling is attached to the periurethral fascia with a 2-0 absorbable suture to prevent rolling of the edge of the sling toward the bladder neck. The free edge of the fascia is folded over, and the appropriate position of the contralateral sutures is determined. The fascia should lie snug against the urethra without excessive tension. In our experience, the use of a right angle clamp placed between the urethra and the sling while deciding proper tension can result in the sling’s being tied too loosely. Once the proper position is determined, the sutures are passed through the folded fascial edge with an 18-gauge needle. The bladder neck suture is placed more medial, and the sutures are subsequently tied. The fascia is then positioned for cystocele repair. The edge of the fascial patch is folded over and held in place with Allis clamps on the top and bottom. The previously placed levator sutures are passed through the edge of the fascia bilaterally and

**Figure 61-7** The bone anchor sutures are passed through the folded edge of the sling portion of the fascia. The bladder neck suture is placed more medial to allow the sling to lie tight against the bladder neck.

**Figure 61-8** The fascial patch is secured to the previously placed sutures to repair the cystocele.

tied to reduce the cystocele (Fig. 61-8). Care should be taken to avoid excess tension on the levator complex that can occur with excess folding of the fascial edge. Lastly, the apical suture within the cervix or vaginal cuff is passed through to secure the proximal aspect of the fascia in place.

Cystoscopy is performed after the administration of intravenous indigo carmine. Examination with a 70-degree lens is done to ensure patency of the ureters and exclude bladder injury. Examination with a 0-degree lens is performed to exclude urethral injury. Irrigation with antibiotic-impregnated solution should be performed throughout the procedure. Once hemostasis is obtained, redundant vaginal epithelium is trimmed, and the incision is closed with a running 2-0 absorbable suture. Care should be taken to avoid excess trimming of redundant epithelium as well as excess tension on the vaginal closure, which can result in either wound separation or vaginal narrowing postoperatively. A Foley catheter and a Betadine-soaked vaginal pack are left in place.

The CaPS technique can be modified to accommodate other techniques of sling placement and alternative sling materials. We

**Figure 61-9** Modification of the cadaveric prolapse repair with sling (CaPS) technique. Cystocele sutures are placed within the levator complex, followed by sling passage using the transobturator technique. The synthetic sling is retracted superiorly while the fascia is attached to the levator sutures to repair the cystocele.

are currently investigating the utility of using a synthetic transobturator sling while continuing to use cadaveric fascia for the prolapse repair.<sup>17</sup> For this modification, the cystocele is dissected off of the vaginal wall to the levator complex bilaterally, as described earlier. Lateral dissection for the transobturator sling is performed before cystocele suture placement. The sling is placed using the transobturator technique, and then a 4 × 7 cm piece of cadaveric fascia lata (Tutoplast) is folded and attached to the levator complex, as described previously (Fig. 61-9). Proper sling tension is decided by positioning Metzenbaum scissors between the urethra and the sling and adjusting accordingly (Fig. 61-10). The vaginal epithelium is then closed with 2-0 absorbable suture, and a vaginal pack and Foley catheter are left in place.

#### POSTOPERATIVE CARE

The vaginal packing and Foley catheter are removed on the morning of the first postoperative day. Patients are restricted to 1500 mL of fluid per day. A voiding trial is given, and residual urine measurement is obtained via intermittent catheterization. Eighty percent of patients void to completion immediately after surgery. If residual urine measurements are greater than 100 mL, patients are reinstructed on self-catheterization. If a suprapubic tube is placed intraoperatively, residuals are checked in this manner. Patients are continued on intravenous antibiotics for 24 hours postoperatively and then begun on oral antibiotics (cephalexin or fluoroquinolone) for 1 week to minimize the risk of osteitis pubis or wound infection. Patients are routinely discharged on postoperative day 1 with oral analgesics and stool softeners in addition to antibiotics. Patients with elevated postvoid residuals are instructed to continue to monitor at home via self-catheterization or suprapubic tube until residuals are consistently less than 100 mL. If a patient is unable to learn or is uncomfortable performing self-catheterization, she can be discharged home with a Foley catheter and return for a trial of void in the office. At the time of discharge, patients are instructed to

avoid heavy lifting or straining and to observe pelvic rest (i.e., no intercourse, no tampons) for 6 weeks postoperatively.

Patients are seen for follow-up at 1 week, 6 weeks, 6 months, 12 months, and yearly thereafter. Evaluation consists of urinalysis, postvoid residual urine measurement, and physical examination, as well as determination of subjective SEAPI scores. Patients are also administered a confidential, validated continence and satisfaction questionnaire every 6 to 12 months postoperatively, the results of which are entered into a prospective patient database.

## RESULTS

### Incontinence Outcomes

The CaPS procedure has been performed on a total of 340 patients. Eighty-four percent (287/340) now have at least 6 months of questionnaire follow-up (range, 6 to 74 months; mean, 27.4 months). Based on the patient questionnaire response, “cure” of incontinence is defined as no incontinent episodes

**Figure 61-10** Transobturator sling tension is adjusted with Metzenbaum scissors between the sling and the urethra.

postoperatively. “Improved” incontinence is defined as greater than 50% improvement in incontinent episodes, and “failure” is arbitrarily defined as less than 50% improvement in incontinent episodes. The overall subjective “cured/dry” rate was 29% (82/287 patients), the “cured/improved” rate was 71% (203 patients), and the “failed” rate was 29% (84 patients). In considering the type of incontinence present in “failures,” 33 of the 287 patients (11%) complained of recurrent SUI, 12 (4%) complained of urge urinary incontinence (UUI), and 24 (8%) complained of mixed urinary incontinence. The remaining 5% of “failures” (15 patients) responded that they were “uncertain” as to their type of incontinence. The time-to-failure is shown in Figure 61-11: 62 (71%) of 87 incontinence “failures” occurred after 12 months of follow-up.

Of the 160 patients who complained of preoperative UUI, 51 (32%) experienced persistent UUI postoperatively. Of the 127 patients with no preoperative UUI, 12 (9.4%) developed de novo UUI.

### Prolapse Outcomes

With regard to cystocele recurrence, physical examination data were available for 325 (96%) of 340 patients with a mean follow-up of 18.8 months and maximum follow-up of 79 months. The symptomatic cystocele cure rate was 94% (306/325 patients). Although 42 patients (13%) had some degree of recurrent anterior vaginal wall descent, 23 (55%) had asymptomatic grade 1 cystocele, for which intervention is not recommended. The de novo grade 2-4 rectocele and apical (vaginal vault and enterocele) prolapse rates were 9% (19/207) and 7% (19/257), respectively.

There were significant changes between preoperative and postoperative SEAPI scores, as shown in Table 61-1. Significant changes were seen within each domain as well as in the overall score. A significant change was also seen in the mean prolapse quality-of-life score; with a possible score ranging between 4 and 20, the mean score decreased from 9.6 preoperatively to 5.5 postoperatively ( $P < .01$ ).

As a measure of overall patient satisfaction with prolapse repair and continence results, patients were asked to rate their satisfaction on a visual analogue scale, with 0 being “not at all satisfied” and 10 being “completely satisfied.” The distribution

**Figure 61-11** Time interval until “failure” after the cadaveric prolapse repair with sling (CaPS) procedure.

**Figure 61-12** Distribution of overall postoperative patient satisfaction.

of scores is seen in Figure 61-12. The mean and median satisfaction scores were 7 and 9, respectively. Seventy-six percent (219/287 patients) had a satisfaction rate of at least 5. When patients were asked whether they would have the surgery again, 208/287 (72%) responded “yes” and 61/287 (28%) responded “no.”

No mortalities have occurred with the CaPS procedure. There have been seven cases of prolonged urinary retention (>30 days), only one of which required urethrolysis. The most common

complication encountered was intravaginal granulation tissue caused by extrusion of Panacryl sutures that were used for cystocele repair early in the patient series. Suture removal and fulguration of granulation tissue was performed in the office without sequelae. Once use of this suture was discontinued, no further granulation tissue developed. With regard to bone anchor fixation, there has been one case of osteitis pubis that was managed conservatively and no instances of infection requiring bone anchor removal.

## CONCLUSION

The CaPS procedure, which uses nonfrozen cadaveric fascia lata for cystocele repair, has several advantages over traditional anterior repair. Both central and lateral defects can be repaired simultaneously, avoiding the use of the patient’s inherently weak tissues. The procedure is performed entirely transvaginally, resulting in minimal morbidity, and avoids the use of synthetic materials in the vagina. Most patients are discharged on postoperative day 1. Sling placement at the time of cystocele repair allows simultaneous treatment of symptomatic SUI, as well as occult SUI demonstrated preoperatively with cystocele reduction, with minimal risk of urinary retention. Results of prolapse repair have been excellent and durable, with a symptomatic cure rate of 94% at long-term follow-up. Continence rates with the cadaveric fascial sling have been less durable, with failure rates approaching 30% at long-term follow-up. In order to improve continence results, we are currently exploring other materials and approaches to sling placement, as mentioned earlier, and continue to use cadaveric fascia lata for cystocele repair given its excellent long-term results.

# TRANSABDOMINAL PARAVAGINAL CYSTOCELE REPAIR

*Danita Harrison Akingba, Michelle M. Germain, and Alfred E. Bent*

### HISTORY

In 1909, Dr. George White described a novel idea for the etiology of cystoceles based on his work with cadaver dissection.<sup>1</sup> He first described the supportive attachments of the vagina. He next illustrated how lateral detachment of the pubocervical fascia from the arcus tendineus fascia pelvis, or white line, results in cystocele. He also outlined the critical steps for the transvaginal paravaginal repair of these types of cystoceles. It is clear after reading the peer review section following his article that his idea was unique at the time and that a fundamental understanding of the three-dimensional relationship of female pelvic anatomy was lacking.

Three years later, White submitted a treatise in which he reviewed the three theories of that period regarding the etiology of cystocele<sup>2</sup>:

1. Cystocele is due to thinning out of the anterior vaginal wall and thus a hernia.
2. Ligaments suspend the bladder, like the stomach.
3. The bladder descends because its ligamentous attachments to the uterus and obliterated hypogastric arteries have been stretched or broken during labor.

In his paper, White rejected each of these theories based on clinical examination findings, lack of histologic and anatomic evidence to support the theories, and, finally, the fact that not all women having hysterectomy developed cystoceles.

White again described his technique for vaginal paravaginal repair for the management of cystocele. He acknowledged that the vaginal approach was more difficult because of limited visibility, but he believed that the surgical approach for treatment of cystocele should remain vaginal because of the then-widespread practice of concurrent perineorrhaphy. He conceded that, “to incise the peritoneum at the side of the bladder, push the bladder aside until the white line comes into view, then by the aid of an assistant’s finger in the vagina, suture the anterior lateral side of the vagina to the white line, and close the peritoneum” may be “the easiest and simplest way to accomplish this.”<sup>2</sup> However, he believed that the abdominal approach was seldom indicated, unless the patient suffered from procidentia. In that case, the patient would be best served by concurrent restoration of the broad and uterosacral ligaments.

White’s papers were largely forgotten for the next 70 years. Historically, it is not clear why his ideas were not readily accepted. Perhaps it was because the approach was difficult to perform, or because his peers lacked a proficient understanding of the lateral

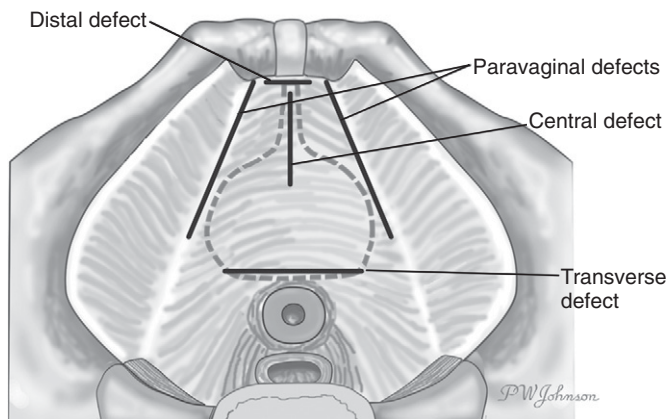

fascial defects and their role in anterior vaginal wall prolapse. Even more significant was the almost simultaneous publication of Howard Kelly’s treatise on cystocele, its repair, and the treatment of stress incontinence.<sup>3</sup> The Kelly plication is straightforward in its conceptualization and technically easier to perform. Failures of the Kelly plication in a large number of cystocele repairs led to a series of “new” techniques for the repair of lateral anterior wall defects, including work by John C. Burch and Cullen Richardson.<sup>4,5</sup>

In 1961, Burch reported his experience with colposuspension in the treatment of stress incontinence. He attached the paravaginal fascia to the white line of the pelvis in the first seven of his patients. He wrote that the maneuver “produced a most satisfactory restoration of the normal anatomy of the bladder neck . . . and a surprising correction of most of the cystocele . . . overcoming the anterior cystocele involving the neck of the bladder, but also the posterior cystocele involving the base of the bladder.”<sup>4</sup> Despite such positive results with correction of both urethral hypermobility and bladder prolapse, Burch believed that the white line held sutures poorly and therefore sought another fixation point. Subsequently, he chose Cooper’s ligament as the point of fixation.

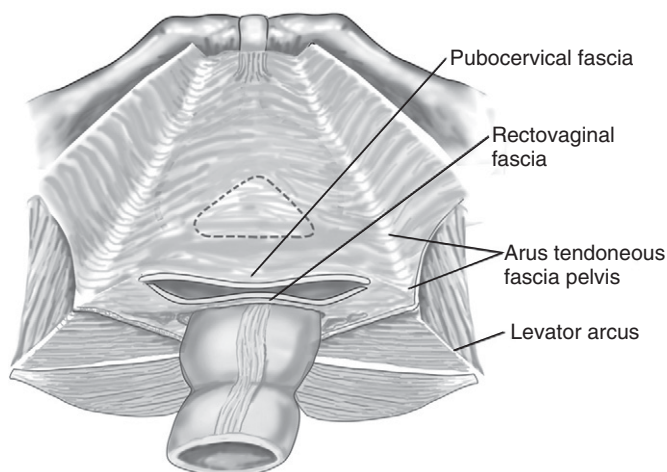

In 1976, Richardson, Lyon, and Williams published a “new” look at pelvic relaxation. They outlined the technique for transabdominal paravaginal repair—echoing the descriptions of White and Burch. They also identified the four areas of defects or breaks in the pubocervical fascia, in their order of occurrence<sup>5</sup>:

1. Lateral (paravaginal), where the pubocervical fascia attaches to the arcus tendineus fascia pelvis or white line
2. Transverse, in front of the cervix, where the pubocervical fascia blends into the pericervical ring of fibromuscular tissue (or at the cuff in a woman who has had a hysterectomy)
3. Central, on anterior vaginal wall between the lateral margins of the vagina
4. Distal, where the urethra perforates the urogenital diaphragm (Fig. 62-1)

Sixty-seven percent of their patients had paravaginal defects. Typically, today, no clinical distinction is made between central and distal tears. In addition, no effort is usually made intraoperatively to distinguish among these types of defects, because Kelly-type plication procedures have been performed for both for years with good results. However, transverse defects require reapproximating the tears in the fascia.

**Figure 62-1** The four locations of breaks in pubocervical fascia: lateral (paravaginal), where the pubocervical fascia attaches to the arcus tendineus fascia pelvis or white line; transverse, in front of the cervix, where the pubocervical fascia blends into the pericervical ring of fibromuscular tissue (or at the cuff in a woman who has had a hysterectomy); central, on the anterior vaginal wall between the lateral margins of the vagina; and distal, where the urethra perforates the urogenital diaphragm. (From Richardson AC: *Operative Techniques in Gynecologic Surgery*. Philadelphia, WB Saunders, 1996.)

**Figure 62-2** The arcus tendineus fascia pelvis extends from the inferior margin of the pubic symphysis to the ischial spine parallel to the levator arcus. Anteriorly, the bladder has been cut away. A cross-section through the vagina reveals the apposition of the rectovaginal fascia to the rectum and perirectal space. (From Richardson AC: *Operative Techniques in Gynecologic Surgery*. Philadelphia, WB Saunders, 1996.)

## ANATOMY

The pubocervical fascia (or endopelvic fascia), a trapezoid-shaped, fibromuscular band of tissue, supports the urethra, bladder, and uterus anteriorly (Fig. 62-2). Its lateral border extends from a point just anterior to the ischial spines, along the arcus tendineus fascia pelvis or white line, to the pubic ramus anteriorly. Posteriorly, it reaches the cervix or vaginal cuff at the level of the base of the broad ligament and cardinal-uterosacral ligaments and reaches across toward the ischial spines.

**Figure 62-3** The arcus tendineus fascia pelvis has separated entirely off the pelvic sidewall. (From Richardson AC: *Operative Techniques in Gynecologic Surgery*. Philadelphia, WB Saunders, 1996.)

Anterior vaginal wall prolapse results from herniation of the pelvic organs normally supported by the pubocervical fascia into the vaginal lumen. Many gynecologists believe that identification and repair of defects in this fascia are essential to achieve successful anterior colporrhaphy. However, the existence of fascial tissue between the vagina and bladder or vagina and rectum has never been proven histologically.<sup>6-9</sup> To examine the histology of surgical fascia used during anterior colporrhaphy, to compare it to rectovaginal fascia, and to determine the consistency with which this tissue is diagnosed surgically, Farrell and his colleagues examined the fascia of women who were scheduled to undergo a primary surgical correction of pelvic organ prolapse.<sup>9</sup> Biopsies taken of surgically identified pubocervical fascia and rectovaginal fascia during colporrhaphy failed to identify a distinct fascial layer. Instead, histologic examinations of tissue identified as fascia intraoperatively showed it to be indistinguishable from deep vaginal wall connective tissue.

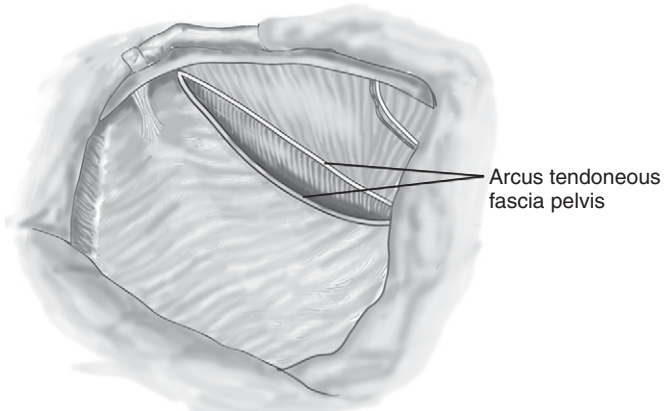

It is possible to have both central and lateral defects concurrently. Lateral detachment of the pubocervical fascia may occur if the entire arcus pulls away from the pelvic sidewall (Fig. 62-3). Alternatively, the entire arcus may remain attached to the sidewall while the pubocervical fascia pulls away.<sup>27</sup> Finally, the arcus could split, with a portion remaining attached to the pubocervical fascia medially and another portion remaining attached to the pelvic sidewall laterally (Fig. 62-4).

Most anterior compartment prolapse results from lateral detachment of the pubocervical fascia.<sup>5</sup> Although Richardson and colleagues were not the first to publish on the anatomic concept of paravaginal defects, they popularized the concept of discrete isolated fascial defects in the mid-1970s. Based on this work, the overall incidence of paravaginal defects was 67%, with the great majority being right-sided defects. Some years later, Barber and Cundiff conducted a retrospective chart review of 70 patients with a preoperative diagnosis of paravaginal defect.<sup>10</sup> Sixty-three percent (44/70) were believed to have unilateral or bilateral paravaginal defects preoperatively, based on clinical examination. The intraoperative findings confirmed the prevalence of paravaginal defects as just 42%.

## Diagnosis

A thorough physical examination in the office is the principal method of diagnosis of paravaginal defects. The patient is examined in the dorsal lithotomy position. With gentle downward traction of the posterior blade of the speculum, the anterior

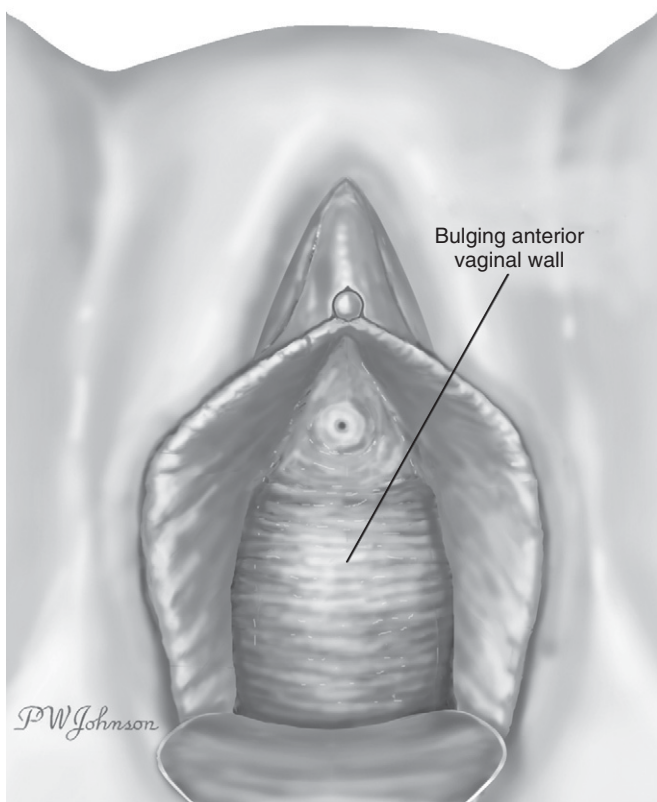

**Figure 62-4** The arcus tendineous fascia pelvis has split down the middle, leaving some of its remnants attached to the pubocervical fascia and some still attached to the pelvic sidewall. (From Richardson AC: *Operative Techniques in Gynecologic Surgery*. Philadelphia, WB Saunders, 1996.)

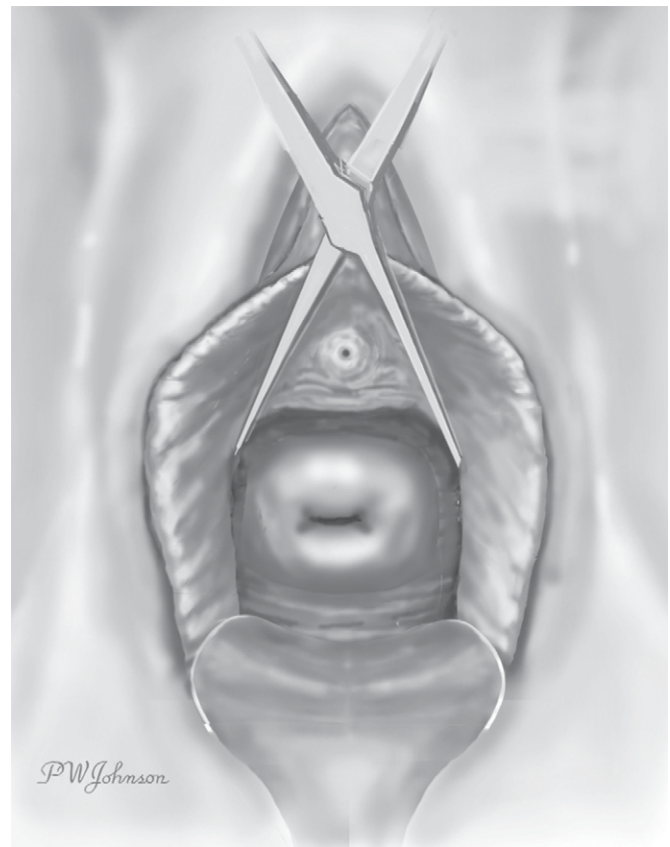

compartment is examined at rest and with maximum Valsalva maneuver. It is important to restore normal anatomy, so a ring forceps, Baden-Walker defect analyzer, or a wooden tongue blade should be used to gently elevate the lateral vaginal sulci, angling parallel to the white line (Fig. 62-5). Each side is checked separately, and then both together by elevating both sulci while the patient bears down. Bilateral paravaginal defects are corrected with this maneuver; central defects will prolapse around the elevating device. Suspected central defects should be supported with these instruments during Valsalva maneuver. If anterior prolapse is only partially reduced by either maneuver, then the patient is thought to have both paravaginal and central defects.

Paravaginal defects can be misdiagnosed. Barber and Cundiff found that the sensitivity of physical examination for the detection of right-sided paravaginal defects was 94% and the specificity was 54%. The positive predictive value of clinical examination was 65%, and negative predictive value was 91%. For left-sided defects, the sensitivity, specificity, positive predictive value, and negative predictive value were 90%, 50%, 57%, and 88%, respectively.<sup>10</sup>

Ultrasound and magnetic resonance imaging have both been used for the diagnosis of paravaginal defects.<sup>11-13</sup> However, given the time and expense of these tests, they are not recommended for routine diagnosis of paravaginal defects in the urogynecologist's office. The clinical examination remains the standard for diagnosis.

### TRANSABDOMINAL REPAIR

In 1976, Richardson described the transabdominal paravaginal repair. Although modifications have been described, the standard accepted technique has not been altered significantly from his original description. The patient is placed in low lithotomy position, and a Foley catheter is passed transurethrally. The bladder should be drained for adequate exposure and visualization into the retropubic space. If the patient has a uterus, the hysterectomy is performed first and the peritoneum is closed before proceeding with the paravaginal repair. A Pfannenstiel fascial incision is used most often. The rectus muscles are divided in the midline and held laterally by a self-retaining retractor. As with the Burch procedure, care must be taken to avoid injury to the inferior epigastric vessels. The space of Retzius is entered bluntly and developed cautiously under direct visualization to avoid injuring the large veins in this space. If the patient has had a prior Burch procedure, this space may be difficult to develop atraumatically (Fig. 62-6). Hemoclips are often required to maintain hemostasis.

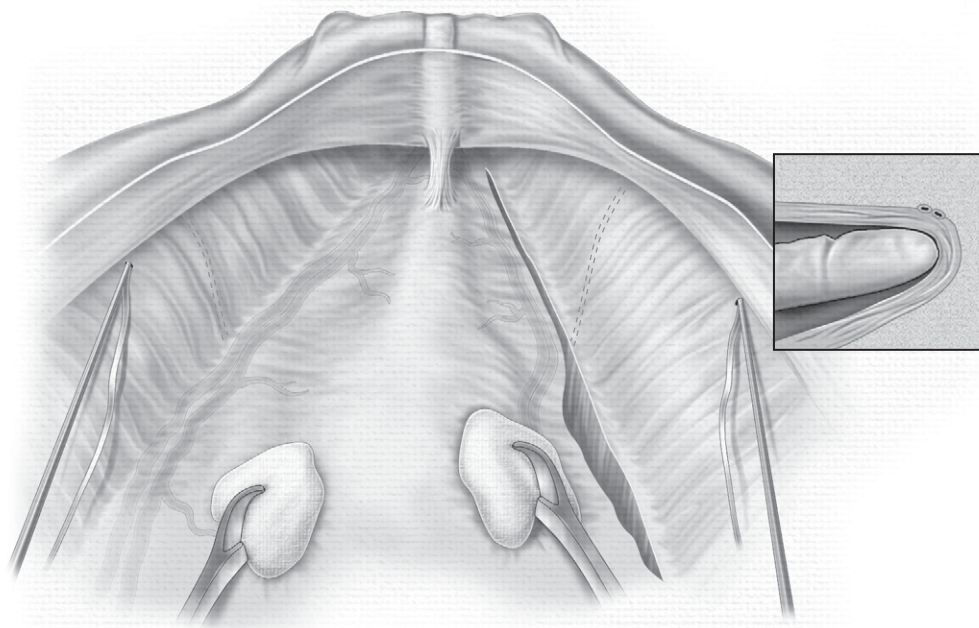

Once the space is fully developed, the retropubic anatomy may be visualized, including the pubic symphysis, the bladder neck in the midline, and the obturator neurovascular bundles and Cooper's ligament laterally. The obturator fossa can usually be identified first by palpation, because it feels like a vertically positioned buttonhole. Care should be taken while dissecting around this fossa to avoid damaging the obturator nerve, artery, and vein. Finally, the white line is identified along the pelvic sidewall as it travels from the inferior border of the pubic symphysis to the ischial spine. Further, blunt dissection using a sponge on a stick or Kittner may be required to remove adipose tissue adherent to the pubocervical fascia.

The surgeon's fingers are placed inside the vagina to elevate the lateral sulcus and aid in demonstrating the white pubocervi-

cal fascia and the superior extent of the vagina (Figs. 62-7 and 62-8). It is important to plan suture locations before actual placement, to avoid undue lateral tension on the vaginal wall when the sutures are tied. Synthetic, nonabsorbable sutures are used. The first suture is placed laterally, near the apex of the vagina, through the paravesical portion of the pubocervical fascia or the detached white line if it is visible. The needle is then passed through the ipsilateral obturator internus fascia around the arcus tendineus fascia pelvis (white line) at its origin, 1 cm anterior to the ischial spine. Three to five sutures are placed sequentially through the pubocervical fascia, distal to the prior fixation point, and attached to the white line or obturator fascia at a corresponding level from the ischial spine to the lateral pubic symphysis. If the patient has bilateral paravaginal defects, the same technique is used on the opposite side. Sutures are usually tagged and held until cystoscopy is performed with the sutures both relaxed and under tension, to ensure the integrity of the bladder and the normal function of both ureters. Gelfoam may be placed into the space of Retzius for hemostasis and to aid scarification of this space. Finally, the sutures are tied so that the lateral vaginal walls are in direct contact with the obturator fascia and arcus tendineus fascia pelvis.

### LAPAROSCOPIC REPAIR

Laparoscopic pelvic floor repair was described in 1995.<sup>14</sup> The laparoscopic paravaginal repair is similar to the laparoscopic Burch procedure. The patient is positioned in low lithotomy position, and a Foley urethral catheter is placed into the bladder. The Foley catheter should be clamped in order to partially distend the bladder and demarcate its boundaries. Some surgeons pass 30 mL of diluted methylene blue or indigo carmine transurethrally and clamp the urethral catheter so that any iatrogenic

**Figure 62-6** Visualization of the entire space of Retzius. (From Richardson AC: In Gershenson DM, Aronson MP (eds): *Operative Techniques in Gynecologic Surgery*. Philadelphia, WB Saunders, 1996, p 71.)

**Figure 62-7** With one finger inside the vagina elevating the lateral sulcus (*insert*), a full-thickness bite of the pubocervical fascia is taken. The needle is then passed through the ipsilateral obturator internus fascia around the arcus tendineus fascia pelvis. Sutures are placed from cephalad to caudad.

**Figure 62-8** All sutures are held and tied down after cystoscopy confirms the integrity of the bladder. (From Richardson AC: In Gershenson DM, Aronson MP (eds). *Operative Techniques in Gynecologic Surgery*. Philadelphia, WB Saunders, 1996, p 72.)

cystotomies are recognized immediately by expression of blue into the operative field.

Placement of trocar ports is left to the discretion of the surgeon. The space of Retzius is entered by making a transverse incision 2 inches above the pubic symphysis, spanning all three

obliterated umbilical ligaments, cephalad to the dome of the bladder. The bladder is then drained. The space of Retzius is dissected bluntly until the retropubic anatomy is clearly visualized. Some advocate removal of retropubic adipose tissue to aid in scarification.<sup>15</sup> The pubic symphysis and bladder neck are noted

in the midline, and the obturator neurovascular bundle, Cooper's ligament, and the white line are noted along the pelvic sidewall. The obturator fossa is identified.

With the operator's fingers elevating the superior lateral sulcus of the vagina, the first suture is placed near the apex of the vagina, through the paravesical portion of the pubocervical fascia or the detached white line if it is visible. The needle is then passed through the ipsilateral obturator internus muscle and fascia and the white line at its origin, 1 cm anterior to the ischial spine. The lateral wall suture technique is facilitated by moving the fingers in the vagina medially to open up the sidewall compartment; this readily exposes the ischial spine and white line. The same technique is used in the open procedure. Three to five sutures are placed sequentially through the pubocervical fascia distal to the prior fixation point on each side, but in this case the sutures are tied as they are placed, using an extracorporeal knot-tying technique without a suture bridge. Often, the third and fourth sutures are placed through Cooper's ligament to support the bladder neck (Burch), and there is usually no room for a fifth suture. Cystoscopy verifies integrity of the bladder and the normal function of both ureters.

Laparoscopic paravaginal repair requires great skill, dexterity, and ingenuity. The learning curve for laparoscopic Burch or paravaginal repair is 20 to 30 procedures. There are many modifications to laparoscopic repair, but ideally the laparoscopic method should be exactly the same as the open method to achieve the same result. The laparoscope is a vehicle for performing a repair and should not be a reason to modify a technique. Seman and his colleagues described two modifications to the laparoscopic paravaginal repair<sup>16</sup>: simultaneous Burch colposuspension and paravaginal repair and the modified paravaginal repair, in which the sutures are placed caudad to cephalad and each one includes a third bite of the ipsilateral iliopectineal (Cooper's) ligament. The use of mesh as a bridge between Cooper's ligament and the endopelvic fascia has also been described in the literature.<sup>17</sup> However, there is a paucity of good data regarding long-term success and feasibility of this approach.

## COMPLICATIONS

Good surgical technique should be used in gaining exposure to the retropubic space. Damage to the large veins coursing along the detrusor muscle can cause massive hemorrhage. Anatomically, there are few structures along the pelvic sidewall that contribute to complications. The obturator neurovascular bundle lies anterior to the white line, and dissection should be limited to the medial aspect of the neurovascular bundle. Cadaver dissection of the tissues underlying and adjacent to the white line

reveals that there are no neurovascular structures along the white line, obturator fascia, or levators that preclude taking a full bite of tissue.<sup>18</sup>

Unlike procedures that create a compensatory distortion of normal anatomy, the paravaginal repair typically does not lead to postoperative problems of de novo detrusor instability or long-term urinary retention. Shull and Baden reported the rate de novo detrusor instability in their patients to be 6% in 1989. Published data reporting objective outcomes and complications of the paravaginal repair are scarce. A review of the literature revealed several articles that comment on complications. Postoperative infections, such as cystitis and wound infection, ranged from 0% to 11%; and pneumonia was reported in 4% of patients.<sup>5,19-21</sup> Miklos and Kohli reviewed the outcomes for 171 consecutive patients who underwent laparoscopic Burch procedure, paravaginal repair, or both concurrently. Cystotomies were noted in 2.3% of patients.<sup>22</sup> C. Y. Liu reported no lower urinary tract injuries, retropubic hematomas, or abscess formation with laparoscopic repair of paravaginal defects.<sup>15</sup>

## OUTCOMES

Few studies have examined the long-term anatomic success of abdominal paravaginal repair. Much of the data focuses on correction of stress urinary incontinence rather than resolution of anterior vaginal wall prolapse. Shull and Baden reported that 97% of patients treated with paravaginal repair for lateral anterior defects and stress urinary incontinence had no postoperative complaints of stress incontinence.<sup>19</sup> Colombo and his group had more sobering results.<sup>23</sup> In 1996, they published the only prospective, randomized, controlled trial comparing Burch colposuspension to paravaginal repair for the treatment of stress urinary incontinence. The objective cure rate was 100% for Burch and 61% for paravaginal repair. Bruce and associates had similar results, with a 72% cure rate for paravaginal repair.<sup>24</sup> Paravaginal repair alone should not be offered for the treatment of stress incontinence. The standard of care for the treatment of stress incontinence remains a Burch or a sling procedure.

There are no good studies directly comparing abdominal paravaginal repair with laparoscopic or vaginal paravaginal repair for the treatment of anterior vaginal wall prolapse. The recurrence rate for cystocele has been reported to be 5% to 50%. Failure rates for paravaginal repair reported in several retrospective studies range from 5% to 13%.<sup>15,20,21,25</sup> De novo enterocele and cuff prolapse developed in 6% of patients who had abdominal paravaginal repair.<sup>19</sup> As far as we know, no studies have reviewed long-term major or minor complication rates of laparoscopic paravaginal repair alone.

# ANTERIOR COLPORRHAPHY FOR CYSTOCELE REPAIR

*Tristi W. Muir*

Pelvic organ prolapse is common in women. The anterior wall of the vagina primarily provides support for the bladder and urethra. If the support for the bladder sags, a cystocele results. The lifetime risk of undergoing an operation for prolapse or urinary incontinence has been estimated to be 11.1%.<sup>1</sup> Of the women undergoing surgery for prolapse with and without urinary incontinence, 48% had an anterior colporrhaphy included in their surgical management. This chapter discusses the anatomy and possible causes of anterior wall prolapse. A discussion of an anterior colporrhaphy for surgical repair of a cystocele is presented.

## ANATOMY AND PATHOLOGY

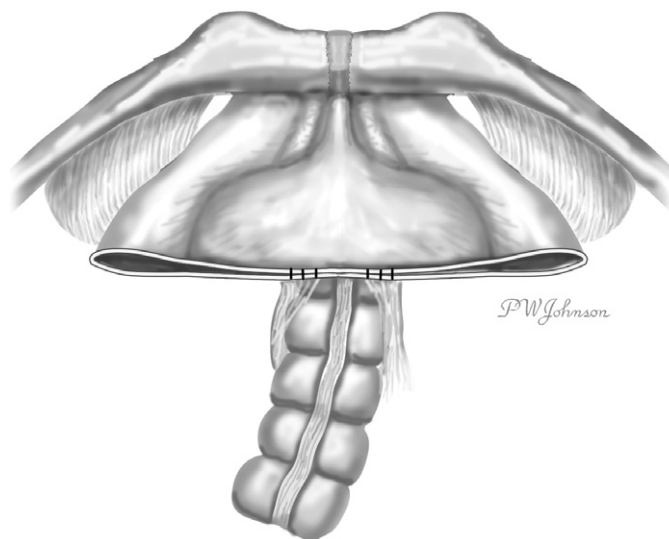

The anterior vaginal wall is the trapezoid of fibromuscularis and provides support to the bladder and urethra. At the apex, the broad portion of the trapezoid, the anterior vaginal wall has suspensory support provided by the cardinal-uterosacral ligaments. The lateral support is provided by a condensation of connective tissue over the levator ani muscles, the arcus tendineus fascia pelvis. The arcus tendineus fascia pelvis extends from the posterior, inferior aspect of the pubic bone to the ischial spine (Fig. 63-1). Nichols and Randall proposed that a cystocele is an end result of either distention (overstretching of the fibromuscularis of the anterior vaginal wall) or displacement (breaks in the connective tissue).<sup>2</sup> In 1976, A. Cullen Richardson popularized the “site-specific” approach to identifying specific breaks in the connective tissue and repairing those defects.<sup>3</sup>

Apical loss of support of the anterior vaginal wall may occur with an apical, transverse separation of the anterior vaginal fibromuscularis with the cardinal-uterosacral ligaments. As abdominal pressure is placed on the lateral connective tissue attachments, these attachments may fail, allowing the anterior vaginal wall to swing toward the hymen (Fig. 63-2). John DeLancey made surgical observations in 71 women undergoing a retropubic procedure for anterior wall prolapse and stress urinary incontinence.<sup>4</sup> He found that 88.7% of these women had a paravaginal defect and that the area of detachment was at the apex near the ischial spine. Detachment from the back of the pubic bone was rare. Although the majority of women with anterior wall prolapse and stress urinary incontinence may have a paravaginal loss of connective tissue support, the support for the anterior wall of the vagina is much more complex than a list of fascial attachments.

The support for the pelvic organs is maintained by the interaction of connective tissue attachments and innervated, intact pelvic floor musculature. The levator ani muscles provide the primary support for the pelvic floor. The pelvic organs are supported within the abdominal cavity, and the levator hiatus, through which the urethra, vagina, and rectum pass, is closed.

The etiology of pelvic organ prolapse is thought to be multifactorial, including abnormalities of connective tissue, pelvic floor muscles, and/or the innervation to the pelvic floor. Norton<sup>5</sup> used the analogy of a boat in a dry dock to describe the interplay of the functioning pelvic floor and connective tissue supports (Fig. 63-3). The pelvic floor muscles (primarily the levator ani muscles) play the supporting role of the water. When the water level is adequate, little stress is placed on the ropes (connective tissue supports) keeping the boat in place. However, if the water level is dropped, the ropes will not be able to hold the boat for long. If the levator ani muscles no longer are able to maintain a closed levator hiatus, the stress of maintaining the pelvic organs is placed on the connective tissue supports. Direct damage to the levator ani muscle or to its innervation may open the hiatus and place the burden of support on the connective tissue of the pelvic organs. Prior damage to the connective tissue support of the anterior vaginal wall may be evident only in light of the loss of levator ani function.

DeLancey and Hurd clinically determined that the levator hiatus is larger in women with prolapse than in those without prolapse.<sup>6</sup> Magnetic resonance imaging (MRI) confirmed that the size of the levator hiatus and levator symphysis gap increases with increasing stage of prolapse.<sup>7</sup> Lennox Hoyte and colleagues evaluated the change in morphology of the levator ani muscles with two- and three-dimensional MRI images.<sup>8</sup> They demonstrated

**Figure 63-1** Apical and sidewall connective tissue support of the anterior vaginal wall as viewed in the retropubic space. ATFP, arcus tendineus fascia pelvis; IS, ischial spine; USL, uterosacral ligaments.

**Figure 63-2** Pelvic floor disorders: the role of fascia and ligaments. The water represents functioning pelvic floor muscles, and the ropes are the connective tissue supports. **A**, With water in the dock (functioning pelvic floor muscles), the ropes can maintain the position of the boat (connective tissue supports the position of the pelvic organs). **B**, With loss of the water (loss of function of the pelvic floor muscles), the support of the boat (pelvic organs) is maintained only by the ropes (connective tissue). (From Norton PA: Pelvic floor disorders: The role of fascia and ligaments. *Clin Obstet Gynecol* 36:926-938, 1993.)

that women with prolapse have significantly more levator ani degradation, laxity, and loss of the integrity of the sling portion of the levator ani compared with asymptomatic controls. This change may occur as a result of direct muscle damage associated with childbirth or chronic straining or damage to the innervation of the pelvic floor.

Abnormalities in the histology of connective tissue have also been described in women with prolapse. Abnormalities of collagen synthesis may derive from an intrinsic abnormality of collagen synthesis (due to abnormal collagen, an imbalance between synthesis and degradation, or an imbalance between collagen types). The environment (e.g., excessive straining) may also contribute to the condition of the connective tissue. Error in the repair of damaged ligaments and fascia or lack of remodeling in mature collagen may occur. Dietz and colleagues examined bladder neck descent in nulliparous twins.<sup>9</sup> A significant genetic contribution was proposed to contribute to the phenotype of the bladder neck mobility.

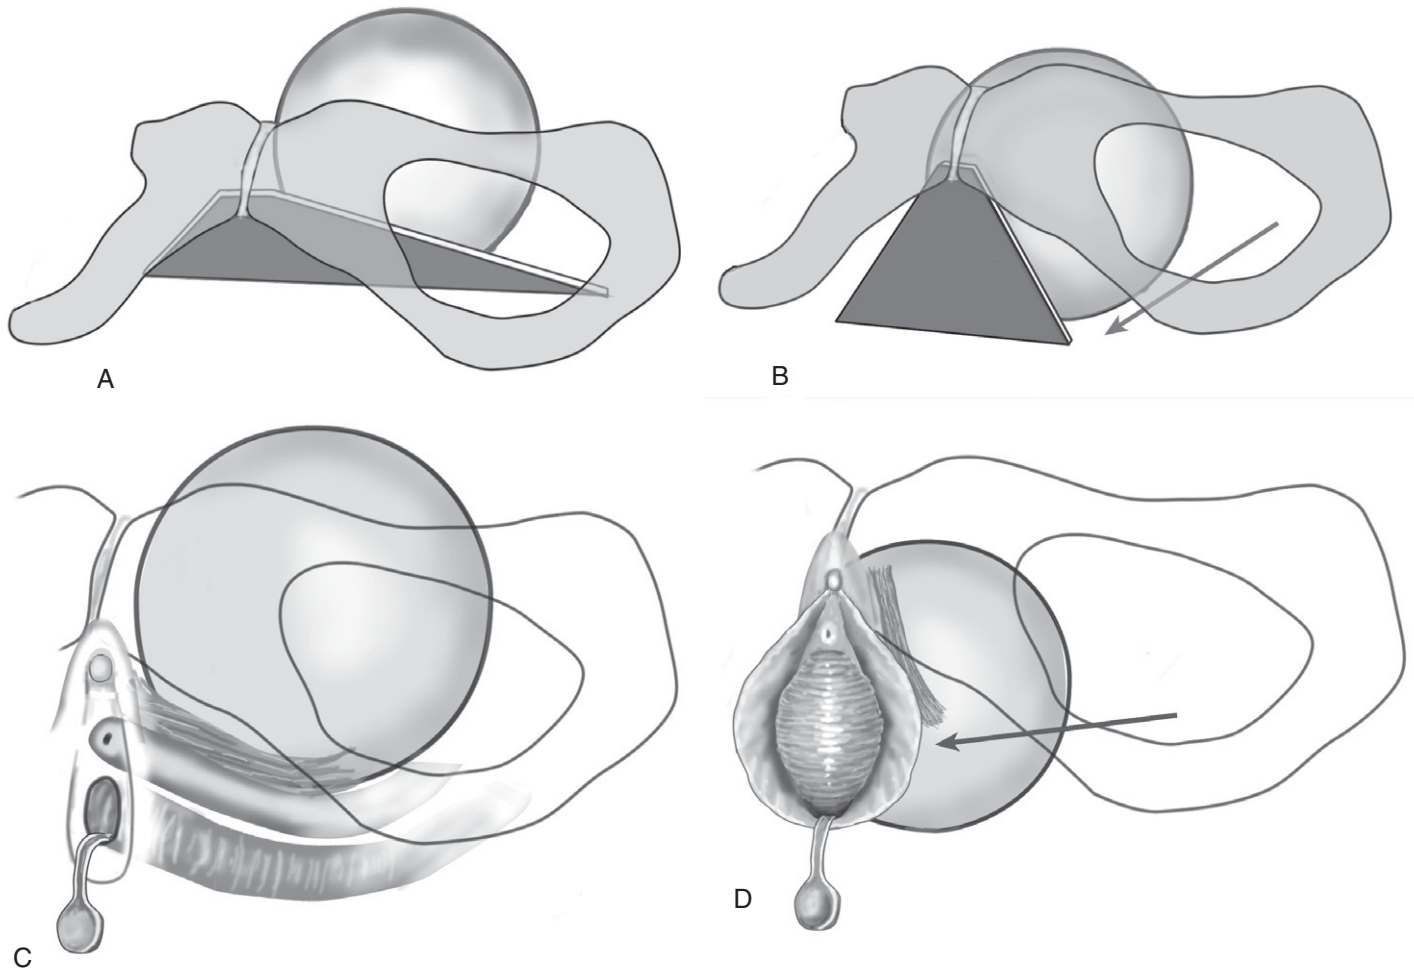

## SIGNS AND SYMPTOMS

A woman with anterior wall prolapse may be asymptomatic, or she may present with symptoms related to a vaginal mass with or without changes in sexual and urinary function. Pelvic pressure, heaviness, or a bulge may occur. Women often feel that their symptoms are more significant as the day progresses and gravity allows the prolapse to fully descend. The bladder follows the anterior vaginal wall as it descends through the genital hiatus in

women with an anterior wall bulge. Because the distal urethra remains fixed under the pubic symphysis, voiding difficulties due to obstruction may arise. Women who have to manually reduce their prolapse to empty their bladder are likely to have more significant prolapse than those who do not.<sup>10</sup> This obstructive effect on the urethra may protect a woman from leaking urine with abdominal stress (occult incontinence). Women with anterior wall prolapse extending more than 1 cm beyond the hymen are less likely to describe stress urinary incontinence than those with lesser prolapse.<sup>10</sup> Sexual function has also been examined in women with prolapse and appears to be similar to that in women without prolapse.<sup>10,11</sup>

The goal of the physical examination is to recreate the woman's symptoms. A validated measure of pelvic organ prolapse is the pelvic organ prolapse quantification (POPQ) method.<sup>12</sup> Measurement of the descent of the anterior vaginal wall is made at maximal strain. If a woman describes prolapse more significant than that observed in the supine or sitting positions, a standing examination may be employed. The woman's position and the degree of bladder distention (empty or full) should be documented. A full bladder may help to recreate the patient's most prominent symptoms of vaginal bulging.

Bob Shull described a method to evaluate the anterior vagina for site-specific defects.<sup>13</sup> Curved ring forceps are placed in the vagina, supporting the lateral anterior vaginal wall to the ischial spine. The patient is asked to bear down in a Valsalva maneuver. If the anterior vaginal wall prolapse is reduced, a paravaginal defect is diagnosed. A bilateral and a unilateral paravaginal defect may be differentiated with alternating unilateral paravaginal

**Figure 63-3** Connective tissue support of the anterior vaginal wall. **A**, Intact connective tissue support. **B**, Loss of apical and paravaginal support (beginning at the ischial spines) allows the anterior vaginal wall to swing toward the introitus. (From DeLancey JOL: Fascial and muscular abnormalities in women with urethral hypermobility and anterior vaginal wall prolapse. *Am J Obstet Gynecol* 187:93-98, 2002).

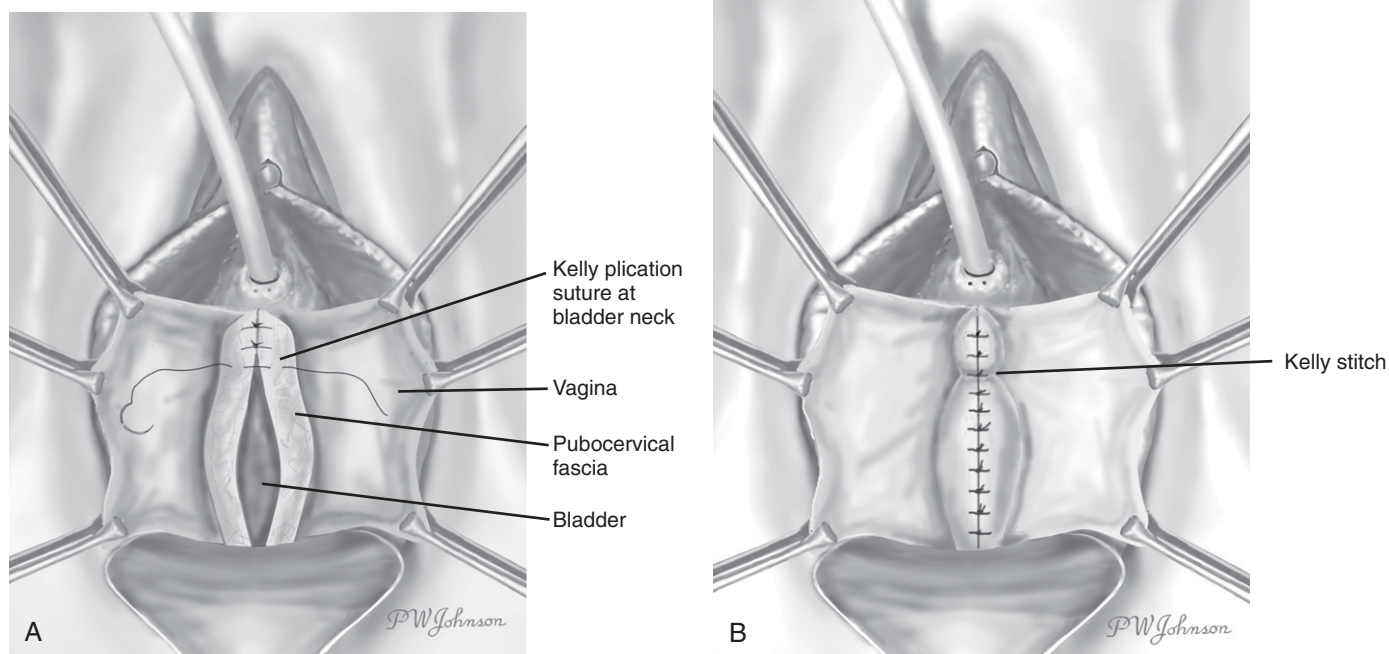

support. If the anterior vaginal wall continues to balloon forward despite paravaginal support, a midline defect is diagnosed. A superior or high transverse defect may be suspected if the prolapse is reduced with apical support. Loss of rugation at one of these sites is also thought to be associated with localization of the defect. Whiteside and colleagues evaluated the inter-examiner and intra-examiner reliability of site-specific defect examination.<sup>14</sup> They found that there was poor examiner concordance for the presence of superior, paravaginal, or central defects. Not surprising is that the reliability of the examination increased with stage of prolapse.

Evaluation of urinary function is important in women with anterior wall prolapse. A postvoid residual volume may be measured by an in-and-out catheterization, or an ultrasonic determination may be made with a bladder scan.<sup>15</sup> A test for hypermobility of the urethra may be performed with a sterile, lubricated cotton swab (Q-tip test). The cotton swab is inserted into the urethra to the level of the bladder neck. Measurement of the resting and straining angles from the horizontal axis may be obtained with a goniometer. Hypermobility of the bladder neck is determined if the difference between the resting and straining angles is more than 30 degrees. For patients with stage 3 or 4 anterior wall prolapse, urodynamic assessment with prolapse reduction has been

suggested to identify those women with occult urinary incontinence. The method of prolapse reduction (pessary, rolled gauze, tampons, ring forceps) has not been standardized, and the reliability of this test has not been established.

#### TECHNIQUE

The anterior colporrhaphy involves a plication of the fibromuscularis of the anterior vaginal wall. This procedure serves to “tighten up” the overdistracted support of the anterior vaginal wall or repair a midline defect. The patient is in the dorsal lithotomy position with the legs elevated. A single dose of perioperative antibiotics is administered. A weighted speculum is placed in the vagina, and a 16-Fr Foley catheter is inserted into the bladder. The epithelium of the anterior vaginal wall is incised in the midline and dissected away from the underlying fibromuscularis or “pubocervical fascia.” Hydrodissection of the vaginal epithelium away from the underlying fibromuscularis with saline or an anesthetic/vasoconstrictive agent may facilitate the dissection. With traction and countertraction, the dissection is carried laterally to the levator ani muscular sidewall. It is important to continue the dissection to the apex of the anterior vaginal wall. If an

**Figure 63-4** Anterior colporrhaphy with Kelly plication.

anti-incontinence procedure is included in the woman's surgery, the anterior wall dissection typically spares the mid-urethra and distal urethra. This area may be palpated with a Foley catheter in place. If the surgeon wishes to provide improved support underneath the urethra and bladder for treatment of a distal anterior wall prolapse (urethrocele), the dissection is continued distally toward the inferior aspect of the pubic bone.

A plication underneath the urethra and bladder neck (a Kelly plication) may be performed to provide a shelf of support underneath the urethra. The fibromuscularis associated with the inferior portion of the pubic bone, just lateral to the urethra, is grasped bilaterally. Interrupted sutures are placed to reapproximate this tissue underneath the urethra, creating a posterior urethral shelf of support. A separate suture is placed plicating the fibromuscularis underneath the bladder neck. Continuation of the midline plication is performed, reducing the width of the fibromuscular wall of the anterior vagina with interrupted sutures (Fig. 63-4).

Attention should be directed to the length of the anterior vaginal wall. In some women with prolapse, an elongated (stretched out) vaginal wall is present. Vertically oriented plication sutures tend to shorten the length of the fibromuscularis.<sup>16</sup> However, some women, particularly those with recurrent prolapse, may have a shortened anterior segment. Horizontally oriented plication sutures will preserve the vaginal length of the anterior segment. More than one row of plicating sutures may be required to reduce anterior wall prolapse in women with stage 3 or 4 prolapse. The aggressiveness of the plication and the longevity of the sutures are dependent on the surgeon's preference. Anne Weber and colleagues described a standard plication and an "ultralateral" plication as two different procedures in a prospective, randomized trial.<sup>17</sup> Placement of the plication sutures should be tailored to the prolapse anatomy of the patient.

The apex of the plicated fibromuscularis of the anterior vaginal wall must be suspended to the apical support of the vagina. If the woman has a well-supported apex, reattachment of the apical

portion of the repair should be performed. If the woman is undergoing a concomitant apical suspension procedure, the apical portion of the anterior colporrhaphy should be attached to the suspension sutures. Without apical suspension of the fibromuscularis, the anterior vaginal wall will continue to sag down toward the introitus.

After plication and suspension of the anterior fibromuscularis, the vaginal epithelium may be trimmed and closed with absorbable suture. The surgeon should be cautious not to overtrim the vaginal epithelium (particularly in the postmenopausal woman with vaginal atrophy). A vaginal pack and Foley catheter are placed for 2 to 24 hours postoperatively. Voiding trials should be performed postoperatively to ensure that the patient is able to void to completion. Hakvoort and colleagues found that removal of the Foley catheter on the morning after surgery, rather than on postoperative day 4, was associated with fewer days requiring catheter drainage and a lower incidence of urinary tract infections.<sup>18</sup>

## SURGICAL OUTCOMES

The anterior colporrhaphy has been performed for more than a century, but few studies have reported the efficacy of the procedure for the treatment of anterior wall prolapse. Most studies have addressed the efficacy (or lack thereof) of the anterior colporrhaphy in the management of stress urinary incontinence. The anatomic cure rate of the procedure for treatment of anterior vaginal wall prolapse varies between 30% and 97% (Table 63-1).<sup>17,19-22</sup>

Clark and colleagues monitored a cohort of women who had undergone anterior colporrhaphy and found that 7% underwent a reoperation by 71 months.<sup>23</sup> Risk factors for recurrent anterior wall prolapse include age less than 60 years and preoperative stage 3 or 4 prolapse.<sup>24</sup>

**Table 63-1 Efficacy of Anterior Colporrhaphy**

Study (Ref. No.)	Year	No. Patients	Mean Follow-up	Anatomic Cure (%)
Goff (19)	1933	86*	1-8 yr	93
Stanton et al (20)	1982	73	3 to 24 mo	89
Porges & Smilen (21)	1994	486 (388 with follow-up)	31 mo	97
Colombo et al (22)	2000	33	8-17 yr	97
Weber et al (17)	2001	57 <sup>†</sup>	23 mo (median)	37

\*Study included 31 patients who underwent excision of the vaginal wall and 55 patients with overlapping fibromuscularis.

<sup>†</sup>Study included both patients who underwent "standard" plication and patients who underwent an "ultralateral" plication.

## COMPLICATIONS

Complications of anterior colporrhaphy include injury to the surrounding organs, deterioration of bladder or sexual function, and recurrence of prolapse. The routine risks of surgery inclusive of blood transfusion are uncommon with this procedure (blood transfusion occurred in 3 of 519 women undergoing prolapse surgery that included an anterior colporrhaphy, most often linked to other prolapse procedures).<sup>25</sup>

### Injury to Ureters, Bladder, and Urethra

Injury to the lower urinary tract may occur during an anterior colporrhaphy. Kwon and colleagues reported a 2% incidence of ureteral obstruction during 346 anterior colporrhaphies, making this procedure the most common cause of unsuspected intraoperative injury to the lower urinary tract in their pelvic reconstructive procedures.<sup>26</sup> The cause was thought to be an aggressive lateral plication of the fibromuscularis, which kinked the ureter at the ureterovesical junction. A case report of bilateral ureteric obstruction after an anterior colporrhaphy has been described.<sup>27</sup> Additionally, recurrent postoperative urinary tract infections may occur because of an unrecognized intravesical suture.<sup>28</sup> R. Peter Beck reported 2 cases of urethrovaginal fistula among 519 women undergoing anterior colporrhaphy for prolapse with or without urinary incontinence.<sup>25</sup> Of note, in an attempt to improve the surgical cure of stress incontinence, Beck's group modified the bladder neck plication by attempting to be more aggressive in differential support of the urethra (to a higher retropubic position) compared with the bladder base. This more aggressive plication technique may result in ischemia or occult injury to the urethra. These cases suggest a role for universal cystoscopy in patients undergoing anterior colporrhaphy to identify and correct injury to the ureters, bladder, or urethra.

### De Novo Urinary Symptoms

De novo urinary incontinence or voiding dysfunction is a known complication of prolapse and incontinence procedures. The risk of postoperative de novo urinary incontinence for women undergoing an anterior colporrhaphy for anterior wall prolapse is 10% (5% for stress urinary incontinence, 4% for overactive bladder with incontinence, and 1% for mixed urinary incontinence).<sup>25</sup> De novo detrusor overactivity may be the result of a number of possible postoperative changes, including outlet obstruction, and changes in detrusor innervation.

Most women who undergo an anterior colporrhaphy are able to obtain postvoid residuals of less than 100 mL by 1 week.<sup>25</sup>

However, urethral obstruction leading to irritative voiding symptoms after an anterior colporrhaphy with Kelly plication has been described.<sup>29</sup> Aggressive plication under the urethra is thought to be the culprit. In some cases, a band of constriction may be palpated by vaginal examination. A vaginal approach to release of the area of constriction may be curative.

Evaluation of the effect of anterior wall dissection on innervation of the urethral sphincters was performed by measuring the terminal motor latency of the perineal branch of the pudendal nerve. Zivkovic and colleagues found that there was not a significant difference between preoperative and postoperative perineal nerve terminal motor latencies in women undergoing an anterior colporrhaphy without a needle urethropexy.<sup>30</sup>

### Sexual Function

Sexual function in women is a complicated issue, one that may be further complicated by the presence of prolapse or incontinence. Many sexually active women with prolapse or incontinence describe preoperative dissatisfaction with their sex lives due to a variety of reasons, inclusive of decreased libido, vaginal prolapse, and fear of urinary incontinence with intercourse. Rogers and colleagues evaluated the sexual and continence functions in women preoperatively and postoperatively.<sup>31</sup> They found that sexual function scores declined from their preoperative values at 3 and 6 months after surgery, despite an improvement in incontinence impact scores. Gungor and colleagues also described a deterioration in sexual function, primarily related to dyspareunia, in 8 (18%) of 44 sexually active women who underwent an anterior colporrhaphy coupled with a posterior colpoperineorrhaphy.<sup>32</sup> However, they found an improvement in 20 (67%) of 30 sexually active women who preoperatively had dissatisfaction in their sexual life.

Sexual function remains a complicated issue in the postoperative period. Patients should be counseled that their sexual function has the potential to improve, remain unchanged, or deteriorate after prolapse surgery. In the operating room, the surgeon should make every effort to maintain vaginal caliber, to reduce the likelihood of postoperative dyspareunia.

## ANTERIOR COLPORRHAPHY WITH KELLY PPLICATION AS AN INCONTINENCE PROCEDURE

Most of the studies evaluating the postoperative results of anterior colporrhaphy with Kelly plication have used cure of stress urinary incontinence as the measure of success. Anterior colporrhaphy with Kelly plication has not been found to be as effective as retropubic urethropexy for the treatment of urinary inconti-

nence, and it has largely been abandoned as a method of operative management of urinary incontinence.<sup>33-35</sup>

## CONCLUSIONS

Anterior wall prolapse most likely develops after loss of levator ani function (through direct muscle damage or nerve damage) and breaks or attenuation of connective tissue supports. Our surgical approach to repair of prolapse focuses on connective tissue support until a time in the future when muscle and nerve regeneration are feasible. The anterior colporrhaphy has been a part of the surgeon's armamentarium for more than a century. The key to support of the anterior vaginal wall is apical support. Because the anterior vaginal wall rarely loses distal support at the posterior aspect of the pubic bone, does it matter, if the other

end of the fibromuscularis hammock of support is reestablished at the apex, how the "sag" is taken out (anterior colporrhaphy versus paravaginal repair)? Even those who advocate paravaginal repair often perform a concomitant anterior colporrhaphy.<sup>36,37</sup> There are no studies comparing the site-specific approach to repair of the anterior vaginal wall, using a paravaginal defect repair with or without a midline defect repair (colporrhaphy), to an anterior colporrhaphy alone. The addition of graft materials in an attempt to decrease the likelihood of recurrent prolapse has been described. Comparative studies are needed to determine the risks and benefits of this practice.

Anterior wall prolapse is often associated with bladder dysfunction. Preoperative evaluation of bladder function may be necessary, especially in patients with stage 3 or 4 anterior wall prolapse. Sexual function is a complex issue. Maintenance of vaginal caliber is important in sexually active women undergoing surgical management.

# TRANSVAGINAL PARAVAGINAL REPAIR OF HIGH-GRADE CYSTOCELE

*Donna Y. Deng, Matthew P. Rutman, Larissa V. Rodriguez, and Shlomo Raz*

Anterior compartment defect or cystocele is defined as anterior vaginal wall relaxation or prolapse with or without urethral hypermobility. It represents one of the most common types of genital organ prolapse. Cystoceles have been described by several different classification systems and were previously categorized based on the relative degree of bladder descent and anatomic defect. More recently, the International Continence Society (ICS) has accepted standardization of the terminology for prolapse of the lower urinary tract.<sup>1</sup> To ensure consistency, examiners must note the conditions of the examination findings, such as rest, strain, or supine positioning. This chapter concentrates on repair of the high-grade cystocele that has prolapsed past the vaginal introitus—grade 3/4 in the Baden-Walker classification or stage 3/4 in the pelvic organ prolapse quantification (POPQ) terminology.

The natural history of a cystocele is a continuous progression from mild to severe prolapse, but the actual risk of progression is unknown. In some patients, the progression is rapid; in others, it can be insidious, taking many years. Most lesser degrees of prolapse (stages 1 and 2) are asymptomatic except when accompanied by urinary incontinence. Pelvic prolapse does not spontaneously regress, nor does it become symptomatic until the descent reaches the introitus.<sup>2</sup> Cystoceles with an isolated central defect represent only 5% to 15% of all cystoceles, whereas a lateral paravaginal defect is present in 70% to 80% of patients. Stage 4 cystoceles usually manifest with both defects. Proposed risk factors for the development of a cystocele have included difficult or prolonged vaginal deliveries, elevated body mass index (BMI), parity, menopause, and previous vaginal surgery.

Cystocele may occur as an isolated defect. However, it is most commonly associated with prolapse of other genital organs, such as rectocele, enterocele, and uterine descensus. Michael and colleagues<sup>3</sup> observed a simultaneous enterocele in 35%, rectocele in 63%, and uterine prolapse in 38% of patients with grade 4 cystoceles. Therefore, in cases of severe anterior compartment prolapse, all of the compartments must be corrected. Treatment must involve a thoughtful and thorough evaluation plus a strong knowledge of pelvic floor anatomy. The goals of surgery must be to restore vaginal depth, vaginal axis, the levator hiatus, and bladder and bowel function, while also preserving sexual function.

### ANATOMY

In a well-supported woman in the standing position, the vagina forms an inverted “C” shape with two distinct vaginal angles. This can be demonstrated on a midsagittal pelvic magnetic

resonance image in a patient with normal anatomy. The distal vaginal canal forms a 45-degree angle from the vertical plane, whereas the proximal vagina lies more horizontally over the posterior levator plate, forming an angle of 110 degrees. The upper vagina is held over the levator plate by the cardinal and uterosacral ligaments, and the angle is maintained by a strong levator plate and the anterior traction of the levator sling and prerectal fascia.

The bony pelvis is a scaffold from which the pelvic structures draw their support. The pelvis can be divided into posterior and anterior regions by a line traversing the ischial spines. The sacrospinous ligaments are true ligaments in that they span between bony structures, arising from the posterior aspect of the ischial spines and connecting with the anterolateral sacrum and coccyx, providing a broad support for the posterior pelvis. A linear fascial condensation arising from the obturator internus muscle, the arcus tendineus, extends from the ischial spine to the lower portion of the pubic symphysis. The arcus tendineus is also the insertion point for the semilunar-shaped levator muscles, and it provides the musculofascial support for a large portion of the anterior pelvis.

The pelvic diaphragm is the superior layer of striated muscle and fascia that provides the inferior support for the pelvic viscera. The levator ani muscle group, composed of the pubococcygeus and iliococcygeus, is a broad muscular structure that originates on each side from the arcus tendineus of the obturator fascia and the inner surface of the pubis anteriorly and sweeps medially to join its contralateral partner in the midline. The levator ani thereby forms a broad hammock upon which the bladder, proximal vagina, and intrapelvic rectum lie. The vagina, rectum, and urethra traverse the pubococcygeus through a funneled hiatus. Pubococcygeal muscle fibers entering this “U”-shaped levator hiatus form the external sphincter of the urethra. Medial fibers of the pubococcygeal portion of the levator, sometimes referred to as the puborectalis, travel posteriorly along the urethra, vagina, and rectum and fuse anterior to the rectum, forming part of the perineal support deep to the perineal body. Reflex and active contraction of the pubococcygeus elevates the urethra, vagina, and rectum, thereby helping to compress the lumens of these structures.

Like the pubococcygeus, the iliococcygeus arises from the tendinous arc, but it sweeps more posteriorly and unites with the contralateral iliococcygeus in the median raphe posterior to the rectum. The coccygeus extends from the ischial spine to the lateral aspect of the sacrum and coccyx, overlying the sacrospinous ligament. The coccygeus is a thin muscle that overlies the strong and fibrous sacrospinous ligament. These two structures are identically shaped, and when they are encountered during

surgical procedures, they are approached as a single complex useful for fixation of the vaginal vault. It is important to realize that the pudendal neurovascular bundle runs in the lateral insertion of the sacrospinous ligament, near the ischial spine.

The pelvic diaphragm has investing connective tissue that is often referred to as “fascia”; it is, however, less organized and less distinct than traditional fascia (e.g., rectus abdominis fascia). This visceropelvic fascia consists of collagen, smooth muscle, and elastin. Microscopic studies suggest that it may be histologically indistinct from the deep vaginal wall and not a separate “fascia.”<sup>4</sup> In our discussion of the musculofascial support, we will continue to refer to this tissue as “fascia” for the sake of accepted nomenclature. The pelvic fasciae have been given a confusing array of appellations by anatomists and surgeons interested in female pelvic organ prolapse. To add to the confusion, the strength of pelvic fasciae can differ significantly among individuals and races, and these differences may predispose some individuals to pelvic prolapse.<sup>5</sup>

The pelvic fascia consists of two leaves—the endopelvic fascia (abdominal side) and the perivesical fascia (vaginal side). The urethra, bladder, vagina, and uterus are all contained within these two layers of fascia. The two leaves fuse laterally to insert along the arcus tendineus. The pelvic fascia can be divided, distally to proximally, into four specialized areas; these areas play important roles in pelvic support and during surgical reconstruction of the female pelvis. They are not true ligaments; rather, they are condensations or a meshwork of connective tissue and smooth muscle that invests the visceral neurovascular pedicles.<sup>1,6</sup> The so-called pubourethral ligaments attach to the lower portion of the pubis and insert on the proximal third of the urethra; they are analogous to the puboprostatic ligaments in the male.<sup>2</sup> The urethropelvic ligaments provide support of the proximal urethra to the lateral pelvic sidewall.<sup>3</sup> The vesicopelvic fascia is the region of the pelvic fascia that attaches and supports the bladder base to the arcus tendineus. Finally, the vesicopelvic ligaments are all of the structures that support the bladder to the lateral pelvic wall. Weakness in the vesicopelvic fascia results in cystocele formation.

Cystoceles are generally classified as being caused by a central defect or a lateral defect. A central defect manifests as a midline weakness. There is good lateral support, but central herniation of the bladder base into the vagina occurs through a separation or attenuation of the vesicopelvic fascia (with separation of the cardinal ligaments). A lateral defect occurs when there is weakness or disruption of the lateral (paravaginal) attachments of the vesicopelvic ligaments to the arcus tendineus fascia pelvis. High-grade cystoceles tend to involve a combination of lateral and central defects with urethral hypermobility.<sup>4</sup> The cardinal-sacruterine ligament complex attaches to the bladder base and cervix (or vaginal vault, if reapproximated during the hysterectomy).

## PATHOPHYSIOLOGY

Pelvic organ prolapse is prevented by several mechanisms. The most important support is from the continuous contraction of the levator ani pelvic muscles. The activity of skeletal muscle is a combination of basic tone, reflex contraction or relaxation, and voluntary contraction or relaxation. The basic tone of the skeletal musculature is similar to that in other areas of the body. Muscles of the pelvic diaphragm contain type I (slow-twitch) fibers, which

provide tonic support to pelvic structures, and type II (fast-twitch) fibers, for sudden increases in intra-abdominal pressure.<sup>7</sup> The continuous contraction closes the urogenital hiatus and forms a shelf for the pelvic organs to rest upon. Patients with multiple deliveries exhibit widening and descent of the levator plate. The musculature becomes less important and the “fascial” structures become the more important elements of support as the organs cross the pelvic floor.

Innervation of the muscles is primarily derived from the ventral rami of the second, third, and fourth sacral nerve roots. These pelvic somatic efferent nerves travel on the pelvic surface of the levator ani in close association with the rectum and are separated from the pelvic autonomic plexus by the endopelvic fascia. They supply the levator ani and extend anteriorly to the striated urethral sphincter.<sup>8,9</sup> Static support is provided by the investing connective tissue layers. Under normal conditions, the levator ani contract, and the ligaments and fasciae are under minimal stress. The fasciae stabilize the pelvic organs.

Because of the complexity of pelvic organ support, the cause of vaginal prolapse is likely to be multifactorial, including myopathic or neuropathic disorders, aging, atrophy, chronic increase in abdominal pressures, multiple deliveries, hysterectomy, and hormonal changes. Poor function of the levator ani muscles may result from direct myopathic injury or from an abnormality of innervation. Loss of tonic contraction causes the urogenital hiatus to widen, increasing the risk of organ prolapse. Pelvic relaxation decreases the angulation of the mid-vagina, so the upper vagina does not lie flat against the pelvic floor plate. Instead of an inverted “C” configuration, the vagina becomes vertically oriented and can more easily intussuscept on itself. The reason for neuropathy in a healthy woman is not clear. Childbirth has been suggested as the cause of pelvic denervation, but studies in this area have shown that uncomplicated childbirth creates only transient neurologic damage to the pelvic floor that is restored after two postpartum months.<sup>10</sup> The pelvic floor neuropraxia related to vaginal delivery is associated with multiple births, prolonged labor, high birth weight, and traumatic deliveries. Other risk factors for neurologic damage are congenital abnormalities, aging, chronic constipation (abdominal straining), and perineal laxity.<sup>11,12</sup> In a study of 50 women with prolapse, Sharf and associates performed electromyography of the levator ani and found evidence of denervation in half of the patients.<sup>10</sup> Other studies have also confirmed evidence of neurologic damage to the urogenital muscles in pelvic prolapse.<sup>13,14</sup>

The connective tissue of the pelvic floor, the endopelvic fascia, can be described as a group of collagen fibers interlaced with elastin, smooth muscle cells, fibroblasts, and vascular structures. These structures may be weakened by pregnancy, parturition, lack of estrogen, aging, diet, chronic straining, and certain connective tissue disorders (e.g., Ehlers-Danlos syndrome, Marfan’s syndrome).<sup>15</sup> However, intrinsic collagen abnormalities and other individual predisposing factors, such as genetics, differences in pelvic architecture, inherent quality of the pelvic musculature, and tissue response to injury, might explain why many patients with known risk factors do not develop prolapse and many patients without risk factors do.

Correction of a cystocele alone, without addressing the entire pelvic floor laxity and alignment, may further alter the vaginal axis as the bladder and vesicopelvic fascia are brought anteriorly. This may increase the likelihood of uterine prolapse, enterocele, and rectocele formation.

## EVALUATION

### Symptoms

Cystoceles are often asymptomatic until pelvic organ prolapse is severe. The most common complaint related to anterior compartment prolapse is vaginal bulging, with or without suprapubic pressure and pain. Other symptoms include urgency, frequency, urge incontinence, recurrent urinary tract infections, back pain, renal failure, staghorn calculi, and urinary retention. Obstructive voiding symptoms are caused by urethral kinking that occurs when the bladder descends beyond the pubic ramus but the urethra remains fixed. This is commonly seen in the setting of previous surgery (bladder neck suspension, urethropexy, sling).<sup>3</sup> Patients may describe using unusual positions to void, such as pelvic tilting, squatting, or standing. In contrast, patients with concomitant urethral dysfunction may present with stress urinary incontinence, especially when the cystocele is manually reduced.

### Clinical Evaluation

There are critical points in the evaluation of a cystocele that must be answered before treatment. The degree of cystocele and other concurrent bladder symptoms (e.g., stress incontinence, detrusor overactivity) and ability to empty the bladder to completion should be known. Surgical planning is also affected by the need to preserve sexual function and vaginal depth. The overall health of the patient must be considered, as well as the quality of vaginal tissue, presence of associated prolapse, bowel and bladder function, hormonal status, and presence of urinary tract infection. It is also important to assess the impact of the symptoms on the patient's quality of life.

### Physical Examination

A thorough physical examination should be done while the patient has a full bladder, at rest and with straining, in both the standing and supine positions. The goal of examination is to determine the degree of prolapse, the specific anatomic defects, and the presence of concomitant organ prolapse. Straining and standing should accentuate the degree of descent. In the supine position, the origin of prolapse should be determined. With a half-speculum blade, the posterior vaginal wall is retracted; the patient is asked to strain while the anterior defect is evaluated. An isolated central defect is identified as bulging in the central region of the vagina (midline) with loss of vaginal rugae. However, in older patients, loss of vaginal rugae alone can be caused by smooth muscle atrophy of the vaginal wall. A lateral defect is identified by loss of the lateral vaginal sulci as the vesicopelvic fascia attenuates from the arcus tendineus fascia pelvis. There will be loss of the "M" vaginal profile (coronal view) and sliding herniation of the bladder into the vagina. After the anatomic defects have been characterized, it is important to reduce the cystocele in order to elicit occult stress urinary incontinence and hypermobility. Similarly, we retract the anterior vaginal wall to determine the presence of any posterior defect. A digital rectal examination assesses rectal tone, presence of impacted stool, attenuation of the prerectal fascia, and perineal laxity. With the use of both blades of speculum, the vaginal vault or cervix can be examined for uterine descent, vault prolapse, and enterocele.

The ICS approved the POPQ validated system for describing pelvic organ support.<sup>1</sup> Six points (two on the anterior vaginal wall, two in the superior vagina, and two on the posterior vaginal wall) are located with reference to the plane of the hymen. The system assigns negative numbers (in centimeters) to structures that have not prolapsed beyond the hymen and positive numbers to structures that protrude. With specific reference to the anterior compartment, point Aa is located in the midline of the anterior vaginal wall, 3cm proximal to the external urethral meatus. Point Ba represents the most dependent position of any part of the upper anterior vaginal wall, from the vaginal cuff or fornix to point Aa. Point C represents either the most distal edge of the cervix or the leading edge of the vaginal cuff after total hysterectomy. This system allows objective and reproducible documentation of the degree of prolapse.

### Imaging Studies

In the setting of a large introital bulge, it may be difficult to differentiate between a severe cystocele, an enterocele, and a high rectocele by physical examination only.<sup>16</sup> Imaging studies should be done to specifically identify which organs are prolapsing. An ideal imaging study should provide precise information about which structures are prolapsed, the presence of urinary retention and obstruction, urethral hypermobility, and urinary incontinence.

#### *Cystourethrography*

For a cystourethrogram, the patient should be upright with a full bladder. Films should be taken during both rest and strain. This examination provides information about bladder position, bladder neck funneling, urethral mobility, stress incontinence, and postvoid residual volumes. The presence of a rectocele can also be inferred if bowel gas is identified below the pubic symphysis. This examination is static and does not provide information about other pelvic organs or soft tissues of the pelvic floor.

#### *Dynamic Fluoroscopy*

Dynamic fluoroscopy (colpocystodefecography, vaginography) relies on making the organs of interest (bladder, vagina, rectum) radiopaque and studying their positional changes with straining under fluoroscopy. This is a dynamic examination done with the patient upright. Standing recreates the setting in which the patient experiences maximal vaginal bulging. For this procedure, contrast paste must be placed into the vagina and rectum, which can be uncomfortable. Vaginography and defecography are little used now, given the increasing experience and precision of magnetic resonance imaging (MRI).

#### *Ultrasonography*

Ultrasound is an attractive imaging modality because it is easy to perform, is minimally invasive, and avoids radiation exposure. Tubo-ovarian and renal disease can also be assessed during the same examination. There is evidence that ultrasound is useful in evaluating bladder neck hypermobility; however, transvaginal imaging for pelvic prolapse does not provide adequate visualization of the soft tissues.<sup>17</sup> Translabial ultrasound can be used to quantify prolapse, although it appears to be better for the anterior compartment and uterine descent than for the posterior compartment.<sup>18</sup> This is not an imaging modality often used for prolapse.

### Dynamic Magnetic Resonance Imaging

MRI is becoming a standard in the evaluation of pelvic prolapse. It is performed quickly, without contrast or ionizing radiation, and permits visualization of the soft tissues as well as the upper urinary tract. Gousse and colleagues<sup>30</sup> showed that, in comparison with findings at surgery, MRI had 100% sensitivity, 83% specificity, and a positive predictive value of 97% in assessing cystoceles. Compared with colposcystodefecography, MRI does not require intravesical catheterization, does not require contrast, is fast, and is noninvasive. The drawback is that MRI may underestimate the extent of cystocele and enterocele, because the examination must be performed with the patient in the supine position, which diminishes the downward forces that can be generated with abdominal straining.<sup>19,20</sup> Standing MRI is the ultimate modality in obtaining an even more precise study for prolapse.

### Videourodynamics

A urodynamic study can be done with or without video assistance. Both methods provide information about bladder compliance, capacity, sensation of filling, detrusor instability, and contractility. An advantage in performing videourodynamics is the additional information gained in terms of anatomy by monitoring the position and funneling of the bladder neck during filling and straining. The choice to use fluoroscopy should be based on cost, availability, and familiarity with this method.

The importance of documenting the presence of urinary incontinence in patients with large cystoceles is controversial. The incidence of occult stress urinary incontinence is believed to be as high as 22% to 80% among patients with high-stage vaginal vault prolapse.<sup>21</sup> Because of the frequent masked urinary incontinence and the high incidence of postoperative de novo stress incontinence, many surgeons routinely perform a concomitant anti-incontinence procedure along with anterior vaginal reconstruction, independent of the continence status. A study by Barnes and colleagues<sup>22</sup> retrospectively reviewed the charts of 38 women who had grade 3/4 prolapse without significant symptoms of stress incontinence. None of the patients demonstrated stress incontinence during physical examination or videourodynamics studies until the prolapse was mechanically reduced. All patients subsequently had documented stress incontinence, with a mean abdominal leak point pressure of 86 cm H<sub>2</sub>O. All patients then underwent surgical repair of the prolapse with placement of a pubovaginal sling. None of the patients developed permanent retention. Recurrent stress incontinence occurred in 5% of the patients. On the other hand, Chaikin and colleagues<sup>23</sup> evaluated 24 “continent” women with severe cystocele. They used a pessary to reduce the cystocele during urodynamic studies and documented incontinence in only 58% of patients. The patients with overt incontinence received an anti-incontinence procedure, and the others did not. With a mean follow-up of 47 months, none of the patients treated only by colporrhaphy developed incontinence. The authors recommended concomitant anti-incontinence procedures only for patients with overt leakage (after the cystocele is reduced). To improve the sensitivity of the urodynamic test to reveal urinary incontinence, a pessary or vaginal pack can be used to reduce the cystocele.<sup>24,25</sup> However, if there is significant pelvic floor relaxation, a pessary may not be able to prevent the prolapse, and it can cause artificial urethral kinking. Additionally, there is no proven correlation between pessary reduction and the reduction obtained with surgery.

Therefore, the results of urodynamic testing with a pessary in place cannot be equated with the urinary symptoms after the surgical repair.

Determining the presence of bladder instability is important in preoperative counseling, because it can affect the postoperative result. In most cases (60% to 80%), urgency resolves after surgery.<sup>26</sup> However, some patients have no change in urgency or a worsening of their urgency with sling placement and/or bladder neck elevation. Urodynamic studies may also suggest urinary obstruction with elevated voiding pressure, low urinary flow, or radiographic evidence of urethral kinking.

### Cystourethroscopy

Cystourethroscopy is performed to rule out concurrent intraurethral or intravesical pathology such as bladder carcinoma, urethral diverticulum, stones, or foreign bodies (i.e., suture material) from previous surgery. Cystoscopic illumination can also be used to differentiate an enterocele from a cystocele.<sup>27</sup> A pelvic examination is performed with the cystoscope in the bladder. The bladder transilluminates through the anterior vaginal wall so that the extent of the bladder prolapse is demarcated. We assess bladder neck competence both at rest and during straining. Cystourethroscopy can also be used as a bedside urodynamic examination, assessing filling sensation, postvoid residual volume, and visual cystometrics for bladder contractions. With a full bladder, a supine Valsalva stress test can be performed, looking for urethral leakage.

### Upper Urinary Tract Evaluation

Patients with a stage 4 cystocele should have upper tract imaging, because there is a 4% to 7% incidence of moderate hydronephrosis among patients with severe vaginal prolapse.<sup>28,29</sup> This risk is greater in patients with procidentia than in those with vault prolapse. Ultrasonography, excretory urography, computed tomography, or MRI may be used. An advantage of MRI is the ability to evaluate the upper urinary tract, tubo-ovarian disease, and pelvic organ prolapse simultaneously.

### Laboratory Evaluations

Patients must have sterile urine before proceeding with an operative procedure. In preparation for surgery, we routinely obtain a complete blood count, basic metabolic panel, and coagulation profile in addition to the urine culture.

### SURGICAL REPAIR

The goal of repair is to restore pelvic anatomic support of the anterior vaginal wall. This is rarely an independent surgery. Often, surgery entails addressing incontinence as well as prolapse of the uterus and posterior compartment. The end result must restore anatomy and function by restoring the normal vaginal axis and depth and preserving urinary, bowel, and sexual function. It must be kept in mind that anatomy does not always correlate with function.

Treatment of high-grade or symptomatic cystocele must address all defects of the pelvic floor. In the anterior compartment, we must correct urethral hypermobility as well as weakness of lateral bladder support (paravaginal), perivesical fascia (central), and the cardinal-sacrouterine ligament complex.

### Transvaginal Paravaginal Repair

This technique simultaneously repairs the four defects present in patients with significant cystocele: support of the hypermobile urethra by a sling procedure, approximation of the cardinal ligaments back to the midline to form the most proximal support of the bladder, repair of the central defect by approximation of the perivesical fascia to the midline, and correction of the lateral defect by support of the bladder neck and bladder base to the obturator fascia using polypropylene mesh. The infralevator obturator “fascia” as it condenses on the pubic bone is the basis of our vaginal paravaginal defect repair; it acts as an immobile structure to secure the mesh. If only the central defect repair is performed, the cystocele may recur (due to the lack of lateral support), and de novo incontinence may ensue because of a poorly supported and hypermobile urethra. On the other hand, if only a bladder neck suspension or plication procedure is performed without correction of the cystocele, the patient may develop aggravation of the prolapse, obstructive symptoms, and urinary retention.

As mentioned, a distal urethral sling is always performed concomitantly with a stage 4 cystocele repair. The sling is placed before the cystocele repair, and the details are described in a separate chapter. Here, we concentrate on the steps of the cystocele repair. If total vaginal prolapse was present, the order of repair would be as follows: transvaginal hysterectomy, vault suspension sutures placed, enterocele repair with pursestring sutures, sling, cystocele repair, vault sutures tied, and rectocele repair.

1. Preparation includes creation of a 1 × 10 cm Prolene mesh sling and a 5 × 5 cm round Prolene mesh disc. Labial sutures are placed, and the weighted speculum is inserted. A suprapubic cystostomy tube and urethral catheter are placed. The bladder is emptied. A ring retractor with multiple hooks is used for additional exposure.
2. A vertical incision is made from the bladder neck to the vaginal cuff. The incision should be superficial enough to avoid bladder perforation but deep enough to expose the perivesical fascia.
3. The vaginal wall is dissected to expose the bladder and proximal urethra. The dissection is carried out in the avascular plane between the vaginal wall and the bladder, *laterally* toward the lateral pelvic wall and obturator fascia and *posteriorly* to expose the cardinal ligaments. The lateral dissection need only extend so far as make it easy to palpate the inferior ramus.
4. A figure-of-eight 2-0 Vicryl suture is applied to the cardinal ligaments to approximate them to the midline. The sutures are not tied at this time. The needle is left attached to the suture and will be used to anchor the mesh later. Intravenous injection of indigo carmine (5 mL) is given at this time, followed by a bolus of 500 mL saline.
5. Interrupted horizontal mattress sutures of 3-0 Vicryl are applied to plicate the attenuated perivesical and periurethral fascia to the midline (anterior colporrhaphy). The sutures are placed superficially but incorporate a wide segment of the perivesical fascia. Deep placement of the sutures should be avoided, to prevent bladder injury or ureteric obstruction. This is not the strength of the central repair but rather facilitates reduction of the defect.
6. Cystoscopy is performed to confirm that the suprapubic tube is in place, the bladder is free of injury, and the ureters excrete indigo-stained urine.
7. The bladder is retracted laterally, using the back of forceps, to facilitate placement of a 2-0 Vicryl suture (CT 1 needle) in the obturator fascia on each side. The key is to palpate the inferior ramus, then place the suture just over the periosteum, taking a strong bite of the infralevator obturator fascia. A strong tug on the suture ensures secure placement. We have found this to be a reliable, strong, nonmobile anchor. Check to make sure the suture was not placed through the vaginal flap.
8. The circular 5 × 5 cm mesh is now used to cover the perivesical fascia and secure the repair. The already placed obturator fascial sutures are used to fix the mesh laterally. Posteriorly, the mesh is fixed to the cardinal ligaments using the previously placed midline suture. Distally, two simple interrupted sutures of 3-0 Vicryl are used to secure the mesh on each side of the bladder neck, taking strong bites of the perivesical fascia. The mesh is trimmed as needed to ensure taut positioning.
9. The excess vaginal wall is trimmed and closed without tension using multiple runs of 3-0 Vicryl. A vaginal packing soaked in antibiotic cream is inserted. No urethral catheter is placed.

### Postoperative Care

The antibiotic-soaked vaginal pack is kept in place until discharge. Most patients go home after 24 hours of observation. The suprapubic tube is capped and attempts at voiding are instituted before discharge. Patients are instructed in the use of the suprapubic catheter to check postvoid residuals at home. Most patients void within 24 hours, so the placement of a suprapubic tube or urethral catheter (and possible preoperative teaching of intermittent catheterization) is the surgeon’s preference. We do keep the suprapubic catheter in place for at least 1 week to minimize possible urinary extravasation with its removal.

### RESULTS

Our early series of 94 consecutive patients with stage 4 cystocele repair showed cure or improvement of the anatomic prolapse in 82% of patients. The range of follow-up was 8 to 22 months. The complication rate was 8%. There was transient retention in two patients and de novo urinary incontinence in 4% of the patients. Although no patient developed recurrent high-grade cystocele, two patients developed mild grade 2 cystoceles. No complications related directly to the mesh were seen; specifically, there were no erosions or graft infections. There have been no cases of permanent urinary retention to date.

### CONCLUSION

Armed with a fundamental grasp of the anatomy and pathophysiology of pelvic support, one can more effectively address patients with deficiencies in pelvic support and appropriately apply the current methods of evaluation and treatment discussed in other chapters of this book.

# CYSTOCELE REPAIR USING BIOLOGIC MATERIAL

*George D. Webster and Neil D. Sherman*

A variety of surgical options are available to the reconstructive surgeon for treatment of anterior vaginal wall prolapse. The traditional surgical approach for cystocele repair is anterior colporrhaphy with plication of the pubocervical fascia. Despite an increased knowledge of pelvic anatomy and advances in surgical techniques, success is variable, and recurrence rates vary from 20% to 40%.<sup>1</sup> Recent literature has suggested that the interposition of graft material over the fascial defect to repair both central and lateral defects of the anterior vaginal wall may increase the success rate of surgery. The purpose of the graft is to allow for replacement or regeneration of fascia by providing a matrix into which in-growth of support tissue will occur.<sup>2</sup> A variety of graft materials are available for such pelvic floor reconstruction.

The properties of an ideal implant (graft material) were described by Cumberland<sup>3</sup> and Scales<sup>4</sup> more than 50 years ago, and the principles remain true today. These characteristics include the proposal that the implant should be elastic or supple, should be easily tailored, and it should have good tensile strength. Additionally, the implant should cause minimal foreign body reaction and allow for good tissue incorporation and collagen in-growth while promoting permanent tissue repair. Finally, the graft must be tolerated in an infected environment and cause minimal wound complications.

To date, the graft that meets all of the above criteria remains elusive. Currently available grafts are most easily classified as biologic or synthetic. Biologic grafts can be further described as autologous, allograft (cadaveric fascia and dermis), or xenograft (e.g., porcine dermis, porcine small intestine submucosa). Synthetic grafts and some biologic biomaterials are discussed elsewhere in the text; this chapter discusses the use of dermal allografts and xenografts for the treatment of anterior vaginal wall prolapse.

### BIOMATERIALS

The United States National Institutes of Health (NIH) defines a biomaterial as “any substance (other than a drug) or a combination of substances, synthetic or natural in origin, which can be used for any period of time, as a whole or a part of a system which treats, augments, or replaces any tissue, organ, or function of the body.”<sup>5</sup> Currently, there are five types of biomaterials being used in the medical environment: polymers (i.e., in catheters), composites, metals and alloys, ceramics, and biologic materials.<sup>6</sup> Each material offers unique capabilities and advantages based on its composition, its architecture, and whether it is biodegradable.

The concern over possible costly litigation resulted in a worldwide shortage of biomaterials in the mid-1990s. In response, the

Biomaterials Access Assurance Act was passed by the U.S. Congress in July 1998 to provide some protection to manufacturers as well as encourage development of new materials.<sup>6</sup> In the United States, the Food and Drug Administration (FDA) regulates medical devices, but not biomaterials, unless they are a component of a medical device. In Europe, any device or apparatus intended for human use is required to have a CE mark, indicating that safety and performance criteria have been met for a particular indication.<sup>7</sup>

Although most would agree that the ideal biomaterial should be reproducible, biocompatible, biodegradable, and nontoxic, less is understood about the properties required to facilitate the colonization and integration of cells into a functional tissue.<sup>8</sup> A principal factor in the success of a new material is its ability to perform with an appropriate host response in a specific application (i.e., its tissue biocompatibility). Tissue reactions to implanted materials vary widely, and the response determines to a great extent whether the material will be biocompatible.<sup>9</sup>

In the urologic and urogynecologic community, there are a broad range of uses for biomaterials. Biomaterials are used in artificial urinary sphincters, in testicular and penile prostheses, and as injectables for stress incontinence. Additionally, they can be used for the restoration of function or structure (i.e., grafts for Peyronie’s disease, bladder augmentation) and for reinforcement of the vaginal wall in prolapse/reconstructive procedures.<sup>7</sup>

The most commonly used natural materials available for prolapse repair include autograft (rectus fascia), allograft (cadaveric fascia), and xenografts. Xenografts may be either nonabsorbable (i.e., Pelvicol) or absorbable collagen (small intestine submucosa [SIS]).

### NONABSORBABLE PORCINE COLLAGEN

Pelvicol (C.R. Bard, Covington, GA) is the most frequently researched and implanted xenograft collagen. It was developed at the University of Dundee in the United Kingdom and was designed for permanent implantation in humans for use in pubovaginal slings, vaginal wall repair, cystoplasty, and phalloplasty.<sup>7</sup> Pelvicol was licensed for use in Europe in 1998 and received approval from the U.S. FDA in 2000. When the tissue is used for applications outside urology and urogynecology, it is distributed under the name Permacol. Porcine collagen is 95% homologous to human collagen, and it appears to provide a strong, nonallergenic scaffold for human tissue growth.<sup>10</sup>

Pelvicol is derived from porcine dermis. A patented process removes all fats and cellular materials, including cells, cell components, and nucleic acids, through a series of organic and enzy-

matic extractions that leave the material without any DNA.<sup>11,12</sup> The final stage of the processing involves stabilizing the matrix with an approved cross-linking agent to maintain strength and provide permanence. Gamma sterilization of the tissue ensures sterility.

Originally, the grafts were cross-linked with glutaraldehyde. However, this agent was associated with significant calcifications,<sup>13</sup> so now diisocyanate, which has less graft mineralization, is used as the cross-linking agent.<sup>10,14</sup> Ultimately, this final product is a piece of fibrous, acellular, cross-linked porcine dermal collagen that is nonallergenic, is nontoxic, and does not elicit a foreign body response.<sup>15</sup> Also, the resulting material conserves the original three-dimensional architecture of the collagen matrix with a small amount of elastin.<sup>12</sup>

The treated tissue is free of DNA remnants as well as foot and mouth disease,<sup>16</sup> and the manufacturing process has been demonstrated to remove the viral and bacteriologic load from Pelvicol implants. Reoviruses are reduced by more than 12 logs and porcine parvoviruses by 6.7 logs, levels that are acceptable to both the FDA and the European United (EU) regulatory authorities.<sup>17</sup> Once implanted in to human tissue, the implant has been shown to be a biocompatible, sterile, and strong biologic matrix that is permanently incorporated into the host tissue.<sup>15</sup> The graft is available in several sizes depending on its clinical use.

There are other nonabsorbable xenograft collagens produced by other companies, but, as of this publication, human use of these grafts has not been reported. One such graft, Cytrix Soft Tissue Repair Matrix (TEI Biosciences, Boston, MA) is a bovine dermis that does not undergo cross-linking.<sup>18</sup> Whether this difference in processing alters graft strength remains to be seen. In a rat model, Rosenblatt showed that this graft was populated by host fibroblasts and a supporting vasculature. Over 15 months, the implant collagen was remodeled and replaced by the host into collagen that repaired the iatrogenic muscle defect.<sup>18</sup>

### Fate of the Graft: Porcine Collagen

Although rejection of porcine dermis has not been reported, case studies suggest an unpredictable tissue response once the graft is implanted. Cole identified a completely encapsulated porcine dermis sling during urethrolysis at 6 months after surgery. Grossly, the sling was intact, and histologically, it was acellular and did not show evidence of human tissue proliferation.<sup>19</sup> Salomon and associates reported on 1 patient who underwent exploratory surgery 1 year after implantation of a transobturator Pelvicol graft for cystocele repair. At the time of surgery, there was no inflammation around the graft which was easily freed from surrounding tissues. Histologic evaluation showed colonization by fibroblasts and blood vessels with minimal inflammatory response.<sup>17</sup>

Gandhi and colleagues reviewed the tissue specimens of seven patients with a prior porcine dermal sling and found limited collagen remodeling and evidence of a foreign body-type reaction in patients with postoperative retention. In cases of recurrent stress incontinence, implants appeared to be completely replaced by dense fibroconnective tissue and moderate neovascularization without evidence of inflammation or graft remnants. The authors concluded that this variable tissue reaction raises questions of tolerability and efficacy and may contribute to unpredictable clinical outcomes.<sup>20</sup>

After implantation, there is a migration of cells, in-growth of tissue, neovascularization, and collagen formation in and around

the graft. Although it is unclear what the ultimate biomechanical properties will be like once the graft is implanted, some researchers believe that this connective tissue surrounding the implant adds to its strength.<sup>21</sup>

On the other hand, Dora and coworkers demonstrated in a rat model that porcine dermis and porcine SIS show a marked decrease in tensile strength and stiffness after being implanted for 12 weeks on the abdominal rectus fascia.<sup>22</sup> Whether this mechanical change is of clinical significance remains unknown. In still another animal study, Macleod and colleagues evaluated Permacol 20 weeks after implantation in the Sprague-Dawley rat. Although the graft maintained its thickness over the 20 weeks, there was a decrease in mean collagen density. These findings suggest an overall loss of collagen over the 20 weeks.<sup>9</sup>

Although it appears that there is not one specific factor that is paramount for porcine dermis graft success, attempts have been made to evaluate the integral pieces necessary for success. One belief is that the graft relies, to some degree, on its capacity to be colonized by host cells, and when recurrence occurs, it may be because of compromised native tissue and vascularity contributing to poor graft behavior.<sup>23</sup> In another evaluation of the tissue, Boon and coworkers implanted the graft subcutaneously in a rat model and found minimal fibroblast in-growth into cross-linked collagen. They suggested that cross-linked collagen may be considered for use in situations where neither incorporation nor dissolution of the biomaterial is desired.<sup>24</sup> Others have also seen a low inflammatory response to the Pelvicol.<sup>21</sup> This "tolerance" may contribute to a more ordered deposition of collagen,<sup>21</sup> perhaps allowing the graft to behave similar to autologous tissue.

With respect to vaginal examination after porcine dermis implantation, we are in agreement with the assessment by others that the Pelvicol implant is difficult to palpate postoperatively, whereas that is not always true with some mesh materials.<sup>2</sup> Additionally, there is minimal to no shrinkage of the material, a key factor in sexually active women and in those with preoperative vaginal stenosis.

Some authors have shown that perforating the porcine dermis improves the graft take and decreases wound infections by allowing for increased tissue in-growth and revascularization of the vaginal epithelium overlying the graft. Tensile strength and suture pull-out strength were maintained in the perforated graft.<sup>25</sup>

### RESULTS: PORCINE COLLAGEN

Long-term data for porcine dermis in cystocele repair are generally lacking, but early results are promising (Table 65-1). De Ridder compared the Raz classic cystocele repair using polyglactin mesh with a modified Raz technique using a Pelvicol implant as an overlay graft material. Follow-up was only 9.3 months, but there were no recurrences or erosions in the Pelvicol group.<sup>2</sup> Fischer used Pelvicol implant for cystocele repair in 14 patients, for rectocele repair in 80 patients, and for combined repair in 10 patients.<sup>26</sup> With follow-up of at least 6 months, there were no cases of extrusion, recurrence, shrinkage, induration, dyspareunia, or urgency-frequency syndrome. Gomelsky used porcine dermis for cystocele repairs with and without anti-incontinence surgery or vault suspension in 70 patients. With follow-up of at

Study (Ref. No.)	N	Follow-up (Mo)	Objective Cure	Recurrence	Adverse Events	Implant Trade Name
De Ridder (2)	28	9.3		None	No erosions	Pelvicol
Fischer (26)	104	>6		Not provided	No extrusion	
Gomelsky et al (10)	70	24		8.6% grade 2, 4.3% grade 3	Superficial wound separation treated conservatively (1 case)	Intexen
Leboeuf et al (23)		15	93%	6.9% (2 pts grade 2, 1 pt grade 3)	4.7% postoperative retention; 11.7% de novo urge incontinence	Pelvicol
Steinberg et al (27)	81	8.5	69%	26% first degree (Baden-Walker); 4.9% second degree	Each preoperative stage of prolapse showed significant improvement postoperatively	Porcine dermis (company not stated)
Salomon et al (17)	27	14	81%	1 pt stage 1, 4 pts stage 2; all pts had stage 3 or 4 preoperatively	Placed via transobturator approach, combined with bilateral sacrospinous fixation; 1 graft removed because of pain at transfixing vaginal stitch	Pelvicol
Ruparelia et al (29)	48	20	85% pt satisfaction rate, 78% symptomatic improvement	2% reoperation rate	2 wound breakdowns	Pelvicol
Kocjancic et al (30)	79	6.5	73% optimal anatomic outcomes		2 poor wound healing managed as outpatient; no graft infection/rejection	Pelvicol
Verleyen et al (31)		8		1 pt stage 1	No infection, erosion, or rejection	Pelvicol
Graul et al (32)	37	6			1 expulsion; 1 small graft erosion	Pelvicol
Flam (33)	59			None	24% anaerobic infection	Pelvicol
Paparella et al (34)	45			1 pt stage 2	No infection, erosion, or rejection	Pelvicol
Cervigni et al (35)		8.8	68% anatomic cure		1 erosion	

pt, patient; pts, patients.

least 12 months, 9 patients (12.9%) had asymptomatic recurrent cystoceles that were managed conservatively.<sup>10</sup> Steinberg used a 6 × 12 cm trapezoid piece of porcine dermis to perform vaginal paravaginal repair. When patients were analyzed stage for stage, there was a statistically significant improvement from preoperative to postoperative stage of prolapse.<sup>27</sup>

Besides anatomic improvement with the use of a graft, Sundar showed that the use of porcine collagen provides a significant overall improvement in quality of life.<sup>28</sup>

### SMALL INTESTINE SUBMUCOSA

SIS is harvested from porcine jejunum and is composed of the stratum compactum of the tunica mucosa, the tunica muscularis mucosa, and the tunica submucosa.<sup>9</sup> Processing leaves the extracellular collagen matrix intact, thus allowing the presence of collagen, growth factors, glycosaminoglycans, proteoglycans, and glycoproteins to promote host cell proliferation through SIS layers.<sup>36</sup> Theoretically, the SIS scaffold should be entirely remod-

eled and replaced by the host's connective tissue in 90 days.<sup>37</sup> SIS for pelvic reconstruction is currently available in 1-ply and 4-ply sheets for prolapse repairs (SurgiSIS and SurgiSIS ES, Cook Inc., Bloomington, IN).

To date, there are few published data available on the use of porcine SIS for the treatment of pelvic organ prolapse. In one small human study, eight patients underwent SurgiSIS-augmented vaginal prolapse surgery. At follow-up, there was adequate support of the vaginal wall, and symptom scores showed improvement.<sup>38</sup> Although the database for pelvic reconstruction is small, SIS has been used as a pubovaginal sling<sup>39,40</sup> and for the treatment of abdominal wall hernias, where it was effective in both clean and clean-contaminated repairs.<sup>41</sup>

As with other biologic materials, *in vivo* human studies for prolapse repair are lacking. Therefore, response of the implant in this application must be extrapolated from its use in pubovaginal sling surgery. In three humans requiring exploration after SIS pubovaginal sling placement, Weidemann and Otto found minimal SIS implant and no inflammatory or foreign body reaction.<sup>42</sup> These results were in stark contrast to the significant inflammatory reaction found after an 8-ply SIS graft was placed as a sling.<sup>43,44</sup> In an attempt to limit the inflammatory response, modifications to the graft and instructions for its use have been made.

A number of animal studies evaluating SIS have been performed. Other authors have used a rat model to show that SIS initially shows a moderate degree of chronic inflammation that falls to minimal levels in a 20-week period of implantation.<sup>9</sup>

In a rabbit model, porcine SIS was shown to decrease in surface area by 41%.<sup>22</sup> The clinical implications for this finding with respect to anterior vaginal wall repair were not expanded on and in reality are unknown.

In a canine model, a piece of SIS was used to replace a portion of bladder wall. Immunohistochemical examination of the regenerated bladder at 15 months showed normal histology (epithelium, muscle, and serosa) and presence of nerves and other constituents (calcitonin gene-related peptide and substance P immunoreactive nerve fibers). Of note, *in vitro* testing of the new bladder wall for compliance and contractility showed it to be similar in function to the original bladder wall. To date, there have been no clinical trials.<sup>45</sup> It remains to be seen how this knowledge can be incorporated into the use of SIS for the generation of a graft for prolapse repair.

Using a rabbit model, Claerhout and colleagues evaluated various materials including SIS and Pelvicol in abdominal wall defects. By 3 months, the SIS appeared as a thin, almost transparent membrane. For SIS, the point of weakness was determined

to be the material itself, whereas for Pelvicol the maximum point of weakness was the interface between graft and native tissue.<sup>46</sup>

## HUMAN DERMIS

The most common cadaveric dermis used in pelvic reconstructive surgery is AlloDerm (LifeCell Corp, Branchburg, NJ); DuraDerm (C.R. Bard Inc, Murray Hill, NJ) has less information for prolapse repair available.<sup>47</sup> Cadaveric dermis is an acellular and immunologically inert biologic biomaterial that works by acting as a biologic scaffold for tissue remodeling.<sup>48</sup> Graft preparation involves decellularization to remove the epidermis and dermis while preserving the basement membrane complex.<sup>49</sup> The graft then undergoes freeze-drying such that the collagen, elastin, and proteoglycans are maintained.<sup>48</sup> The biomechanical properties of dermal grafts have been shown to be similar to those of autologous rectus fascia and solvent-dehydrated cadaveric fascia.<sup>50</sup>

Although intact DNA has been found in acellular cadaveric dermis,<sup>51</sup> it has not been associated with disease transmission in recipients. The American Association of Tissue Banks is the organization responsible for maintaining screening and procurement standards.

Dermal allograft has been used for many different surgical procedures,<sup>52,53</sup> including pelvic floor reconstruction.<sup>54-57</sup> One potential benefit of the tissue is its ability to maintain elasticity. However, it remains unclear whether this characteristic prevents recurrence by allowing the vaginal wall to stretch with Valsalva maneuvers and then return to its original position, or whether the elasticity contributes to failure because it may be stretched too far.<sup>57</sup> Histologically, it appears that dermal allograft completely incorporates into the host fibromuscular layer, with no significant inflammation and no identifiable graft 2 years after implantation.<sup>58</sup> Variations in processing may affect success rates with cadaveric fascia, but studies with cadaveric dermis are lacking.<sup>59</sup> If complications such as graft extrusion occur, they can be managed conservatively with topical estrogen cream.<sup>60</sup>

Human studies for anterior wall reconstruction are limited; results are shown in Table 65-2.

## BOVINE PERICARDIUM

Experience with bovine pericardium for cystocele repair is extremely limited, and indeed, in our opinion, very suspect. McLennan used this graft in 61 patients undergoing vaginal paravaginal repair. With a mean follow-up of 7.25 months, 6.5% of

**Table 65-2 Results of Cadaveric Dermal Graft for the Treatment of Anterior Vaginal Wall Prolapse**

Study (Ref. No.)	N	Follow-up (Mo)	Outcome	Complications
Jelovsek et al (54)	9	18.4	44% stage 0-1	20% site granulation tissue (includes posterior repairs)
Chung et al (55)	19	28	16% objective failure	
Clemonset al (57)	33	18	41% objective failures (stage >2); 3% subjective failures	No erosion/rejection
Graul & Hurst (61)	67	10.2	2 failures defined as stage 2 or greater	1 erosion treated conservatively; 1 graft expulsion

patients had a stage 2 or greater anterior wall prolapse. There were no cases of graft erosion, and the authors noted that by 6 weeks vaginal tissue was supple and normal.<sup>62</sup> However, when bovine pericardium was used for pubovaginal sling procedures, the rate of erosion was much more significant.<sup>63,64</sup>

## SURGICAL TECHNIQUE

Surgery is performed with the patient under either general or spinal anesthesia. Sequential compression devices are placed preoperatively, and prophylactic antibiotic coverage is given on call to the operating room. The patient is placed in dorsal lithotomy position with Allen stirrups.

Concomitant procedures such as a hysterectomy or pubovaginal sling can be performed at the same sitting. Usually, prolapse repair is completed before anti-incontinence surgery or rectocele repair and after hysterectomy. If the patient has had a prior hysterectomy, the uterosacral ligaments are sutured and tagged for easier identification. The vaginal epithelium is injected with 0.25% Marcaine. Incision of the vaginal epithelium is usually in the midline. Lateral vaginal flaps are elevated superficial to the pubocervical fascia, all the way to the obturator fascia laterally and the uterosacral/cardinal ligaments proximally. The endopelvic fascia is perforated, and dissection is carried into the space of Retzius bilaterally. The arcus tendineus fascia pelvis is identified laterally where it attaches to the obturator internus fascia.

The native fascia may be brought together in the midline with absorbable or nonabsorbable suture depending on surgeon preference. The graft is prepared on the back table according to the manufacturer's recommendations and then brought into the vagina and trimmed to an appropriate size. Initial tapering should err on the large side so as not to foreshorten the graft. The graft is secured to the vaginal cuff and uterosacral ligaments proxi-

mally at the vaginal apex and then laterally to the obturator fascia, using interrupted 2-0 polyglycolic acid suture. Distally, the graft should be affixed to the arcus or the fascia overlying the inferior ramus of the pubis at the level of the bladder neck. Tailoring of the graft shape is accomplished as the graft fixation progresses distally. Copious antibiotic irrigation may be used throughout the procedure. Cystoscopy is performed to confirm integrity of the bladder and ureters.

After the graft has been secured in place, redundant vaginal epithelium is trimmed, and the vaginal wall is closed with interrupted absorbable suture. If an anti-incontinence procedure is necessary, it may be performed at this time via a separate incision.

## CONCLUSION

Biologic biomaterials may have a valuable role in reconstructive procedures for anterior vaginal wall prolapse. When graft material is required, the surgeon must identify the positive properties of each option and determine the most appropriate material for the individual patient. Future technologic advancements may one day provide the ideal graft material that meets all the necessary criteria for long-term durability and success.

## Disclaimer

The authors have been asked to review the use of particular biologic materials in the repair of anterior vaginal wall defects and to provide comment. This does not represent endorsement of use of such materials, and it should be stated that "the jury is still out" regarding the optimal approach and materials one should use to enhance the success of repairs of the anterior vaginal compartment.

# TENSION-FREE CYSTOCELE REPAIR USING PROLENE MESH

*Mauro Cervigni and Franca Natale*

Pelvic organ prolapse (POP) is one of the emerging problems in women, considering the aging population in Western countries together with already known risk factors such as race, genetic predisposition, pregnancy, parity, obstetric trauma, menopause, and previous gynecologic surgery. Among these factors, certainly white Caucasian women have a higher odds ratio (1.0) with respect to African American and Hispanic women (0.6 and 1.2, respectively).<sup>1</sup>

Considering the different segments involved in the development of POP, the anterior vaginal wall, and in particular the bladder, represented the site most frequently affected in a study of 27,000 American women; the posterior segment (rectocele) was present in 19%, and uterine prolapse in 14%.<sup>1</sup>

Mant and colleagues, in 1997, studied a group of 17,000 women and observed that the incidence of anterior colporrhaphy was 37%, compared with a 24% rate of vaginal hysterectomy.<sup>2</sup>

Numerous surgical procedures have been proposed in the last century to correct all types of anterior vaginal wall defects (central, paravaginal, combined), using either an abdominal or vaginal approach. Despite improved understanding of pelvic anatomy and organ function and the advancement of surgical techniques, the long-term success rate is still variable. Recurrence rates for the various surgical procedures used to treat anterior vaginal prolapse range from 3%<sup>3</sup> to 20%<sup>4</sup> after single anterior colporrhaphy, from 22%<sup>5</sup> to 92%<sup>6</sup> if the anterior colporrhaphy is combined with other procedures (sacrospinous ligament suspension), from 2%<sup>7</sup> to 59%<sup>8</sup> after four-corner suspension, and from 5%<sup>9</sup> to 50%<sup>10</sup> after vaginal paravaginal repair. The reasons for such discrepancies are several and include poor patient selection, sub-optimal surgical technique, inappropriate choice of suture material, and persistence of predisposing risk factors for prolapse (constipation, chronic respiratory disease).<sup>11</sup> Moreover, Farrell and colleagues emphasized that the very existence of the pubocervical fascia used during anterior colporrhaphy is doubtful. They observed in samples obtained during surgical procedures for the correction of anterior defect that the so-called fascia is adequately identified only 58% of the time and concluded that this finding calls into question techniques that rely on isolated fascia for the repair of anterior and posterior defects.<sup>12</sup>

In addition, recent information on the biochemical and ultra-structural composition of the connective tissue of the pelvic floor has provided new insight into its role in stabilization of the pelvic organs and in the healing processes after surgery.

### EVOLUTION OF SURGICAL PROCEDURES

In the last 20 years, the repair of anterior vaginal wall prolapse has shifted from a classic anterior repair to a more detailed surgi-

cal procedure (site-specific repair) with an attempt to identify the precise localization of the tissue defect. For example, Richardson and associates proposed the vaginal paravaginal repair using native tissues to restore the anatomy.<sup>13</sup> These concepts were further explored in surgery of the posterior compartment. However, despite encouraging results, the anterior segment (i.e., the connective tissue supporting the bladder) remained the site of least durability.<sup>14,15</sup>

Moreover, the rate of complications was not insignificant (11% ureteral occlusion), and the conclusions of Barber and Bump were that a correct vaginal reconstruction is best accomplished in women with severe stress conditions (severe constipation, chronic pulmonary disease, occupation and recreational straining, severe compromise of pelvic floor neuromuscular function) with techniques that do not rely solely on the patient's native tissue for support and that this is often achieved with the use of synthetic mesh or tissue graft substitution.

### CONNECTIVE TISSUE AND ITS ROLE IN THE PELVIC FLOOR

Connective tissue is analogous to a fiber-reinforced composite, containing fibrous elements (collagen and elastin) and a visco-elastic matrix including proteoglycans (large polysaccharides attached to proteins). The cells in the connective tissues, which form about 20% of the tissue volume, are embedded in the extracellular matrix. The biomechanical properties of a soft tissue are determined by the various extracellular matrix components. Collagen, which accounts for a large proportion of tissue strength, is a protein produced by fibroblasts with a specific pattern that is remarkable for its consistency. The amino acid glycine allows collagen to form a tight helix, one of its important attributes. Two other amino acids are present in its structure, namely proline and hydroxyproline. These amino acids form cross-links that stabilize the collagen chains. The collagen fibers responsible for the tensile strength of the tissue are a family of 16 different types distributed in different parts of the body. Of these, type I (the most common and strongest) and type III (smaller and randomly organized with type I), are found in tissue that requires strength and flexibility.

Elastin and laminin are two other glycoproteins that may play a role in elasticity of the ground substance. Elastin provides the ability of a tissue to be stretched and is found not only in the bladder as a component of compliance but also in the urethra. Elastin is degraded by elastase, which is part of a protease-antiprotease control mechanism found in the plasma. It has recently been demonstrated that there is an increase in the percentage activity of elastase in women with stress urinary inconti-

nence (SUI) compared with aged-matched controls.<sup>16</sup> Several factors, such as age, stress, hormones, and growth factors, are involved in the regulation of connective tissue metabolism.<sup>17</sup>

Collagen turnover slows down with increasing age, and the concentration increases after menopause.<sup>18-21</sup> The changes during menopause seem to generate a connective tissue with a higher collagen concentration but with alterations in cross-linking,<sup>22</sup> and there is also an increase in fibril diameter in the cardinal and uterosacral ligament in patients with POP and SUI. This produces a tissue with an increased load-bearing ability but decreased elasticity.<sup>23</sup> Based on biochemical assays, Sayer and colleagues<sup>24</sup> reported modification of cross-linking in women with bladder neck prolapse and SUI. A reduction of collagen in the pubocervical fascia<sup>25</sup> and in nonsupportive pelvic tissue has also been observed.<sup>26</sup> Recent studies indicate that women of fertile age with SUI demonstrate changes in the extracellular matrix of the paraurethral connective tissue resulting in a stiffer and less supportive connective tissue and a defect in the connective tissue glue.<sup>27-30</sup> In women with genital prolapse after menopause, there seems to be a difference in collagen metabolism suggesting a change in the degradation of collagen related to matrix metalloproteinases and with a significant reduction in the ratio of type I to type III collagen.<sup>31</sup> Therefore, it is not the amount of collagen but the amount of fresh elastic collagen that is important for the mechanical strength of supporting fascia layers.

#### HEALING PROCESS AFTER SURGICAL REPAIR

When a wound is created, such as an anterior vaginal wall and pubocervical fascia incision, fibrous protein synthesis and remodeling reestablish tissue strength. Collagen is a central factor in wound healing. The first day after injury, immature fibroblasts synthesize and secrete collagen and proteoglycans. A weaker and more elastic flexible type III collagen is the principal type found in early wounds. After 2 weeks, the majority of regenerated tissue is composed of type III collagen, which accounts for only 7% of its final tensile strength. With maturation of the scar, a stronger type I gradually replaces the type III collagen. In this way, an organized cross-linked pattern regains some tensile strength, but the new tissue is never as strong as the original tissue.<sup>32</sup> The factors that influence healing and scar maturation are still incompletely understood, even though we know that the gene for type III collagen seems to be activated more than the gene for type I collagen.<sup>33</sup>

Elastin is a protein that the body does not seem to be able to synthesize and remodel, as it does collagen. Lack of elastin and high amounts of the less strong type III collagen may explain why new scars lack strength and elasticity.

#### WHAT HAPPENS WHEN A MESH IS IMPLANTED IN THE BODY

When a graft is introduced into a biologic tissue, there is a strong immediate (antibody-mediated) foreign body reaction, followed by blood flow increase, temperature rise, macrophage migration, and attempted phagocytosis of the foreign body. The graft incorporation process includes a cascade of events: first, there is a rapid activation of polymorphonuclear cells and macrophages; 60 hours later, there is fibroblast proliferation with a subsequent slow phenomenon of fibroplasia and blood vessel proliferation

**Figure 66-1** In-growth of tissue in mesh implants. PMN, polymorphonuclear cells.

(angiogenesis) with in-growth of capillaries. These modifications lead to synthesis of collagen and then to maturation of these new fibers (cross-linking).

These events happen as a result of the interaction between the graft materials (biologic or synthetic) and the tissue interface, which is of prime importance; for this reason, we need to reduce the intensity and time of the inflammatory period, in particular with regard to reducing potential complications (erosion and extrusion) (Fig. 66-1).

Once the prosthetic material has been implanted, there are four types of tissue reactions: minimal response with a thin layer of fibrosis around the implant; chemical response with a severe and chronic inflammatory reaction around the implant; physical response with an inflammatory reaction to certain materials and the presence of giant cells; and necrotic tissue, a layer of necrotic debris produced as a result of in situ exothermic polymerization.<sup>34</sup>

#### WHAT MATERIALS ARE CURRENTLY AVAILABLE FOR THE SURGICAL REINFORCEMENT OF PELVIC TISSUE?

The following materials are currently available for the surgical reinforcement of pelvic tissue: synthetic material, which acts as a substitute for natural tissue; autograft, which is tissue obtained from another area of the patient's body; allograft, which is tissue obtained from a human donor; and acellular collagen matrix, such as dermal (skin) tissue from pigs.

#### PROPERTIES OF SYNTHETIC BIOMATERIALS

*Biocompatibility* is the capability of a material to provoke a favorable reaction when introduced into a living system. Consequently, a biomaterial is any material, natural or man-made, or any biomedical device that performs, augments, or replaces a natural function. One definition of biocompatibility is "the utopian state where a biomaterial presents an interface with a physiologic environment without the material adversely affecting that environment or the environment adversely affecting the material." The biomaterials employed can come close to this utopian state, but we must accept compromises between the

Figure 66-2 Type I synthetic mesh: monofilament polypropylene.

Figure 66-3 Type I synthetic mesh: Marlex.

benefits and the undesired reactions caused to the living system by the material.

Cumberland<sup>35</sup> and Scales<sup>36</sup> delineated a series of properties of an “ideal” synthetic biocompatible materials:

- Chemically and physically inert
- Noncarcinogenic
- Mechanically strong
- Does not cause allergic or inflammatory reactions
- Can be sterilized
- No physical modification by body tissue
- Convenient and affordable format for clinical use

At the present time none of the synthetic meshes meet all of these criteria.

Although from the chemical point of view all of the synthetic meshes are completely biocompatible, some physical and structural properties of the prosthesis are associated with certain complications. Prevention of biomaterial-related complications requires a profound knowledge of the physical properties of prostheses, of which the *porosity* (*pore size*) of the materials are of paramount importance.

Based on their pore size, the most common synthetic meshes can be classified into four types:

*Type I:* totally macroporous materials such as Atrium, Marlex, Prolene, and Trelex. These meshes contain pores larger than 75  $\mu\text{m}$  (microns), which is the required size for admission of macrophages, fibroblasts (fibroplasia), blood vessels (angiogenesis), and collagen fibers into the pores (Figs. 66-2 and 66-3).<sup>37,38</sup>

*Type II:* totally microporous materials such as expanded polytetrafluoroethylene (PTFE; Gore-Tex), Surgical Membrane, and Dual-mesh. These meshes contain pores smaller than 10  $\mu\text{m}$  in at least one of their three dimensions (Fig. 66-4).

*Type III:* macroporous materials with multifilamentous or microporous components, such as PTFE mesh (Teflon), braided Dacron mesh (Mersilene), braided polypropylene mesh (Surgipro), and perforated PTFE patch (MycroMesh) (Figs. 66-5 and 66-6).

Figure 66-4 Type II synthetic mesh: Gore-Tex (expanded PTFE).

Figure 66-5 Type III synthetic mesh: polytetrafluoroethylene (PTFE).

*Type IV*: biomaterials with submicronic pore size, such as Silastic, Cellgard (polypropylene sheeting), Preclude Pericardial membrane, and Preclude Dura-substitute.

Another important property is the *composition of fibers* (Table 66-1). Polypropylene meshes are monofilaments, whereas the other commonly used meshes are multifilaments. One theoretical disadvantage of multifilament meshes is that the interstices are smaller than 10  $\mu\text{m}$ ; this allows small bacteria to infiltrate and proliferate, but macrophages and neutrophilic granulocytes that could eliminate the bacteria are too large to enter a 10- $\mu\text{m}$  tridimensional pore.<sup>39-41</sup> In addition, because of their wide pores, type I materials (but not types II and III) allow rapid in-growth of vascularized fibrous tissue, as was demonstrated by Chvapil and colleagues<sup>42</sup>; this leads to fibroplasia and angiogenesis, which not only prevent infection but also form fibrous connections to the surrounding tissue. Therefore, pore size is a key factor in determining inflammatory response and the growth of fibrocollagenous tissue.

*Flexibility* or *stiffness* is another important property that appears to be related to pore size. Marlex has higher flexural rigidity (stiffness) than Mersilene or Teflon. Marlex is also shown to wrinkle more than Mersilene. Prolene is composed of knitted filaments of polypropylene, as is Marlex; however, it has a pore size twice as large as that of Marlex (1500 versus 600  $\mu\text{m}$ ) and therefore is more flexible.<sup>43</sup> Because of this property, Prolene seems to have a lower erosion rate through the vagina and adja-

cent viscera, but up to now there are insufficient data to prove it. Atrium mesh, because of its intermediate pore size (800  $\mu\text{m}$ ), is more pliable and thinner than Marlex or Prolene. Table 66-2 reports data about mean stiffness and mean peak load of the main synthetic materials.

### COMPLICATIONS OF SYNTHETIC MATERIALS

Biomaterial-related complications frequently encountered are infection and sinus tract formation, seroma, intestinal adhesion, erosion and fistula formation, and shrinkage.

Infection and sinus tract formation is caused by infiltration and proliferation of bacteria; it is frequently due to the use of multifilamentous suture materials for fixation of the mesh, although it may be mistaken as being caused by the mesh itself.<sup>44-46</sup> The reported infection rate ranges from 9.6% to 50% in type II/III prostheses,<sup>47,48</sup> whereas in type I it has never been reported. More important, with type I mesh, infection may be managed simply by drainage of the infected area, followed by local wound care.<sup>49-51</sup> On the contrary, total removal of type II and at least partial removal of type III is required to manage infection.

Prosthetic-related seroma formation is caused by the host inflammatory reaction to the prosthesis and by the dead space created between the artificial mesh and host tissue. Types I and III allow a rapid penetration of host proteinaceous materials into their pores,<sup>52</sup> with rapid fibrinous fixation. Therefore, the chance of seroma formation is minimized.<sup>53</sup> Type II, because of its inadequate pore size, has a higher rate of seroma formation ranging, from 9.6% to 14.6%.

At the present time, all available artificial meshes, absorbable or nonabsorbable, adhere to the intestine.<sup>54-56</sup> Covering the mesh on its intestinal side with a layer of absorbable material such as Vycril or expanded-PTFE patch partially solves this problem. Composites that combine type I and type IV mesh can prevent these complications.

A dangerous side-effect is erosion or migration of the artificial mesh when it is in direct contact with organs that do not have a serosal covering, such as rectum, bladder, and the intestinal tract.

Contraction of the mesh fibers during the scarring process leads to shrinkage of the mesh by approximately 20% compared to the original shape.

Table 66-3 shows the main complications related to each type of mesh.

Figure 66-6 Type III synthetic mesh: multifilament mesh.

Table 66-1 Composition and Types of Fibers

Chemical Component	Trade Name (Manufacturer)	Type
Polypropylene	Marlex (CR Bard, Branston, RI)	Monofilament
	Prolene (Ethicon, Somerville, NJ)	Monofilament
	Atrium (Atrium Medical, Hudson, NH)	Monofilament
Polytetrafluoroethylene (PTFE)	Teflon (CR Bard, Haverhill, MA)	Multifilament
	Gore-Tex (WL Gore, Flagstaff, AZ)	Multifilament
Polyethylene tetraphthalate	Mersilene (Ethicon, Somerville, NJ)	Multifilament
Polyglycolic acid	Dexon (absorbable) (Davis and Geck, American Cyanamid, Danbury, CT)	Multifilament
Polyglactin 910	Vicryl (absorbable) (Ethicon, Somerville, NJ)	Multifilament

## TECHNIQUES

### The Pioneers

A recent metaanalysis of the European Union Hernia Trialists Collaboration compared mesh versus nonmesh methods of open groin hernia repair in 4005 patients. They concluded that mesh repair was associated with fewer recurrences (1.4% versus 4.4%;  $P < .001$ ). This concept, using synthetic mesh applied “tension-free,” and the long-term successful outcome incited researchers to transfer an analogous rationale to pelvic surgery.

Therefore, surgeons, in the early fifties, introduced synthetic materials to correct the anatomic position of the visceral organs in the pelvic cavity. In 1955, tantalum mesh was used to reinforce tissues in patients with POP.<sup>57</sup> In 1970, collagen mesh was proposed for the treatment of pelvic descensus.<sup>58</sup> The “fashion” for using polypropylene to repair prolapse started in 1992, with the first published data on Marlex appearing in 1996.<sup>59</sup>

### Evolving Concepts

The goal of prosthetic surgery, compared with site-specific autologous tissue repair, is to replace the damaged visceral fascia, restoring cohesion between visceral and parietal fascia and rebuilding the hammock connected to the arcus tendineus fascia pelvis (ATFP), thus respecting the bladder neck and stabilizing the bladder hammock. Initial experience used an overlaid synthetic mesh reinforcing a traditional anterior colporrhaphy.<sup>60</sup> Meanwhile, the new concept of transvaginal suspension of pelvic floor repair was introduced by the four-corner suspension.<sup>7</sup> The

**Figure 66-7** Tension-free cystocele repair.

evolution of this technique included a prosthetic reinforcement of the central segment, using a mesh applied with a double-needle suspension.<sup>61</sup>

The new “tension-free” concept acquired by general surgeons in treating abdominal hernia and the *revolution* in the treatment of female SUI brought about by the tension-free vaginal tape (TVT) were translated into POP repair. A new proposal was developed that used a Prolene mesh applied below the bladder inserted “tension-free” without any fixation.<sup>62</sup> Since then, other authors have proposed various transvaginal “tension-free” mesh repairs.<sup>63-65</sup>

In 2001, a new approach, using the transobturator route, was proposed to treat SUI patients in the same tension-free manner as TVT.<sup>66</sup> The excellent preliminary results incited the development of a wider concept of transperineal pelvic floor repair.<sup>67-69</sup> Therefore, studies employing larger meshes covering all the pelvic defects, using Prolene material (soft or traditional) applied “tension-free,” extended to stronger pelvic structures: transobturator foramina and sacrospinous ligaments.

### The Italian Experience

In 1998, Cervigni and coworkers developed a tension-free cystocele repair (TCR) technique applying a traditional Prolene mesh below the bladder with two wings inserted paraurethally without any fixation.<sup>62</sup> The rationale of this technique was to use a wider mesh to cover all the bladder, avoiding any specific site defect evaluation, to reinforce pubocervical and endopelvic fascia. Because the mesh is applied tension-free, there is a reduction of anatomic distortion, which reduces future sequelae in the other vaginal segments (Fig. 66-7).

Nicita published a Prolene technique mesh repair that was anchored with stitches to the arcus tendineus levator ani and sacrospinous ligaments with a central hole to allow a pelvic reconstruction with the uterus in situ.<sup>70</sup> Migliari and Usai, using the Raz concepts, developed a four-corner suspension using a Prolene mesh to reinforce a central defect.<sup>61</sup>

### The Australian Experience

In 1990, Petros and Ulmsten published the *Integral Theory* to explain the mechanism of incontinence and other pelvic dysfunction.<sup>71</sup> They postulated that all pelvic floor defects start from fascial, ligamentous, and muscular deficiency. There are forward forces (pubococcygeus and puborectalis muscles) and backward/downward forces (levator plate and ileococcygeus muscles) that could be impaired. A new surgical proposal based on this concept, developed by Farnsworth, uses a Prolene mesh with the aim to restore the normal anatomy by a complete prosthetic fascial substitution.<sup>72</sup> The mesh is sutured tension-free in the normal anatomic insertion of the native fascia, restoring the three levels of vaginal support described by DeLancey.<sup>73</sup>

### The French Experience

In 2000, a group of nine surgeons developed a transvaginal POP repair using Prolene soft, a wide mesh with four arms introduced into the transobturator canal for the anterior compartment and two arms transfixing the sacrospinous ligaments for the posterior compartment, which they inserted tension-free with the straps transferred using a long curved needle without any fixation. To reduce the risk of shrinkage, they put the four arms at the more distal part of the ATFP, and to avoid the risk of erosion, they used midline colectomy instead of a “T” incision and the vaginal wall is not trimmed.<sup>74</sup> A different approach, called the “triple perineal operation,” used posterior IVS for the suspension of the vaginal vault; an interposition of mesh in the vesicovaginal space for the correction of cystocele, fixed posteriorly to the cervix; and a third mesh in the rectovaginal space to treat rectocele, fixed to the posterior IVS and distally to the fibrous central nucleus of the perineum.<sup>75</sup>

## THE NEW TRANSOBTURATOR CYSTOCELE REPAIR

Transobturator cystocele repair can be accomplished in several ways. With the transvaginal mesh repair (TVM), Prolene soft (Gynemesh) is delivered with the use of a single, reusable, long curved needle and anchored with low tension (friction) in a Velcro effect. The mesh is placed tension-free in the vesicovaginal space, the space of Retzius, and the paravesical space. The two superficial and two deeper arms are positioned apically and distally at the ATFP (Fig. 66-8).

With the Perigee transobturator repair system, polypropylene is delivered with the use of four Deschamps nonreusable needles connected with a special connector. A low-tension (friction) anchoring system is used (Velcro effect). The mesh is applied tension-free in the vesicovaginal space, the space of Retzius, and the paravesical space. The two superficial and two deeper arms are positioned apically and distally at the ATFP (Fig. 66-9).

The Avaulta system uses polypropylene covered by collagen in the central part. This is positioned like the Perigee and TVM systems, with the use of a single, reusable curved needle (Fig. 66-10).

## TRANSVAGINAL MESH CYSTOCELE REPAIR

In 1996, Julian first published a study assessing the efficacy and complications of Marlex mesh in repairing severe recurrent ante-

rior vaginal wall prolapse.<sup>59</sup> Twenty-four patients entered the study and were divided into control and treatment groups. Transvaginal repair was similar between groups except for reinforcement of the anterior vaginal wall with synthetic mesh. After 2 years, four patients in the control group and none in the treatment group had recurrent anterior vaginal wall prolapse ( $P < .05$ ). A similar technique was carried out by Flood and colleague in a more consistent group of patients.<sup>60</sup> They obtained the same cure rate of prolapse with a longer follow-up; there was also a concomitant treatment of SUI in 74% of their patients. Mage<sup>76</sup> had the same results using a polyester mesh sutured to the vaginal angles. Migliari and Usai applied the same principle, using mixed fiber mesh to correct grade 4 cystocele; the mesh was positioned during a modified four-corner procedure.<sup>61</sup> With this technique, there was no recurrence of cystocele except in 1 patient, and 13 of 15 patients were continent.

Nicita proposed a new method to support female prolapsed pelvic organs, using a hammock-shaped Prolene mesh anchored transversally between the two arcus tendineous portions of the endopelvic fascia and between the bladder and uterine neck.<sup>70</sup> He treated 44 patients presenting with various degrees of incontinence and combinations of cystocele and pelvic prolapse. All patients affected by incontinence or vaginal prolapse were satisfied; uterine prolapse partially recurred in three patients.

Another original technique, the TCR, was proposed by Cervigni and associates in 1998. This approach uses a Prolene mesh in a double wing shape applied without sutures between the pubocervical fascia and vagina. The procedure was carried out in 138 women; after a mean follow-up of 18 months, there was a complete anatomic recovery in 135 patients (97.8%).<sup>77</sup> In a further experience with a longer follow-up, the success rate (cystocele grade <2, Baden-Walker classification) was 15.9%, and only six cases of recurrent cystocele (2.1%) were symptomatic. Erosion appeared in 7.3%. Quality of life was improved.<sup>78</sup> The results are reported in Table 66-4.

Table 66-5 shows the preliminary results of the use of transobturator mesh in the treatment of anterior vaginal vault prolapse.

## EVIDENCE-BASED MEDICINE

In the Third International Consultation on Incontinence, held in June 2004, the 17th Committee on Prolapse Repair summarized the evidence regarding the use of mesh in prolapse repair as follows:

- Level II:* Transvaginal placement of permanent mesh may reduce anterior wall recurrence but has an unacceptably high rate of complications that include erosion, infection, sepsis, dyspareunia, and other functional symptoms.
- Level III:* Transvaginal placement of biologic graft may reduce anterior prolapse recurrence rates, although the evidence is conflicting.

Research recommendations were as follows:

- Grade B:* Transvaginal permanent grafts for prolapse repair have a poor risk-benefit ratio; therefore, use of these materials should occur only in approved clinical trials.
- Grade D:* There is no evidence to support the routine use of biologic or permanent synthetic grafts for transvaginal POP repair.

A

C

SS = sacrospinous ligament

ATFP = arcus tendineus fascia pelvis

anterior TVM

posterior TVM

B

Two research priorities were identified. First, techniques to reduce recurrence rates, especially in the anterior wall, are urgently needed. Second, clinical trials are needed to establish the need for ancillary transvaginal material in POP repairs.<sup>79</sup>

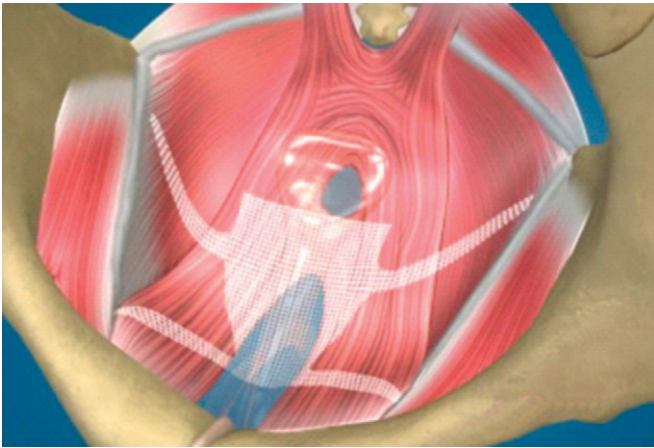

## CONCLUSIONS

The pelvic surgeon, in the past and in some instances up till now, has preferred choosing a weakened and damaged autologous tissue to treat pelvic floor defects, fearing the related complications of the use of synthetics, including foreign body reaction, infection, rejection, and erosion. In the last few years there has been an explosion in the use of prosthetic materials in the surgical approach to POP repair, stimulated either by apparent simplicity and feasibility of the new kits or by surgeon demand in order to approach complex POP cases in a more straightforward manner.

Figure 66-8 A through C, Tension-free vaginal mesh repair (TVM).

The first series of transvaginal mesh cystocele repair was promising, with low rates of recurrence and mesh erosion, even though complications occurred later. Although, up to now, no case of bladder erosion has been reported after transvaginal cystocele repair with mesh, the complications and related dysfunctional problems are not completely solved. The request of symptomatic POP patients is mainly to obtain a solution of their symptoms, because they have a strong impact on the patient's quality of life. In this sense, the more cautious recommendations proposed by Third International Consultation on Incontinence aim to reduce as much as possible any avoidable complications while maintaining reliable and long-term results.

The ideal synthetic materials for pelvic surgery have yet to be identified, but new knowledge of molecular biology will contribute to the definition of new materials, improving the management of POP and related dysfunction. Tissue engineering, at the moment one of the more promising of new medical fields, should in the near future respond to patient demands to resolve the problem without any bothersome complications.

# SACROSPINOUS LIGAMENT SUSPENSION FOR VAGINAL VAULT PROLAPSE

*Sylvia M. Botros, Roger P. Goldberg, and Peter K. Sand*

Several techniques are used for suspension of the vaginal vault, including the sacrospinous vaginal vault suspension, abdominal sacrocolpopexy, bilateral uterosacral vaginal vault suspension, McCall culdoplasty, iliococcygeus vault suspension, levator myorrhaphy, and many tension-free mesh techniques. The optimal surgical approach for advanced prolapse of the vaginal apex remains a subject of debate and is not well studied. Some surgeons prefer the abdominal route for younger women with advanced prolapse; however, these women are at increased risk for morbidity from the surgery, subsequent volvulus from abdominal adhesions, and foreign body reactions due to graft materials. Other surgeons prefer the vaginal route to decrease postoperative pain and morbidity and for women who are at increased operative risk.

What constitutes success or failure is not delineated in the literature, partly because indications for prolapse surgery are not uniform and the degree and site of prolapse are not always clearly defined. The Pelvic Organ Support Study (POSST) was a multicenter, observational study of 1004 women between the ages of 18 and 83 years that evaluated the prevalence of pelvic organ prolapse in a general gynecologic office setting. The investigators found that 24% of the women had stage 0 prolapse, 38% had stage I, 35% had stage II, and 2% had stage III.<sup>1</sup> The prevalent findings of stage II prolapse suggest that a stage II recurrence may not necessarily represent an anatomic failure after reconstructive pelvic surgery. These data support the need for the evaluation of anatomic and functional outcomes. According to some surgeons, the correction of all anatomic defects and restoration of normal anatomy should be the overarching goal. Others regard a compensatory postoperative anatomy as acceptable and perhaps even preferable in certain cases to achieve long-term functional outcomes with minimal risk of recurrent or de novo prolapse.

Sacrospinous vaginal vault suspension has the advantage of a transvaginal approach performed within the retroperitoneal space, with relatively limited dissection beyond that needed for transvaginal enterocele, rectocele, and cystocele repair. Advocates of the vaginal route argue that sacrospinous vaginal vault suspensions are fast, safe, less costly, require a shorter recovery period, lack an abdominal incision, and avoid the use of a graft. Ideally, to achieve optimal outcomes for each patient, the reconstructive surgeon should maintain a high level of skill with several techniques and tailor surgery to the individual patient.

## HISTORY

The vaginal vault suspension was first described in 1892 by Zweifel,<sup>2</sup> who tried to suspend the vaginal vault to the sacrotuberous ligament. Richter and Albrich<sup>3</sup> later described successful application of this procedure. Nichols introduced the operation to the United States in 1971.<sup>4</sup>

Several modifications of the sacrospinous vaginal vault suspension have been described. The original technique described by Nichols involves suspension of the vaginal vault to the sacrospinous ligament through the posterior compartment. A modification of this technique was introduced by Winkler and colleagues<sup>5</sup> in 2000, suspending the vault to the sacrospinous ligament through the anterior compartment. This technique was developed to address the limitations of the posterior sacrospinous vault suspension by reducing postoperative proximal vaginal narrowing and lateral deviation of the upper vagina.<sup>6</sup> In 2003, Kearney and DeLancey<sup>7</sup> described the Michigan four-wall sacrospinous suspension, which suspends four points of the open vaginal apex to the sacrospinous ligament. The excess vagina is removed to avoid laxity in the anterior and posterior wall.<sup>7</sup> In 1993, Kovac and Cruikshank<sup>8</sup> described successful outcomes, even after childbirth, with sacrospinous hysteropexy, in which the uterus was suspended bilaterally to the sacrospinous ligaments.

## UNILATERAL AND BILATERAL SACROSPINOUS LIGAMENT SUSPENSIONS

The anterior and posterior sacrospinous suspensions can be performed unilaterally or bilaterally; the right-sided unilateral suspension is most commonly performed. Performing the procedure on the patient's right side provides an anatomic advantage resulting from the absence of the sigmoid colon on the right. A mechanical advantage exists for right-hand-dominant surgeons as well.

Bilateral suspension has been emphasized in earlier reports.<sup>3,9</sup> Pohl and Frattarelli<sup>10</sup> reported no recurrent apical prolapse among 40 women treated with bilateral sacrospinous ligament suspension after 6 to 40 months of follow-up. Cespedes<sup>11</sup> reported good success after bilateral sacrospinous fixation by the anterior vaginal approach; at 17 months, no recurrent vault prolapse was

seen in 27 of 28 women with grade 3 or 4 prolapse. However, there is little evidence to suggest that bilateral suspension improves outcomes compared with the unilateral approach.<sup>12</sup> Moreover, compared with the unilateral sacrospinous ligament suspension, the bilateral procedure entails more extensive dissection and requires generous width at the vaginal apex to avoid causing tension between fixation points. Because of these additional challenges and its lack of clear advantage, the bilateral technique is used far less often than unilateral fixation in post-hysterectomy vault prolapse.

## INDICATIONS

The most common indication for sacrospinous ligament vaginal vault suspension is resuspending a symptomatic prolapsed post-hysterectomy vaginal apex. The incidence of post-hysterectomy vault prolapse requiring surgery has been estimated at 3.6 per 1000 years.<sup>13</sup> The risk increases from 1% to 5% 15 years after hysterectomy. The risk also increases for women who had prolapse as the primary indication for their initial surgery.<sup>14,15</sup> For women with pelvic ligaments and connective tissue supports that are severely attenuated or absent, the sacrospinous ligament provides a consistent and strong site for apical fixation. Sacrospinous ligament fixation may be performed at the time of hysterectomy in cases of severe apical prolapse if the uterosacral ligaments are attenuated. The use of the sacrospinous ligament fixation prophylactically at the time of hysterectomy, however, is not widely accepted. Surgeons argue that there is an increase in time and morbidity associated with the procedure, which may not be warranted by the outcomes compared with resuspension using the uterosacral ligaments. Cruikshank and Cox<sup>16</sup> performed sacrospinous suspensions at the time of hysterectomy on 48 of 135 women without apparent excess in morbidity. In contrast, Colombo and Milani<sup>17</sup> retrospectively compared 62 women who underwent sacrospinous vaginal vault suspensions with 62 women who underwent McCall culdoplasty during vaginal hysterectomy and pelvic reconstruction operations and found significant increases in operative time and blood loss in the sacrospinous group. The rate of recurrent vault prolapse was similar for the two groups.<sup>17</sup>

Another indication for sacrospinous suspension occurs when women desire to preserve fertility or preserve the uterus. It may also be used to decrease operative time and morbidity in elderly patients who have no evidence of endometrial hyperplasia or cancer. There is an increasing body of evidence that uterine hysteropexy may be just as effective as vaginal hysterectomy for recurrent prolapse. Sacrospinous ligament uterine suspension has been successfully used for women with symptomatic uterovaginal prolapse.<sup>8,18,19</sup>

Kovac and Cruikshank<sup>8</sup> evaluated 19 women (average age, 27 years) who underwent uterine-sparing sacrospinous ligament suspension and reported that 4 of 5 women subsequently had successful pregnancies and vaginal deliveries without recurrent apical prolapse. Hefni and colleagues<sup>18</sup> evaluated 109 women (61 with uterine suspension and 48 with vaginal hysterectomy and concomitant sacrospinous suspension). The mean age of these cohorts was 60 years, and after a mean follow-up period of 34 months, success rates were comparable with regard to vault prolapse and cystocele recurrences. They found significantly less blood loss, shorter operative time, and fewer complications with uterine preservation.<sup>18</sup> Maher and coworkers<sup>19</sup> retrospec-

tively compared 34 women with sacrospinous ligament hysteropexy with 36 women with hysterectomy and sacrospinous vaginal vault suspension for symptomatic uterine prolapse. The mean follow-up was 36 months for the hysterectomy group and 26 months for the hysteropexy group. Subjective and objective success rates were similar, and they found a significant reduction in operative time and blood loss with uterine preservation.<sup>19</sup>

The sacrospinous hysteropexy entails fixation of the distal uterosacral ligaments and paracervical tissue to the sacrospinous ligament. Bilateral rather than unilateral suspension was performed in 15 of the 19 subjects in Cruikshank's series to avoid lateral deviation of the uterus and any adverse effect it might have on reproductive capacity.<sup>8</sup> Alternatively, Hefni and associates<sup>18</sup> performed all of their hysteropexies unilaterally.

## ANATOMY

The sacrospinous ligament is an excellent support structure for the apex of the vagina. In 1992, DeLancey<sup>20</sup> described the anatomic aspects of vaginal eversion after hysterectomy and found that the structures supporting the vagina could be divided into three levels, primarily vertical in orientation. The first level of support, which is suspensory in nature, occurs in the upper vagina adjacent to the cervix and is suspended above by long connective tissue fibers.<sup>20</sup> These suspension points should lift the apex of the vagina to the level of or above the ischial spine. These apical or level I vaginal supports are increasingly recognized as a critical component in overall pelvic floor support.<sup>21</sup> Loss of level I support can occur after abdominal or vaginal hysterectomy in as many as 2% to 45% of patients due to failure to resuspend the vaginal cuff to the uterosacral ligaments. Resulting vaginal vault prolapse can occur with or without an enterocele.<sup>21,22</sup> The sacrospinous ligament provides a good option for level I support.

A good understanding of the anatomy of the sacrospinous ligament helps to minimize complications at the time of surgery. Few structures are at risk for injury in a correctly performed procedure. The sacrospinous ligament attaches laterally to the ischial spine and medially to the lateral margins of the sacrum and coccyx.<sup>23</sup> The pudendal nerve leaves the pelvis through the greater sciatic foramen, medial to the sciatic nerve and internal pudendal vessel, between the piriformis and coccygeus muscles and passes under the sacrospinous ligament close to its attachment to the ischial spine.<sup>24</sup> Verdeja found that the pudendal neurovascular bundle ranges from 0.90 to 1.30 cm medial to the ischial spine; the sciatic nerve is located 3.10 to 3.30 cm medial to the spine.<sup>25</sup> Based on these anatomic relationships, neurovascular injury seems most likely along the lateral third of the sacrospinous ligament when suturing. Another series of cadaver dissections, performed by Barksdale and colleagues,<sup>26</sup> showed the pudendal neurovascular bundle to be relatively shielded from injury by the ischial spine and sacrospinous ligament. The inferior gluteal artery—with a more perpendicular course relative to the ligament—was the vascular structure whose location appeared most vulnerable to injury. These researchers referred to three elements of the operation that may carry particular risk: suture placement along the posterior ligament, retractor placement beyond the ligament, and overly aggressive denuding of the ligament surface.<sup>26</sup>

## PREOPERATIVE AND PERIOPERATIVE CONSIDERATIONS

The decision about which suspension procedure to perform must be individualized for every patient. The patient's age, medical history, sexual activity, specific anatomic features, prior and concomitant pelvic surgical procedures, and personal wishes for future fertility or preservation of the uterus should be taken into consideration when planning the procedure. For a patient with significant medical comorbidities, a vaginal surgical approach may benefit the patient over a procedure that would require an abdominal incision or a prolonged laparoscopic operation. For women with prior intra-abdominal surgery, pelvic adhesions, or other contraindications to abdominal surgery, the fully retroperitoneal nature of a sacrospinous vaginal vault suspension may confer advantages with respect to surgical risk, operative time, and speed of recovery. After a vaginal approach is decided on, the type of vaginal suspension should be chosen from the available options. The sacrospinous vaginal vault suspension has been studied extensively and is a reliable and safe procedure for the repair of post-hysterectomy vault prolapse.

If the patient is not sexually active, is elderly, has already failed a pelvic reconstructive procedure, or has multiple medical comorbidities and is a poor surgical candidate, an obliterative procedure such as the LeFort colpocleisis may be suitable. Alternatively, a sacrospinous vaginal vault suspension may be done under local anesthesia.

Richardson<sup>27</sup> has described site-specific defects in the endopelvic fascia in the anterior, posterior, and apical vaginal wall as the anatomic basis for cystocele, rectocele, and enterocele, respectively. He believed that the surgeon should be able to recognize and repair all existing pelvic floor support defects at the time of surgery. He described the post-hysterectomy enterocele as a defect in the endopelvic fascia at the vaginal apex due to failure to reconstitute pubocervical and rectovaginal fascia in this region. This allows small bowel and peritoneum to herniate into the rectovaginal septum and come in direct contact with vaginal epithelium without intervening muscle or fascia.<sup>21,27</sup> An unrecognized enterocele is often to blame for the rare case of recurrent apical prolapse after sacrospinous vaginal vault suspension. Cruikshank and Muniz<sup>28</sup> suggested the importance of the site-specific repair in a longitudinal study of 695 patients who underwent sacrospinous vaginal vault suspensions over a 16-year period. Their cohort was divided into three groups. The first group, treated between 1985 and 1990, had only sacrospinous suspensions with or without a hysterectomy ( $n = 173$ ); the second group, treated between 1991 and 1994, had anterior and posterior colporrhaphies and high cul-de-sac closures performed concomitantly with the sacrospinous suspensions ( $n = 221$ ); and the third group, treated between 1995 and 2000, had a more inclusive, site-specific approach with the suspensions ( $n = 301$ ). Recurrence rates dropped significantly between the first and third groups, with the third group having the highest success rates.<sup>28</sup> Appropriate patient selection and flexibility in the operating room can maximize the odds of success.

Preoperative evaluation should include assessment of bony and soft tissue pelvic anatomy. Markedly foreshortened bony pelvic dimensions, such as a true platypoid pelvis, may limit the surgeon's ability to preserve adequate vaginal length and weigh against the choice of sacrospinous suspension for sexually active patients. When considering soft tissue, the length of the vaginal vault should be sufficient to avoid tension after sacrospinous

fixation, which may predispose to suture pullout, anatomic distortion, and possibly unmasking potential urinary incontinence due to posterior displacement of the urethra from the pubic bone.<sup>29</sup> In the absence of adequate length, operative revision of the cuff or suspension to a more anterior or distal structure, such as iliococcygeus fascia, may be performed.<sup>30</sup> Consideration of concomitant sacrospinous vaginal suspension on the right, with an iliococcygeal suspension on the left at a slightly more distal point, may lead to improved apical support and diameter.

Preoperative planning should include assessment of estrogen status for postmenopausal women and consideration of local estrogen therapy before surgery if the vaginal cuff epithelium appears thin or poorly vascularized. Estrogen improves vaginal vascularization, epithelial thickness, and collagen in the connective tissue.<sup>31</sup> A well-estrogenized vaginal epithelium can facilitate healing at the site of suture fixation and reduce the likelihood of subsequent surgical failure resulting from suture pullout from the vaginal side.

Prophylactic antibiotics should be given 30 minutes before the first incision. In the operating room, the patient should be placed in the dorsal lithotomy position. Appropriate positioning is essential to avoid neurologic injury that can result from improper positioning. An examination under anesthesia should be performed to assess the pelvis, the true extent of vault prolapse, the length of the vagina, and the site of apical suture placement.

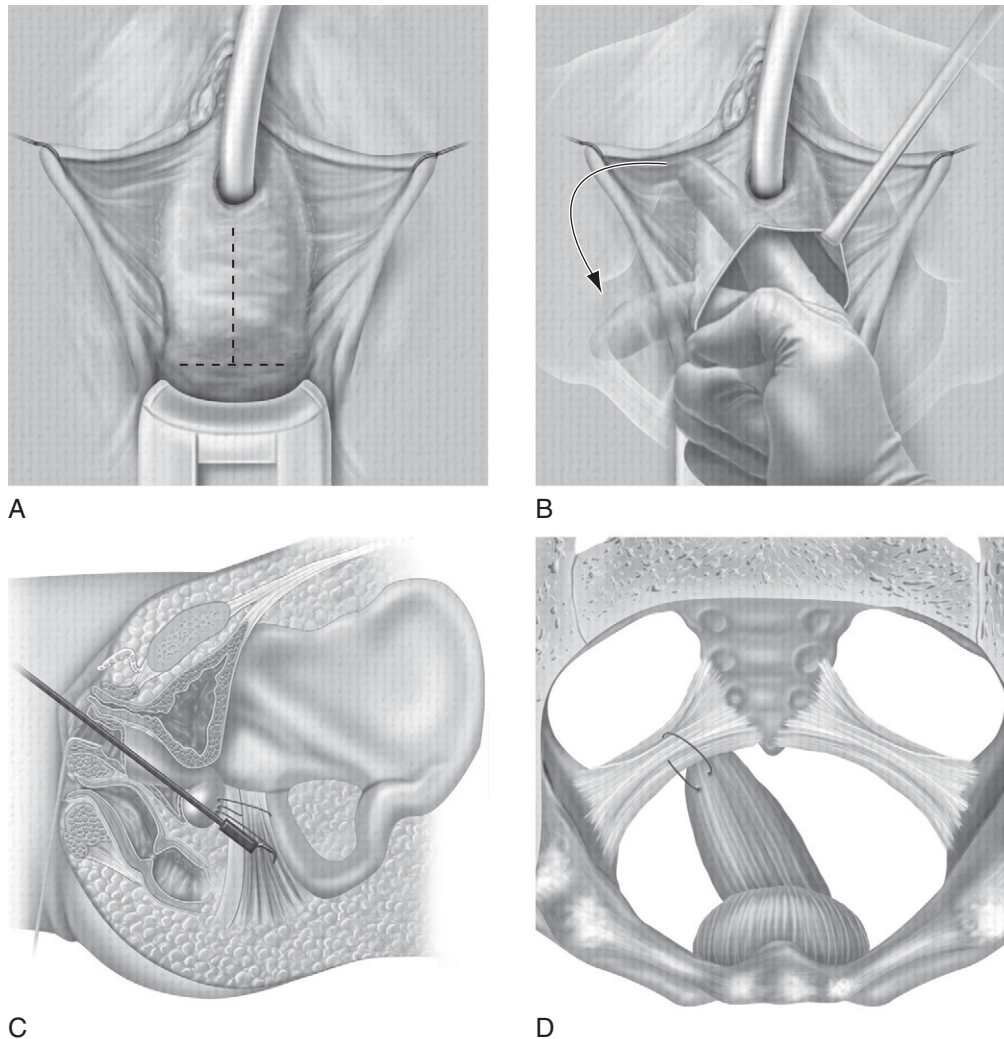

## TECHNIQUE

### Exposing the Ligament

Access to the sacrospinous ligament and coccygeus muscle can be achieved by several means. The most common approach, as described by Nichols,<sup>4</sup> involves a posterior vaginal incision and posterior colporrhaphy dissection, facilitating perforation of the rectal pillar near the ischial spine. With blunt dissection of the pararectal space medial to the ligament, the coccygeus muscle and sacrospinous ligament are exposed. The anterior sacrospinous suspension technique (Fig. 67-1)<sup>5,6</sup> involves perforation into the retropubic space through an anterior vaginal wall incision, as would be performed for an anterior colporrhaphy, and dissection of the ipsilateral paravesical and paravaginal area from the level of the bladder neck to the ischial spine along the arcus tendineus fasciae pelvis (Fig. 67-2). The dissection is performed in a manner similar to that for a vaginal paravaginal repair. This dissection opens a large space for the vaginal apex and avoids the narrowing often found in posterior approaches with perforation through the rectal pillars. For cases involving mainly anterior compartment defects with no rectocele, the anterior approach facilitates suspension of the vaginal apex without a posterior vaginal incision.

The Michigan four-wall technique approaches the sacrospinous ligament by resecting a diamond-shaped patch of excess epithelium at the most advanced portion of the prolapsed vaginal cuff—a region of the vaginal skin that overlies an enterocele in most cases. After the repair of the enterocele, the ligament is exposed with posterolateral dissection within the retroperitoneal plane.<sup>7</sup> Because this apical approach exposes the anterior vaginal epithelium with underlying pubocervical fascia and the posterior vaginal epithelium with rectovaginal fascia, sutures can be anchored through both of these cuff edges. Breisky-Navratil

**Figure 67-1** Dissection for anterior sacrospinous vaginal vault suspension. **A**, Incision; **B**, Perforation into retropubic space through anterior vaginal wall incision and dissection; **C**, Placement of suture in sacrospinous ligament with straight capio device; **D**, Suspension of vaginal vault to sacrospinous ligament.

retractors are well suited for exposing the coccygeus muscle and sacrospinous ligament without obstructing the surgical field. A  $17 \times 2.5$  cm Breisky-Navratil retractor is placed medially to sweep the rectum medially off the ligament. A  $12 \times 3$  cm Breisky-Navratil retractor is placed laterally. A Heaney retractor can then be placed posteriorly, just in front of the coccygeus muscle at the 7-o'clock position, perpendicular and on the distal edge of the coccygeus muscle for adequate retraction. Care should be taken so the tips of the retractors do not extend beyond the ischial spine. Some surgeons find retractors or suction devices mounted with a fiberoptic light source to be particularly useful for identifying the retroperitoneal anatomy.

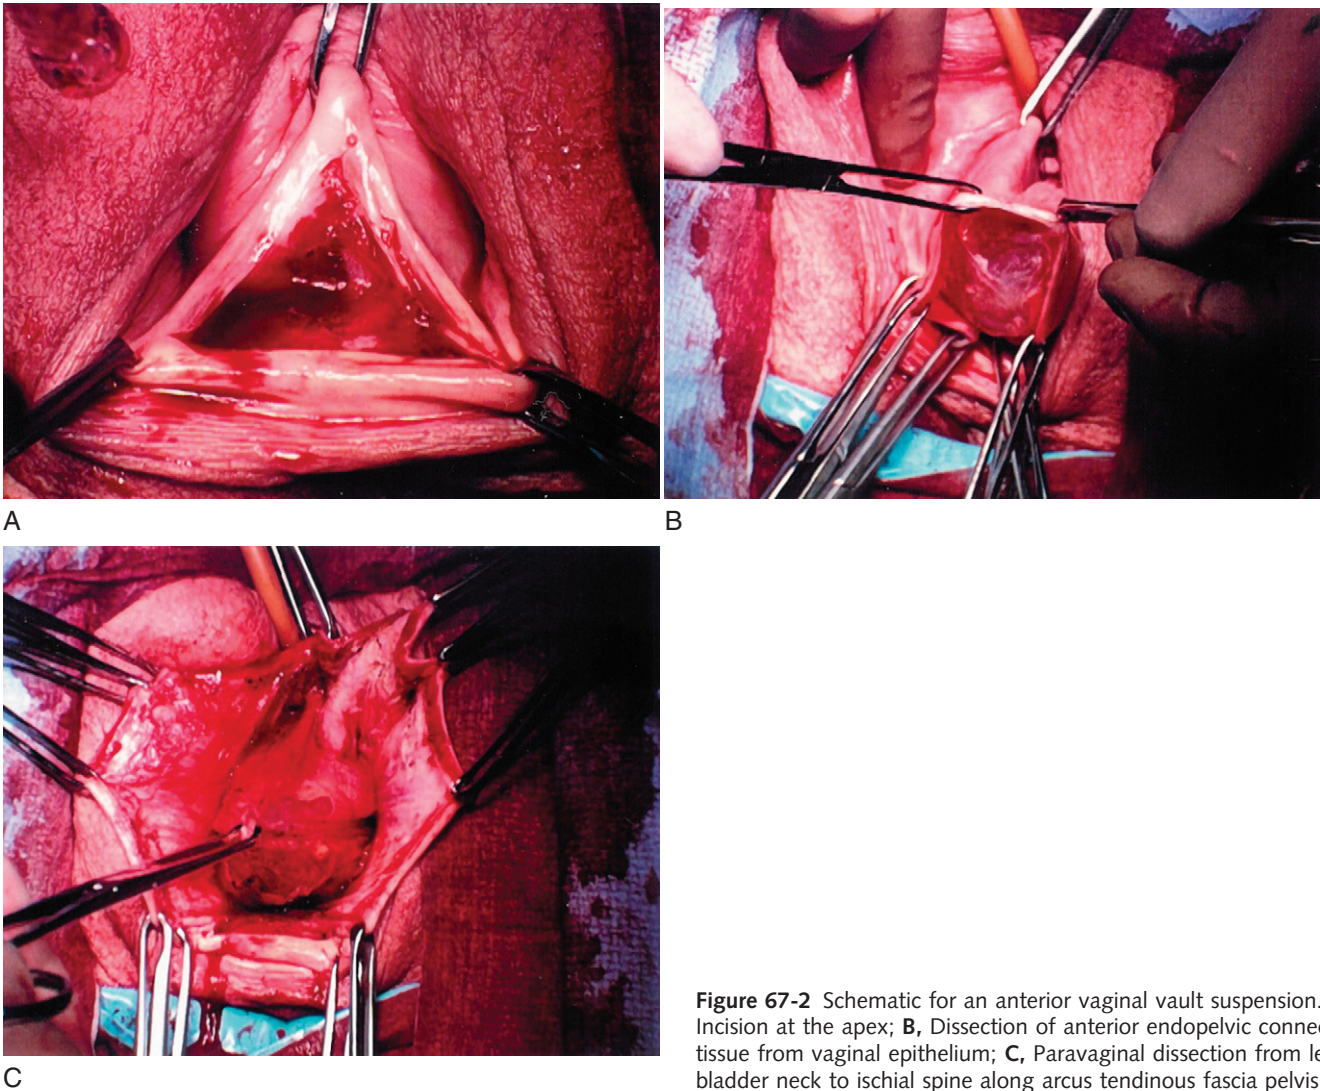

### Suture Placement

Various devices have been used to place sutures into the sacrospinous ligament, including the Deschamps ligature carrier, Miya Hook,<sup>32</sup> Schulte device, and Capio in-line “push and catch” suturing devices.<sup>33</sup> With proper assistance, some surgeons find a standard long, curved needle holder to be sufficient.

Suturing into the sacrospinous ligament should be performed with key anatomic landmarks in mind. The lateral suspension

suture is placed through the ligament 1 to 2 cm medial to the ischial spine to safeguard against injury to the pudendal vessels, although the risk of injury to the pudendal complex with the newer suturing devices may be overestimated.<sup>26</sup> Most of these devices deliver sutures into the sacrospinous ligament and underlying coccygeus muscle over a defined arc from anterior to posterior positions and cannot reach the pudendal complex posterior to the muscles. Medial rather than lateral placement of sutures in the ligament allows for a more cephalad suspension of the vaginal vault. Medially, the rectum represents the anatomic boundary for suture placement. During placement of the sacrospinous sutures, the surgeon must ensure that all retractors maintain their proper position. Traumatic insertion of retractors beyond the ligament or excessive medial traction against the rectum and presacral area is a potential source of bleeding and neuropathy.

Fixation of the vaginal apex is most commonly performed with permanent monofilament sutures, but some surgeons prefer synthetic absorbable material to reduce the risk of suture erosion and granulation tissue formation.<sup>34</sup> Preparation of the vaginal apex for fixation can involve full cuff closure or a circumferential whip stitch for securing hemostasis, followed by apposition of the

**Figure 67-2** Schematic for an anterior vaginal vault suspension. **A**, Incision at the apex; **B**, Dissection of anterior endopelvic connective tissue from vaginal epithelium; **C**, Paravaginal dissection from level of bladder neck to ischial spine along arcus tendineus fascia pelvis.

open cuff against the ligament. Right and left anchoring sutures are secured to the undersurface of the posterior vaginal cuff epithelium for the posterior approach, to the anterior vaginal cuff epithelium for the anterior approach, or to both for the apical approach. Although scarring and fibrosis at the interface of the ligament and vaginal apex may theoretically eliminate the need for sutures after the initial healing phase, the relative advantages of permanent versus absorbable sutures have not been scientifically evaluated.

Regardless of the type of suture used or anatomic approach to the ligament, a few principles for suture placement are universal. The surgeon should avoid the creation of a suture bridge between the vagina and ligament. The use of pulley stitches (i.e., one arm of the suture placed through the vaginal cuff is tied to itself with a surgeon's knot), which attach one end of each suture to the vaginal cuff epithelium and smooth muscle, may help in applying the vagina directly against the ligament. Maintaining a width of at least 2 cm between the medial and lateral sutures at their sacrospinous origins and vaginal apex insertions can minimize the risk of constriction at the vaginal apex.

Dissection and suture placement for the uterine hysteropexy is similar to that of the anterior or posterior vault suspension and

can be performed through either compartment. The difference is that after suture placement in the sacrospinous ligament, each suture is brought through the uterosacral ligaments as they insert into the cervix and then through the vaginal epithelium. If performing the technique unilaterally with a posterior approach, the sutures are placed one on either side of the cervix, with the medial suture placed on the contralateral uterosacral ligament at its insertion into the cervix. After the upper half of the vaginal wall is closed, sutures are tied down with the pulley stitch. Kovac and Cruikshank<sup>8</sup> and Hefni and colleagues<sup>18</sup> describe their techniques in detail in the original articles.

## COMPLICATIONS

Numerous complications have been associated with sacrospinous vaginal vault suspensions, but most are mild and self-limited. Local neurologic complications may include pudendal, sciatic, and sacral neuropathy.<sup>35</sup> Cruikshank and Cox<sup>16</sup> found that 20 (14.8%) of 135 women experienced buttock pain after sacrospinous ligament suspension, with all cases resolving spontaneously by 6 weeks. Sciatic nerve irritation after sacrospinous suspension

has been described.<sup>12</sup> Nerve injury is commonly cited as a complication; however, direct injury to major nerves is rare. Nichols<sup>36</sup> described injury to the sciatic nerve in two patients; one required reoperation, and the problem resolved spontaneously in the other.<sup>36</sup> Pudendal nerve entrapment may result in pain localizing in the buttocks or perineum, and it may improve after replacement of lateral fixation sutures more medially. One case of pudendal nerve entrapment was described by Alevizon and Finan.<sup>37</sup> The pain resolved spontaneously after release of the sacrospinous sutures. Buttock pain may occur because of the wide distribution of nerve fibers throughout the ligament, which are most concentrated in its medial portion.<sup>38</sup> Any evidence of direct injury to the sciatic or pudendal nerves requires reoperation in a timely fashion to remove the suture. Gluteal pain or paresthesias may occur after sacrospinous suspension, possibly due to peripheral nerve trauma.<sup>11,39,40</sup> Although these symptoms usually are transient and self-limited, they may persist for weeks to months postoperatively.

Serious vascular injury is a rare complication of sacrospinous ligament suspension, but it can be life threatening. Morley and DeLancey<sup>12</sup> reported a transfusion rate of only 4% and one infected hematoma resulting in sepsis in their review of 71 women. Various other series have reported transfusion rates ranging from 2% to 28%.<sup>41,42</sup> To effectively manage pelvic hemorrhage, familiarity with the surrounding anatomic landmarks is essential.

For most cases involving significant bleeding, ligation with sutures or surgical clips can be achieved under direct exposure with simple retraction. A rectal examining finger can be particularly useful for tamponade and exposure of medial vessels. Systematic inspection of the superior, inferior, and lateral surfaces of the dissected space facilitated by the slow removal of each Breisky-Navratil retractor should be performed, with particular focus on the ligament and adjacent coccygeus muscle, right medial rectal surface, and endopelvic connective tissue adjacent to the perforation of the rectal pillar. Throughout the 16-year experience of performing more than 400 sacrospinous ligament suspension procedures at our center, hemorrhage requiring vascular embolization or repeat surgery has occurred only once. In his review of the literature, Slack<sup>43</sup> found only 64 transfusions among 1901 reported cases.

Significant bleeding during sacrospinous vaginal vault suspension usually results from injury of small vessels along the medial aspect of the rectum<sup>39,44</sup> by overzealous medial dissection and retraction. Less commonly, the medial retractor can disrupt deeper vessels in the presacral area. If an individual vessel cannot be visualized with adequate retraction and lighting, the use of prolonged pressure packing may become necessary. Selective arterial embolization may be considered in hemodynamically stable patients if a defect or injured vessel cannot be localized.<sup>26</sup>

Infectious complications may occur. Hardiman and Drutz<sup>45</sup> reported a 10% incidence of febrile morbidity after vaginal reconstructive surgery that included sacrospinous ligament suspension; however, the risk of clinically significant infection resulting from the apical suspension itself appears to be low. The lack of a tissue graft eliminates the risk of foreign body infection, but suture abscesses can develop occasionally.<sup>3,29</sup> Proctotomy has been reported,<sup>4,41</sup> but significant injuries to the bowel are rare. In contrast to uterosacral vault suspension techniques, ureteral injuries are also rare, although bladder laceration has been reported.<sup>3</sup>

## ANATOMIC OUTCOMES

### Support of the Vaginal Apex

The long-term efficacy of sacrospinous ligament suspension for resuspending a prolapsed vaginal cuff has been supported in several clinical series. The success rates of the larger reports and their mean follow-up intervals are listed in Table 67-1. Although most outcomes reported for the sacrospinous ligament suspension have referred to the posterior or apical approach, later reports evaluating the anterior sacrospinous ligament suspension have found similar rates of success. Goldberg and coworkers<sup>6</sup> retrospectively evaluated 168 women after anterior ( $n = 76$ ) or posterior ( $n = 92$ ) sacrospinous vault suspension and found no measurable differences with respect to apical support, vaginal caliber according to maximum dilator size, or angle of the vaginal vault between the two groups.

**Table 67-1 Sacrospinous Vaginal Vault Outcomes**

Study	No. of Patients	Mean Follow-up (mo)	Success of Apical Support (%)
Richter and Albrich, <sup>3</sup> 1981	81		98
Nichols, <sup>4</sup> 1982	163	≥24	97
Morley & DeLancey, <sup>12</sup> 1988	71	≥12	96
Cruikshank and Cox, <sup>16</sup> 1990	48	8-38	83
Shull et al, <sup>30</sup> 1992	81	≥48	98
Pasley, <sup>41</sup> 1995	156	35	94.4
Hardiman and Drutz, <sup>45</sup> 1996	125	6-60	97.6

Meschia et al, <sup>67</sup> 1999	91	≥12	85
Winkler et al, <sup>5</sup> 2000	75	8.5	93
Cespedes, <sup>11</sup> 2000	28	17	96.4
Lantzsch et al, <sup>68</sup> 2001	123	57	96.7

After sacrospinous ligament suspension, the apex of the vagina is retroverted and laterally positioned—anatomic changes that appear to have no functional consequences. Morley and DeLancey<sup>12</sup> thought this asymmetry might confer a functional benefit postoperatively by positioning the vaginal vault away from the urogenital hiatus and over the levator muscles, lessening the intra-abdominal pressures applied to the vaginal apex. Narrowing of the vaginal apex into a conical shape, due to the excision of excess anterior or posterior vaginal epithelium, is thought by some to be a desired anatomic consequence of unilateral sacrospinous suspension.<sup>46</sup> After bilateral suspension, a T-shaped or Y-shaped (with concomitant enterocele repair) vaginal apex may be created, but it appears to confer no functional disadvantage.

### Comparison with Abdominal Procedures

Benson and associates<sup>47</sup> performed the first prospective, randomized trial comparing abdominal and vaginal apical suspensions. They randomized 48 women to vaginal sacrospinous ligament suspension with paravaginal repair, and 40 women were randomized to have abdominal sacrocolpopexy, paravaginal repair, and possible retropubic urethropexy. They found after 2.5 years that the vaginal route was unsatisfactory in 33% of patients, compared with 16% of patients in the abdominal group, and they terminated the study early. Their conclusion was that the abdominal approach was more effective in treating uterovaginal prolapse than the vaginal approach.<sup>47</sup>

In contrast, Maher and colleagues<sup>48</sup> evaluated 95 women with vault prolapse in a randomized, controlled trial. Forty-seven women were allocated to abdominal sacral colpopexy and 48 women to vaginal sacrospinous colpopexy. Both groups underwent Burch urethropexies if stress urinary incontinence was present. After 2 years of follow-up, they found that subjective and objective (76% abdominal versus 69% vaginal;  $P = .48$ ) cure rates were similar for the two groups. Abdominal surgery was associated with longer operating times, slower return to activities, and greater cost in both studies.<sup>48</sup>

### Anterior Vaginal Wall Support

If apical support is the sole parameter by which success is measured, the success rates range from 80% to 90%. When evaluating the entire pelvic floor, however, the anterior vaginal compartment appears to represent a particularly vulnerable site. Perhaps this is a consequence of vaginal retroversion predisposing to a compensatory abnormality. Several clinical series, but not all,<sup>49</sup> have demonstrated an elevated risk of cystocele formation after sacrospinous ligament suspension. Recurrent cystoceles have been reported in 7.6% to 92% of women after sacrospinous ligament vaginal vault suspension, depending on the other concurrent procedures performed.<sup>3,12,41,50</sup>

Although early series found recurrent cystoceles in 6% of women who had satisfactory support at the apex,<sup>12</sup> Paraiso and colleagues<sup>51</sup> reported significant anterior wall defects in 26.7% of women after sacrospinous ligament suspension. Smilen and coworkers<sup>49</sup> evaluated 322 women and divided them into two major groups. The first group had anterior wall defects and underwent anterior repairs with or without sacrospinous vaginal vault suspensions. The second group did not have anterior wall defects, and no anterior repairs were performed, but other recon-

structive procedures were performed with or without sacrospinous vaginal vault suspensions. The investigators found that the addition of sacrospinous vaginal vault suspensions did not increase the occurrence of postoperative cystoceles in either group.

Sze and associates<sup>39</sup> described 96 women who had pelvic organ prolapse to the hymen or beyond, and they compared women who underwent sacrospinous vaginal vault suspension with or without concomitant transvaginal needle suspension. Recurrent prolapse was observed in 33% of women when the two procedures were performed concurrently, compared with 19% of women who underwent sacrospinous suspension only. The difference did not reach statistical significance.<sup>39</sup> Barber and colleagues<sup>52</sup> reported a 21% incidence of stage III cystoceles after sacrospinous vaginal vault suspension at a mean follow-up interval of 19 months. The incidence rose to 36% when sacrospinous suspensions were performed concomitantly with endoscopic needle suspensions.<sup>52</sup> The increased incidence of cystoceles in these two studies might have been associated with the needle suspension alone or the specific combination of procedures. Alternatively, Goldberg and associates<sup>53</sup> found that bladder neck slings decreased recurrence rates of cystoceles from 42% to 19%, even when performed concomitantly with sacrospinous vaginal vault suspensions. Anterior sacrospinous vault suspensions were not independently predictive of recurrent cystoceles, and posterior sacrospinous vault suspensions were predictive of recurrent cystoceles only when combined with anti-incontinence procedures, not including slings.<sup>53</sup>

The precise mechanisms leading to recurrent anterior vaginal wall prolapse have yet to be outlined. It has been proposed that posterior deflection of the vaginal vault after sacrospinous vaginal vault suspension leads to increased exposure of the anterior compartment to intraperitoneal forces.<sup>54,55</sup> Shull and colleagues<sup>30</sup> suggested that underestimation of the severity of anterior prolapse on preoperative examination or overreliance on the apical suspension for compensation of anterior support defects may play a role. In their series, 16% of patients with anterior vaginal wall prolapse before surgery had no repair of the anterior vaginal wall performed during the initial surgery. Accurately identifying all areas of prolapse preoperatively and modifying the pelvic reconstruction according to intraoperative findings are key to obtaining a successful outcome.

### Vaginal Anatomy and Sexual Function

Most studies of sacrospinous vaginal vault suspension have focused on anatomic outcomes, particularly on the rates of recurrent apical, posterior, and anterior vaginal prolapse. Few studies have addressed functional outcomes, such as vaginal length, caliber, axis, and sexual satisfaction. Morley and DeLancey<sup>12</sup> reported vaginal stenosis in 4 of 71 women evaluated at least 1 year after sacrospinous vaginal vault suspension and 1 patient with vaginal foreshortening requiring subsequent vaginoplasty. Elkins and coworkers<sup>54</sup> and Given and associates<sup>56</sup> quantified postoperative vaginal anatomy in more detail, reporting an average vaginal length after sacrospinous ligament suspension of 8.3 and 8.2 cm, respectively. Paraiso and colleagues<sup>51</sup> evaluated an even wider variety of outcomes after sacrospinous suspension at a mean interval of 98.8 months. Vaginal length averaged 8.0 cm, and the vaginal caliber was less than 2 fingerbreadths in 17%; new onset of vaginal constriction was reported in 7.4%.<sup>51</sup>

Sexual dysfunction after pelvic reconstruction with sacrospinous suspension was reported in 14% of patients by Paraiso and co-workers<sup>51</sup>; however, less than one half represented de novo cases. Surprisingly, vaginal length, caliber, and the presence of specific support defects did not correlate with reported sexual activity in this series. Holley and associates<sup>50</sup> concluded that postoperative vaginal narrowing was a significant predictor of decreased sexual activity after sacrospinous suspension and vaginal reconstruction, with 25% reporting postoperative sexual dysfunction. When vaginal narrowing did not occur, sexually active patients reported unchanged or improved sexual function.<sup>50</sup> These reports, in agreement with others,<sup>17,50</sup> concluded that vaginal narrowing and sexual dysfunction after sacrospinous ligament suspension was most often the result of anterior colporrhaphy and the repair of other concomitant defects rather than the sacrospinous suspension itself. Retroversion of the vaginal apex and deviation after unilateral sacrospinous suspension appear to have no adverse effects on coital function postoperatively.

We addressed sexual outcomes in a retrospective analysis of 133 women after sacrospinous vaginal vault suspension (76 after posterior sacrospinous suspension and 57 after anterior suspension) at a median interval of 41 months. Before surgery, 19 (33%) were sexually active in the anterior vault suspension group, with 9 (13%) reporting dyspareunia. At long-term follow-up, two patients in the anterior vault suspension group and two in the posterior vault suspension group reported new-onset dyspareunia. Three of these four cases of de novo dyspareunia were referable to severe atrophy or recurrent grade 3 prolapse; none was attributed to vaginal narrowing or shortening.<sup>6</sup> Sacrospinous ligament vaginal vault suspension appears to have minimal or no impact on sexual function postoperatively, and the choice of anterior or posterior technique has no discernable impact on sexual outcomes. Perhaps most encouraging was that five women in this series reported dyspareunia preoperatively that resolved after vaginal reconstruction with sacrospinous vaginal vault suspension.

## PREDICTORS OF SUCCESS

The long-term success of sacrospinous vaginal vault suspension depends on a multitude of factors, including the quality of endopelvic connective tissues, postoperative convalescence, lifestyle factors, and the repair of all coexisting pelvic floor support defects at the time of surgery. Two studies have evaluated predictors of success for reconstructive surgery. Whitesides and colleagues<sup>58</sup> found that age older than 60 years and preoperative stage III or IV prolapse were independent predictors of recurrent prolapse. They also found that bladder neck plication and posterior colporrhaphy were associated with recurrent anterior prolapse. In contrast, Burch or bladder neck sling procedures had a lower risk of recurrent anterior vaginal wall prolapse but a greater risk of posterior vaginal prolapse. Goldberg and coworkers<sup>53</sup> and Cross and associates<sup>57</sup> found decreased risks of anterior vaginal wall prolapse with bladder neck sling procedures. Patients who had three or more concomitant procedures were more likely to have recurrent prolapse, although this factor did not reach statistical significance.<sup>58</sup> Nieminen and coworkers<sup>59</sup> identified vaginal cuff infection (OR = 6.13) and urinary tract infection (OR = 3.65) as predictors of vaginal vault recurrence.

It appears that a successful initial healing process may herald long-term success. Shull and colleagues<sup>30</sup> reported that among 81

women treated with sacrospinous ligament suspension and pelvic reconstruction, the absence of any pelvic support defect at the 6-week postoperative visit was associated with only a 3% likelihood that the patient would require subsequent reconstructive surgery within 2 to 5 years.<sup>30</sup>

## ALTERNATIVE TRANSVAGINAL VAULT SUSPENSION PROCEDURES

### Iliococcygeus Suspension

In 1963, Inmon<sup>60</sup> described iliococcygeus fixation. The iliococcygeus fascia was selected as an alternative fixation point because it required less dissection than a sacrospinous suspension, with the proposed advantage of decreasing the incidence of neurovascular injury or future cystocele.<sup>21</sup> One drawback of the iliococcygeus suspension, however, is the lack of level I apical support.

Shull and colleagues<sup>61</sup> described 42 patients in whom he performed iliococcygeus suspension, with follow-up periods of 6 weeks to 5 years, and they found only a 5% rate of recurrence. Alternatively, Maher and associates<sup>62</sup> compared sacrospinous suspension to iliococcygeus fixation for prolapse of the vaginal apex in matched cohorts and reported higher “patient satisfaction” scores among the sacrospinous group at a mean follow-up of 20 months. Nonsignificant trends indicated better support after the sacrospinous approach according to subjective and objective outcomes.<sup>62</sup>

### Bilateral Uterosacral Suspension

Uterosacral suspension is another alternative to sacrospinous suspension. Karam and coworkers<sup>22</sup> described this procedure in women who underwent primary uterosacral suspension (at the time of hysterectomy) compared with women being treated for recurrent prolapse. Among 168 women with follow-up data, there was a 5% reoperation rate for any defect in the vagina. Only two women had recurrent, symptomatic enterocele or vault prolapse of grade 2 or greater. The investigators were unable to perform the operation in 6 of 200 cases due to exposure or because an enterocele was not found.

Barber and associates<sup>52</sup> described the outcomes of bilateral uterosacral suspension and found that 3 of 46 women needed reoperation. Symptomatic prolapse recurred in four women (10%), two (5%) with apical prolapse. They reported a very high (11%) ureteral occlusion rate.<sup>52</sup> Shull and colleagues<sup>63</sup> found an objective cure rate of 87% (251 of 289 patients) in his series, and Jenkins<sup>64</sup> reported no failures among 50 women.

Suspension of the vaginal apex to the proximal uterosacral ligaments can achieve an excellent anatomic and functional outcome. However, the uterosacral tissues occasionally lack sufficient tensile strength for an effective vault suspension, and the risk of ureteral injury may be as high as 11% when multiple fixation sutures are placed into the uterosacral ligament.

## CONCLUSIONS

Based on the existing literature, it appears that each of these operations, in experienced hands, can provide excellent long-

term outcomes. Prospective comparisons between sacrospinous ligament vaginal vault suspension and its alternatives will hopefully be the subject of future research.

For the surgical management of advanced prolapse of the vaginal apex, sacrospinous ligament vaginal vault suspension represents a highly reliable transvaginal alternative. Familiarity

with the various methods for approaching the ligament and anchoring the vaginal apex allows the surgeon to easily combine this operation with a variety of other vaginal reconstructive procedures. Adherence to fundamental anatomic and surgical principles ensures that a functional vaginal anatomy is maintained and that complications are minimized.

# REPAIR OF VAGINAL VAULT PROLAPSE USING SOFT PROLENE MESH

*Matthew P. Rutman, Donna Y. Deng, Larissa V. Rodríguez, and Shlomo Raz*

Vaginal vault prolapse results from elongation or detachment of the sacrouterine-cardinal ligament complex. It commonly manifests with other vaginal defects, such as cystocele, enterocele, and rectocele. Patients typically present with symptoms similar to uterine prolapse: a mass protruding vaginally, dyspareunia, low back pain, or perineal pressure. Sometimes, patients present with symptoms of voiding dysfunction, such as incomplete emptying, retention, recurrent infections, or incontinence.

An enterocele is a hernia of the peritoneum, with its contents extending between the vagina and rectum at the level of the vaginal vault. The use of dynamic magnetic resonance imaging (MRI) has allowed routine identification of the contents: small bowel, sigmoid, fluid, or omentum. Most enteroceles are acquired as a result of prior surgery on the anterior vaginal wall altering the vaginal axis or poor closure of the cul-de-sac at the time of hysterectomy. The incidence of enterocele in patients who underwent gynecologic surgery is as high as 16%.<sup>1</sup> For the purposes of this chapter, we divide enteroceles into simple and complex types. A simple enterocele exists when there is no concomitant vault prolapse. The only defect is between the perivesical and prerectal fascia, which allows the peritoneum to herniate through, creating an enterocele. In a complex enterocele, there is concomitant vault prolapse. Many techniques have been described for supporting the vaginal vault after enterocele repair and hysterectomy.

### APICAL VAGINAL WALL PROLAPSE: ANATOMY AND PATHOPHYSIOLOGY

The most proximal portion of the vagina, called the vaginal cuff or vault, is supported by the cardinal ligaments and uterosacral ligament complex. The cardinal ligaments are thick, anteriorly based fascial condensations originating from the greater sciatic foramen and inserting into the lateral fascia of the cervix and adjacent vaginal wall. They provide critical uterine and apical vaginal support. The uterosacral ligaments originate from the sacral vertebrae and insert into the lateral vaginal fornices, fusing with the cardinal ligaments posteriorly and stabilizing the uterus, cervix, and apical vagina in a posterior direction toward the sacrum. The broad ligaments, located more superiorly, attach the lateral walls of the uterine body to the pelvic side wall, providing additional uterine support. They contain the fallopian tubes, the round and ovarian ligaments, and the uterine and ovarian blood supply.

Lateral walls of the rectum are supported to the lateral pelvic wall and sacrum by condensations of connective tissue to the

levator muscle extending to the sacrum (i.e., pillars of the rectum). The rectovaginal septum is a fascial extension of the peritoneal cul-de-sac between the vaginal apex and the anterior rectal wall. The septum consists of two distinct fascial layers: posterior vaginal fascia and prerectal fascia. The layers fuse with the cardinal-uterosacral ligament complex proximally, stabilizing the posterior vaginal apex. The two layers fuse distally and insert into the perineal body. The perineal body is a tendinous structure located in the midline of the perineum between the vagina and anus, and it provides additional pelvic support to the posterior vaginal wall and rectum. It serves as a central insertion point for the superficial and deep transverse perineal, bulbospongiosus, and external sphincter muscles. The perineal membrane consists of the distal 3 to 4 cm of the vagina and serves as an attachment point for the levator musculature. This is a critical anatomic landmark in posterior repair.

The musculature of the pelvic floor provides the main support for the pelvic viscera. It is composed of the coccygeus and levator ani muscles. The horizontal levator plate allows maintenance of the normal vaginal axis. The levator hiatus refers to the midline openings of the levator ani that allow passage of the urethra, vagina, and rectum. The proximal vagina and rectum rest on the levator floor and remain well supported with increases in intra-abdominal pressure in patients with normal pelvic support.

Pelvic floor relaxation results in vaginal wall prolapse. Multiparity, obesity, hormonal changes, increasing age, and tissue and nerve damage can play important roles in vaginal prolapse. The resulting area of prolapse depends on the location of muscular and ligamentous damage.

### EVALUATION

Patients found to have small vault prolapse or enteroceles on physical examination are typically asymptomatic. As the vault prolapse increases, patients may report symptoms of vaginal and perineal fullness or lower back pain that improves with supine positioning. Other complaints include dyspareunia and symptoms of voiding dysfunction, such as incomplete emptying, retention, recurrent infections, or incontinence. Patient with voiding symptoms should be evaluated with video urodynamic studies. The physical examination is essential for diagnosis, and it usually reveals a bulging mass at the vaginal apex. An enterocele can be difficult to distinguish from a high rectocele or cystocele. Separate examination of the vaginal walls with a half-blade of a Graves speculum is routine with Pelvic Organ Prolapse Quantification measurements.

Simultaneous rectal and vaginal examination may aid in differentiating an enterocele from a high rectocele. Examination in the standing position and cystoscopic light in the bladder also may assist in making the proper diagnosis.<sup>2</sup> Any concomitant defects should be documented.

Many radiologic modalities have been used in the diagnosis of enterocele, including defecography, fluoroscopy, dynamic cystocolpoproctography, and MRI. Dynamic MRI provides superior imaging of all three vaginal compartments and may help differentiate introital masses.<sup>3</sup> In patients with severe prolapse of the anterior and apical vaginal wall, the upper urinary tract must be evaluated (e.g., renal ultrasound, pyelogram, computed tomography urography) because severe prolapse can cause severe angulation of the ureters resulting in ureteral obstruction.

## CONSERVATIVE TREATMENT

Conservative treatment, which is best for early prolapse and poor surgical candidates, includes pelvic muscle rehabilitation, hormone replacement therapy, and pessary use. Patients should be instructed to avoid constipation and activities such as heavy lifting and straining. Pessary fitting can be quite challenging, and improper placement and poor hygiene can lead to erosions into the vaginal mucosa and adjacent structures. As the severity of prolapse increases, it becomes increasingly difficult to retain a pessary, which mandates formal surgical repair. Concomitant prolapse should be addressed at the same time. Colpocleisis can be performed with minimal anesthesia as an alternative to definitive repair. This is a less morbid option in the sexually inactive elderly patient with multiple comorbidities.

## SURGERY

### Surgical Indications

Treatment is driven by patients' symptoms. Low grades of prolapse are often asymptomatic and can be managed nonoperatively. Patients who are symptomatic and have concomitant prolapse, ulcerations, and obstructive voiding require surgical intervention. Patients with severe prolapse causing obstruction of the upper tracts and hydronephrosis also require intervention. Simultaneous repair of other vaginal prolapse should be performed.

### Surgical Techniques

Numerous techniques have been described for vault prolapse and enterocele repair, including abdominal, vaginal, and laparoscopic repair. Because several of these procedures are discussed in detail in other chapters, they are mentioned briefly here as a reference only. Abdominal repair, with sacrocolpopexy or hysterectomy, closes the cul-de-sac using one of two popular techniques. The Moschcowitz repair obliterates the cul-de-sac using purse-string sutures from the bottom of the sac to the most cephalad aspect. The Halban repair obliterates the cul-de-sac by placing sutures in the sagittal plane between the anterior rectal wall and the posterior vaginal wall. Vaginal repair avoids the morbidity of a laparotomy and has the advantages of decreased hospital costs and quicker recovery time. In the following sections, we describe two techniques used for transvaginal sacrouterine fixation.

### *Transvaginal Sacrouterine Fixation for Vault Prolapse with Enterocele Repair*

The patient is placed in the high lithotomy position after anesthesia is provided. The lower abdomen and vagina are prepared and draped in a sterile fashion. The labia minora are retracted, and a Foley catheter is placed. A ring retractor with hooks is positioned, and the enterocele is grasped with two Allis clamps. In patients undergoing concomitant hysterectomy, the peritoneal cavity is exposed. The vaginal apex is located by identifying the scar at the lateral apex. It is marked bilaterally with electrocautery. A vertical incision is made anteriorly from the base of the bladder extending posteriorly to the prerectal area. Sharp dissection is used to free the peritoneal sac from the vaginal wall. Special attention is necessary to avoid inadvertent bladder or rectal injury during the dissection. Cystoscopic illumination of the bladder can help define the bladder base.

The peritoneal sac is opened, exposing the bowel contents. After freeing any adhesions, two Betadine-soaked laparotomy pads are placed to pack the abdominal contents, and deep right-angle retractors (Haney) are used to retract for optimal exposure. This maneuver protects the bowel and bladder during the procedure. Vault suspension sutures are placed at this time to support the cuff to the sacrouterine ligaments. In patients with vault prolapse and enterocele, the procedure obliterates the cul-de-sac and suspends the vaginal cuff high on the levator plate. A 1-0 Vicryl suture is passed through the vaginal wall (apex) inside the peritoneal cavity incorporating prerectal fascia and the ipsilateral origin of the sacrouterine ligament complex (i.e., iliococcygeus muscle). The sacrum, coccyx, and the coccygeus muscle and its underlying sacrospinous ligament (i.e., strong, firm, rectangular structure) are palpated. The rectum is retracted medially, and a strong purchase is taken posterolaterally in the groove between the iliococcygeus muscle and rectal wall. We also incorporate the prerectal fascia, resulting in reduction of the rectocele. It is essential to take a strong bite of tissue in the pararectal area. The suture is brought out the vaginal wall 1 cm from the original entry point. The same maneuver is performed on the contralateral side. The culdosuspension sutures are left untied.

The enterocele (peritoneal cavity) is closed with two 1-0 Vicryl sutures in a purse-string fashion. These sutures incorporate the sacrouterine-cardinal ligament complex laterally, prerectal fascia posteriorly, and perivesical fascia anteriorly (i.e., base of the pubocervical fascia). This obliterates the potential space between the prerectal fascia and the perivesical fascia. Distal suture placement preserves adequate vaginal depth. It is important to take strong bites of the perivesical fascia, including the posterior peritoneal surface of the bladder, with careful attention to staying in the middle (i.e., ureters run laterally). This ensures closure of the enterocele and reapproximates the prerectal and perivesical fascia. The excess peritoneal sac is excised after tying the sutures. Indigo carmine is administered intravenously and cystoscopy is performed to rule out iatrogenic ureteral obstruction from suture placement.

At this point, we perform a sling or cystocele repair if required. The vault suspension sutures are tied after we reduce the vault using a weighted speculum and Allis clamp to reduce the cuff to the most posterior and deep position. This provides depth and support of the cuff and restores the normal banana-shaped vaginal axis (in the lithotomy position). Excess vaginal wall is trimmed, and the vaginal wall is closed with a running, locking 2-0 Vicryl suture.

The rectocele is repaired next. The posterior fourchette is excised, and a triangular flap of posterior vaginal wall is excised 4 cm from the hymen, exposing the perineal membrane and the levator plate. A 1-cm strip of posterior vaginal wall is excised to expose the pillar of the rectum and the prerectal fascia. The proximal vagina is repaired with 2-0 delayed absorption sutures that include the edge of the vaginal wall and the pillar of the rectum. In the distal vagina, figure-of-eight sutures are used to repair the levator hiatus by incorporating the edge of the vaginal wall and the perineal membrane (indirectly approximating the levator musculature). The perineal body repair is completed. The vagina is packed with an antibiotic-impregnated gauze.

Most vault suspension and enterocele repairs are performed as outpatient surgery. The vaginal pack is removed after 2 hours, and patients are discharged home and remain on several days of oral antibiotics.

We previously reported data for 104 patients who underwent transvaginal culdosuspension with enterocele repair or hysterectomy, or both.<sup>4</sup> This cohort had the procedure performed without mesh reconstruction. Concomitant prolapse was repaired in 82 patients. Perioperative complications included two patients with cuff infections, two patients with ileus and one patient with ureteral obstruction. Both patients with ileus responded to conservative management. The vaginal cuff infections did not require operative intervention and responded to antibiotics and local wound care. The patient with ureteral obstruction required ureteroneocystostomy. The patients were followed for a mean period of 17.3 months. Recurrence occurred in four patients (3.8%). All four had repeat transvaginal culdosuspension, and each was free of prolapse at the last follow-up. No patients had vaginal foreshortening, urinary retention, or rectovaginal fistula. One patient had prolonged dyspareunia that resolved after 6 months.

#### *Mesh Repair for Concomitant Vault Prolapse, Enterocele, and Rectocele*

In patients with apical and posterior compartment prolapse, we restore the sacrouterine ligament complex and repair the pelvic floor with the use of a polypropylene mesh. This method also is used in patients undergoing vaginal hysterectomy. Most patients with vault prolapse have widening of the levator hiatus and descent of the levator musculature. The technique addresses reconstruction of the pelvic floor and prevents levator descent. Prior experience with anterior wall failures without the use of surrogate materials has ignited our interest in total mesh reconstruction for durable recreation of vaginal anatomy. Addressing perineal body descent is important to prevent recurrent prolapse and anorectal disorders.

A T-shaped soft Prolene mesh is cut from a sheet of 6 × 6 inch soft polypropylene mesh. The two transverse arms are measured to 4 × 1 cm, and the vertical segment is 3 × 6 cm (Fig. 68-1). The two transverse arms mimic the sacrouterine ligaments in support of the cuff. The vertical segment recreates the prerectal fascia inserting at the perineal membrane (Fig. 68-2). Vault suspension sutures are placed as described earlier, incorporating the origin of the sacrouterine ligament. The sutures are brought through the transverse arm of the mesh, and a second purchase of the sacrouterine ligament is taken (Fig. 68-3). We also incorporate the prerectal fascia, resulting in full support of the cuff by the two arms of the mesh because it mimics the normal sacrouterine ligament support. This also aids in reducing the rectocele. The enterocele closure is performed in purse-string fashion as done earlier with the posterior bites (of the prerectal fascia), including

Figure 68-1 T-shaped mesh.

Figure 68-2 Mesh recreation of the sacrouterine ligament–prerectal fascia complex.

Figure 68-3 Transverse arm of mesh recreating the sacrouterine ligament origin.

**Figure 68-4** Closure of an enterocele, including mesh with prerectal fascia.

**Figure 68-5** Mesh exiting at the distal vagina.

small purchases of the proximal vertical mesh segment (Fig. 68-4). The vertical segment of the mesh is then tunneled to the posterior vaginal wall for a distance of 2 to 3 cm to avoid incorporation of the mesh during the vaginal cuff closure. The mesh is eventually brought out to the distal vagina over the prerectal fascia (Fig. 68-5). The vertical segment of the mesh acts as surrogate tissue to improve the rectocele repair and prevent levator descent. The proximal vagina is repaired with 2-0 delayed absorp-

tion sutures, including the edge of the vaginal wall and the pillar of the rectum. In the distal vagina, figure-of-eight sutures are used to repair the levator hiatus by incorporating the edge of the vaginal wall, the edge of the vertical mesh segment, and the perineal membrane and levator musculature. The excess mesh is excised, and the perineal body repair is completed.

We have performed the previous procedure on more than 100 patients since February 2004. Forty percent underwent concomitant vaginal hysterectomy. We have had no intraoperative complications. Pelvic Organ Prolapse Quantification staging has revealed restoration of normal vaginal anatomy. Two patients (2.5%) have had recurrent enteroceles without vault prolapse; one required a second procedure. One patient had a small mesh erosion at the posterior vaginal wall that was cured with office excision. An additional patient had unilateral ureteral obstruction requiring ureteroneocystostomy. Longer follow-up will be reported as our data matures.

#### *Other Techniques for Treating Vault Prolapse and Enterocele*

Pelvic reconstructive surgeons have described other techniques of transvaginal uterosacral fixation for apical prolapse. Shull and colleagues<sup>5</sup> reported a total of 302 consecutive patients who underwent transvaginal reconstructive surgery for apical prolapse by a single surgeon. In patients with prior hysterectomy and vault prolapse, a vertical midline incision was made in the vaginal epithelium. The epithelium was dissected off the underlying enterocele sac. The pubocervical and rectovaginal fascia were identified, and the enterocele sac was found between the two planes. The enterocele sac was opened and the bowel packed. The remaining uterosacral ligaments were identified medial and posterior to the ischial spine at 4- and 8-o'clock, respectively. A double-armed nonabsorbable suture was then placed from lateral to medial aspects through the ligament on the sacral side of the ischial spine. Two additional sutures were then placed distal and medial to the initial suture. The same maneuver was then performed on the contralateral side.

At this point, six sutures were tagged and labeled. Central defects in the pubocervical and rectovaginal fascia were then repaired by plication technique. The double-armed sutures were brought through the superior aspect of the rectovaginal and pubocervical fascia, respectively. Before securing the sutures, indigo carmine was administered intravenously. The sutures were secured, resulting in the pubocervical fascia and rectovaginal fascia being anchored together at the vaginal apex. The suspensory sutures were all secured, and cystoscopy ensured ureteral patency. The vaginal epithelium was trimmed and closed with a running polyglycolic suture. Concomitant retropubic urethropexy and perineal body repair were performed if necessary. There was no closure of the peritoneal cavity in this technique.

This transvaginal technique was used in 302 patients between 1994 and 1998.<sup>5</sup> The means follow-up period was 1.18 years. In this cohort, 289 had at least one postoperative examination, and 87% had no subsequent support defect, with the remaining 13% having some degree of pelvic support loss. Only 5% of the patients had development of grade 2 or greater support defects. One patient required a unilateral ureteroneocystostomy for a ureteral injury discovered at the time of surgery consisting of a hysterectomy, cystocele repair, rectocele repair, enterocele repair, and vaginal cuff suspension. Three patients required homologous blood transfusion. One elderly patient with dementia died at home 4 days after release from the hospital.

High uterosacral vaginal vault suspension with fascial reconstruction for enterocele and vault prolapse was performed by Karram and coworkers<sup>6</sup> for a large cohort at the University of Cincinnati. Exposure was similar to the previously described technique. After the peritoneal cavity was exposed and the bowel packed, a wide retractor was used for optimal exposure. The ischial spines were palpated, and the remnants of the uterosacral ligaments were identified. An Allis clamp was placed at the 5- and 7-o'clock positions. Permanent sutures were then passed through the ligaments from side to side, incorporating the peritoneum between the two sides. A total of two to four sutures were placed. Anterior wall surgery was then performed if required. The anterior and posterior vaginal walls were suspended by their underlying fascia high to the uterosacral ligaments on each side, using four to six sutures. All other indicated repairs were performed.

Follow-up was available for 168 of the 202 women who underwent high uterosacral vaginal vault suspension.<sup>6</sup> Only two women (1%) had recurrent symptomatic enterocele or vault prolapse of grade 2 or greater. A total of 4.5% underwent reoperation for symptomatic anterior or posterior vaginal wall prolapse. An additional 5% had recurrent prolapse of grade 2 or greater that was asymptomatic or for which no further therapy was desired by the patient. At a mean of 21.6 months after surgery, 89% of the 168 women were "happy" or "satisfied" with their procedure. There were five cases of ureteral injury, four of which were diagnosed at the time of surgery and reversed by cutting of the suspension sutures. One case required a ureteral reimplantation due to a ureterotomy. One patient had a small bowel injury and required a laparotomy. Another patient developed a pelvic abscess requiring exploration and a diverting colostomy.

The McCall procedure and several later modifications close the cul-de-sac using an abdominal or vaginal approach. This technique plicates the uterosacral ligaments in the midline and suspends the posterior vaginal fornix to these ligaments.

The sacrospinous ligament fixation is a commonly performed procedure, particularly by urogynecologists. It is described in chapter 67 in full detail. It was initially described by Nichols<sup>7,8</sup> and Randall,<sup>8</sup> who had slight variations in their techniques. Both attach the vaginal vault to the sacrospinous ligament medial to the ischial spine, but Randall does it under visual control and Nichols under digital control. The procedure can be done unilaterally or bilaterally, and it typically uses a posterior extraperitoneal approach.<sup>8</sup> Several surgeons have criticized the approach for altering the vaginal axis and predisposing the patient to anterior compartment recurrences. An article with a 2.5-year follow-up reported a 29% rate of recurrent cystocele.<sup>9</sup> Additional complications described in the literature include hemorrhage (2%), gluteal pain (3%), pudendal nerve injury, and rarely, cystotomy or proctotomy.

Iliococcygeus fascia colpopexy involves suturing the vaginal cuff to the iliococcygeus fascia near the ischial spine bilaterally.<sup>10,11</sup> A similar procedure, called levator myorrhaphy, uses the levator ani fascia as the supporting structure for the vault suspension. Extraperitoneal and intraperitoneal approaches have been described, and both have had excellent reported results.<sup>12</sup>

Abdominal sacrocolpopexy (open or laparoscopic) is another approach advocated by some for vaginal vault prolapse. Through

an intraperitoneal abdominal incision, the sacral promontory and vaginal apex are exposed. The cul-de-sac is closed. A piece of sterile mesh or fascia is then attached to the apex of the vagina and eventually fixed to the sacrum using permanent sutures. The overlying peritoneum is closed, providing coverage of the mesh. This procedure adds the morbidity of a laparotomy and does not address severe anterior and posterior wall prolapse. Nevertheless, it has consistent long-term cure rates of more than 90%.<sup>13,14</sup> Because the procedure does not require excision of the vaginal wall, it helps to preserve vaginal length, leading some surgeons to advocate the procedure as first-line treatment in younger patients with vault prolapse who are sexually active.<sup>15,16</sup>

The major complications associated with abdominal sacrocolpopexy are hemorrhage from the presacral veins and mesh erosion. Several series have reported hemorrhage rates ranging from 1.2% to 2.6%.<sup>16,17</sup> Mesh erosion is reported to occur in up to 5% of cases.<sup>17</sup> A comprehensive review reported an overall rate of mesh erosion of 3.4%. The same review reported a 1.1% rate of small bowel obstruction requiring reoperation.<sup>18</sup>

Laparoscopic sacral colposuspension for apical defects has been described in numerous reports. It is done in a manner similar to the open approach, with four or five ports in the lower abdominal wall and a sponge stick in the vagina. Long-term outcomes have yet to be reported, but short-term results are in the same neighborhood as the open approach.

Although enterocele repair has been performed for approximately a century, few long-term outcomes have been reported. Previous studies report 86% to 96% cure rates at 15 and 17 months of follow-up, respectively.<sup>4,19</sup>

## COMPLICATIONS

Intraoperative complications include bleeding, ureteric and bladder injury, and rectal injury. Ureteral injury most commonly occurs from placement of the purse-string or culdosuspension sutures. Cystoscopy after intravenous indigo carmine can establish ureteral patency. When there is lack of efflux, passage of ureteral catheters can help exclude obstruction. Delayed complications include recurrent prolapse, vaginal shortening, dyspareunia, ileus, and bowel obstruction.

## CONCLUSIONS

The best approach to vaginal vault prolapse remains unknown. The surgeon's comfort and preference and proper patient selection are essential. A prospective study of 95 patients randomized to abdominal or vaginal repair showed no statistical difference in subjective or objective success. Longer operating times and longer convalescence were statistically significant in the abdominal cohort.<sup>9</sup> The transvaginal sacrouterine fixation for vault prolapse recreates the sacrouterine-ligament complex in support of the vaginal vault. The use of polypropylene mesh prevents levator descent, along with restoring the sacrouterine ligament complex and repairing the levator hiatus. It is a safe and effective procedure for preventing and treating enterocele and vaginal vault prolapse.

# USE OF A POSTERIOR SLING FOR VAGINAL VAULT PROLAPSE

Peter E. Petros

## HISTORY

The first posterior sling operation was performed in 1992. Initially, the operation was used only for repair of significant vaginal vault and uterine prolapse (i.e., restoration of structure). Over the past 12 years, it was found that coexisting symptoms of abnormal emptying, nocturia, pelvic pain, urge, and frequency—a group of symptoms now described as the posterior fornix syndrome<sup>1</sup>—also were being improved in approximately 80% of patients (i.e., restoration of function). Although the generic name for this procedure is infracoccygeal sacropexy,<sup>2</sup> the operation is universally known as the posterior IVS or posterior sling operation.

## RESTORATION OF STRUCTURE

### Dynamic Structural Mechanism of the Uterus and Vaginal Vault

The uterus and vaginal vault are anchored passively by the suspensory ligaments, the uterosacral ligaments (USLs) and arcus tendineus fasciae pelvis (Fig. 69-1), and they are anchored actively by the three directional muscle forces that stretch the vagina against these ligaments.<sup>3,4</sup> The USLs, the apical segment of the vagina, rectovaginal fascia, and perineal body (see Fig. 69-1) work synergistically as a subsystem,<sup>3</sup> and repair of all three is often required.

### Fibromuscular Supports of the Uterus and Vagina

The inherent strength of the rectovaginal fascia and its backward stretching by the levator plate are major factors in preventing prolapse, which is really a form of intussusception (Fig. 69-2). The cervix is a key anchoring point for the pubocervical fascia anteriorly and the rectovaginal fascia posteriorly, and the anterior and posterior fascial supports may need repairing in a patient with uterine or vault prolapse.

Hysterectomy may weaken the fascial side wall support and weaken the USLs, perhaps by removing a major part of the blood supply. Conservation of the uterus may be important in preventing vaginal prolapse and incontinence.<sup>5</sup>

### Vaginal Fascia as a Tensor of the Vagina

This concept, that vaginal fascia functions as a tensor of the vagina, was originally proposed by Sturmdorf in 1916,<sup>6</sup> and it was confirmed by an observational radiologic study.<sup>7</sup> During effort, the rectovaginal fascia was stretched backward against the perineal body and downward against the USLs to compress level 2 (Fig. 69-3). In contrast, there is no compression of level 2 in the

multipara with damaged tissues (Fig. 69-4), even though the muscles appear to be contracting normally, as evidenced by downward angulation of the anterior part of levator plate and forward movement of the distal urethra.

Compression of the vaginal canal appeared to be related to the angle “a” formed between the upper vagina and the horizontal at rest.<sup>7</sup> When the angle was more than 45 degrees to the horizontal (Fig. 69-5), only 2 of 23 patients demonstrated angulation and compression of the vagina on straining, compared with 100% when the angle was less than 45 degrees to the horizontal ( $n = 27$ ). If the vaginal fascia is lax, the stretching forces (see Fig. 69-5) may not be able to grip, and there is no angulation or compression (see Fig. 69-4B). The damaged vaginal tissues become vulnerable to the forces generated by the abdomen and pelvis (see Fig. 69-5) to create cystocele, rectocele, and enterocele.

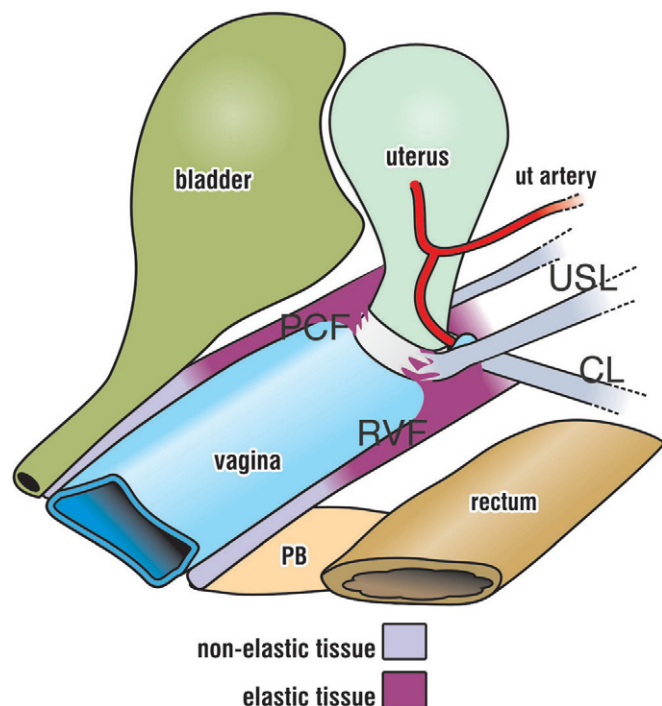

A short vagina may prevent angulation and compression (see Fig. 69-5). The vagina is a cylinder. Excising vaginal tissue during

**Figure 69-1** Active anchoring of the vagina, shown in a three-dimensional sagittal view from above and behind. During effort, the levator plate (LP) stretches the rectovaginal fascia (RVF) backward against the perineal body (PB). Downward contraction of the longitudinal muscle of the anus (LMA) against the uterosacral ligaments (USL) compresses the vagina. The uterus and vaginal vault are anchored passively by the suspensory ligaments (USL) and arcus tendineus fasciae pelvis and anchored actively by the three directional muscle forces (labeled arrows). EAS, external anal sphincter; PCM, m. pubococcygeus; PRM, m. puborectalis; PS, pubic symphysis; PUL, pubourethral ligament; S, spine.

surgery may shorten or narrow the vagina. It is possible to conclude the following from these findings:

1. Vaginal tissue should be conserved wherever possible.
2. The vaginal fascia should be restored to its preoperative tension by approximation of the separated edges.
3. The whole system may need repair, including the USLs, rectovaginal fascia, and perineal body.

**Figure 69-2** The fibromuscular supports of the vagina. CL, cardinal ligament; PB, perineal body; PCF, pubocervical fascia; RVF, rectovaginal fascia; USL, uterosacral ligament; ut, uterine.

## CORRECTIVE SURGERY

The late David Nichols stated that vaginal vault prolapse is a significant longer-term complication in patients undergoing hysterectomy.<sup>8</sup> Nichols emphasized the need for axial repair, conservation of vaginal form and function, and the requirement to repair coexisting cystoceles, rectoceles, and enteroceles. The biomechanical rationale for this is presented in Figure 69-5.

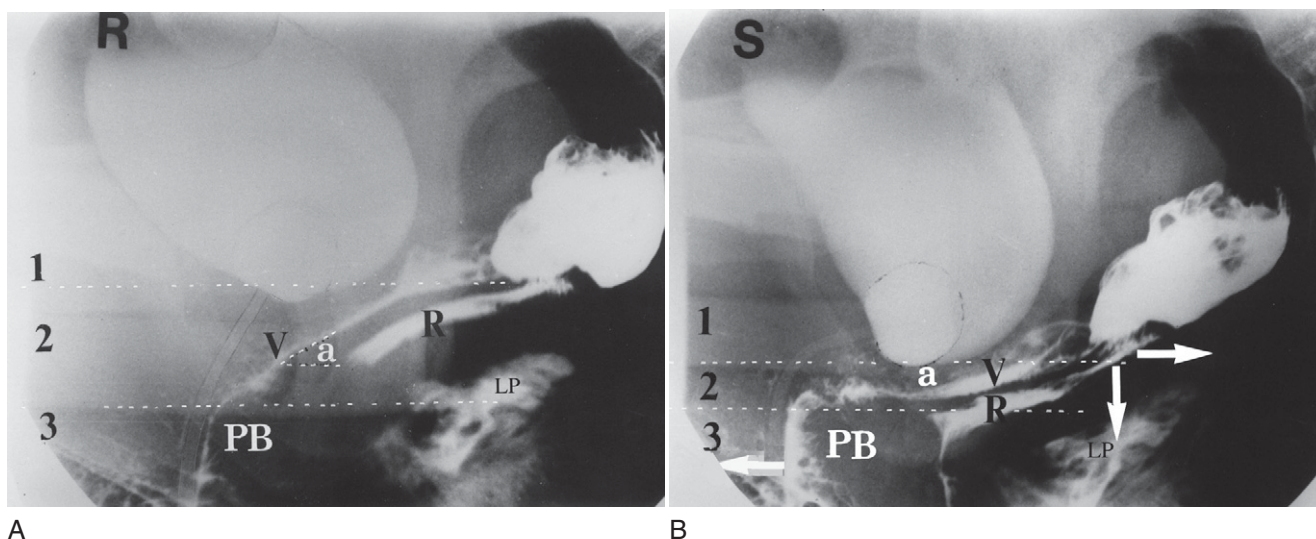

### Posterior Sling Operation

With the posterior sling operation, the aim was to create an axial procedure for cure of uterine and vaginal vault prolapse using plastic tapes to create artificial collagenous neoligaments. It was reasoned that this approach would avoid the morbidity and complications associated with alternative techniques: nerve injury and dyspareunia with sacrospinous colpopexy, bleeding from sacral veins and peritoneal adhesions with abdominal sacropexy, and ureteric injury with the McCall culdoplasty.<sup>9</sup>

### Posterior IVS Operation for Vaginal Vault Prolapse

A more evolved technique than that originally described<sup>2</sup> for the posterior IVS operation is presented. Posterior IVS (i.e., infracoccygeal sacropexy) reinforces the distal part of USLs and anchors the vaginal apex to the posterior muscles of the pelvic floor with a polypropylene tape. A full-thickness incision approximately 2.5 to 3 cm long is made in the posterior vaginal wall just below the hysterectomy scar line (Fig. 69-6). Using dissecting scissors with the tip pressed against the vaginal skin, a channel is made in the direction of the ischial spine sufficient to insert the index finger. The ischial spine is located, and the point of entry through the pelvic muscles for the IVS tunneler (Tyco) is determined. If an enterocele is opened, it is ligated with a high purse-string suture.

Bilateral skin incisions 0.5 cm long are made in the perianal skin at the 4- and 8-o'clock positions halfway between the coccyx and external anal sphincter in a line 2 cm lateral to the external

**Figure 69-3** **A**, Nullipara at rest. The numbers 1, 2, and 3 represent the three levels of connective tissue support for the vagina. **B**, Nullipara during straining. The vagina and rectum are stretched downward and backward by directional muscle forces (arrows). Note forward movement of the distal urethra. Level 2 is compressed. a, angle of the vagina compared with the horizontal; LP, levator plate; PB, perineal body; R, rectum; V, vagina.

**Figure 69-4** **A**, Multipara with damaged tissues. There is no angulation of the vagina around angle a. **B**, Multipara straining. The organs are directionally stretched by three forces (arrows), but level 2 is not compressed, and angle a is unchanged. Notice the downward bulging of the vagina. a, angle of the vagina compared with the horizontal; LP, levator plate; PB, perineal body; R, rectum; V, vagina; 1, 2, and 3, levels of connective tissue support for the vagina.

**Figure 69-5** The role of the muscle forces in angulation and compression of the vagina is shown in a schematic, three-dimensional, sagittal view. The abdominal and pelvic forces (long arrows) act on the vagina (V) to stretch it to the V1 position, where it is compressed by the intra-abdominal forces.

border of the external anal sphincter (Fig. 69-7). The tunnel is pushed 3 to 4 cm into the ischioanal fossa, keeping the plastic tip parallel to the floor (Fig. 69-8). The index finger is placed into the tunnel created in the vagina to locate the tip of the tunnel, which penetrates the levator muscles 1 cm medial and dorsal to the ischial spine (Fig. 69-9). At this point, the tunnel is safely sited well away from rectum and peritoneum.

With the index finger continually applied to the plastic tip (see Fig. 69-9), the tunnel is gently inclined medially, toward the vaginal vault, and pushed through the incision. A rectal examination is made to ensure there has been no perforation. The insert

**Figure 69-6** Vaginal incision, as viewed looking into the posterior vaginal wall. Sc, hysterectomy scar.

is reversed. An 8-mm polypropylene tape is threaded into the eye of the plastic insert, bringing the tape into the perineal area. The procedure is repeated on the contralateral side, leaving the tape as a U-shaped configuration entirely unfixed at the perineal end.

**Figure 69-7** Insertion of the tunneler. G, gluteus muscle; IRF, ischioanal fossa; IRV, inferior rectal veins; LP, levator plate; PC, pudendal canal.

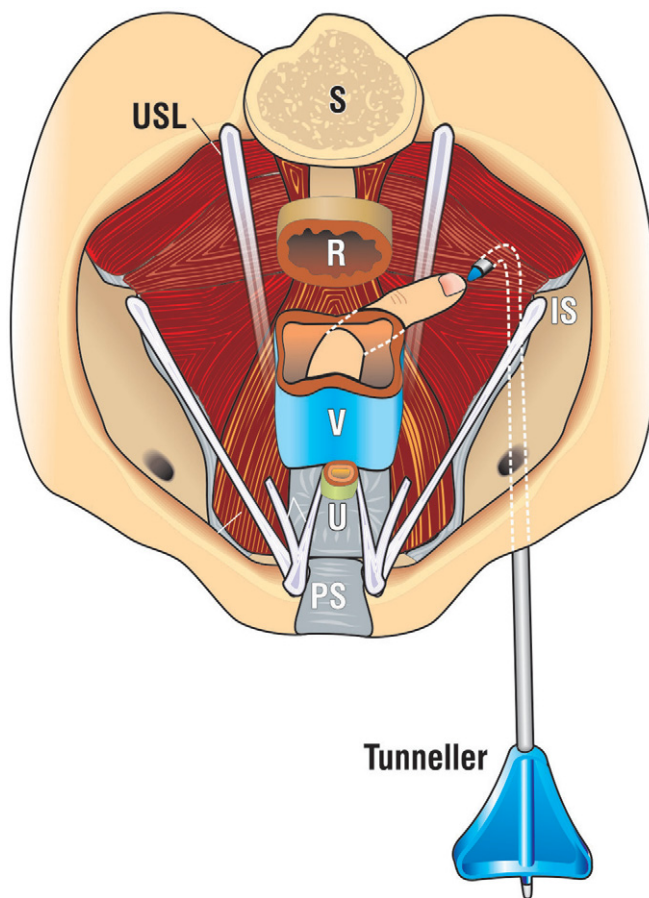

**Figure 69-8** As the tunneler is inserted in a supine patient, it passes across the anterior wall of the rectum.

Ensuring the tape is kept flat, the tape is sutured securely with interrupted 2-0 Dexon sutures to the fascia behind the hysterectomy scar (Fig. 69-10), ensuring the tape is positioned well away from the incision to minimize erosion. The remnants of the USLs and attached fascia are brought across to cover the tape.

The perineal ends of the tape are pulled to full extension, cut, and left free without suturing. The skin incision may be sutured without tension or apposed with Steri-Strips. If sutures are used, it is advisable to remove them in 24 hours because this is usually the most painful part of the operation.

**Posterior IVS Repair of Uterine Prolapse**

In the posterior IVS repair of uterine prolapse, the principles followed are similar to those for the Manchester repair, and the

**Figure 69-9** Perforating the pelvic muscles. The finger tip guides the tip through the tunnel to the vaginal incision. IS, ischial spine; PS, pubic symphysis; R, rectum; S, spine; U, urethra; USL, uterosacral ligament; V, vagina.

**Figure 69-10** Anchoring the apex. The tape is sutured to the fascia of vagina (V). Fibrosis attaches the vagina to the posterior pelvic floor muscles, which contract to retain it in position. LP, levator plate; PB, perineal body; PM, perineal membrane; R, rectum; S, sacrum; 1, 2, and 3, levels of connective tissue support for the vagina.

approach is combined with a posterior IVS operation. An elongated cervix is amputated. An incision is made just below the junction of the vaginal skin to cervix and opened out. This brings the USLs into view. Having reconstituted the cervix, the posterior IVS tape is inserted. If possible, exit of the tunneler is directed between USLs and cervix. The tape is sutured into the USLs near their cervical insertion.

Posterior IVS with apical defect repair (enterocele) follows the same surgical principles as vault prolapse repair. Care is taken to free the enterocele sufficiently to locate the cardinal ligaments and USLs. The enterocele is not routinely opened. With a large prolapse, the enterocele is dissected clear. If entered, closure is completed with a purse-string suture. A posterior IVS operation is performed, and the tape is anchored to the USLs or behind the hysterectomy scar. The USLs and attached fascia are approximated as described previously. Excess vaginal tissue is not excised; it is instead sutured down into the approximated rectovaginal fascia.

### Rectovaginal Fascia and Perineal Body Repair

The main surgical principles include conservation of vaginal tissue to prevent dyspareunia and a short vagina, and avoidance of tension during suturing. The vagina has a visceral nerve innervation, and like bowel, it is extremely susceptible to pressure. Laterally displaced fascia and perineal body are approximated. If mesh is to be used for the posterior wall, it can be set deeply below the vaginal epithelium by threading the tape through the mesh before the tape is brought through into the vagina. The mesh is then trimmed and left free, or sutured laterally and to the perineal body. Surgery on the perineal skin, which has somatic nerve innervation, should also be avoided. Confining the incisions within the vaginal epithelium makes for a far less painful operation.

### Operation Characteristics of the Posterior IVS Operation

In the first reported study,<sup>2</sup> 75 patients were prospectively studied over 4.5 years. Preoperatively, 22 had second-degree prolapse, 45 had third-degree prolapse, and 8 had fourth-degree prolapse. Recurrence rates are detailed in Table 69-1, but no further surgery was required in two of three recurrences. The operating time for the sacropexy itself was generally less than 15 minutes. Total operating time, including posterior vaginal repair, varied between 25 and 50 minutes. Blood loss from the sacropexy itself was minimal. Mean blood loss from the posterior vaginal repair was 120 mL (range, 20 to 800 mL); the most blood lost was in a patient with undiagnosed von Willebrand's disease. No patient required transfusion. All 75 patients were discharged the day of or day after surgery without indwelling catheters. All patients returned to normal activities (including jobs) within 7 to 10 days, some within 2 to 3 days. Minor bruising was observed around the incisions in 10% of patients. No hematoma or postoperative pyrexia was reported.

## Potential Complications of Posterior Sling Repair

### Hematoma

Anatomically, the tunneler is inserted into the ischioanal fossa, well away from the perirectal veins or the pudendal nerve. The blunt tip of the tunneler reduces but does not eliminate the risk of hematoma. Infection is rare. A hematoma from the vaginal repair is more likely.

### Rectal Perforation by the Tunneler

Two uneventful perforations were reported in the initial series,<sup>2</sup> but they have not occurred since the present technique was adopted 4 years ago. Any perforation is extraperitoneal and punctate, and like a bladder perforation with the anterior sling, it is closed by smooth muscle contraction. If perforation occurs, the surgeon removes the tunneler and repeats the procedure. Any small injury is sutured with two sutures applied from the vaginal end. Fistula formation is highly unlikely and has never occurred in my personal series of more than 1500 cases.

### Tape Erosion with Polypropylene Tapes

Tape erosion with polypropylene mesh tape may occur in 1% to 3% of patients, and usually occurs centrally. The erosion is usually a simple surfacing, or it may be a foreign body reaction. The latter may extend to the perineum. Both conditions are benign. If the tape has surfaced, it is grasped, and the vaginal mucosa is pushed down around it. Under tension, the eroded segment is trimmed with scissors pushed down below the vaginal mucosa. Sometimes, the segment may need excision. Deeply burying the tape behind the hysterectomy scar at the time of surgery helps reduce the erosion rate considerably (BN Farnsworth, personal communication, 2004). A purulent discharge at the perineum usually is caused by a foreign body reaction. The patient is afebrile, with a normal white blood cell count. Bacteriologic swabs generally do not grow bacteria. Sterile pus surrounds the whole tape, and this makes removal a simple matter of finding the vaginal sinus at the apex, grasping the tape with a hemostat, and pulling it out. This is simpler and more effective than attempts to remove it through the perineum. Clinical infection is rare and is accompanied by pyrexia and an increased white blood cell count. It is advisable to perform bacteriologic swabs to identify pathogenic bacteria and to treat the patient with appropriate antibiotics before any surgical intervention.

### Total Rejection of Polypropylene Tapes

Complete tissue rejection occurs rarely with polypropylene tapes. The tapes are easily removed in toto by grasping the vaginal end and pulling gently.

### Risk of Rectal Perforation During Vaginal Repair

In patients with a scarred perineum, it is critical to dissect only under tension to minimize the risk of rectal perforation. Finger

**Table 69-1 Cumulative Herniation Rate after Posterior IVS Operations**

Condition	6 Weeks n = 75	1 Year n = 71	2 Years n = 64	3 Years n = 56	4.5 Years n = 40
Vault prolapse	0 (0%)	2 (2.6%)	4 (5.2%)	4 (5.2%)	4 (5.2%)
Anterior wall prolapse	0 (0%)	6 (8%)	12 (16%)	12 (16%)	12 (16%)
Partial rectocele	0 (0%)	3 (4%)	3 (4%)	3 (4%)	3 (4%)

dissection in these circumstances is especially dangerous. Hemostats placed on the edge of the vagina and on the rectal wall adhesions are stretched so that dissection is performed under tension using dissecting scissors, a prerequisite to avoid rectal perforation. An assistant creating countertension and the operator's finger in the rectum may also be helpful. If the rectum is perforated, the rectal wall must be mobilized sufficiently from the adjacent scar tissue to facilitate a tension-free repair in at least two layers.

### Restoration of Posterior Zone Anatomy with a Tissue Fixation System

The tissue fixation system (TFS) posterior sling is a promising new technique, and it is similar to the McCall operation (Fig. 69-11). It uses two small anchors attached to a strip of polypropylene mesh tape as a U shape in the exact position of the USLs. It relies on adequate tissue for the anchor to grip. A full-thickness incision is made in the vaginal apex. Fine dissecting scissors create a 4-cm space between the vagina and USLs on both sides. The TFS applicator is inserted to a depth of 4 cm and set with a tug. This insertion is repeated contralaterally. The tape is tightened and trimmed 1 to 1.5 cm from the TFS. The overlying USLs and fascia are approximated and the vagina sutured. There is minimal intraoperative bleeding and postoperative pain. Mean operating time is 5 to 6 minutes.

**Figure 69-11** Posterior tissue fixation system, TFS viewed from above. The tape is placed along the exact position of the uterosacral ligament (USL). The arrows indicate that the remnants of the USL and the cardinal ligaments (CL) need to be approximated if the apex is wide to prevent enterocele formation.

The TFS was used to treat major structural defects in 67 patients<sup>10</sup> (Table 69-2). The rectovaginal fascia and perineal body were repaired when required. Very few complications were seen in 67 posterior TFS operations at mean of 9 months' review.<sup>10</sup> In one patient, one half of the sling was found in the vagina covered by a large granuloma, with no vault prolapse and no posterior zone symptoms. This was attributed to surgeon error in not anchoring the tape sufficiently. The prolapsed part of the sling was excised and the vagina sutured. It was not possible to insert a TFS in one patient who had previously undergone pelvic clearance for extensive endometriosis. A posterior IVS operation was successfully performed. There was one vaginal infection after a standard rectocele repair. One patient reported with severe de novo urgency immediately after surgery. Transperineal ultrasound demonstrated a 2-cm-diameter hematoma at the bladder base. The symptoms settled within 6 weeks after the hematoma was absorbed.

### RESTORATION OF FUNCTION

In 1993, improvement in an apparently unrelated group of symptoms grouped together as the posterior fornix syndrome<sup>1</sup> was observed after repair of the USLs. The symptoms were urgency, frequency, nocturia, pelvic pain, and abnormal emptying. These symptoms constitute the main body of the symptoms within the posterior zone (Fig. 69-12). Although the concept that posterior zone symptoms were potentially curable surgically was initially controversial, there has since been a growing acceptance after reports by Farnsworth<sup>11</sup> and others of up to 80% cure rates for urgency, nocturia, and pelvic pain after posterior IVS operations. Later data using the posterior TFS are presented in Table 69-3.

**Table 69-2** Structural Outcome for Posterior Zone Prolapse Repair

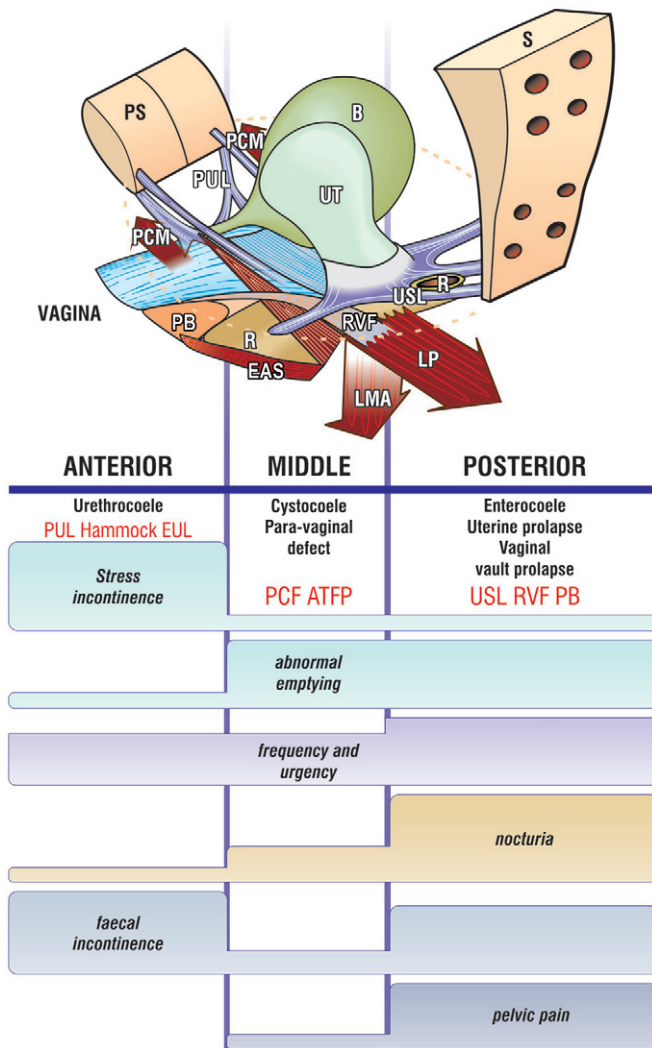

Operation	No. of Patients	Recurrences
Posterior with a tissue fixation system (TFS)	67	1
Trans-TFS for rectocele	9	0

\*Symptom change with surgery (percent cure in parentheses).

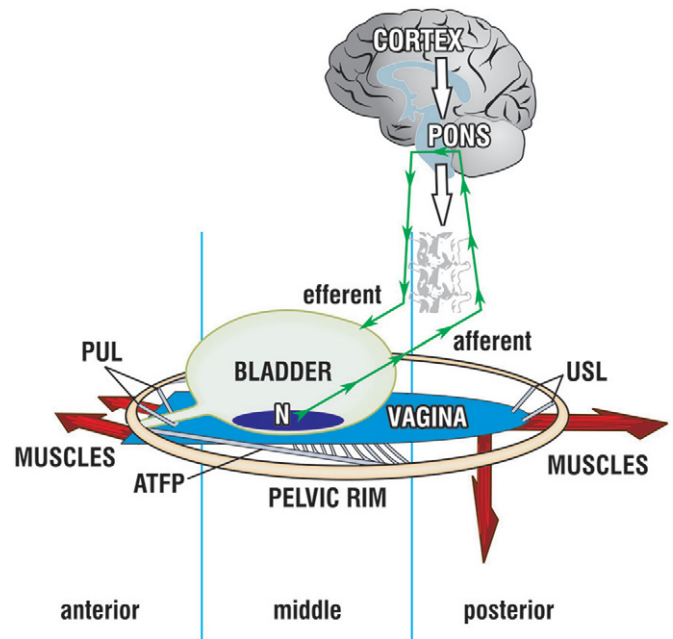

**Figure 69-12** The pictorial diagnostic algorithm summarizes the relationships between structural damage in the three zones of vaginal support and symptoms. The size of the bar gives an approximate indication of the prevalence (probability) of the symptom. The same connective tissue structures in each zone may cause prolapse and abnormal symptoms. B, bladder; EAS, external anal sphincter; PB, perineal body; PCM, m. pubococcygeus; PRM, m. puborectalis; PS, pubic symphysis; PUL, pubourethral ligament; R, rectum; RVF, rectovaginal fascia S, spine; USL, uterosacral ligament; UT, uterus. (From Petros P: The Female Pelvic Floor. New York, Springer-Verlag, 2004.)

Twenty-eight of these patients had only minor posterior zone prolapse, Table 69-2.

Lax ligaments may cause urge, frequency, and nocturia. In the normal patient, the cortex coordinates urinary retention and micturition (Fig. 69-13).<sup>3</sup> As the bladder fills, the stretch receptors send afferent impulses to the cortex.<sup>12</sup> If it is inconvenient to micturate, the impulses are blocked by the inhibitory centers and by contraction of the three pelvic muscle forces. These stretch the vaginal membrane like a trampoline to support the hydrostatic pressure of the urine, relieving the pressure on the receptors, thereby diminishing the afferent impulses to the cortex.

Like a trampoline with loose springs, lax ligaments may not allow the muscles to tension the vaginal membrane, and the

**Figure 69-13** The vaginal trampoline. The vagina is suspended by the pubourethral ligaments (PUL), arcus tendineus fasciae pelvis (ATFP), and uterosacral ligaments (USL). Red arrows represent pelvic muscle forces. White arrows indicate the central inhibitory mechanism. (From Petros P: The Female Pelvic Floor. New York, Springer-Verlag, 2004.)

receptors (see Fig. 69-13) fire, activating the micturition reflex prematurely. The sequence of events in patients with urodynamically demonstrated detrusor instability (Fig. 69-14) was similar<sup>13</sup> to that in normal patients about to micturate: sensory urgency, urethral relaxation, detrusor contraction (Fig. 69-15), and urine loss.<sup>14</sup> This “premature micturition” may be symptomatically expressed as frequency, urgency, and nocturia. The rationale for surgical cure of these symptoms is that firm ligaments and fascia permit the vagina (see Fig. 69-13) to be stretched sufficiently to offer support. This concept can be confirmed as an office procedure using the technique of simulated operations.<sup>15</sup> The patient’s bladder needs to be sufficiently full for her to have urge symptoms in the supine position. In its simplest form, the vagina is supported below bladder base digitally, by a ring forceps, or by gentle compression of the vaginal tissue just behind bladder neck with a Littlewood forceps.

Unmyelinated nerves run along the USLs. A lax ligament may not be able to support these nerves, and they become subjected to the force of gravity. This explains the dragging nature of the pain experienced and symptom relief on lying down.

Compared with a normal patient at rest (Fig. 69-16), it has been demonstrated radiologically and electromyographically<sup>4</sup> that after relaxation of the forward force, the bladder base and urethra are pulled open (i.e., funneling), apparently by pelvic contraction, during micturition (Fig. 69-17). The downward force acts against the USLs, and lax USLs diminish the opening forces. As the intraurethral resistance varies inversely with the fourth power of the radius, failure of the pelvic muscles (see Fig. 69-17) to open the urethra increases the resistance geometrically, which is perceived as obstructed micturition. For example, if the radius of the urethra in a normal patient (see Fig. 69-17) is

**Figure 69-14** Detrusor instability: premature activation of the micturition reflex. The arrows indicate synchronous pressure variations in the urethra and bladder. B, bladder pressure; c to c1, rise in detrusor pressure; CP, closure pressure; r to r1, fall in urethral pressure; U, urethral pressure. (From Petros P: *The Female Pelvic Floor*. New York, Springer-Verlag, 2004.)

R, expelling urine through a urethra which can open only to a radius of  $R/2$ , will require an expulsion pressure 16 times greater than that required for R.

### CONCLUSIONS AND FUTURE DIRECTIONS

The use of posterior slings for vault and uterine prolapse repair is becoming well accepted. The future challenge is to explore their use in patients with major symptoms and minimal prolapse to more accurately assess which other connective tissue structures may be contributing to dysfunction and how best to repair these structures.

**Figure 69-15** Control of detrusor instability by stretching the vagina. Some seconds after the release of vaginal tension, the detrusor begins to contract. (From Petros P: *The Female Pelvic Floor*. New York, Springer-Verlag, 2004.)

# TRANSVAGINAL REPAIR OF APICAL PROLAPSE: THE UTEROSACRAL VAULT SUSPENSION

*Raymond T. Foster, Sr., and George D. Webster*

For decades, the reconstructive treatment of uterine prolapse or post-hysterectomy vaginal cuff descent has included suspension of the vaginal apex. Reconstructive urologists and gynecologists have developed many techniques, including abdominal, laparoscopic, and vaginal routes of surgery, for the correction of apical descent.<sup>1</sup> Our understanding about which technique or approach is superior with regard to efficacy, safety, and durability is limited by a relative lack of level I evidence. Although many well-designed, retrospective reports (each with a large study population and long-term follow-up) exist to give us useful information about particular procedures for the correction of vault descent,<sup>2-17</sup> we are still unsure which procedure is best for any particular patient. The techniques used to treat pelvic organ prolapse are largely shaped by each surgeon's experience and

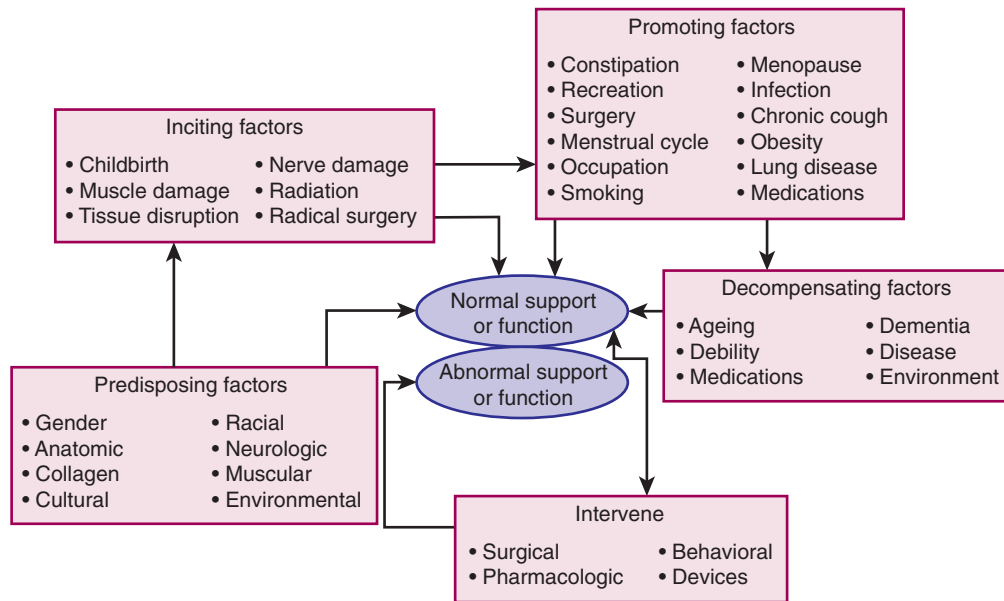

training and not necessarily influenced by prospective, outcomes-based research.

To compound the problem of sparse well-designed and executed, randomized surgical trials, we are also handicapped by confounding, coexisting pelvic support problems. It is difficult to study apical prolapse in isolation, because most patients present for treatment with many support defects (Fig. 70-1) and associated pelvic floor dysfunction (e.g., urinary incontinence, defecatory dysfunction, pelvic pain, difficulty with sexual intercourse). We are, for example, unsure of how our choice of treatment for cystocele or urethral hypermobility may affect the outcome of our vault suspension.

Operative technique in other fields is often driven by an understanding of the cause and natural history of the surgical

**Figure 70-1** Prolapse of the vaginal vault with associated apical enterocele. **A**, Vaginal vault prolapse with cystocele. **B**, Vaginal vault prolapse with a proximal rectocele.

**Figure 70-2** Model developed by Bump and Norton<sup>18</sup> to propose a mechanism for the development and progression of pelvic floor dysfunction, including pelvic organ prolapse.

problem, and this often helps guide surgical therapy. Unfortunately, we are still uncertain about these variables in pelvic organ prolapse. Bump and Norton<sup>18</sup> have provided a useful model with which we can consider how prolapse develops and progresses (Fig. 70-2), but in their own words, the model is “based mainly on expert opinion and supported by limited epidemiologic and clinical evidence. None of the factors has been studied in a longitudinal fashion in a representative study.”

The surgical goal in treating pelvic organ prolapse is to select a technique that can maximize the chance of anatomic and functional cure and minimize the occurrence of intraoperative injury or complication, but we must recognize that surgeons have preferred techniques based on training and experience. We favor a transvaginal surgical correction of apical prolapse, and our goal is to review the history of the uterosacral ligament vault suspension, a procedure that is often considered to be the gold standard in transvaginal surgery for apical prolapse.

## HISTORY

Written history of gynecologic surgery documents that uterosacral ligaments have been used in vaginal reconstructive surgery for at least the past century, but it is difficult to say who was the first person to conceive of the importance of these structures in supporting the uterus and vaginal apex. John Burns, a renowned Scottish anatomist and surgeon, was the first person to write about the importance of the uterosacral ligaments. In his 1839 book, *The Principles of Midwifery including the Diseases of Women and Children*, Burns<sup>19</sup> wrote:

*By experiments made on the dead subject, we find that prolapsus is chiefly prevented by the fascia passing off from the cavity of the pelvis to the upper part of the vagina, and thence reflected to the face of the rectum. It is also prevented by the fascia of the outlet of the pelvis, and levator ani, which contribute to support the vagina. . . . The greatest aid,*

*however, is afforded by the levator ani and the pelvic fascia, particularly that part of it which is deep in the cavity of the pelvis.*

Burns published earlier editions to this enormously popular text in 1810, 1813, 1814, 1817, 1824, 1831, 1832, and 1837. In some earlier editions (1810 and 1813), he was discouraged that apical prolapse could not be created in cadavers by disrupting the round ligaments and applying traction to the cervix through the vagina, but he and his students continued their cadaver work, and their writings became exponentially more informed.

The first mention of the use of uterosacral ligaments to suspend the vaginal apex as treatment for prolapse was by the American gynecologist Norman F. Miller, who in 1927 described the placement of a “no. 2 chromic catgut suture on a small full curved needle passed through the peritoneum and underlying fascial and muscular structures at the base of the sacro-uterine ligament, approximately 1½ inches below the promontory of the sacrum.” Since this report, the use of the uterosacral ligament for apical prolapse has been described by other surgeons. McCall first described his transvaginal culdoplasty technique for treating enterocele with associated vault prolapse in 1957.<sup>20</sup> Lee and Symmonds<sup>21</sup> published what became known as the *Mayo modification* in 1972. As vaginal surgeons made developments in the treatment of apical prolapse with the uterosacral ligament (among other attachment sites, including the iliococcygeus fascia<sup>22</sup> and the sacrospinous ligament<sup>23</sup>) throughout the 20th century, parallel progress was being made in the abdominal<sup>24, 25</sup> and laparoscopic<sup>26</sup> approaches to vault prolapse. In the later half of the 20th century, less attention was attributed to a vaginal uterosacral vault suspension as other techniques and approaches became widely used with acceptable results.

Four prominent gynecologic surgeons—Cullen Richardson (1923–2001), William Saye, Tom Elkins (1950–1998), and Bob Shull—met in Atlanta in the fall of 1992 to review videos of laparoscopic support procedures and discuss surgical strategies for the treatment of pelvic organ prolapse (interview with B. Shull,

2005). Richardson had previously stressed the importance of finding specific fascial defects and repairing them to achieve optimal restoration of pelvic anatomy.<sup>27</sup> After working together, Richardson and Saye developed what is now known as the Richardson-Saye laparoscopic technique of enterocele repair and vault suspension, which applies the principles of site-specific repair<sup>26</sup> to the laparoscopic approach. During their meeting in 1992, it occurred to the assembled group that they could find specific fascial defects, repair them, and resuspend the newly reconstructed vault to the uterosacral ligaments from a vaginal approach. In 2000, Shull and colleagues<sup>6</sup> published their technique and experience with this approach in 302 consecutive women. With only minor modifications, this is the surgical technique that we now use for the transvaginal correction of apical prolapse, and it is this procedure that we describe in this chapter.

### TECHNICAL ASPECTS OF THE UTEROSACRAL LIGAMENT VAULT SUSPENSION

We are inclined to offer transvaginal repair to most of our patients. In our hands, this route of surgery has been safe, efficacious, and durable.<sup>3</sup> We have developed a bias, however, in that we prefer the abdominal sacral colpopexy to treat apical prolapse in our younger and more physically active patients. We are also likely to consider abdominal sacral colpopexy in patients with complete vaginal vault inversion.

Preoperatively, we discuss with the patient the reported incidence of complications associated with such major surgery in general and with this technique in particular. The ureteral obstruction rate is between 0% and 11%.<sup>2,4-6</sup> Intraoperative or postoperative blood transfusion may be required in up to 1% of patients.<sup>2,4-6</sup> It is important that the patient have realistic expectations of what can be achieved and that recurrent prolapse of the vault or the development of other vaginal defects is not uncommon. Interference with sexual function, in particular loss of vaginal depth and caliber, is not uncommon.

Patients are placed in the dorsal lithotomy position using padded, adjustable (Allen) stirrups and wearing sequential compression hose. The rectum is packed with an open, wet Kerlix sponge to the level of the ischial spines to aid the identification of the rectum and decrease the incidence of intraoperative injury during placement of the uterosacral suspensory sutures. A self-retaining vaginal retractor (Lone Star Medical Products, Houston, TX) and a weighted speculum are used to obtain good visualization. If the patient is being treated for uterine prolapse, a vaginal hysterectomy is performed as previously described by Lee<sup>28</sup> with minor modifications. In patients being treated for vault descent alone, a silk marking suture is placed in the vaginal epithelium at 3-o'clock and 9-o'clock positions at the vaginal apex for later reference. At these positions, the surgeon usually can see an epithelial dimple indicating the prior attachment point of the uterosacral ligaments to the vaginal cuff.

The vaginal epithelium is incised in the midline along the extent of the prolapsed vaginal segments. The dissecting scissors are used to separate the vaginal epithelium from the underlying pubocervical and rectovaginal connective tissues as needed to expose the entire fascial defect, including the enterocele sac. With the patient in Trendelenburg position, the enterocele sac is identified and opened sharply. A wet Kerlix sponge is used to pack the bowel out of the operative field into the upper peritoneal

cavity. We have learned by experience to protect the posterior peritoneum (with an instrument such as a Breisky-Navratil retractor) to avoid tearing the peritoneum during the packing process, which invariably leads to bleeding and poor visualization of anatomic structures along the pelvic side wall.

For correct and safe placement of the uterosacral suspensory sutures, good exposure is critical. To provide adequate illumination in this deep cavity, we are accustomed to using a surgical headlight or a cool lighting system adherent to our retractor that is designed to be placed within the pelvis (LightMat surgical illuminator, Lumitex, Inc., Strongsville, OH). Various techniques have been used to expose the pelvic side wall, but we have been most satisfied using Breisky-Navratil retractors. Three Breisky-Navratil retractors are placed anteriorly, laterally, and posteriorly so that the bladder, ureter, and rectum, respectively, are protected while the uterosacral ligament is easily visualized. The posterior retractor, placed in the angle between the packed and easily identifiable rectum and the pelvic side wall, can be used to sweep the rectum to the contralateral side during placement of the uterosacral suspensory suture. By placing light tension on the uterosacral ligament, by traction on the earlier placed silk suture at the dimples at the vaginal cuff, identification of this ligament becomes much easier. A no. 1 polyglactin suture is passed through the uterosacral ligament medial and cephalad to the ischial spine. We have had excellent anatomic outcomes using a single absorbable suture through each uterosacral ligament, but this procedure has been described by others with as many as three suspensory sutures through each uterosacral ligament (Fig. 70-3). Tension placed on each uterosacral suspensory suture is used to confirm placement at a sturdy location and to visualize an attachment point in the proximal uterosacral ligament.

After a suture has been placed through each uterosacral ligament, the sutures are held with a tag for later use in suspending the vaginal apex. At this point, the patient is given 5 mL of intravenous indigo carmine dye and 5 mg of intravenous furosemide. The Foley catheter is removed, and a 70-degree cystoscope is used to inspect for spill of blue urine from each ureteral orifice while the uterosacral suspensory sutures are held on tension. If ureteral obstruction is suspected, the ipsilateral suspensory suture is released to confirm ureteral efflux. If necessary, the suspensory suture is removed and replaced in a more medial position. The anterior arm of each suspensory suture is passed through the apical portion of the pubocervical connective tissue, and the posterior arm of each suture is passed through the apical portion of the rectovaginal connective tissue. A Mayo needle is used where necessary (see Fig. 70-3). Both ends of each suspensory suture are passed through the vaginal epithelium near the silk marking sutures that were placed at the outset of the procedure.

Once satisfied with placement of the uterosacral suspensory sutures, attention is directed toward site-specific repair of any remaining prolapse defects. Typically, we use an anterior colporrhaphy to correct cystocele and a posterior colporrhaphy with or without allograft material (i.e., cadaveric dermis) to correct rectocele. Anterior and posterior colporrhaphy work well to reestablish a clearly defined transverse (apical) portion of the pubocervical and rectovaginal connective tissue. Colporrhaphy also aids in the preservation of acceptable vaginal length. Besides repair of the anterior and posterior defects, we commonly perform high ligation and excision of the enterocele sac using a 2-0 polyglactin suture. If stress urinary incontinence was a preoperative complaint or if a positive stress test result or urodynamic evidence of stress urinary incontinence existed with the

Double-Armed Suture Through Pubocervical Fascia  
Retrovaginal Fascia, and Left Uterosacral Ligament

**Figure 70-3 A and B**, By passing one end of the each uterosacral suspensory suture through the apical (transverse) portion of the pubocervical connective tissue and the opposite end through the apical (transverse) portion of the retrovaginal connective tissue, the surgeon can elevate the vaginal cuff and reapproximate the endopelvic fascia simultaneously with two or more such sutures. AD, Apical Defect; B, Bladder; PCF, Pubocervical Fascia; USL, Uterosacral Ligament.

prolapse replaced, a pubovaginal sling also is performed. Sling tension is adjusted after the uterosacral sutures have been tied and after completion of the anterior repair.

The uterosacral suspensory sutures are then tied to close and suspend the vaginal cuff to the point of retroperitoneal uterosacral ligament fixation. The surgeon is reassured of excellent placement of these sutures if the knots seat in a posterior direction toward the sacral hollow. Redundant vaginal epithelium (after associated anterior and posterior repair by fascial plication or allograft placement) is excised and the epithelium closed. A digital vaginal examination is next performed to assess the axis and depth of the vaginal canal (Fig. 70-4). A vaginal pack is placed if deemed necessary, and a digital rectal examination is performed at completion to confirm the absence of suture material in the rectal lumen.

#### POSTOPERATIVE CARE AND PATIENT INSTRUCTIONS

Although patients are able to ambulate and tolerate a diet on the evening of the day of surgery, we usually leave in the Foley cath-

eter in place until the morning of postoperative day 1. With few exceptions, we consistently use scheduled dosing of oral narcotic analgesics in lieu of intravenous narcotics (i.e., patient-controlled analgesia by intravenous morphine pump). Our typical postoperative pain control regimen includes a 12-hour dosing schedule of controlled-release oxycodone combined with a 6-hour dosing schedule of intravenous ketorolac or oral ibuprofen. Anecdotally, we observe less postoperative nausea, pruritus, and respiratory depression when we avoid using narcotics through an intravenous pump.

On the morning of postoperative day 1, the nursing staff is instructed to fill the patient's bladder with 300 mL of fluid (i.e., normal saline or sterile water) through the Foley catheter. The Foley catheter is removed, and the patient is instructed to void. The amount of urine voided is measured. If the postvoid residual urine volume exceeds the amount voided, the patient is sent home with instructions to do self-catheterization as necessary; patients are taught how to perform self-catheterization preoperatively. If the patient can spontaneously empty more than 50% of the total bladder contents, she is dismissed without an indwelling catheter or self-catheterization program.

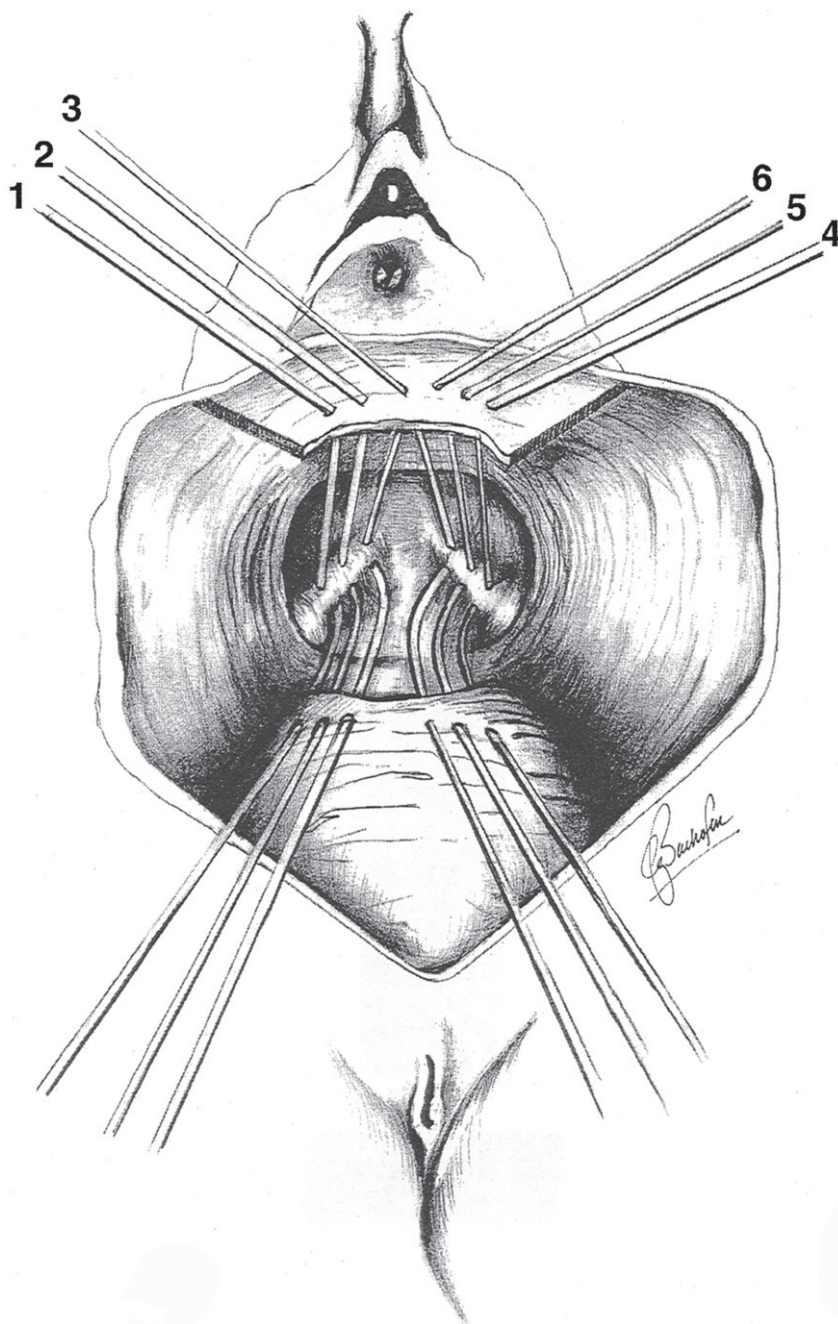

Figure 70-3 cont'd

B

We use printed discharge instructions that outline answers to common questions patients have in the postoperative period. The instruction sheet covers postoperative activity level (we discourage heavy lifting and straining for 90 days), constipation management, bathing, driving, vaginal bleeding, catheter program parameters, and other areas of interest and frequent concern to our patients. Patients usually are followed in the clinic after vaginal reconstructive surgery at 6 weeks, 6 months, and 1 year postoperatively. We typically allow patients to resume intravaginal intercourse and employment activities after the first postoperative visit. At the 6-month and 1-year postoperative visit, we reassess the patient's pelvic support using the Pelvic Organ Prolapse Quantification (POP-Q) scoring system.<sup>29</sup> The POP-Q

score is compared with our preoperative evaluation so that we can assess the efficacy and durability of surgery.

#### CONCLUSIONS AND FUTURE DIRECTIONS

Transvaginal suspension of the vaginal vault to the uterosacral ligament for the treatment of apical prolapse is a safe, efficacious, and durable procedure.<sup>2-6</sup> Although reports have been published comparing the treatment of apical prolapse using the vaginal and abdominal approaches with mixed outcomes,<sup>30,31</sup> we believe that in our hands, transvaginal surgery affords most patients

**Figure 70-4** At the conclusion of the procedure, a digital vaginal examination is performed to assess the vaginal axis and depth. B, Bladder; PCF, Pubocervical Fascia; R, Rectum; RVF, Rectovaginal Fascia; USL, Uterosacral Ligament.

the best chance of cure with the least morbidity and shortest convalescence.

The care of patients with prolapse will continue to evolve as our understanding of the natural history of this disease becomes more informed. Pelvic organ prolapse, including apical prolapse, is a widespread problem among women in the United States and abroad. The lifetime risk for pelvic organ prolapse surgery in women is reported to be more than 11%.<sup>32</sup> Pelvic organ prolapse often coexists with urinary and fecal incontinence, sexual dysfunction, and defecatory dysfunction.

Despite myriad procedures to correct the anatomic circumstances arising with pelvic organ prolapse, there is often poor correlation between the anatomic and functional outcomes of surgery. The best operation designed to restore normal pelvic anatomic relationships can leave women with suboptimal functional outcomes. The best therapies therefore are measures taken to prevent prolapse in asymptomatic women.

The most efficient way to employ preventive measures is to identify women at risk and intervene in that group of patients. Little has been written about the epidemiology of pelvic floor dysfunction, including pelvic organ prolapse.<sup>29</sup> Our current understanding of the development of prolapse correlates this problem with risk factors that include vaginal parity, age, race, obesity, and chronic constipation.

Pelvic organ prolapse, urinary incontinence, and fecal incontinence have been associated with denervation injury of the pelvic

floor muscles during vaginal childbirth.<sup>33</sup> Vaginal childbirth may be a time in the early stages of the natural history of pelvic organ prolapse when intervention could significantly prevent prolapse later in life. Some have advocated elective cesarean section as an intervention. It may be possible, however, to treat nerves damaged during vaginal childbirth so that denervation of the pelvic floor may be minimized or eliminated. We are involved in ongoing research with the squirrel monkey model of pelvic organ prolapse to define the role of parturition-induced nerve injury and to eventually propose pharmacologic intervention that would decrease the risk of permanent nerve injury after pelvic floor trauma, such as that incurred during vaginal childbirth.

Until the results of research in humans and animal models are available to help us understand the cause of prolapse, we will continue to treat prolapse with conservative, nonsurgical techniques and with invasive procedures designed to provide anatomic and functional cure. The procedure described in this chapter has a reported efficacy between 87%<sup>6</sup> and 100%,<sup>5</sup> with patients followed for up to 4 years. The morbidity and postoperative recovery associated with the transvaginal uterosacral vault suspension is acceptable and satisfying to surgeons and patients. We believe that this particular procedure will continue to be the gold standard for the treatment of apical prolapse in the hands of experienced vaginal surgeons for many years to come.

# VAGINAL HYSTERECTOMY IN THE TREATMENT OF VAGINAL PROLAPSE

*Christopher M. Rooney and Mickey M. Karram*

Hysterectomy continues to be one of the most commonly performed surgical procedures in the United States, second only to cesarean section. Approximately 800,000 hysterectomies are performed annually in the United States.<sup>1</sup> According to the National Center for Health Statistics, 3,525,237 hysterectomies were performed in the United States between 1994 and 1999, at a rate of 5.5 per 1000 women. The most common indication for hysterectomy continues to be uterine leiomyoma, accounting for approximately 38% of all hysterectomies. Endometriosis accounts for 18% of all hysterectomies, followed by uterine prolapse (16%) and endometrial hyperplasia (4%).<sup>1</sup> As the population of women older than 65 years continues to rise, the practitioner can anticipate an increase in the number of women presenting with these indications.<sup>2</sup> Most hysterectomies are performed by the abdominal route, with the rate of vaginal hysterectomy remaining stable over the past several decades.<sup>1</sup> Vaginal hysterectomy in the appropriately selected patient has been reported to result in a shorter hospital stay, less operative blood loss, and less postoperative pain compared with the abdominal route of hysterectomy. Patients presenting for evaluation and surgical correction of pelvic organ prolapse are particularly appropriate candidates for vaginal hysterectomy.

### ANATOMY OF PELVIC SUPPORT

Normal pelvic support is a complex interaction between the muscular and fascial structures that line the pelvic cavity, collectively known as the *pelvic floor*. The levator ani complex (i.e., coccygeus, iliococcygeus, and pubococcygeus) stretches from the coccyx to the symphysis pubis anteriorly in the erect woman. Laterally, the levator complex attaches to the arcus tendineus fasciae pelvis (“white line”). The arcus tendineus fasciae pelvis extends from the symphysis pubis to the ischial spines bilaterally. The levator ani complex is typically described in two parts: the diaphragmatic portion (i.e., coccygeus and iliococcygeus) and the pubovisceral portion (i.e., pubococcygeus). The coccygeus muscles run bilaterally from the sacrum and coccyx to the ischial spines and are associated with the sacrospinous ligaments. The iliococcygeus muscles pass laterally from the symphysis pubis to the arcus tendineus fasciae pelvis, where they attach and turn medially to join the coccygeus at the coccyx, forming the levator plate. The pubovisceral portion, or pubococcygeus, is associated with the puborectalis, arising from the posterior surface of the symphysis pubis and extending back to the ventral surface of the coccyx.<sup>3</sup>

Normal pelvic support is provided by the pelvic floor and by the connective tissue attachments. The pelvic organs rest on the pelvic floor and are stabilized by the connective tissues. In 1992,

DeLancey described the stabilization of the vagina in levels. Level I support is derived from the cardinal-uterosacral complex and is responsible for holding the upper vagina and cervix in a superior position in relation to the genital hiatus. Level II support is responsible for lateral support of the midvagina to the arcus tendineus fasciae pelvis. Level III support is responsible for distal support of the lower vagina by means of connections to the perineal body and perineal membrane<sup>4</sup> (Fig. 71-1).

### PELVIC ORGAN PROLAPSE

The cause of pelvic organ prolapse is multifactorial. Uterovaginal prolapse results from damage to the cardinal-uterosacral complex, or level I support.<sup>5</sup> The uterus and upper vagina normally lie over the pelvic floor and are directed to the hollow of the sacrum. Increased intra-abdominal pressure is directed toward the levator ani complex. Attenuation of the levator ani complex may result in inadequate support to the overlying pelvic organs. Such attenuation may be the result of childbirth and some connective tissue disorders. Conditions or maneuvers that result in repeated increases in intra-abdominal pressure may lead to attenuation of the pelvic floor and aggravate pelvic organ prolapse. These conditions may include occupations that require heavy lifting or medical conditions such as chronic constipation resulting in excessive straining or chronic obstructive pulmonary disease with chronic coughing.

Age also has been implicated as an etiologic factor in pelvic organ prolapse. Age is widely accepted to be associated with decreased muscle tone and decreased quality of underlying fibroblasts and collagen fibers, both of which can aggravate the underlying prolapse. Postmenopausal women who are not receiving hormone replacement therapy may also present with signs and symptoms of pelvic organ prolapse.

### PELVIC ORGAN PROLAPSE

#### Diagnosis

Patients with uterovaginal prolapse may present with a multitude of symptoms. A carefully tailored history and physical examination are important in gaining insight into the complaint and any affect on the patient’s quality of life. Patients may present with a vaginal mass, sometimes described by them as a bulge. They may complain of pelvic pain, pressure, or dyspareunia. Patients may describe urinary urgency or frequency or incontinence. In cases of severe prolapse, patients may complain of urinary retention, because of the effect of the prolapse on the anatomy of the lower urinary tract. The typical patient describes symptoms that are

**Figure 71-1** Levels of support of the upper and middle vagina. Level I support represents the apical support of the vagina by means of the uterosacral-cardinal complex. Level II support represents the lateral support of the vagina by means of attachments to the arcus tendineus fasciae pelvis. (From DeLancey JOL: Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 166:1717, 1992.)

worse with standing or activity and that improve on assuming a supine position. If the diagnosis of pelvic organ prolapse is obscure, it is important to consider performing the examination of the patient at the end of the day, when the prolapse is likely to be at its worst.

### Physical Examination

The result of physical examination remains one of the most important pieces of information in the evaluation of pelvic organ prolapse. The diagnosis of uterovaginal prolapse is confirmed by significant descensus of the uterus on pelvic examination. A bimanual examination is important to ascertain the size and mobility of the uterus and any underlying pathology such as uterine leiomyoma or adnexal masses. The caliber of the genital hiatus is measured to predict the success of a vaginal hysterectomy. The coexistence of anterior or posterior vaginal wall prolapse should be determined. In our experience, it is advisable to evaluate the patient with uterovaginal prolapse in the supine and standing positions. The patient should be examined with an empty bladder because the prolapse may not be fully appreciated in the presence of a subjectively full bladder.<sup>6</sup> It is important to evaluate for the sign of stress incontinence with the bladder full and the prolapse reduced to its normal anatomic location to exclude potential or occult stress incontinence.

### Classification

The severity of pelvic organ prolapse is described to standardize findings among examiners. For decades, the Baden-Walker system was used to describe the presence of pelvic organ prolapse.<sup>7</sup> The Baden-Walker system, still in use today, is also known as the *halfway system*. It involves description of the most dependent position of the pelvic organs during a maximum Valsalva maneuver or during standing in relation to the hymenal ring (Table 71-1).

In 1996, Bump and colleagues<sup>8</sup> standardized the terminology of female pelvic organ prolapse for the International Continence Society (ICS). The Pelvic Organ Prolapse Quantification (POP-Q) system involves measurement of six anatomic points (in centimeters) in relation to the hymenal ring, as well as the genital hiatus, perineal body, and total vaginal length. The hymenal ring, defined as zero, is chosen as the reference point because it is a fixed anatomic point from which interobserver variability can be standardized. Prolapse distal to the hymenal ring is described in positive centimeters from the hymenal ring. Prolapse proximal to the hymenal ring is defined in negative centimeters from the hymenal ring. The six anatomic points can be divided into two points on the anterior vaginal wall (Aa and Ba), two points on the posterior vaginal wall (Ap and Bp), and two points in the superior vagina (C and D) (Fig. 71-2).

The genital hiatus (gh) is measured from the posterior fourchette to the middle of the urethral meatus. The perineal body

(pb) is measured from the posterior fourchette to the middle of the anus. Total vaginal length (tvL) is measured with point C and point D reduced to their normal anatomic positions.

Table 71-2 represents the stages of pelvic organ prolapse as defined by the POP-Q system. Because of the use of measure-

ments revolving around fixed anatomic landmarks, the POP-Q system is a much more precise method of defining pelvic organ prolapse compared with previous systems. Interexaminer variability is markedly reduced, which is important for clinical standardization and for the purposes of research.

**Table 71-1 Baden-Walker Classification of Pelvic Organ Prolapse**

Cystocele	First degree: Anterior vaginal wall and bladder descend halfway to the hymen. Second degree: Anterior vaginal wall and bladder descend to the hymenal ring. Third degree: Anterior vaginal wall and bladder are outside the hymen.
Uterine or vaginal vault prolapse	First degree: Cervix or vaginal apex descends halfway to the hymen. Second degree: Cervix or vaginal apex extends to the hymen or over the perineal body. Third degree: Cervix and uterine corpus extend beyond the hymen, or the vaginal vault is everted and protrudes beyond the hymen.
Rectocele	First degree: Posterior vaginal wall descends halfway to the hymen. Second degree: Posterior vaginal wall descends to the hymen. Third degree: Posterior vaginal wall extends beyond the hymen.
Enterocele	Presence of the enterocele sac, relative to the hymen, should be described anatomically, with the patient in the supine and standing positions during a Valsalva maneuver.

## VAGINAL HYSTERECTOMY AND RELATED PROCEDURES

### Indications

The most frequent indication for hysterectomy is the leiomyomatous uterus. Patients with uterine fibroids may complain of pelvic pain or pressure. Other patients may complain of low back pain or urinary symptoms. Dysfunctional uterine bleeding is a common complaint of the woman with uterine fibroids. The

**Table 71-2 Stages of Pelvic Organ Prolapse**

Stage 0	No evidence of pelvic organ prolapse. Points Aa, Ba, Ap, and Bp are all defined at $-3$ cm. Points C and D are located within 2 cm of the tvL (i.e., $\leq \text{tvL} - 2$ cm).
Stage 1	Most distal portion of the prolapse is $> 1$ cm above the level of the hymen (i.e., $\leq 1$ cm).
Stage 2	Most distal portion of the prolapse within 1 cm of the hymenal ring, proximal or distal (i.e., $\geq -1$ cm but $\leq +1$ cm)
Stage 3	Most distal portion of the prolapse is more than 1 cm distal to the hymenal ring but not more than 2 cm less than the tvL (i.e., $> +1$ cm but not more than $\text{tvL} - 2$ cm).
Stage 4	Complete eversion of the tvL

tvL, total vaginal length.

**Figure 71-2** Six anatomic sites (points Aa, Ba, C, D, Bp, and Ap), the genital hiatus (gh), perineal body (bp), and total vaginal length (tvL) are used to describe the degree of pelvic organ prolapse. (From Bump RC, Mathiason A, Bo K, et al: The Standardization of Terminology of Female Pelvic Organ Prolapse and Pelvic Floor Dysfunction. *Am J Obstet Gynecol* 175:10, 1996.)

patient with symptomatic uterine fibroids is a safe candidate for vaginal hysterectomy assuming the uterus is mobile and the total uterine size is less than 12 weeks' gestational size.<sup>9</sup>

Vaginal hysterectomy is particularly appropriate for the patient with symptomatic uterine prolapse when additional pelvic reconstruction may be indicated. These patients rarely present with isolated uterine prolapse, often having coexistent prolapse of the anterior or posterior vaginal walls, requiring a tailored and thoughtful pelvic reconstruction. Other indications for vaginal hysterectomy include adenomyosis, pelvic pain, and endometrial hyperplasia.

### Contraindications

With an appropriate understanding of pelvic anatomy, the experienced surgeon encounters few contraindications to the vaginal route of hysterectomy. Even the large fibroid uterus can be removed vaginally in the hands of a skilled surgeon. Uterine immobility can make a vaginal hysterectomy difficult if abdominopelvic adhesions or scarring are present. A narrow, or stenotic, vaginal introitus can complicate removal of the uterus vaginally, and consideration should be given to an abdominal approach in this case. Selected cases of endometriosis are a contraindication to the vaginal route of hysterectomy. In 1995, Kovac<sup>10</sup> assigned 617 women to abdominal, vaginal, or laparoscopically assisted vaginal hysterectomy based on uterine size and risk factors suggesting pelvic disease. In his series, 548 women were able to undergo successful vaginal hysterectomy. In the case of laparoscopically assisted vaginal hysterectomy, all but 2 of the 63 cases could have undergone successful vaginal hysterectomy based on laparoscopic findings. In his series, Kovac reported a 99.5% success rate for the vaginal route of hysterectomy using the techniques of morcellation, bivalving, and uterine coring (discussed later).<sup>10</sup> The suspicious adnexal mass and high-grade endometrial carcinoma present absolute contraindications to the urogynecologic surgeon. In some cases, low-grade endometrial carcinoma may be managed with a vaginal hysterectomy.

### Technique

For a simple vaginal hysterectomy, after the patient is in the operating suite, anesthesia is administered. The patient is then appropriately placed in the dorsal lithotomy position. We prefer the use of candy cane stirrups. A careful examination of the anesthetized patient is performed to confirm the findings of the previous examination. The patient is then prepared using a povidone-iodine solution or chlorhexidine gluconate and is draped in the usual fashion. The bladder is allowed to drain after placement of a 16-Fr, 5-mL Foley catheter. After complete drainage, the catheter is clamped using a Kelly clamp.

Simms retractors are used to retract the anterior and posterior vaginal walls to fully visualize the cervix. The cervix is then grasped at the 3-o'clock and 9-o'clock positions with single-tooth tenaculums. The uterus is mobilized downward toward the introitus by traction on the tenaculums. Careful attention is paid to the location of the bladder. A solution of 1% lidocaine with epinephrine is then injected into the cervicovaginal junction in a circumferential fashion. The injection solution serves two purposes. First, it aids in hydrodissection, allowing the appropriate plane to be entered more efficiently. Second, the injection solution results in vasoconstriction, which facilitates visualization because of decreased operative blood loss.

**Figure 71-3** Using a scalpel, the initial incision begins circumferentially at the reflection of the vaginal mucosa and the cervix.

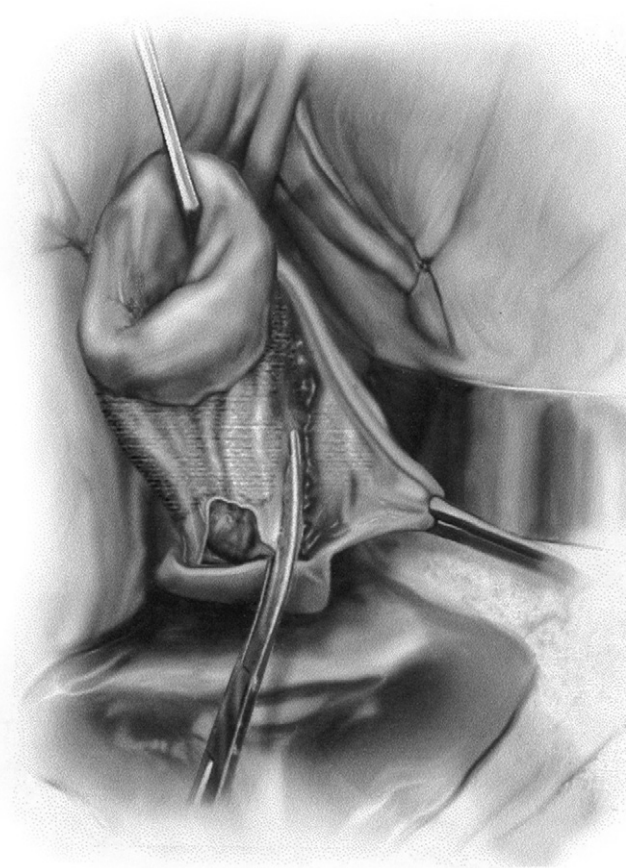

An incision is made from the 9-o'clock position anteriorly to the 3-o'clock position. A similar incision is made posteriorly around the cervix (Fig. 71-3). Appropriate traction is applied to the cervix in the direction opposite the incision to facilitate separation of the underlying cervical stroma from the overlying vaginal wall. Side wall retractors are used by the assistants to aid in visualization. The full-thickness vaginal mucosa is dissected off of the underlying connective tissues using curved Mayo scissors. A right angle Heaney retractor or Deaver retractor can be used to retract the anterior vagina away from the underlying cervix to correctly identify the plane of cleavage. Posteriorly, a similar dissection is undertaken, completely separating the full thickness posterior vaginal mucosa from the overlying cervix (Fig. 71-4). After the peritoneum of the posterior cul-de-sac can be palpated, a posterior colpotomy is performed, and entrance into the peritoneal cavity is confirmed using a finger (Fig. 71-5). A right-angle Heaney retractor is used to deflect the rectosigmoid colon away from the operative field.

Assuming the bladder has been sufficiently mobilized cephalad, the uterosacral ligaments can be secured to release the natural pelvic support of the cervix. We prefer the latter method because release of the uterosacral attachments facilitates anterior dissection (Fig. 71-6). Care must be taken to adequately retract the bladder away from the clamps. Heaney clamps are used to secure the uterosacral ligaments, incorporating the posterior peritoneum. The Heaney clamps are rotated laterally so that the tips of

**Figure 71-4** Posteriorly, the full-thickness vaginal mucosa is sharply or bluntly dissected from the cervix.

**Figure 71-6** The uterosacral ligaments are clamped to gain access to the vesicouterine space.

**Figure 71-5** The posterior cul-de-sac is sharply entered using Mayo or Metzenbaum scissors.

the clamp are almost perpendicular with the plane of the cervix. The results in shortening of the uterosacral ligaments and helps avoid injury to the bladder and ureters laterally. The uterosacral ligaments are then released from the uterus using Mayo scissors. The pedicles are then secured using a suture ligature of a 1-0 absorbable suture. At this point, attention is turned anteriorly. The full-thickness vagina is separated from the underlying cervix with the Mayo scissors. The dissection ultimately leads to the vesicouterine space (Fig. 71-7). A history of cesarean section may lead to scarification. Elevating the cesarean scar with forceps allows the surgeon to separate the scar from the underlying lower uterine segment. In this fashion, the vesicouterine space is entered. A right-angle Heaney retractor or Deaver retractor is then used to deflect the bladder anteriorly to identify the vesicouterine fold. The vesicouterine fold can be visualized as a semi-lunar, white line. The vesicouterine fold is then elevated, and the peritoneum is incised below the level of the forceps with Mayo scissors (Fig. 71-8). Entrance into the anterior cul-de-sac is confirmed by palpation. A retractor is used to deflect the bladder away from the surgical field.

Lateral dissection using Mayo scissors aids in separation of the vaginal wall from the cervix. Heaney clamps are then used to secure the uterine vessels bilaterally as they run in the cardinal ligament. The pedicles are released from the uterus and secured using a 1-0 absorbable suture. We prefer to use a suture ligature, incorporating the previous uterosacral ligament pedicle. With this technique, the dead space between pedicles is obliterated, preventing tearing of tissue and bleeding from the small cervical

**Figure 71-7** The anterior vaginal wall is dissected from the cervix using Mayo or Metzenbaum scissors. This plane will ultimately lead to the vesicouterine space.

**Figure 71-8** The vesicouterine fold is elevated and entered sharply using Metzenbaum scissors.

branches (Fig. 71-9). The cardinal ligament is secured in successive bites as previously described, ensuring that the anterior peritoneum and posterior peritoneum are incorporated. This technique fuses the anterior and posterior leaves of the broad ligament, preventing extensions of the peritoneal incisions into the vasculature of the broad ligament. Care must be taken to clamp medial to the previous pedicle to avoid uterine injury. With adequate descensus, the fundus of the uterus is reached. An adequate examination should be performed to exclude pelvic adhesions or abnormal pathology. The utero-ovarian ligaments are then clamped with Heaney clamps (Fig. 71-10). The surgeon must proceed with caution to avoid bowel injury. The pedicles are released from the uterus using Mayo scissors. The uterine specimen is then submitted for pathologic analysis. The utero-ovarian pedicles are secured first using a free tie of a 1-0 absorbable suture, followed by a distal suture ligation of a 1-0 absorbable suture.

At this time, all of the pedicles are inspected for hemostasis. Packing the bowel with moist tail sponges or the use of a sponge stick can aid in visualization. The ovaries should be palpated to look for abnormal pathology.

### Managing the Adnexa

The decision to proceed with vaginal oophorectomy at the time of hysterectomy is a controversial topic and should involve a thoughtful preoperative discussion with the patient. The indications for vaginal oophorectomy should be similar to the indica-

tions for oophorectomy at the time of abdominal hysterectomy. After vaginal hysterectomy, the ovaries are not as accessible, leading to a more technically difficult procedure than oophorectomy at the time of abdominal hysterectomy.<sup>11</sup> However, adhering to the surgical principles of mobilization and adequate visualization can lead to successful adnexectomy in more than 90% of cases, without increased morbidity.<sup>12</sup>

At the start of the procedure, the adnexa are identified. Using gentle traction on the round ligaments often affords the surgeon adequate visualization. Alternatively, a Babcock clamp can be used to grasp the adnexa, which are then brought into the surgical field. A finger can be used to palpate the ipsilateral ureter through the broad ligament. A curved clamp, such as a Heaney or Satinsky vascular clamp, can be used to clamp across the infundibulopelvic ligament (Fig. 71-11). Care should be taken to clamp as close to the ovary as possible to avoid ureteral injury. After adnexectomy, we prefer to secure the infundibulopelvic ligament with a free tie of 1-0 Vicryl, followed by a transfixion suture of 1-0 Vicryl placed distal to the free tie. The pedicle should be held until adequate hemostasis has been ensured to avoid retraction of an inadequately secured infundibulopelvic ligament high into the pelvis.

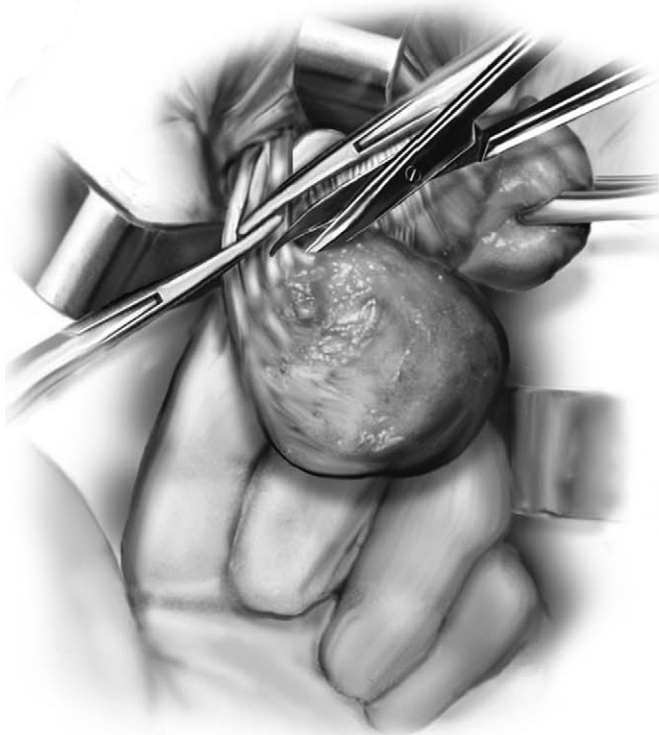

### Vaginal Vault Suspension

After vaginal hysterectomy, the cul-de-sac should be routinely evaluated to determine if an enterocele coexists. Based on the size of the enterocele and the degree of vault prolapse, the appropriate

**Figure 71-9** Proper technique for clamping the uterine vessels. The vascular pedicle is suture ligated to the previously ligated pedicle. This technique ensures that the dead space between pedicles is obliterated and guards against bleeding from small cervical branches.

**Figure 71-10** A finger is placed behind the utero-ovarian pedicle to prevent injury to the hollow viscus or other structures while the pedicle is cut with scissors.

procedure to obliterate the cul-de-sac and support or suspend the vaginal apex can be determined.

With the bowel packed away using moist tail sponges and the patient in a slight Trendelenburg position, an assessment can be made about the presence or absence of an enterocele by simple digital palpation of the posterior cul-de-sac. An identifiable pocket confirms the presence of an enterocele and determines the need for excision of redundant peritoneum and posterior vaginal wall. Subsequently, the excess vaginal mucosa and peritoneum may be removed in a wedgelike fashion using Mayo scissors or Bovie cautery (Fig. 71-12). Allis clamps are then used to grasp the peritoneum and corresponding vaginal mucosa at the 5-o'clock and 7-o'clock positions. Outward traction and elevation of the Allis clamps at a 45-degree angle in relation to the patient allow the surgeon to palpate the uterosacral ligaments coursing back toward the sacrum. With the same finger, the surgeon can palpate the position of the ipsilateral ureter in relation to the uterosacral ligament. The ureter can be found ventral and lateral to the ischial spine.

The McCall culdoplasty was first described in 1957 by Milton McCall. In the initial description, McCall used several non-absorbable sutures to plicate the uterosacral ligaments in the midline, incorporating the intervening, redundant peritoneum. This resulted in effective obliteration of the posterior cul-de-sac. External absorbable, McCall sutures were placed through the full-thickness vagina, incorporating the ipsilateral uterosacral ligament and intervening peritoneum before crossing the midline and incorporating the contralateral uterosacral ligament and passing back through the full-thickness vagina (Figs. 71-13 and

**Figure 71-11** The infundibulopelvic ligament is secured using a curved Haney or Satinsky vascular clamp. The pedicle is secured first using a free tie of a 0 absorbable suture followed by a suture ligation.

**Figure 71-12** A finger in the posterior cul-de-sac can be used to confirm the presence of an enterocele. The redundant wedge of posterior vaginal wall and peritoneum can then be excised.

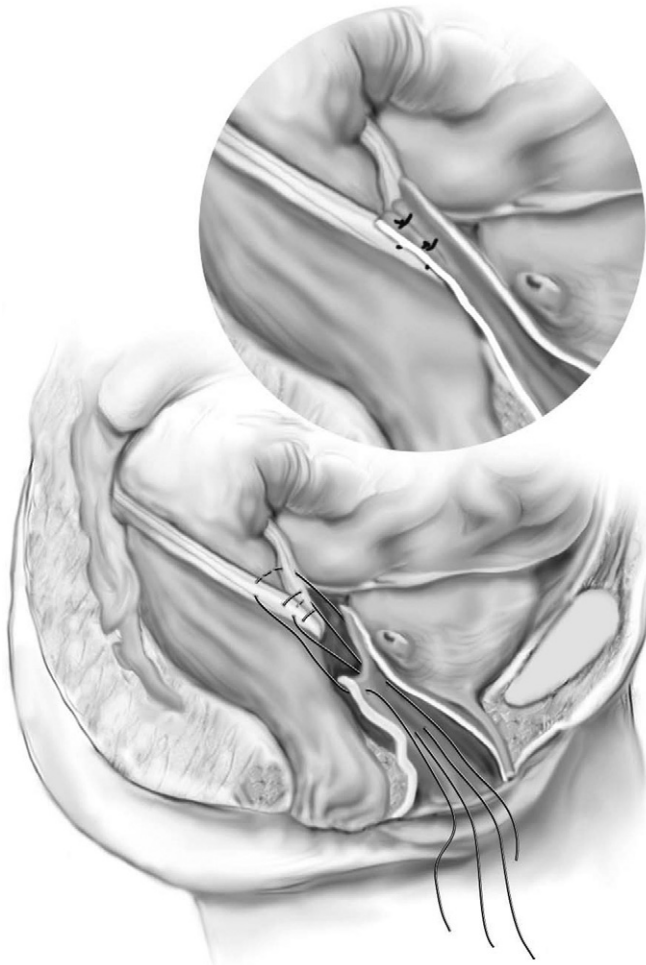

**Figure 71-13** The technique of McCall culdoplasty. Two internal sutures (permanent) and two external sutures (absorbable) have been placed.

71-14). After tying the external McCall sutures, cystoscopy is performed to confirm ureteral patency.

Some patients have more advanced vaginal vault prolapse. In these cases, it may be appropriate to perform a more formal vaginal vault suspension, such as a sacrospinous fixation, high uterosacral ligament suspension, or iliococcygeus suspension.

To more adequately reestablish level I support, a high uterosacral ligament suspension can be performed. The bowel is packed away as previously described, and a Heaney retractor is used to lift the bowel out of the posterior cul-de-sac. Traction on the previously placed Allis clamps enables palpation of the remnants of the uterosacral ligaments. For the right-handed surgeon, the left index finger is used to deflect the sigmoid colon medially. As the assistant places traction on the patient's left uterosacral ligament, the surgeon places a figure-of-eight 1-0 absorbable suture through the left uterosacral ligament (lateral to medial) at the level of the ischial spine. With traction on the first suture, the surgeon then places a second figure-of-eight 1-0 absorbable suture through the left uterosacral ligament approximately 1 cm proximal to the first suture. This throw is higher and slightly more medial than the first suture because of the natural course of the uterosacral ligament. A similar procedure is performed on the opposite site, with careful attention to the location of the ureter. These four sutures are tagged and held. We prefer to use

**Figure 71-14** Cross section of the upper vagina before and after the McCall sutures have been tied down toward the hollow of the sacrum.

1-0 nonabsorbable sutures to obliterate the posterior cul-de-sac by plicating the distal portions of the uterosacral ligaments across the midline. The nonabsorbable sutures are then tied down, obliterating the posterior cul-de-sac. At this point, it is essential to confirm ureteral patency by cystoscopy after administration of intravenous indigo carmine.

In the absence of anterior or posterior vaginal wall prolapse, the high uterosacral ligament suspension sutures are passed out through the full-thickness vagina. The bowel packing is removed, and the vaginal cuff is closed using interrupted figure-of-eight 1-0 absorbable sutures in a transverse or longitudinal fashion. If an anterior repair is needed, the cuff is usually closed after the colporrhaphy. After hemostasis is confirmed, the vaginal mucosa is pushed toward the hollow of the sacrum, around the vault suspension sutures. The suspension sutures are then tied down. Examination should allow 2 fingerbreadths to be comfortably passed through the vaginal introitus toward the vaginal apex. The ultimate vaginal length should be a minimum of 8 cm.

#### THE DIFFICULT VAGINAL HYSTERECTOMY

Vaginal hysterectomy can be complicated in the face of pelvic floor relaxation or coexistent pelvic pathology.

#### Complete Uterine Procidentia

The technical aspects of vaginal hysterectomy in the patient with complete procidentia are the same as those for the simple vaginal hysterectomy. However, a careful preoperative evaluation must be performed to determine whether the prolapse represents a true procidentia or an elongated cervix. Severe descensus of the uterus in the case of procidentia results in anatomic distortion of the entire pelvis. The surgeon must remember that the course of the ureters is likely distorted in the wake of chronic traction associated with a large cystocele.

If it is determined preoperatively that the prolapse represents a severely elongated cervix with the uterus in a normal anatomic location, the surgeon must be careful not to amputate the cervix prematurely, because this will complicate the remainder of the procedure. Alternatively, the surgeon should take successive extraperitoneal bites until the anterior and posterior peritoneal reflections are reached (Fig. 71-15). After the anterior and posterior cul-de-sacs have been entered, the vaginal hysterectomy proceeds in a normal fashion.

#### Narrow Vaginal Introitus

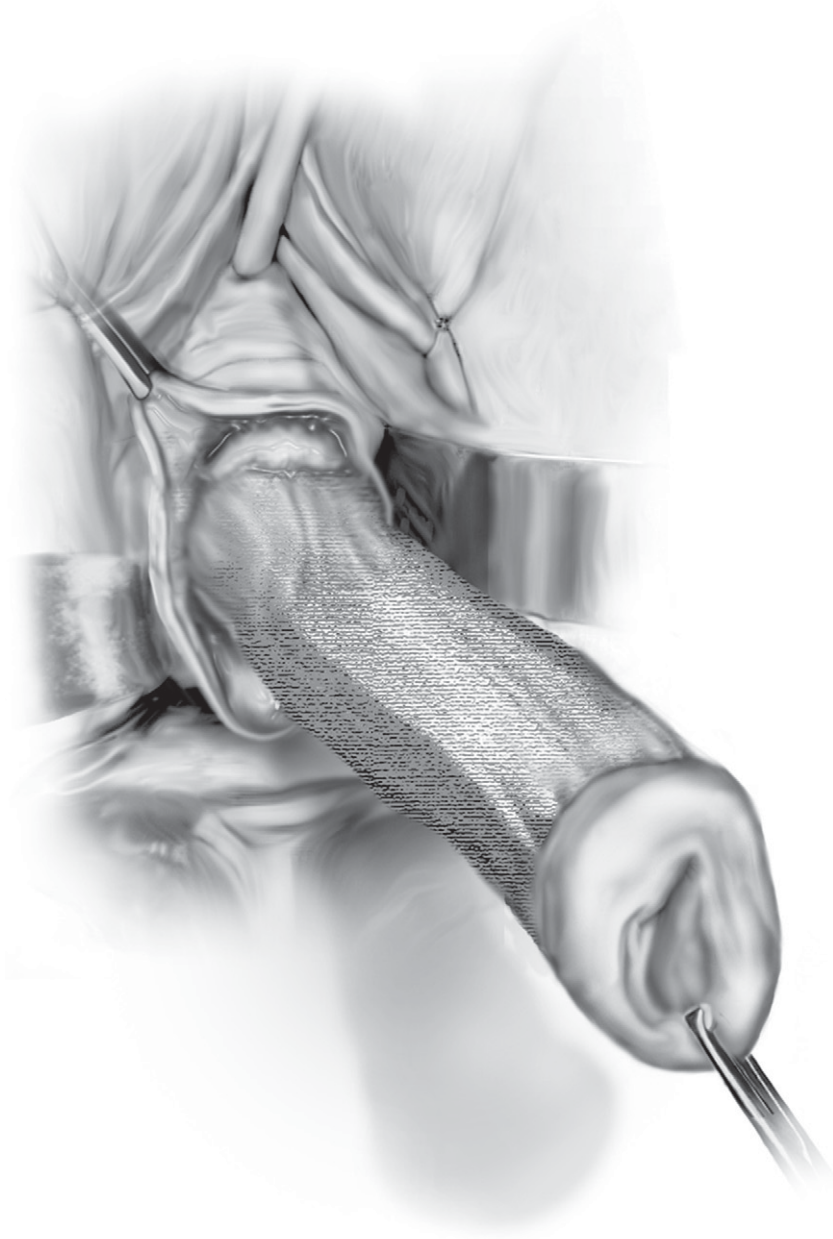

A lack of uterine descensus or a narrow vaginal introitus, particularly in a nulliparous patient, are not contraindications to the vaginal route of hysterectomy. A thorough examination under anesthesia should be performed to determine the size and mobility of the uterus to assess the feasibility of a successful vaginal hysterectomy. A relaxing episiotomy may be necessary to afford the surgeon more room in the pelvis. If necessary, the surgeon may use a Schuchardt incision, which is made into the lateral vaginal wall and carried down to the perineal body. The Schuchardt incision resembles a sulcal tear after an operative vaginal delivery. These techniques alter the integrity of the perineal muscles and the levator muscles. The surgeon must ensure that normal anatomy has been restored after vaginal hysterectomy.

#### Obliterated Vesicouterine Fold

A history of multiple cesarean sections or endometriosis may complicate vaginal hysterectomy by obliterating the vesicouterine fold. As long as the bladder has been sufficiently dissected off of the cervix, anterior colpotomy is not mandatory. Alternatively, the surgeon may proceed with successive bites posteriorly until the fundus is palpated with a finger. Passing a finger around the fundus anteriorly may expose the anterior peritoneum, allowing the surgeon to safely enter the anterior cul-de-sac and effectively avoiding inadvertent cystotomy (Fig. 71-16). If the surgeon suspects an obliterated cul-de-sac based on patient history or exam under anesthesia, the dissection should proceed sharply, rather than bluntly. Blunt dissection follows the path of least resistance, tearing into the bladder.

#### Obliterated Cul-de-Sac of Douglas

A history of pelvic surgery, endometriosis, or pelvic inflammatory disease may result in an obliterated cul-de-sac of Douglas. This scenario predisposes to rectal injury or injury to the small bowel during attempted posterior colpotomy. If necessary, the anterior cul-de-sac should be entered first, and a finger wrapped should be around the fundus to palpate for adhesions or scarifi-

**Figure 71-15** Technique of removal of an elongated cervix. Successive extraperitoneal bites are taken until the anterior and posterior peritoneal reflections are reached.

cation. In their absence, the posterior-cul-de-sac can then be entered safely without fear of rectal injury.

### **Massive Leiomyomatous Uterus**

The uterus measuring less than 12 weeks' gestational size poses few problems for the vaginal route of hysterectomy, provided the surgical principles outlined earlier are followed. The uterus measuring more than 12 weeks' gestational size is not an absolute contraindication to the vaginal route of hysterectomy in the hands of a skilled surgeon. The large leiomyomatous uterus poses several difficulties to the surgeon.

The leiomyomatous uterus may be enlarged to the point that en bloc removal of the uterus by the vaginal route is impossible. In this situation, several techniques may be used to facilitate vaginal hysterectomy, including morcellation, bivalving of the

uterus, or intramyometrial coring. Ligation of the major blood supply to the uterus, the uterine arteries, is a prerequisite for the use of these techniques. It is prudent to enter the anterior and posterior cul-de-sac to prevent injury to the bladder and rectum. After the uterine vessels have been secured, morcellation may begin. The cervix is amputated with a scalpel. Tenacula are used to grasp the posterior aspect of the uterus, which is brought down into the surgical field. A scalpel or Mayo scissors is then used to remove the tissue within the tenacula en bloc (Fig. 71-17). The entire body of the uterus is then morcellated.

After the fundus has been identified, the remainder of the uterus can be bivalved, securing the lateral pedicles as outlined earlier (Fig. 71-18). In patients with a massive uterus because of leiomyomas or adenomyosis, the fundus may not be deliverable posteriorly. In this case, intramyometrial coring is particularly appropriate (Fig. 71-19).

**Figure 71-16** An obliterated vesicouterine fold. **A**, Adhesions are seen between the bladder and anterior cervix. **B**, Blunt dissection in this setting may lead to inadvertent cystotomy, because a finger will follow the path of the least resistance. **C**, Passing a finger around the fundus of the uterus often leads to identification of the appropriate plane of the dissection.

### COMPLICATIONS OF VAGINAL HYSTERECTOMY

Complications of vaginal hysterectomy are uncommon but can include bleeding, infection, or inadvertent injury to the bladder, ureters, or bowel. Postoperative complications can include hematoma or abscess formation. Risk factors include previous abdominal surgery, a history of endometriosis or pelvic malignancy, cervical or broad ligament myomas, congenital anomalies, the presence of inflammation or pelvic adhesions, or a history of pelvic irradiation. Patient factors such as large uterine size or morbid obesity can reduce visualization. An inexperienced surgeon or inadequate retraction or lighting can add to the risks posed during the vaginal hysterectomy.

Inadvertent cystotomy remains one of the most common complications of vaginal hysterectomy. The incidence of inadvertent cystotomy during vaginal hysterectomy is reported to be between 1% and 1.8%. In 2002, Carley and colleagues<sup>13</sup> performed a retrospective review of 590 vaginal hysterectomies. The rate of inadvertent cystotomy was 1.9%. Cases were matched with five controls with similar procedures performed. Patients who suffered inadvertent cystotomy had a longer operative time and greater intraoperative blood loss than similarly matched controls.<sup>13</sup> As the rate of cesarean section continues to rise, concerns have surfaced regarding the risk of inadvertent cystotomy because of scarification in the lower uterine segment. Rooney and associates<sup>14</sup> performed a retrospective analysis of more than 5000

hysterectomies in 2004. They found an odds ratio of incidental cystotomy of 3.00, which approached statistical significance for women undergoing a total vaginal hysterectomy who had a history of prior cesarean section. The odds ratio for incidental cystotomy at the time of laparoscopically assisted vaginal hysterectomy in women with a history of prior cesarean section was found to be significant at a value of 7.50.<sup>14</sup>

One of the most serious complications of gynecologic surgery is iatrogenic injury to the ureters. The literature reports an incidence of iatrogenic ureteral injury of 0.02% to 0.8% during vaginal hysterectomy.<sup>15</sup> The ureters can be burned, clipped, ligated, kinked, or partially or completely transected. Intraoperative recognition is essential because of the subsequent risk of fistula formation or hydronephrosis resulting in loss of renal function. Most iatrogenic ureteral injuries occur when securing the uterine vessels. Particular care should be taken to keep the surgical clamps medial to the uterosacral ligament pedicles when performing the vaginal hysterectomy.

Iatrogenic injury to the ureter is the most common complication of the vaginal vault suspension, whether the surgeon has performed a traditional McCall culdoplasty or a high uterosacral ligament suspension. Karram and colleagues<sup>16</sup> reported a 2.4% risk of iatrogenic ureteral injury during 168 high uterosacral ligament suspensions. Barber and coworkers reported an 11% risk of ureteral injury during the same procedures.<sup>16</sup> Intraoperative cystoscopy with intravenous indigo carmine must be used to verify ureteral patency after the procedure. Webb and colleagues

**Figure 71-17** Technique of morcellation in the massively leiomyomatous uterus. **A**, An elliptical wedge of tissue is excised from the posterior uterus. **B**, The edges of the incision are brought together with the tenacula. A second wedge of tissue is removed in a similar fashion. The procedure is repeated until the fundus is reached and the uterus is delivered.

described 660 women who underwent a modified Mayo McCall culdoplasty in 1998.<sup>16</sup> In addition to ureteral injury, lacerations to the bowel and rectum were reported in 2.3% of cases. Other complications of the McCall culdoplasty include vault hematoma in 1.3% and cuff abscess or infection in 0.6% of patients. Webb reported a blood transfusion rate of 2.2%.<sup>16</sup>

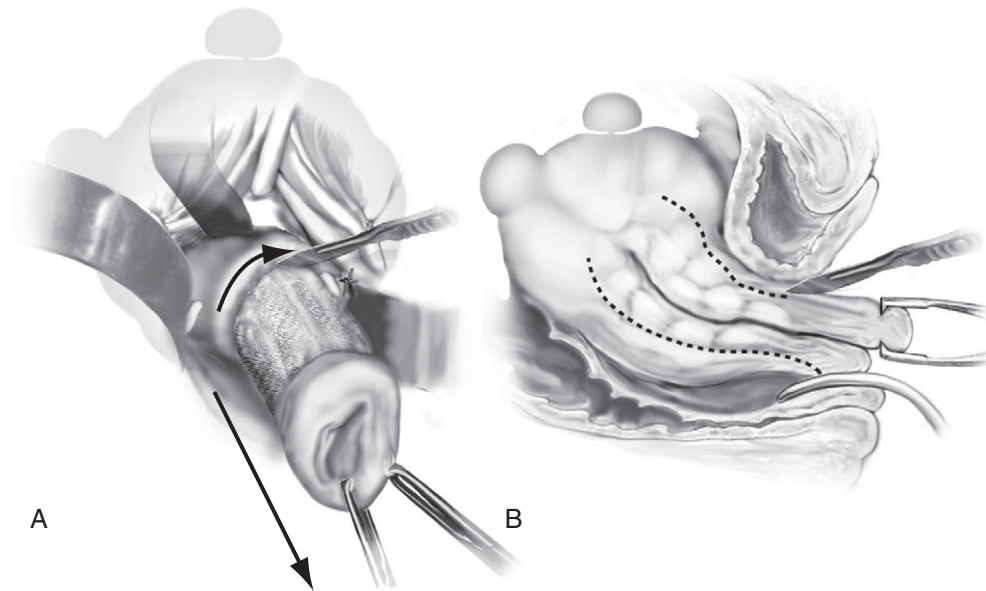

Injuries to the rectum during vaginal hysterectomy are rare, with most occurring during attempted entry into the pouch of Douglas. Mathevat and colleagues<sup>17</sup> performed a retrospective review of more than 3000 vaginal hysterectomies with or without additional procedures. They reported five rectal injuries, all of

which occurred during attempted entry to the posterior cul-de-sac.<sup>17</sup> Posterior colporrhaphy also poses a risk of rectal injury. In the same series, Mathevat and colleagues<sup>17</sup> reported 11 rectal injuries associated with posterior colporrhaphy. The overall incidence of rectal injury in their series was 0.45%.<sup>17</sup>

Hematoma formation is a rare complication of vaginal hysterectomy and is usually the result of inadequate hemostasis at the end of the procedure. Particular attention must be given to the pedicles in the post-hysterectomy patient to confirm hemostasis is adequate. After the vaginal hysterectomy with or without concomitant reconstructive procedures, we prefer to pack the

**Figure 71-18** Technique of hemisection of the uterus. **A**, The midportion of the uterus. **B**, Lateral view demonstrates many uterine myomas.

**Figure 71-19** Technique of intramyometrial coring. **A**, A scalpel is used to create a cylinder of tissue. **B**, Lateral view of the technique of intramyometrial coring. Downward traction on the cervix will deliver the specimen, everting the uterine fundus.

vagina with 2-inch iodoform gauze to apply pressure to small amounts of venous oozing. The packing is removed the next morning, and hemostasis is confirmed.

## CONCLUSIONS

As the population continues to increase, the gynecologist can expect a concurrent rise in the number of women presenting for

hysterectomy. Currently, the rate of abdominal hysterectomy exceeds the rate of vaginal hysterectomy. Reducing the rate of abdominal hysterectomy could result in a reduction in hospital stay and postoperative recovery. With appropriate patient selection and in the hands of an experienced surgeon, vaginal hysterectomy represents a useful adjunct in the treatment of pelvic organ prolapse.

# LAPAROSCOPIC SACRAL COLPOPEXY

*Marie Fidela R. Paraiso*

Laparoscopic sacral colpopexy was first reported by Nezhat and colleagues in 1994.<sup>1</sup> Adoption of this procedure has increased in the past decade and has evolved to include robotic assistance. The possible advantages of laparoscopic surgery are improved visualization of anatomy of the peritoneal cavity because of laparoscopic magnification, insufflation effects, and improved hemostasis; shortened hospitalization resulting in potential cost reduction; decreased postoperative pain and more rapid recovery and return to work; and better cosmetic appearance of smaller incisions. Disadvantages of laparoscopic surgery include a steep learning curve in acquiring suturing skills, technical difficulty of presacral dissection, increased operating time early in the surgeon's experience, and possibly greater hospital cost because of increased operating room time and the use of disposable surgical instruments. These disadvantages, inadequate experience in advanced laparoscopy in residency and fellowship programs, surgeon preference for vaginal route surgery, and recently introduced minimally invasive apical suspension procedures have thwarted widespread adoption of laparoscopic surgery for pelvic organ prolapse.

The indications for laparoscopic vaginal apex prolapse and enterocele repair are identical to those for vaginal and abdominal routes. The choice of laparoscopic route is determined by the preferences of the surgeon and patient and by the laparoscopic skill of the surgeon. Additional factors that should be considered include history of pelvic or anti-incontinence surgery, previous failed transvaginal colpopexy, short vagina, severe abdominopelvic adhesions, the patient's age and weight, the need for concomitant pelvic surgery, and the patient's ability to undergo general anesthesia.

The technique of laparoscopic sacral colpopexy described in this chapter follows standard procedures for operative laparoscopy for access and is identical to the more proven open abdominal sacral colpopexy (see Chapter 73). Clinical outcome and complications are summarized.

### ANATOMY

Thorough knowledge of the anatomy of the anterior abdominal wall is mandatory for safe and effective trocar insertion. The umbilicus is approximately at the L3-to-L4 level, and the aortic bifurcation is at the L4-to-L5 level. In obese women, the umbilicus is caudal to the bifurcation. The intraumbilical trocar should be introduced at a more acute angle toward the pelvis in thin women and closer to 90 degrees in obese women. The left common iliac vein courses over the lower lumbar vertebrae from the right side and may be inferior to the umbilicus. Common iliac arteries course 5 cm before bifurcating into the internal and external iliac arteries. The ureter crosses the common iliac artery at or above its bifurcation.

The superficial epigastric artery, a branch of the femoral artery, courses cephalad and can be transilluminated. The inferior epigastric artery branches from the external iliac artery at the medial border of the inguinal ligament and runs lateral to and below the rectus sheath at the level of the arcuate line. It is accompanied by two inferior epigastric veins.

When considering the anatomy of the repair of pelvic organ support, a surgeon must keep in mind the three levels of support of the vagina described by DeLancey in 1992.<sup>2</sup> The upper fourth of the vagina (level I) is suspended by the cardinal-uterosacral complex, the middle half (level II) is attached laterally to the arcus tendineus fasciae pelvis and the medial aspect of the levator ani muscles, and the lower fourth (level III) is fused to the perineal body. The endopelvic fascia laterally blends with the muscularis of the vagina. All pelvic support defects, whether anterior, apical, or posterior, represent a break in the continuity of the endopelvic fascia or vaginal muscularis and a loss of its suspension, attachment, or fusion to adjacent structures. The goals of pelvic reconstructive surgery are to correct all symptomatic defects, thereby reestablishing vaginal support at all three levels, and to maintain or restore normal visceral and sexual function.

The key anatomic landmarks of sacral colpopexy are the middle sacral artery and vein; the sacral promontory with anterior longitudinal ligament; the aortic bifurcation and the vena cava, which are at the level of L4 to L5; the right common iliac vessels and right ureter, which are at the right margin of the presacral space; and sigmoid colon, which is at the left margin. The left common iliac vein is medial to the left common iliac artery and can be damaged during dissection or retraction. The sacral foramina are only 1 to 1.5 cm from the midline, and the sympathetic chain is lateral. The ureter, which crosses over the common iliac artery bifurcation and courses along the pelvic sidewall, is approximately 1 to 1.5 cm lateral to the uterosacral ligament as it passes underneath the uterine artery.

The anatomic landmarks during laparoscopic sacral colpopexy graft attachment are the pubocervical fascia (i.e., anterior vaginal muscularis with overlying endopelvic fascia) and the rectovaginal muscularis (i.e., fibromuscular layer of the posterior vaginal wall above the rectovaginal septum). The rectovaginal septum is ideally the posterior point of attachment of the sacral colpopexy mesh, allowing continuity with the perineal body.

### SURGICAL TECHNIQUE

#### Operative Laparoscopy for Pelvic Organ Prolapse: Setup, Instrumentation, and Trocar Placement

Ideal stirrups for combined laparoscopic cases are the Allen stirrups and Yellofins (Allen Medical Systems, Acton, MA), which have levers that can quickly convert the patient from low to high

lithotomy position while preserving sterility of the field. A sterile pouch attached to each thigh is equipped with commonly used instruments such as unipolar scissors, bipolar cautery, blunt-tipped graspers, bowel graspers, and suction irrigation.

The monitor screens should be placed lateral to the legs in direct view of the surgeon standing on the opposite side of the table. The scrub nurse should be centered between the two monitor screens that are used; otherwise, the scrub nurse is located behind one surgeon and the electrosurgical unit or harmonic scalpel on the opposite side. After the three-way Foley catheter and uterine manipulator (if needed) have been placed, the vaginal tray with cystoscope can be set aside for later use.

For standard suturing technique, needle holder preference is determined by comfort of the surgeon. Conventional and 90-degree, self-righting German needle holders (Ethicon Endo-Surgery, Cincinnati, OH) have ratchet spring handles, and the Talon curved needle drivers with spring handles (Cook OB/GYN, Spencer, IN) self-right the needle at an angle of 45 or 90 degrees to the needle driver shaft, depending on the style chosen. The Storz Scarfi needle holder and notched assistant needle holder (Karl Storz Endoscopy, Culver City, CA) are most like conventional needle holders used during laparotomy. However, the handles are difficult to maintain and may pop open after extended use. The needle holder tips may become magnetized, which hampers needle grasping. Disposable suturing devices that have been introduced include the Endo-stitch (U.S. Surgical Corp., Norwalk, CT) and the Capio CL (Microvasive Boston Scientific, Natick, MA; CL refers to Cooper's ligament). Suturing devices are not recommended when performing laparoscopic sacral colpopexy because the depth of stitch placement in the vaginal muscularis is difficult to gauge tactically with these devices.

Extracorporeal knot tying is preferred because of technical facility and the ability to hold more tension on the suture, although some surgeons prefer intracorporeal suturing. When robotically assisted laparoscopic sacral colpopexy is performed, all suturing is done in an intracorporeal fashion. The choice of an open-ended or close-ended knot pusher for extracorporeal knot tying depends on surgeon preference. Our suture of choice is the single- or double-armed 1-0 Ethibond 36-inch suture on a CT-1 needle (Ethicon, Somerville, NJ). Our alternative choice for suture is 1-0 Gore-Tex (W.L. Gore and Associates, Phoenix, AZ). A 48-inch suture is preferred when suturing from ports at the level of the umbilicus. Sterile steel thimbles may be used by the surgeon or assistant when elevating the vagina while the surgeon is placing the stitches in the vaginal wall. However, vaginal manipulation when placing sutures is best achieved with endoanal anastomosis (EAA) sizers or fiberglass stents.

Intraumbilical or infraumbilical incisions depend on the anatomy of the umbilicus. Many variations of the accessory trocar sites have been described. For laparoscopic sacral colpopexy, we use three to four additional trocars: a 5- to 12-mm disposable trocar with reducer in the right and left lower quadrants lateral to the inferior epigastric vessels and a reusable 5-mm port or an additional 5- to 12-mm disposable trocar with reducer in the left upper quadrant at least 8 cm lateral to the umbilicus. Trocars are placed lateral to the rectus muscle, approximately 3 cm medial to and above the anterior superior iliac spine. Based on an anatomic study by Whiteside and coworkers<sup>3</sup> in 2003, we know that ilioinguinal and iliohypogastric nerve entrapment during fascial closure may be reduced if the ports are placed at least 2 cm cephalad to the anterior superior iliac spines. For more

extensive reconstructive surgery, an additional 5-mm port may be placed on the principal surgeon's side so that he or she can operate with two hands. Reusable and disposable ports may be secured with circumferential screws to prevent port slippage. Versa Step Plus trocars (U.S. Surgical Corp.) allow easy introduction of needles, maintain pneumoperitoneum during extracorporeal knot tying, and prevent port slippage because of the expandable sleeve.

### General Intraoperative and Postoperative Procedures

The patient is instructed to take one bottle of magnesium citrate or equivalent bowel preparation and limit her diet to clear liquids on the day before surgery. Placing an orogastric or nasogastric tube to decompress the stomach at the time of surgery is also helpful. Patients receive prophylactic intravenous antibiotic therapy 30 minutes before surgery. Pneumatic compression stockings are routinely used. The operations are performed under general anesthesia in the low lithotomy position. A 16-Fr, three-way Foley catheter with a 20- to 30-mL balloon is attached to continuous drainage, and the irrigation port is connected to sterile water or saline.

After all sutures are placed and tied, transurethral cystoscopy or suprapubic teloscopy is done to document ureteral patency and absence of sutures in the bladder. A suprapubic catheter is placed, if desired. The surgeon must again inspect the pelvis for bleeding while reducing the carbon dioxide insufflation. Routine closure of the peritoneum is performed based on the surgeon's preference. All ports are removed under direct visualization, and the peritoneum and fascia of all 5- to 12-mm incisions are reapproximated with the fascial closure instrument (Karl Storz, Tuttingen, Germany) or the Grice needle (New Ideas in Medicine, Clearwater, FL). The skin is closed in a subcuticular fashion. The fascia and subcutaneous fat can be infiltrated with a long-acting local anesthetic, such as 0.5% bupivacaine hydrochloride.

Postoperative care consists of oral pain medication (intravenous, if needed), rapid diet advancement, and ambulation. If an anti-incontinence procedure is concomitantly performed, voiding trials begin as soon as the patient is ambulatory. Intermittent self-catheterization protocols can begin immediately, especially if the patient was taught the technique preoperatively. Some patients are able to go home on the same day if adequately counseled preoperatively. Preoperative teaching includes discussion of postoperative analgesics, the need for a caretaker at home during the immediate recovery period, instruction in catheter care or intermittent self-catheterization, and explanation of goals to be reached before outpatient discharge. Patients are instructed to refrain from sexual intercourse and lifting objects heavier than 10 pounds for at least 8 weeks. They are cautioned to heed to these instructions despite rapid recovery.

### Technique of Laparoscopic Sacral Colpopexy

Vaginal obturators, spongsticks, or equivalent vaginal manipulators (EEA Sizer, U.S. Surgical Corp.; CDH, Ethicon Endo-Surgery) are used for delineation of the vaginal apex and rectum. After all ancillary ports are placed, the presacral space is dissected (Fig. 72-1). If exposure of the sacral promontory and presacral space is not adequate, the patient should be tilted to her left and a reusable snake retractor (Snowden Pencer, Tucker, GA) or fan retractor (Origin Medsystems, Menlo Park, CA) placed through

**Figure 72-1** Dissection of the presacral space.

**Figure 72-3** Anterior attachment of polypropylene mesh to the muscularis of the vaginal apex.

**Figure 72-2** Dissection of the rectovaginal space.

**Figure 72-4** Fixation of two separate polypropylene meshes during sacral colpopexy.

an ancillary port. A suture may be placed through the sigmoid epiploicae and placed on traction outside of the abdomen lateral to the left lower quadrant port to keep the sigmoid colon retracted throughout the surgery, thereby freeing an operative port. The peritoneum overlying the sacral promontory is incised longitudinally with laparoscopic scissors or harmonic scalpel (Gynecare, Somerville, NJ) and extended to the cul-de-sac. A laparoscopic dissector or hydrodissection is used to expose the periosteum of the sacral promontory. If blood vessels are encountered during the dissection, coagulation or clip placement is used to achieve hemostasis. Some surgeons prefer to dissect the presacral space first, eliminating the most technically difficult portion of the procedure. A Halban procedure or Moschowitz culdoplasty may be performed based on the surgeon's preference or when a deep cul-de-sac is encountered. When a concomitant culdoplasty is performed, it is completed after posterior mesh placement.

To dissect the rectovaginal septum, the peritoneum between the vaginal apex and rectum is placed on countertraction by manipulating the EAA sizers, pointing the vagina toward the pubic bone and the rectum toward the sacrum (Fig. 72-2). Anterior dissection is performed after the bladder is filled with 300 ml

of sterile water. Dissection is extended to the bladder base. This dissection can be very difficult if a patient has undergone a previous anterior colporrhaphy or vaginal suspension procedure.

Our technique incorporates two pieces of 15 × 4 cm polypropylene mesh or biologic tissue. We sew the posterior mesh on first. The most caudal stitch is placed on the posterior vaginal wall and rectovaginal fascia. After placement of the first stitch, the mesh is threaded through the stitch before introducing the mesh into the peritoneal cavity. The corresponding contralateral stitch is taken and threaded through the mesh to anchor the inferior border of the mesh to the rectovaginal septum or perineum (a 15- to 18-cm mesh length may be required for laparoscopic sacral colpoperineopexy). The sutures are tied extracorporeally as they are placed. Care is taken to place the stitches through the entire thickness of the vaginal wall, excluding the epithelium. The mesh is sutured to the posterior vaginal apex and rectovaginal septum with three to four similar rows of suture and to the vaginal apex anteriorly with two to three pairs of No. 0 nonabsorbable sutures (Figs. 72-3 and 72-4). The surgeon sutures the mesh to the longitudinal ligament of the sacrum with two

**Figure 72-5** Attachment of the mesh to the anterior longitudinal ligament of the sacrum without tension.

**Figure 72-6** Biologic mesh implantation in sacral colpopexy.

No. 0 nonabsorbable sutures (Fig. 72-5). No undue tension is placed on the mesh. Titanium tacks or hernia staples may also be used to attach the mesh to the anterior longitudinal ligament of the sacrum. The redundant portion of the mesh is excised. Biologic tissue may also be used, especially when concomitant bowel resection is performed (Fig. 72-6). The peritoneum is reapproximated over the mesh with 2-0 polyglactin suture. If the mesh remains exposed, sigmoid epiploic fat may be sutured over it.

### CLINICAL RESULTS AND COMPLICATIONS

The current gynecologic literature for laparoscopic sacral colpopexy is sparse and consists of case series from surgeons subspecializing in advanced laparoscopy and urogynecologic surgery. Comparative, adequately powered studies of laparoscopic surgery for vaginal apex prolapse do not exist.

In 1994, Nezhat and colleagues<sup>1</sup> reported a series of 15 patients who underwent laparoscopic sacral colpopexy for whom the

mean operative time was 170 minutes (range, 105 to 320 minutes) and the mean blood loss was 226 mL (range, 50 to 800 mL). The mean hospital stay was 2.3 days, excluding a case converted to laparotomy because of presacral hemorrhage. The cure rate for apical prolapse was 100% at 3 to 40 months. In 1995, Lyons and Winer<sup>4</sup> reported 4 laparoscopic sacrospinous fixations and 10 laparoscopic sacral colpopexies with operative times comparable to those for vaginal and abdominal approaches. He reported less intraoperative and postoperative morbidity with the laparoscopic route; this was attributed to a superior anatomic approach and visualization of anatomic structures. Nezhat and associates<sup>1</sup> and Lyons and Winer<sup>4</sup> used mesh and suture, and they sometimes stapled the mesh into the longitudinal ligament of the anterior sacrum.

In 1997, Ross<sup>5</sup> evaluated 19 patients with post-hysterectomy vaginal apex prolapse prospectively with extensive preoperative and postoperative testing, including multichannel urodynamics and transperineal ultrasound. All patients underwent sacral colpopexy, Burch colposuspension, and modified culdoplasty. Paravaginal defect repair and posterior colporrhaphy were added as indicated. Ross reported seven complications: three cystotomies, two urinary tract infections, one seroma, and one inferior epigastric vessel laceration. Five patients had recurrent defects that were all less than grade 2 (two paravaginal defects and three rectoceles). Vaginal length ranged from 10.8 to 12.1 cm, and all sexually active patients reported no sexual dysfunction. All but four patients voided spontaneously, and none required more than 4 days of catheterization. All were discharged within 24 hours. The cure rate at 1 year was 100% for vaginal apex prolapse and 93% for stress incontinence, although two patients were lost to follow-up. In another study reported in 2004, Ross<sup>6</sup> prospectively analyzed 51 cases of laparoscopic sacral colpopexy for grade III or IV apical vaginal vault prolapse. Forty-three patients demonstrated an objective cure rate of 93% at the vaginal apex during their 5-year follow-up visit. Complications included one partial small-bowel obstruction resulting from bowel adherence to the mesh and two locally treated mesh erosions. Ross concluded that patient recovery was greatly enhanced, with most patients requiring only overnight hospitalization.

The largest series of laparoscopic sacral colpopexies is a retrospective cohort of 83 patients published by Cosson and associates<sup>7</sup> in the French literature. The investigators performed concomitant laparoscopic supracervical hysterectomy in 60 patients and converted six cases to laparotomy. Operative time decreased from 292 to 180 minutes with increased experience. One patient required reoperation for prolapse, and two patients underwent procedures for stress incontinence. The median length of follow-up was 343 days. In 2004, Gadonneix and coworkers<sup>7</sup> reported the use of two separate meshes for laparoscopic sacral colpopexy with or without Burch colposuspension in 46 consecutive patients with primary vaginal apex prolapse with or without primary stress incontinence. Mean operating time was 171 minutes, and mean hospital stay was 4 days. Median follow-up was 24 months (range, 12 to 60 months). Eleven percent of patients required conversion to laparotomy. Complications included de novo urge incontinence in 5% of patients, laparoscopically treated bladder injury in 7%, and recurrent rectoceles in 12% (occurring only in women who had undergone laparoscopic Burch colposuspension compared with no colposuspension,  $P = .036$ ). One patient developed obstructed defecation, which the study authors attributed to excessive mesh tension.

At the Cleveland Clinic Foundation, we compared our first 56 consecutive laparoscopic sacral colpopexies with 61 consecutive open sacral colpopexies performed during the same period.<sup>9</sup> Mean follow-up was 14 and 16 months for the laparoscopic and open groups, respectively. Laparoscopic sacral colpopexy and concomitant procedures required a significantly longer operating room time compared with open sacral colpopexy, with mean operating room times of 269 and 218 minutes, respectively. However, mean hospital stay was significantly longer for the open group than the laparoscopic group (4 versus 1.8 days). We found similar clinical outcomes and reoperation rate. Our sample size was too small to determine differences in complications.

## CONCLUSIONS

Laparoscopy is a means of achieving less invasive surgical access, and its use is expanding rapidly in all surgical specialties. The technique for laparoscopic sacral colpopexies should be as close as possible to the operative technique for open sacral colpopexy. Bladder injury is probably more common with laparoscopy, but the risk of cystotomy decreases with surgical experience. Complications associated with laparotomies, such as wound infection and hernias, are rare with the laparoscopic route.

The benefits of improved visualization of anatomic structures and the small incisions associated with the laparoscopic approach are desirable, particularly in obese patients. The advantages of less postoperative pain, shorter hospitalization, a shortened recovery period, and earlier return to work are very popular with patients, but these advantages are partially offset by increased operating time and possibly by increased cost. The operating time and cost will likely decrease as surgeons gain experience with the advanced laparoscopic techniques of suturing and knot tying. Laparoscopic approaches for pelvic organ prolapse may be somewhat underused because of the greater technical difficulty associated with surgical dissection and laparoscopic suturing. The emergence of vaginal mesh kit procedures and tunneling techniques may thwart widespread adoption of laparoscopic sacral colpopexy. However, the greatest potential for laparoscopic advances and innovations may be in operations for prolapse. We believe that laparoscopic sacral colpopexy will gain popularity because abdominal sacral colpopexy remains the most proven and effective surgery for cure of severe apical prolapse. Pelvic floor surgeons in specialized centers strive to offer their patients pelvic reconstruction by laparoscopic route, many employing robotic assistance. More comparative studies and prospective clinical trials with long-term follow-up are warranted.

# OPEN ABDOMINAL SACRAL COLPOPEXY

*Chi Chiung Grace Chen and Marie Fidela R. Paraiso*

Pelvic organ prolapse is a condition that physicians are likely to encounter as women are living longer and more emphasis is placed on maintaining their physique and capacity for sexual activity. It has been estimated that more than 300,000 surgeries are being performed annually to correct pelvic organ prolapse at a cost of greater than \$1 billion dollars.<sup>1</sup> The number of women seeking attention for these disorders is projected to increase by 45% in the future.<sup>2</sup>

Management of pelvic organ prolapse depends on the goals and expectations of the patient and on the patient's comorbidities. For example, women who have minimal symptoms or those with prolapse that does not extend beyond the hymen may benefit from pelvic floor exercises and behavioral modifications. Patients who have many comorbidities and are poor surgical candidates may benefit from vaginal pessaries. Women who do not desire preservation of sexual capacity may benefit from a less morbid obliterative procedure, such as colpocleisis. When contemplating the surgical correction of pelvic organ prolapse, the surgeon must also consider the existence of other support defects and any dysfunction of bladder or bowel. The surgeon must decide whether to approach these repairs abdominally, vaginally, or laparoscopically. In this chapter, we will focus on abdominal sacral colpopexy or suspension of the vagina to the sacral promontory, which is considered the gold standard procedure for correcting pelvic organ prolapse.

Abdominal sacral colpopexy should be considered if the patient has severe vaginal apical prolapse and requires concomitant pelvic or anti-incontinence surgery by the abdominal route. Other indications include previous failed transvaginal colpopexy, foreshortened vagina, weakened pelvic floor, and chronic increases in abdominal pressure as a result of medical comorbidities (e.g., chronic obstructive pulmonary disease, chronic constipation) or occupation (e.g., heavy manual labor). Some pelvic surgeons also prefer abdominal sacral colpopexy for young patients with severe apical prolapse.

### **"GENERAL INTRAOPERATIVE PROCEDURES" TO "ANATOMY AND GENERAL INTRAOPERATIVE PROCEDURES"**

As the relevant abdominal and pelvic anatomic landmarks for open sacral colpopexy are the same as for laparoscopic sacral colpopexy, please refer to Chapter 72. Furthermore, some general intraoperative considerations are also the same and include placement of the patients in low lithotomy position under general anesthesia, prophylactic intravenous antibiotics before initiation of surgery, pneumatic compression stockings on the patients' lower extremities, and placement of a 16-Fr three-way Foley catheter to continuous drainage with the irrigation port attached to sterile water or saline to facilitate retrograde filling of the

bladder to assist in dissection of the bladder off the vaginal apex during surgery.

## **SURGICAL TECHNIQUE**

### **General Intraoperative Procedures**

Specifically, the ideal stirrups for combined abdominovaginal cases are the Allen stirrups and Yellofins (Allen Medical Systems, Acton, MA), which have levers that can quickly convert the patient from low to high lithotomy position while preserving sterility of the field. A transverse or vertical laparotomy incision is made based on surgeon preference or concomitant procedures. For obese patients, a Maylard incision may be useful for improved exposure compared with a Pfannenstiel incision.

The patient is placed in a Trendelenburg position. The small bowel is packed upward, and the sigmoid colon is packed to the left paracolic gutter. The Bookwalter retractor or Balfour retractor is placed to hold the sides of the incision open, giving exposure to the operative field. The Bookwalter retractor is ideal for obese patients. Sterile towels are placed below the lateral points of the Balfour retractor to decrease compression of the psoas muscle, safeguarding against femoral neuropathy.

The sacral promontory is palpated, and the respective landmarks of the presacral space are delineated. The presacral peritoneum is tented and incised down to the level of the posterior cul-de-sac. The peritoneum may be retracted laterally by placing tagged 2-0 absorbable sutures, which can be tied together after the procedure is complete for closure of the peritoneum. Alternatively, a tunnel can be made in the right pararectal peritoneum from sacral promontory to the posterior cul-de-sac rather than completely incising the peritoneum. Kittners (i.e., endoscopic, blunt dissectors with radiopaque tips) are used to clear away the areolar tissue of the sacral promontory, delineating the anterior longitudinal ligament of the sacrum and the middle sacral vessels. Care must be taken to avoid trauma to the presacral vessels because these vessels retract easily, and life-threatening hemorrhage may ensue. If bleeding does occur, pressure, hemostatic clips, cautery, fibrin glue, and Gelfoam may be applied. If these measures are not successful, bone wax and sterile thumbtacks should be used. The presacral nerve should be preserved to decrease the risk of temporary postoperative urinary retention and constipation.

Manipulators are placed in the vagina and rectum for delineation. For example, fiberglass obturators or endoanal anastomosis (EAA) sizers may be placed in the vagina and rectum for traction in opposite directions to delineate the rectovaginal space. The peritoneum is incised, rectovaginal space entered, and blunt dissection performed along the length of the posterior vaginal wall. In cases of abdominal sacral colpopelvicopexy, this dissection is extended to the perineum. The bladder is filled with 300 mL in

a retrograde fashion with a three-way Foley catheter hooked to irrigation to delineate the superior border of the bladder. The bladder peritoneum is incised, and the bladder is sharply dissected downward to the bladder base off the vagina. Palpation of the Foley catheter bulb aids in this dissection. Care should be taken not to cauterize the bladder and vagina to a great extent. Peritoneum should be preserved at the vaginal apex if possible to decrease risk of mesh erosion.

After dissection of the bladder and preparation of the rectovaginal space, several rows of 1-0 nonabsorbable suture are stitched into the posterior vaginal muscularis. The most distally placed sutures are at the perineum during colpoperineopexy. The stitches should be placed at least halfway down the length of the posterior vagina for a sacral colpopexy. It is preferable to avoid through-and-through stitches into the vaginal epithelium. Each row of sutures should be placed 2 cm apart. The sutures are tagged, and after all sutures are placed, the ends of the suture are brought through the pores of a 4 × 15 cm polypropylene mesh. Polypropylene suture is easy to work with in this setting; when cut, it is easily passed through the pores. A longer piece of polypropylene mesh is required for the sacral colpoperineopexy. The sutures are then tied without strangulating the tissue to decrease erosion. If a Halban or Moschcowitz procedure is performed to obliterate the pouch of Douglas, these sutures can be placed before or after posterior mesh placement, but they should not be tied until the posterior mesh is placed. A 2-0 nonabsorbable suture is adequate for the culdoplasty procedures.

Approximately two or three rows of 1-0 nonabsorbable suture are placed on the anterior vaginal wall. The ends of the sutures are then brought through the pores of a second 4 × 15 cm piece of polypropylene mesh and tied. The vaginal manipulator is used to place the vagina under no tension in the right pararectal space. The securing point of the mesh to the anterior longitudinal ligament at the S1 or S2 level is then marked. Two or three polypropylene sutures are placed transversely into the anterior longitudinal ligament. The suture ends are then brought through the pores of both leaflets of mesh so that each leaflet can be secured without tension.

After the mesh is tied down and hemostasis ensured, the peritoneum is reapproximated over the mesh with a 3-0 absorbable suture. This is an important step to decrease risk of small-bowel obstruction below the mesh and mesh adhesion to viscera. Care must be taken not to kink the right ureter or the rectosigmoid. Sigmoid epiploica and bladder peritoneum may be used to cover the mesh. After all sutures are placed and tied, transurethral cystoscopy or suprapubic telescopy is done to document ureteral patency and absence of sutures in the bladder. The incision is closed in the customary fashion after concomitant abdominal procedures are performed. Vaginal route procedures, if necessary, are completed after the abdominal procedures are performed (see Chapter 72 for photographs of the procedure).

Postoperative care consists of intravenous analgesia for the first 12 to 24 hours after surgery. Oral pain medication, diet advancement, and ambulation are the rule on the first postoperative day. If an anti-incontinence procedure is concomitantly performed, voiding trials begin as soon as the patient is ambulatory. Preoperative teaching includes a discussion about postoperative analgesics, the need for a caretaker at home during the immediate recovery period, instruction in catheter care or intermittent self-catheterization, and the goals to be reached before discharge. Patients are able to go home on postoperative day 2 or 3. Patients

are instructed to refrain from sexual intercourse and lifting objects heavier than 10 pounds for at least 8 weeks.

### Clinical Results

The effectiveness of abdominal sacral colpopexy to correct pelvic organ prolapse can be examined from two perspectives: patient satisfaction or resolution of symptoms and restoration of normal anatomy (Table 73-1). The rate of patient satisfaction or resolution of symptoms in different studies range from 85% to 100%. Unfortunately, many of these studies do not include a description of the outcome tools used to assess satisfaction. In one study, a visual analogue score using a 10-point scale was used to determine that the overall patient satisfaction rate was 85% with a follow-up interval of 3 years.<sup>3</sup> In another study with patient follow-up assessments ranging from 1 to 13 years (median, 4 years), 29% of patients experienced “no improvement,” 39% experienced “considerable improvement,” and 32% felt that they were “fully cured.”<sup>4</sup>

To examine anatomic success, common measures of vaginal support include the Baden-Walker grading scale and the Pelvic Organ Prolapse Quantification (POP-Q) system (see Chapter 54).<sup>5,6</sup> In a review article by the Pelvic Floor Disorders Network, abdominal sacral colpopexy resulted in the cure of vaginal apex prolapse in 78% to 100% and the cure of prolapse in all vaginal segments in 58% to 100%, with follow-up ranging from 6 months to 3 years.<sup>7</sup>

The success rate of sacral colpopexy drops when it is defined as the absence of all vaginal prolapse regardless of apical, anterior, or posterior location. It is therefore important when looking at outcomes to consider recurrent or de novo anterior and posterior vaginal wall prolapse. For example, one study found that only 7% of patients after surgery experienced recurrent apical prolapse, whereas 30% developed new enterorectoceles.<sup>8</sup> The investigators thought that this discrepancy reflected the inconsistent use of culdoplasty and consequently recommended that this procedure be routinely performed with all sacral colpopexies. Brubaker<sup>9</sup> reported that 29% (19 of 65) of patients with a follow-up of 3 months had new or persistent anterior prolapse despite having undergone sacral colpopexy with a posterior graft attachment and a separate anterior compartment repair. However, only two patients were symptomatic. Sacral colpopexy is an effective method to correct apical prolapse, but its effects on other compartment defects and the optimal management of those defects remain unclear.

The need for reoperation to correct persistent, recurrent, or de novo pelvic organ prolapse may depend on factors other than surgical techniques. These factors include vaginal tissue quality, coexisting defects, and medical conditions such as chronic obstructive pulmonary disease. In one large data series, it was found that one of three patients who underwent a procedure for urinary incontinence or prolapse had to undergo reoperation within 4 years.<sup>10</sup> The Pelvic Floor Disorders Network reported the median reoperation rate to be 4.4%, with follow-up intervals between 6 months and 3 years.<sup>7</sup> The reoperations predominately were for anterior or posterior prolapse and not for apical defects.

Patients after abdominal sacral colpopexy for pelvic organ prolapse are also at risk for persistent or de novo stress urinary incontinence. The Pelvic Floor Disorders Network reported the rate of operations for stress incontinence to be 4.9% after sacral colpopexy.<sup>7</sup>

**Table 73-1 Clinical Outcomes of Abdominal Sacral Colpopexy**

Study	No. of Patients	Follow-up (mo)	Success Rate (%)	Criteria for Success
Snyder and Krantz, 1991	147	43	93	No recurrence of symptoms for at least 6 months
Sullivan et al, 2001	236	64	100	No recurrence of vaginal or rectal prolapse
Culligan et al, 2002	245	61	85	Any POPQ point < stage II
Brizzolara and Pillai-Allen, 2003	124	36	98	No recurrent vault prolapse
Timmons et al, 1992	163	33	99	Good vaginal vault support
Lecuru et al, 1994	203	33	87-100	Anatomically good results
De Vries et al, 1995	101	48	32	Fully cured (patient satisfaction based on questionnaire)
Ocelli et al, 1999	271	66	98	Cured for prolapse
Patsner, 1999	175	≥12	97	No mesh failures
Lindeque and Nel, 2002	262	≥16	99	No vaginal vault prolapse

POPQ, Pelvic Organ Prolapse Quantification system.

It is also pertinent to compare the effectiveness of open abdominal sacral colpopexy with vaginal procedures to correct pelvic organ prolapse. In a retrospective case series of 80 abdominal sacral colpopexies compared with 130 attempted vaginal sacrospinous vault suspensions (five were abandoned because of technical difficulties), the incidence of recurrent prolapse was not statistically different (1.3% and 2.4%, respectively) (Table 73-2).<sup>11</sup> The complication rates were similar in both groups, except that the mean estimated blood loss was higher in the abdominal sacral colpopexy group compared with the vaginal sacrospinous vault suspension group (745 versus 567 mL,  $P = .04$ ). Moreover, in the sacral colpopexy group, one patient developed stress incontinence; this complication was not seen after sacrospinous suspension. Concomitant incontinence and other gynecologic procedures were performed with various frequencies in the different groups. The results must be interpreted in light of these inconsistencies.

Three randomized trials compared open abdominal sacral colpopexy and vaginal procedures for pelvic organ prolapse and had different results (Table 73-3). Benson and colleagues<sup>12</sup> and Lo and Wang found that sacral colpopexy was more effective at correcting pelvic organ prolapse than sacrospinous suspension. However, Maher and coworkers<sup>13</sup> found that the abdominal and vaginal approaches were equally efficacious at correcting pelvic organ prolapse. It is difficult to compare efficacy in the different studies because most of these operations were performed simultaneously with various combinations of different incontinence and gynecologic procedures. There are also no consistencies between the different studies with regard to a propensity for complications with the abdominal or vaginal approach.

## COMPLICATIONS

Intraoperative complications of abdominal sacral colpopexies include those associated with any gynecologic laparotomies, such as enterotomy, proctotomy, cystotomy, and ureteral injury. The Pelvic Floor Disorders Network found that enterotomy or proctotomy occurred in 1.6%, cystotomy in 3.1%, and ureteral injury in 1.0% of operations.

Although uncommon, one of the most morbid complications associated with this procedure is hemorrhage from the presacral

vessels. Hemostasis is especially difficult to achieve in this area because the vessels form a complex interlacing network above and underneath the sacral periosteum. Once lacerated, these vessels retract, making it even more impossible to isolate single vessels. The presacral vessels often form communications with adjoining pelvic vessels, especially the left common iliac vein, resulting in even more extensive hemorrhage if they are damaged. Although the incidence of presacral vascular injury in the literature has not been specifically addressed, the requirement overall rate of hemorrhage with or without transfusion is 4.4%. Management of this complication include packing the presacral space, which is often only a temporizing measure and has the added possibility of lacerating more of these delicate vessels as the pack is removed. Other measures include using electrocautery, sutures, and metallic vascular clips. These procedures are especially successful if the lacerations are small or individual vessels that can be visualized. If these strategies are not successful, other interventions include using bone wax and orthopedic bone thumbtacks.<sup>14</sup> To avoid this complication, some surgeons recommend minimal dissection of the presacral space by attaching the graft to the ligament,<sup>15</sup> and others advocate careful, extensive dissection of this space to prevent inadvertent injury to unseen vessels.

Postoperative complications include urinary tract infection, ileus and small bowel obstruction, deep venous thrombus or pulmonary embolus, extrafascial wound problems, and granulation tissue in the vagina. Urinary tract infection was the most commonly reported complication in the literature, occurring in 2.5% to 25.9% of patients. Postoperative ileus occurred in 3.6% of cases, and reoperation for small bowel obstruction occurred in 1.1% of operations. Deep venous thrombus or pulmonary embolus was reported in 3.3% of cases. Extrafascial wound complications such as hematoma, infection, or superficial separation occurred in 4.6% of operations, and 5.0% of procedures resulted in incisional hernias requiring subsequent repairs. Other uncommon complications reported in the literature include femoral, obturator and sciatic neuropathies, fascial dehiscence, vertebral osteomyelitis, and gluteal necrotizing myofasciitis.

One of the most discussed but uncommon postoperative complication is mesh erosion. In one retrospective series of 155 abdominal sacral colpopexies using Mersilene mesh (Johnson & Johnson) with a median follow-up of 6.5 months (range, 1 to 87

**Table 73-3 Erosion Rates with Different Mesh Materials**

Mesh Material	Manufacture	Reported Rates of Erosion
Polypropylene	Prolene Ethicon Endo-Surgery, Inc.	0.5%
Polyethylene terephthalate	Mersilene Johnson & Johnson	3.1%
Gore-Tex	W.L. Gore & Associates, Inc.	3.4%
Teflon	E.I. DuPont de Nemours & Co.	5.5%
Polyethylene	Marlex Phillips Sumika Polypropylene Co.	5.0%

Data from Nygaard IE, McCreery R, Brubaker L, et al: Abdominal sacrocolpopexy: A comprehensive review. *Am J Obstet Gynecol* 104:805-823, 2004.

months), the erosion rate was 3.2%, with a median time to the appearance of erosion of 15.6 months (range, 2 to 33 months).<sup>16</sup> Although the true incidence of this complication is unknown because most reported studies have short follow-up intervals, the Pelvic Floor Disorders Network found that the reported rate to be 3.4% at 6 months to 3 years.<sup>7</sup> Moreover, the reported rate of reoperations for mesh-related complications, including

erosion and infection, is 3.0%. Although mesh erosion has been reported with all available synthetic graft materials (see Table 73-3), there are no published randomized trials comparing the erosion rates of these different graft materials. Not surprisingly, case series involving nonsynthetic grafts such as autologous, cadaveric fascia or dura mater reported no cases of erosion.

## POSTERIOR WALL PROLAPSE: SEGMENTAL DEFECT REPAIR

*Tristi W. Muir*

Pelvic organ prolapse is common in women. The lifetime risk for undergoing an operation for prolapse or urinary incontinence is estimated to be 11.1%.<sup>1</sup> The posterior wall of the vagina primarily provides support over the anterior rectum and posterior cul-de-sac. Prolapse of the posterior vaginal wall may result from the presence of an enterocele, sigmoidocele, rectocele, or a combination of these entities. This chapter focuses on the herniation of the anterior rectum into the posterior vaginal wall as the cause of the prolapse. A variety of surgical procedures are available for the management of posterior vaginal wall prolapse, including posterior colporrhaphy, site-specific defect repair, posterior fascial replacement, transanal or transperineal repair, and a sacral colpoperineopexy. Posterior colporrhaphy and site-specific defect repair for surgical repair of posterior wall prolapse are discussed.

### ANATOMY AND PATHOPHYSIOLOGY

The support of the vagina is provided by an interaction of the bony pelvis, pelvic floor musculature (i.e., levator ani and coccygeus muscles), and the connective tissue supports. The vagina is a fibromuscular tube, which must maintain its position but have enough mobility to accommodate urinary, sexual, and defecatory functions. This vaginal tube also must distend to allow for childbirth. The pelvic floor muscles are composed of two functional components, one horizontal and the other vertical. The coccygeus muscle and horizontal portion of the levator ani muscles provide a backstop of support of the abdominal contents. The urethra, vagina, and rectum exit the abdominal cavity through the levator hiatus. A muscular sling that is chronically contracted to close this hiatus but capable of relaxing open to allow for urinary, defecatory, and sexual function is provided by the puborectalis portion of the levator ani. A continually contracted levator ani muscle closes the levator hiatus and angulates the rectal and vaginal tubes toward the pubic symphysis. Anatomically, there are no native fibers of the levator ani muscles traversing the rectovaginal space.

The connective tissue supports of the posterior vaginal wall are in continuity from the apical support of the vaginal vault (originating at the sacrum) to the perineal body. The apical portion of the anterior and posterior vaginal wall is provided by the suspensory support of the cardinal-uterosacral ligaments. The cardinal-uterosacral ligaments provide a mesentery of

support directed toward the sacrum (S2 to S4) and pelvic side wall. The broad posterior fan of support directs the proximal (apical) portion of the vaginal axis posteriorly, and the contracted levator ani muscles direct the midportion of the vagina and rectum anteriorly toward the pubic symphysis. This orients the proximal vagina and rectum in a horizontal plane, supported over the pelvic floor muscles rather than a vertical orientation through the levator hiatus.<sup>2</sup> The connective tissue attachments of the midsection of the posterior vaginal wall are directed laterally and cranially to the levator ani muscular side wall.<sup>3</sup> The proximal halves of the posterior and anterior vaginal wall are attached to the same condensation of endopelvic fascia on the levator ani muscles, the arcus tendineus fasciae pelvis. The distal half of the posterior vaginal wall has a separate, caudal attachment to the pelvic side wall, the arcus tendineus fasciae rectovaginalis.<sup>4</sup> These separate lines of attachment of the anterior and posterior vaginal wall give the distal portion of the vagina an H shape (Fig. 74-1).

The perineal body is the central connection between the two sides of the perineal membrane, which originates bilaterally on the medial portion of the ischiopubic rami. Within the perineal body lie the bulbocavernosus muscle, superficial transverse perineal muscle, and the external anal sphincter and the rectovaginal septum, or Denonvilliers' fascia. Extending from the posterior cul-de-sac to the perineal body, the rectovaginal septum is the fused, endopelvic fascial remnant of the embryonic posterior cul-de-sac.<sup>5,6</sup> The role of the perineal body is to resist caudally directed force provided by the rectum and provide a physical barrier between the vagina and rectum. The perineal body's mobility is limited by an intact connective tissue support within the vagina from the sacrum to the perineal body and an intact perineal membrane from ischiopubic ramus to ischiopubic ramus.<sup>3</sup>

An increase in intra-abdominal pressure, such as a Valsalva maneuver, flattens the horizontally oriented upper vagina against the rectum and pelvic floor musculature. In the distal vagina, a Valsalva maneuver causes an equal increase in pressure against the anterior and posterior vaginal walls. No net strain is placed on the connective tissue support of the vaginal wall (Fig. 74-2). However, if the levator hiatus is widened or not closed, two things may happen. First, the vagina may lose the horizontal orientation of its axis. As the vagina becomes more vertically oriented, intra-abdominal pressure pushes the pelvic organs through the levator hiatus and toward the genital hiatus. The

**Figure 74-1** Lateral attachment of the anterior and posterior vaginal walls. The lateral support of the anterior wall fuses at the arcus tendineus fasciae pelvis (ATFP), which extends from the back of the pubic bone to the ischial spine (IS). The distal lateral connection of the posterior vaginal wall is more posterior, the arcus tendineus fasciae rectovaginalis (ATFR). The proximal connection of the posterior vaginal wall is the ATFP. (Courtesy of the Cleveland Clinic Foundation.)

**Figure 74-2** Equalization of pressure in the anterior and posterior vaginal walls (arrows). The pressure on the anterior vaginal wall and the posterior vaginal wall (PVW) is equal, and no strain is placed on the connective tissue supports of the vaginal walls. The perineal body (PB) is intact and resists the downward intrarectal force. ARW, anterior rectal wall. (Courtesy of the Cleveland Clinic Foundation.)

anterior and posterior vaginal walls then do not lie in apposition. An increase in intra-abdominal or intrarectal pressure, such as that obtained with straining for a bowel movement, is not met with an equal measure of pressure of the anterior vaginal wall. Instead, the posterior vaginal wall pressure meets the atmospheric pressure present in the open vagina (Fig. 74-3). In both situations, an increase in abdominal pressure places a net force on the connective tissue supports of the posterior vaginal wall. This force on the connective tissue supports may attenuate or break

**Figure 74-3** Rectocele. In a woman with an open vagina, the pressure within the rectum is met by atmospheric pressure. The anterior vaginal wall does not provide equilibrating force, and there is stress (arrow) placed on the posterior vaginal wall's connective tissue. This may lead to rectocele formation. (Courtesy of the Cleveland Clinic Foundation.)

the posterior vaginal wall, or it may uncover damage done by a prior event, such as childbirth.

Anything that damages the pelvic floor musculature, its innervation, or the connective tissue of the posterior vaginal wall may result in prolapse. Damage to the levator ani muscles or innervation may be traumatic (usually related to childbirth) or be a result of neuromuscular diseases or aging. Connective tissue may be damaged through trauma (i.e., childbirth or constant straining with defecatory dysfunction), congenital disease, or aging. A combination of these factors is the likely recipe for the manifestation of prolapse.

## SIGNS AND SYMPTOMS

Many women with posterior wall prolapse are asymptomatic. Women who have prolapse that protrudes beyond the hymenal ring are more likely to be symptomatic.<sup>7</sup> This bulge may be associated with vaginal pressure or pain, which worsens as the day progresses or with abdominal straining. This bulge may affect urinary, sexual, and defecatory functions.

As the posterior vaginal wall balloons upward toward the anterior vaginal wall and outward toward the genital hiatus or beyond, urinary function may be altered. Inside the vagina, the distended posterior vaginal wall may provide additional support of the urethra and mask or decrease the severity of urinary incontinence. Urodynamic investigations, with and without reduction of the posterior wall prolapse, have demonstrated that when the posterior wall prolapse is retracted, there are significant decreases in the maximum urethral closure pressure and functional urethral length and an increase in leak volumes.<sup>8</sup> Beyond the genital hiatus, posterior wall prolapse may partially obstruct the external urethral meatus, altering the stream of urine.

Sexual function is a complicated issue involving both partners' psychological and physical well-being. Prolapse protruding beyond the genital hiatus may lead to an altered body image and self-esteem. This may be worsened by fear of urinary or anal incontinence. Prolapse may be significant enough to require

reduction before even attempting to have vaginal intercourse. A widened genital hiatus may decrease sensation for both partners during intercourse. The woman's partner may also be concerned about causing pain or discomfort or about contributing to worsening of the prolapse.

Defecatory dysfunction and pelvic organ prolapse often coexist in women. A ballooning of the anterior rectum into the posterior vaginal wall or perineal body may alter the process of defecation. Stool may be trapped in the distended rectal pouch, leading to incomplete rectal emptying. Women may employ digitally placed pressure in the vagina, on the perineal body, or within the rectum to evacuate the stool. Some woman may perceive this as constipation (i.e., straining to have a bowel movement or an unproductive urge to defecate). However, constipation is often unrelated to a rectocele, such as that related to irritable bowel syndrome, slow-transit colon, or secondary constipation related to medications or neurologic disorders. Determining if the woman's defecatory dysfunction is related to her posterior prolapse may be difficult to discern. Weber and colleagues<sup>9</sup> examined bowel function and severity of posterior wall prolapse and found no correlation. If a woman's sole defecatory complaint is incomplete rectal emptying that resolves with vaginal splinting, she is likely to have functional improvement after surgical correction.

A thorough history, including direct questions about fecal incontinence, should be obtained. Fecal incontinence may also coexist with posterior vaginal wall prolapse. There is an association with a rectocele, which protrudes beyond the hymen and anal incontinence.<sup>10</sup> A descending perineum may provide stretch on the pudendal nerve, which innervates the external anal sphincter. This stretch injury may lead to denervation of the external anal sphincter and fecal incontinence. Prior obstetric trauma that injures the external anal sphincter may also result in fecal incontinence.

The goal of the physical examination is to recreate the woman's symptoms. A validated measure of pelvic organ prolapse is the Pelvic Organ Prolapse Quantification (POPQ) system.<sup>11</sup> The POPQ examination includes measures of the uterus or vaginal cuff, posterior cul-de-sac, anterior and posterior vaginal walls, perineal body, and genital hiatus at maximal strain. Total vaginal length is assessed at rest. The posterior vaginal wall may be visualized with the posterior blade of a bivalve speculum or with a Sims speculum with the woman in the dorsal lithotomy or semirecumbent position. In most women, there is excellent correlation between the dorsal lithotomy and standing positions.<sup>12</sup> Confirmation of the recreation of the woman's maximal protrusion can be facilitated with a hand-held mirror. If a woman describes prolapse that is more significant than that observed in the supine or sitting positions, a standing examination may be employed.

A rectovaginal examination should accompany the physical examination. The tone of the external anal sphincter at rest and with squeeze may be assessed. With digital pressure directed toward the anterior rectal wall, areas of weak support and perineal body mobility can be evaluated. The clinical examination for identifying site-specific defects through a rectovaginal examination was found to be inaccurate when compared with site-specific defects found intraoperatively.<sup>13</sup> However, the rectovaginal examination may help to differentiate an enterocele from a rectocele. Palpation of loops of bowel between the rectum and vagina is consistent with an enterocele. This may be more evident in the standing position or with a Valsalva maneuver. Digital pressure placed on the posterior wall of the vagina directed toward the rectum may uncover rectal prolapse.

A focused neurologic examination to evaluate S2 to S4 should accompany the physical examination. Sensation may be determined by asking the patient to discriminate between sharp and dull sensations. Pelvic floor strength may be determined with the examiner's two fingers in the vagina and asking the patient to contract the pelvic floor (i.e., perform a Kegel exercise). Strength and duration of this contraction can be determined. Tenderness or spasm of the levator ani muscles may be uncovered on clinical examination. If a woman is unable to relax the levator ani muscles, anismus may be the cause of her obstructed defecation. Anismus, or paradoxical puborectalis contraction, often responds to bio-feedback or botulinum toxin.<sup>14,15</sup> Reflex testing of the bulbocavernosus reflex and anal wink may be performed.

Ancillary tests may be considered in the evaluation. Urodynamics with prolapse reduction may be indicated in a woman with complaints of urinary incontinence or for evaluation of potential urinary incontinence. Anorectal or colonic transit studies may help differentiate the potential causes of defecatory dysfunction. If the woman's primary complaint is related to her defecatory dysfunction rather than the bulge of the posterior vaginal wall, further defecatory testing should be performed before surgery. Incomplete emptying of the rectum may be caused by a paradoxical puborectalis contraction or slow-transit colon. Endoanal ultrasonography is useful in a woman with fecal incontinence to determine whether there is an anatomic defect in the external and internal anal sphincters. Imaging studies such as defecography and magnetic resonance imaging are used uncommonly for further elucidation of the anatomy of the prolapse.

## TECHNIQUE

The vaginal epithelium is opened with a transverse incision at the posterior fourchette. The posterior vaginal epithelium is then opened in the midline to a level proximal to the bulge and dissected away from the underlying fibromuscularis. The dissection is extended laterally to the endopelvic fascial attachment of the posterior vaginal wall to the arcus tendineus fasciae pelvis and arcus tendineus fasciae rectovaginalis (Fig. 74-4).

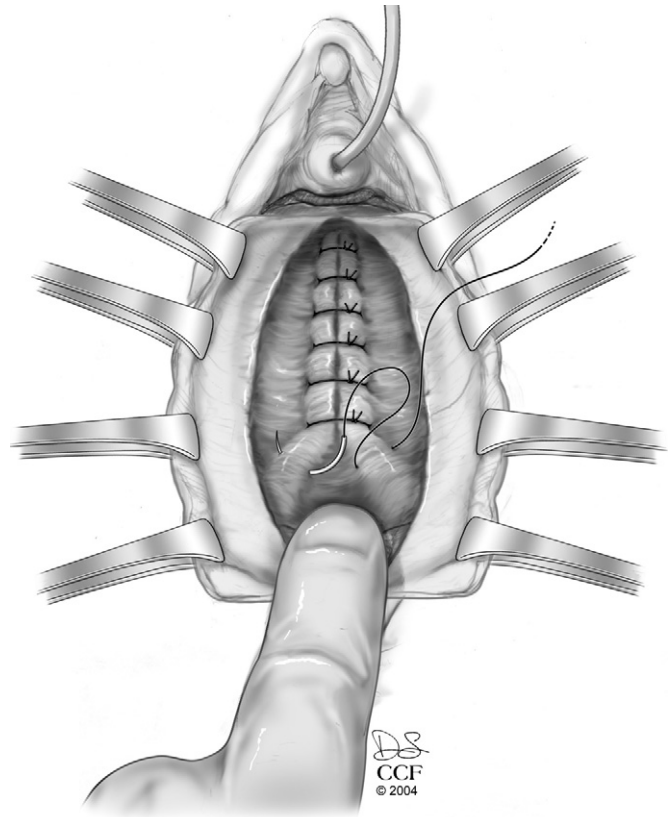

## Posterior Colporrhaphy

The underlying fibromuscularis of the posterior vaginal wall is exposed. A posterior colporrhaphy uses interrupted sutures to reduce the redundancy of the posterior fibromuscularis (Fig. 74-5). A delayed-absorbable 2-0 suture is used. A vertically oriented suture may reduce the length and width of the posterior vaginal wall. Care should be taken to maintain adequate vaginal caliber (i.e., approximately 3 fingerbreadths) and to avoid ridging of the posterior vaginal wall. If a suture constricts the vagina or creates a ridge, the suture should be removed and replaced. The vaginal epithelium is trimmed and closed with a 2-0 absorbable suture. It is important to avoid over-trimming the vaginal epithelium, particularly in a postmenopausal woman with vaginal atrophy or a woman with prior vaginal surgery and a constricted vagina. A perineorrhaphy may be performed to correct perineal body defects.

A plication of the levator muscles in the midline has been performed in conjunction with a posterior colporrhaphy in some patients. This may be indicated in a woman with a significantly widened levator hiatus. This is not the anatomic position of the

**Figure 74-4** Dissection of the posterior vaginal wall epithelium. The underlying fibromuscularis of the posterior vaginal wall is exposed, and the perineal body is opened in the midline. (Courtesy of the Cleveland Clinic Foundation.)

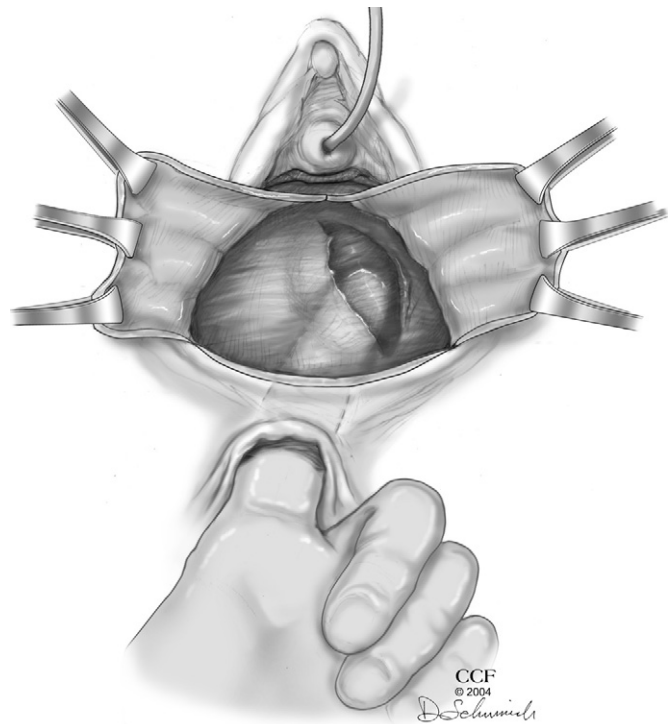

**Figure 74-5** Posterior colporrhaphy. A midline plication of the fibromuscularis of the posterior vaginal wall is performed with interrupted sutures. (Courtesy of the Cleveland Clinic Foundation.)

levator ani muscles, but it may further narrow the vaginal caliber. A levator plication has been suggested to be a contributor to postoperative dyspareunia in women undergoing this procedure.<sup>16</sup>

A vaginal pack and Foley catheter are placed for 2 to 24 hours postoperatively. Voiding trials should be performed postoperatively to ensure that the patient is able to void adequately.

### Site-Specific Defect Repair

After dissection of the posterior vaginal epithelium off the underlying fibromuscularis, the fibromuscularis (i.e., rectovaginal fascia) is carefully inspected to identify breaks. Irrigation and a digital rectal examination, placing upward pressure in the anterior rectal wall, may facilitate identification of the defects in the fibromuscularis (Fig. 74-6). Defects of the posterior vaginal wall may occur as isolated defects in the lateral, distal, midline, and superior portions of the wall or as a combination of defects (Fig. 74-7). The identified breaks are individually isolated and repaired (Fig. 74-8). Delayed-absorbable or nonabsorbable 1-0 or 2-0 suture may be used. If the fibromuscularis of the posterior wall has lost apical attachment, the fibromuscularis should be reattached to the apical support (through reattachment to a well-supported vaginal apex or attachment to the concurrent apical support procedure, such as a sacrospinous or uterosacral vaginal vault suspension). Apical lateral support may be obtained with a unilateral or bilateral iliococcygeal suspension of the fibromuscularis. The suture is placed through the iliococcygeus fascia on

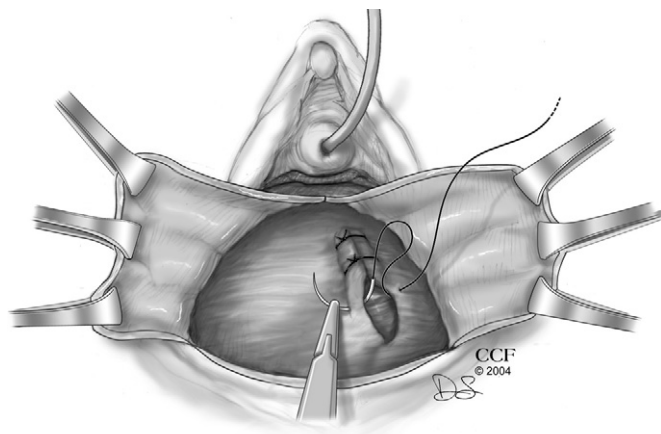

**Figure 74-6** Identification of site-specific defects. After dissection of the posterior vaginal wall epithelium, a rectovaginal examination is helpful in the identification of defects in the fibromuscularis of the posterior vaginal wall. (Courtesy of the Cleveland Clinic Foundation.)

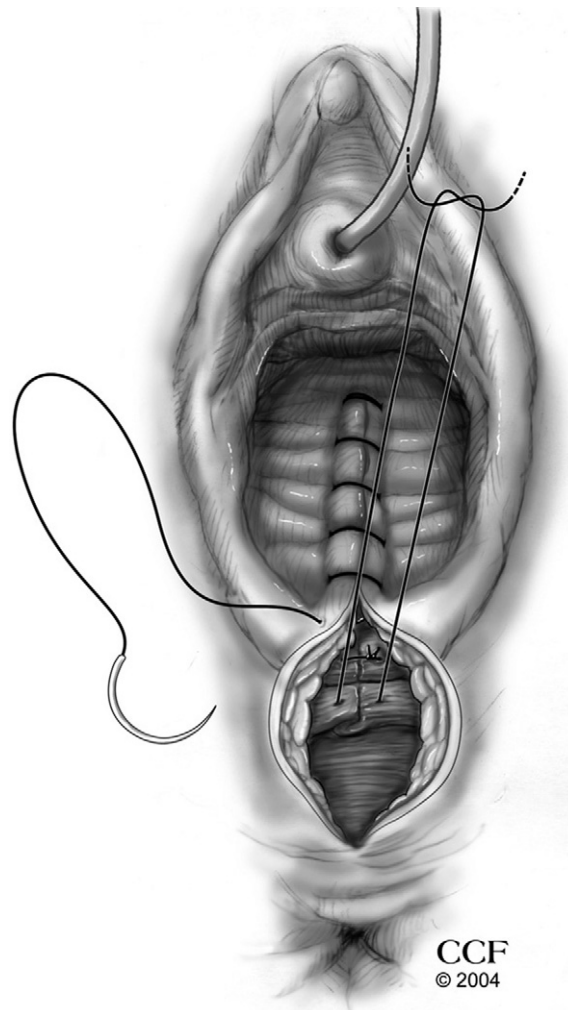

**Figure 74-7** Location of site-specific defects in the fibromuscularis of the posterior vaginal wall. Transverse defects (T) may be apical or distal. Lateral defects (L) may occur as the fibromuscularis separates from its lateral attachment. Midline defects (M) may also occur. Often, a combination of these defects is found. (Courtesy of the Cleveland Clinic Foundation.)

**Figure 74-8** Repair of a left lateral defect with interrupted sutures. (Courtesy of the Cleveland Clinic Foundation.)

the lateral side wall (distal to the ischial spine) and then through the ipsilateral apical portion of fibromuscularis. If a distal defect is present, such as a separation of the fibromuscularis from the perineal body, the defect is repaired with absorbable suture in an attempt to reduce the incidence of postoperative dyspareunia. The vaginal epithelium is closed without significant trimming. Perineal body defects are also repaired with interrupted sutures. A levator plication is not performed.

A vaginal pack and Foley catheter are placed for 2 to 24 hours postoperatively. Voiding trials should be performed postoperatively to ensure that the patient is able to void adequately.

**Figure 74-9** Perineorrhaphy. After the completion of the posterior repair, the perineal body is reconstructed by plicating the bulbocavernosus muscles and the transverse perineal muscles. (Courtesy of the Cleveland Clinic Foundation.)

### Perineorrhaphy

The perineal body should be in continuity with the posterior vaginal wall repair. The perineal body may be opened with a midline, vertical incision. In a woman with a very short perineal body, a transverse or curvilinear incision may be made to expose the perineal body. The bulbocavernosus muscles are identified bilaterally and plicated. Similarly, the superficial transverse perineal muscles are plicated (Fig. 74-9). The plicated bulbocavernosus muscles may be reattached to the repaired rectovaginal fibromuscularis with an interrupted suture. With these sutures, the perineal membrane is reestablished, and the perineal body is in continuity with the support of the vagina.

### SURGICAL OUTCOMES

The goals of pelvic reconstructive surgery are to correct the anatomic defect, improve function, and avoid complications. The difficulty in achieving these goals lies in function. The woman's defecatory dysfunction may coexist with her prolapse rather than

<sup>†</sup>Cure defined as no prolapse beyond the hymenal ring.

<sup>‡</sup>Defined as constipation.

be a symptom of her prolapse. In this case, anatomic correction will be unlikely to improve her function. Surgical correction may interfere with defecatory and sexual functions. Historically, efficacy has been related to anatomic cure, but evaluating functional outcomes is equally important.

The posterior colporrhaphy was introduced in the 19th century. The goals of this procedure were to narrow the vaginal tube and genital hiatus and to create a shelf of support. It has remained a commonly performed surgical procedure for posterior wall prolapse. The traditional posterior colporrhaphy has an anatomic cure rate of 71% to 100% (Table 74-1).<sup>16-23</sup>

The site-specific defect repair approach to rectocele repair relies on theory advocated by A. Cullen Richardson, that the herniation of the rectum into the vagina is the result of identifiable defects in the fibromuscularis (rectovaginal fascia) or its attachment to the pelvic side wall.<sup>24</sup> The anatomic cure rate of the site-specific posterior repair is 77% to 100% (Table 74-2).<sup>23,25-29</sup>

The primary reason that this method of repair of posterior wall prolapse has been embraced is that it more often avoids the risk of postoperative dyspareunia. With the exception of the retrospective review by Abramov and colleagues<sup>23</sup> of women undergoing a site-specific posterior repair, there was no change or a

decrease in dyspareunia in the series involving site-specific posterior repairs (see Table 74-2).<sup>25-29</sup> Abramov and colleagues<sup>23</sup> were the first to compare anatomic and functional outcomes in women who underwent a site-specific posterior repair (undertaken in women with specific defects identified in the fibromuscularis intraoperatively) with those who had undergone a posterior colporrhaphy without a levator plication (undertaken in women without identifiable breaks in the fibromuscularis) during the same time period.<sup>23</sup> Objective and subjective anatomic outcomes were better for the women undergoing a posterior colporrhaphy compared with those undergoing a site-specific repair. Functional outcomes were similar for the two groups. Improvement in defecation has also been described with this method of repair (see Table 74-2).<sup>23,25-29</sup>

Cundiff and coworkers<sup>25</sup> did not perform a perineorrhaphy in women who underwent a site-specific posterior repair. However, the perineal body was stabilized through reestablishment of the continuity of connective tissue support within the posterior vaginal wall from the sacrum to the perineal body. The stabilization of the perineal body was reflected in a significant reduction in the size of the genital hiatus despite not having performed a perineorrhaphy (4.8 cm preoperatively versus 2.5 cm postoperatively,  $P < .0001$ ).<sup>25</sup>

## COMPLICATIONS

Short-term complications associated with a posterior colporrhaphy or site-specific posterior repair include pain, constipation, and temporary urinary retention. Hematoma, infection, and inclusion cyst formation occasionally occur with all vaginal operations. Injury to the rectum with subsequent development of a rectovaginal or rectoperitoneal fistula is uncommon. Recurrent prolapse and de novo defecatory complaints may occur. Postoperative development of dyspareunia is widely reported after a posterior colporrhaphy (see Table 74-1).<sup>16-23</sup> This complication paved the road of acceptance of the site-specific posterior repair.

Postoperative sexual dysfunction related to prolapse repair, primarily dyspareunia, has been reported for decades. Francis and Jeffcoate<sup>17</sup> reported that 70 (50%) of 140 women who had undergone an anterior and posterior colporrhaphy with perineorrhaphy said they had apareunia or dyspareunia. Most (43 of 70) of the women with postoperative apareunia or dyspareunia were found to have a significantly narrowed postoperative vagina that would admit only one finger. Kahn and Stanton<sup>16</sup> found an increase in the number of women with dyspareunia from 18% (preoperative evaluation) to 27% (postoperative evaluation) after an anterior and posterior colpoperineorrhaphy. The investigators routinely plicated the levator ani muscles and proposed that pressure atrophy of the levator ani and resultant scar formation contributed to the development of postoperative dyspareunia. Haase and Skibsted<sup>30</sup> reported that 5 (21%) of 24 women who underwent a prolapse operation that included a posterior colpoperineorrhaphy experienced worsening or de novo dyspareunia. The appeal of the site-specific posterior repair is that ridging or excessive narrowing of the posterior vaginal wall can be avoided, which decreases the likelihood of the postoperative development of dyspareunia.

Although most studies of women undergoing a posterior colporrhaphy or site-specific defect repair have found an improvement in rectal emptying (see Tables 74-1 and 74-2), rectocele repair has been associated with postoperative fecal incontinence. Kahn and Stanton<sup>16</sup> reported that de novo fecal

incontinence occurred in 14 (8%) of 171 women after a posterior colporrhaphy. A strong association was found between fecal incontinence and a history of more than one posterior colporrhaphy.<sup>16</sup>

## CONCLUSIONS

The posterior vaginal wall is composed of interactions among the bony pelvis, pelvic floor muscles, and connective tissue supports. Alterations or injuries to these support units may lead to prolapse.

Posterior vaginal wall prolapse may be asymptomatic and require no treatment. Women with symptoms of vaginal protrusion, pressure or pain, defecatory dysfunction (specifically outlet obstruction leading to incomplete evacuation or need to splint to have a bowel movement), or sexual dysfunction may desire surgical management.

Surgical options commonly employed include posterior colporrhaphy (with and without a levator plication) and site-specific defect repair. Both of these posterior vaginal wall repairs may be performed with or without the addition of a perineal body repair (i.e., perineorrhaphy). Posterior colporrhaphy is effective at reducing the vaginal mass of the rectocele, but some studies have associated this anatomic improvement with an increased incidence of de novo dyspareunia and fecal incontinence. Levator plication may increase the risk of dyspareunia. It is essential to maintain adequate vaginal caliber and to avoid ridging of the vaginal tube when performing a posterior colporrhaphy. Site-specific defect repair is also effective at correcting prolapse, although Abramov and colleagues<sup>23</sup> suggest that it is not as anatomically successful as the posterior colporrhaphy. The vaginal caliber usually is maintained with a site-specific defect approach, and the risk of postoperative de novo dyspareunia is lower than with a posterior colporrhaphy. Augmentation of prolapse repair surgery has been performed using biologic and synthetic grafts. Prospective, randomized trials are needed to compare techniques and their outcomes, including anatomic and functional efficacy and complication rates.

# POSTERIOR REPAIR USING CADAVERIC FASCIA

*Sarah A. Rueff and Gary E. Leach*

Traditional posterior colporrhaphy for symptomatic rectoceles has been associated with failure rates as high as 35% and de novo dyspareunia rates ranging from 6% to 41%.<sup>1</sup> The technique involves midline plication of the levator muscles and rectovaginal fascia to obliterate the fascial defect and perineorrhaphy to reapproximate the central tendon and perineal body.<sup>2</sup> Inherent problems exist with traditional posterior repair. First, the success of the repair relies on the patient's own tissue, which has already shown a propensity for weakness. Second, by attempting to obliterate the fascial defects, the patient's anatomy is inevitably distorted, and the procedure can result in vaginal narrowing and dyspareunia. The patient may complain of constriction of the vaginal tube or may feel a ridge in the midline of the posterior wall due to suture placement.

The use of defect-specific rectocele repair is an attempt to alleviate the vaginal narrowing and dyspareunia associated with traditional repair. The technique involves identification of fascial tears and plicating nearby durable fascia over the defect. Recurrence rates of 18% to 23% with mean follow-up periods of 12 to 18 months have been reported along with variable improvements in bowel habits.<sup>3-5</sup> As with traditional colporrhaphy, the repair relies on the patient's inherently weak tissues to repair fascial defects. By failing to address the entire posterior vaginal wall, all areas of fascial weakness may not be identified, increasing the likelihood of failure.

Rectocele repair with cadaveric fascia attempts to address the inherent problems of traditional and defect-specific rectocele repair. First, by graft interposition, all areas of weakness within the posterior compartment are addressed simultaneously. Second, the use of solvent-dehydrated, nonfrozen cadaveric fascia lata avoids the use of the patient's own weak tissues. Third, the fascia is secured to the levator complex without tension, as is often necessary with traditional repair, preventing vaginal narrowing. Fourth, avoidance of tissue plication prevents the patient from feeling a ridge in the midline and preserves the width of the introitus. For these reasons, we think rectocele repair with cadaveric fascia offers several advantages over traditional posterior vaginal reconstruction techniques.

### CADAVERIC FASCIA

The choice of fascia for rectocele repair with cadaveric fascia is of utmost importance in determining surgical outcome. Fascia lata is strong, regardless of a patient's age or medical condition, and it has three to four times more tensile strength than rectus fascia.<sup>6</sup> Our choice of fascia is Tutoplast (Mentor Corp., Santa Barbara, CA). Tutoplast is prepared by a five-step process that involves screening of donors, cleansing, denaturation of anti-

gens and viruses, solvent dehydration, and gamma irradiation. The tensile strength and tissue stiffness of nonfrozen cadaveric fascia lata has been investigated, and it is comparable to that of autologous fascia lata.<sup>7</sup> Studies have compared solvent-dehydrated and freeze-dried cadaveric fascia lata, another commercially available preparation. Solvent-dehydrated fascia lata has significantly greater stiffness, maximum load to failure, and maximum load per unit of graft compared with freeze-dried fascia lata.<sup>8</sup>

All commercially available cadaveric fascia lata is not the same. The method used to prepare the tissue ultimately affects its tensile strength and subsequent surgical outcomes. We prefer the use nonfrozen cadaveric fascia to commercially available synthetic mesh material, which carries inherent risks of erosion and infection. Milani and colleagues<sup>9</sup> described 31 women who underwent posterior repair with Prolene mesh who had an erosion rate of 6.5%. Other studies have reported similar findings, with erosion rates as high as 48%.<sup>10</sup>

### PREOPERATIVE EVALUATION

Before undergoing rectocele repair, a thorough history is obtained focusing on the symptoms associated with posterior prolapse. Based on the results of a series of questions in the Rectocele Symptom Inventory (Table 75-1), patients are assigned a preoperative score that correlates with the degree of symptoms. Questions focus on three areas of symptoms: bowel function with symptoms that include straining, stool trapping, the need to manually reduce the rectocele to facilitate defecation, or a feeling of incomplete emptying after defecation; prolapse symptoms, which include vaginal pressure or the feeling of sitting on a ball; and sexual function, which includes dyspareunia and overall sexual satisfaction. We do not routinely repair rectoceles that are asymptomatic or low grade because the theoretical risks of surgery or its side effects outweigh the benefit gained. For patients who present with constipation or bowel dysfunction that does not correlate with the severity of posterior prolapse, referral to a gastroenterologist or colorectal surgeon may be beneficial before considering surgical repair.

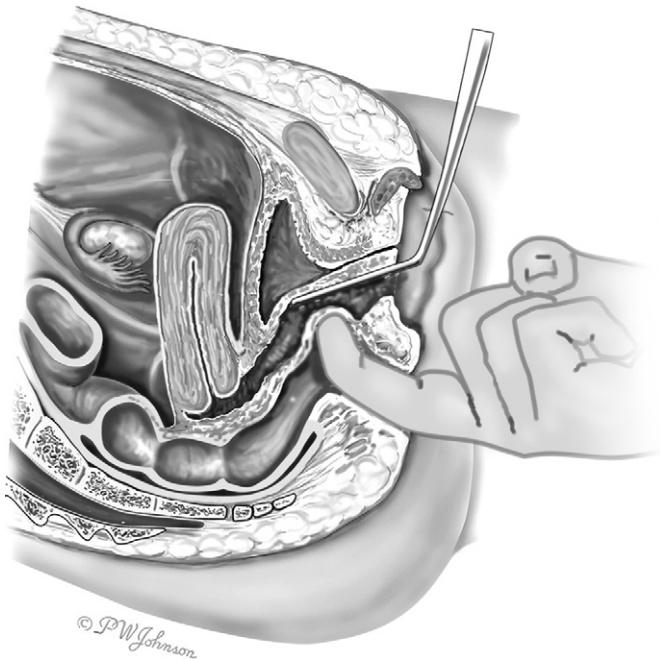

### Physical Examination

A systematic examination of the anterior, apical, and posterior compartments is performed with the patient in the dorsal lithotomy position. The posterior blade of a Graves speculum is used to displace the anterior vaginal wall and examine the posterior wall at rest and with straining. A simultaneous rectal examination using the index finger is performed to push the posterior vaginal

**Table 75-1 Rectocele Symptom Inventory**

In the past month, how often have you experienced the stated symptoms?	Scoring*				
	All of the time (4)	Most of the time (3)	Some of the time (2)	Rarely (1)	Never (0)
I have to push or strain to have a bowel movement					
I feel the stool "gets stuck" when having a bowel movement					
I assist my rectum by placing my finger in the vagina or pressing on the skin outside of the vagina to have a bowel movement					
I feel that I have not completely emptied my bowels after having a bowel movement					
I feel the sensation of pressure in my rectum or vagina or have the sensation of "sitting on a ball"					
I have pain with sexual relations					
My ability to have sexual relations is satisfactory to me	Not sexually active (0)	Most of the time (0)	Some of the time (2)	Not satisfactory (4)	

\*On the Rectocele Symptoms Inventory (RSI), the total score may range between 0 and 28.

**Figure 75-1** Examination of the posterior compartment with the index finger inserted into the rectum. Using the finger to push the posterior vaginal wall forward may reveal posterior wall weakness consistent with rectocele.

wall forward (Fig. 75-1). Finger examination allows simultaneous assessment of the integrity of the rectovaginal fascia and the integrity of the external anal sphincter. Sphincter evaluation is especially important in patients who complain of fecal incontinence, and it can rule out other causes of defecatory dysfunction

**Table 75-2 Baden-Walker Rectocele Classification**

Anatomic Grade	Description
Grade 1	Posterior wall protrusion toward introitus with strain
Grade 2	Posterior wall protrusion to the introitus with strain
Grade 3	Posterior wall protrusion outside of the introitus with strain
Grade 4	Posterior wall protrusion outside of the introitus at rest

(e.g., rectal prolapse or intussusception, large hemorrhoids, skin tags). The perineal body should be evaluated for associated defects. Patients who present with a widened vaginal introitus or a shortened perineum, signified by a decreased distance between the posterior margin of the vagina and the anterior margin of the anus, may benefit from a simultaneous perineal repair.

We use the Baden-Walker system to classify rectoceles preoperatively (Table 75-2). In most cases, grade 1 rectoceles are incidental findings and asymptomatic. Only patients with grade 2 to grade 4 rectoceles and associated symptoms of stool trapping or the need to splint the vagina or perineum to facilitate defecation are considered candidates for surgical repair.

#### Ancillary Testing

No further evaluation is necessary in patients who present with symptomatic posterior prolapse without complicating factors. Patients with associated voiding complaints or anterior wall prolapse should undergo urodynamic evaluation before surgical intervention.

When patients have anatomic abnormalities (e.g., sigmoidocele, rectal prolapse, internal hemorrhoids) that can cause overlapping symptoms, defecating proctography may provide additional anatomic information. The study can also provide functional information regarding the efficiency of rectal emptying.<sup>10</sup> In other situations, given the patient's body habitus or limitations in lower extremity mobility, it may be difficult to delineate the exact compartment of prolapse. Dynamic magnetic resonance imaging (MRI) provides additional information that enables the appropriate treatment recommendation to be made. The study is performed with the patient in the standing position and consists of rapid-sequence MRI of the pelvis at rest and during Valsalva maneuvers. By simultaneous examination of all intrapelvic compartments, for example, an enterocele can be distinguished from a high rectocele and the appropriate operative procedure recommended.

### PREOPERATIVE PREPARATION

Before performing prolapse repair, the urine is confirmed to be sterile. Patients are not routinely instructed on self-catheterization unless simultaneous transvaginal sling or cystocele repair is planned or the patient has incomplete emptying preoperatively. Preferably, patients should be started on stool softeners preoperatively in an attempt to regulate bowel function. Patients with vaginal wall atrophy should use estrogen vaginal cream for 4 to 6 weeks before surgery. Patients are instructed to use one third of an applicator of estrogen cream three times each week to improve the quality of tissue and postoperative healing properties. A povidone-iodine vaginal douche and a Fleet enema are performed the night before and the morning of surgery. Perioperative antibiotics are administered, preferably using a first-generation cephalosporin, ampicillin, or vancomycin (if allergic to penicillin) combined with an aminoglycoside.

When indicated, simultaneous transvaginal repair of associated anterior or apical prolapse is performed with the rectocele repair with cadaveric fascia. When multiple repairs are to be done, the rectocele repair with cadaveric fascia is performed last. A thorough discussion of the risks and complications of the procedure is undertaken with the patient before repair. Patients are counseled regarding the goals of surgery, which include restoration of anatomy, improvement of or relief from associated symptoms, and maintenance or restoration of visceral and sexual function.<sup>11</sup> Paraiso and coworkers<sup>12</sup> evaluated preoperative and postoperative symptoms that may predict outcome after a traditional posterior colporrhaphy. They found that preoperative constipation or straining to defecate predicted poor outcome after rectocele repair.<sup>12</sup>

### OPERATIVE PROCEDURE

The procedure is performed with the patient in the dorsal lithotomy position. A Foley catheter is placed, and a Scott retractor (Lonestar, Houston, TX) is secured to the medial buttocks with towel clamps. When other procedures will be performed (e.g., transvaginal sling, cystocele repair, vaginal hysterectomy, enterocele repair, vaginal vault suspension), the procedures are completed, and the vaginal epithelium is closed before rectocele repair. To begin, a 1-0 silk suture is used to mark the apex of the rectocele, and the posterior vaginal wall is infiltrated with saline.

**Figure 75-2** The rectum is dissected off of the posterior vaginal wall until the levator complex is exposed bilaterally.

**Figure 75-3** Two 1-0 polydioxanone sutures are placed within the levator complex on each side for attachment to the nonfrozen cadaveric fascia.

A midline incision is made in the posterior vaginal wall from the marking suture to the vaginal introitus. Using Metzenbaum scissors, the posterior vaginal wall is dissected off of the rectum on the white, shiny layer of the inner aspect of the vaginal wall. Dissection is continued until the levator complex, consisting of the levator ani musculature and the remaining rectovaginal fascia, is exposed bilaterally (Fig. 75-2). Four 1-0 polydioxanone attachment sutures (two per side) are placed laterally into the levator complex (Fig. 75-3), a fifth suture is placed at the apex of the rectocele near the previously placed marking suture, and a sixth suture is placed distally within the perineal body (Fig. 75-4).

A 4 × 7 cm piece of nonfrozen cadaveric fascia lata (Tutoplast), presoaked in antibiotic solution, is used to close the

**Figure 75-4** Sutures are in place within the levator complex bilaterally. Sites for apical suture and distal perineal suture are exposed.

**Figure 75-6** The remaining sutures are passed through the fascia and tied with the proper amount of tension.

**Figure 75-5** Sutures on one side are passed through the folded fascial edge and tied.

**Figure 75-7** Vaginal width and depth are maintained after the rectocele repair with cadaveric fascia.

rectovaginal fascial defect. The edges of the fascia are folded over to minimize chances of suture pull-through.<sup>13</sup> The previously placed sutures are passed through the fascia on one side and tied (Fig. 75-5). The contralateral fascia edge is folded over, and the site for suture placement is measured to allow for proper tension. The contralateral sutures, apical suture, and distal suture are then passed through the fascia and tied (Fig. 75-6). Irrigation with antibiotic solution is performed throughout the procedure. After hemostasis is obtained, redundant vaginal epithelium is trimmed, and the incision is closed with running 2-0 absorbable suture. Care should be taken to avoid excess trimming of the vaginal epithelium and resultant tension on the vaginal closure, which can result in wound separation or vaginal narrowing postoperatively.

In patients with whom perineal reconstruction is indicated, Allis clamps are placed on the posterior fourchette at the 5-o'clock and 7-o'clock positions. The mucocutaneous junction and the underlying tissue are excised to expose the underlying perineal body. Vertical mattress sutures using 1-0 absorbable sutures are placed to reapproximate the central tendon, which is formed by the bulbocavernosus, superficial, and deep transverse perinei muscles (i.e., the urogenital diaphragm) and the external anal sphincter musculature at their junction with the levator ani musculature.<sup>14</sup> A subcuticular stitch is used to reapproximate the perineal skin.

At the conclusion of the repair, the vagina should comfortably admit two or three fingers (Fig. 75-7). A Foley catheter and a Betadine-soaked vaginal pack are left in place.

**Figure 75-8** Rectocele Symptom Inventory: preoperative to postoperative changes. BM, bowel movement.

## POSTOPERATIVE CARE

The vaginal packing and Foley catheter are removed on the morning of the first postoperative day. Fluid intake is restricted to 1500 mL per day. A voiding trial is administered, and residual urine measurement is obtained by means of intermittent catheterization. If residual urine measurements are more than 100 mL, patients are again instructed on self-catheterization. Urinary retention is a temporary complication reported for up to 12.5% of patients after posterior repair.<sup>15</sup>

Patients are continued on intravenous antibiotics for 24 hours postoperatively and then begun on an oral antibiotic (cephalexin or fluoroquinolone) for 1 week to minimize the risk of wound infection. Patients are routinely discharged on postoperative day one with oral analgesics. Stool softeners are continued for 1 month, and patients are counseled to avoid straining with defecation. Patients with elevated postvoid residual volumes are instructed to continue to monitor at home by self-catheterization until residual urine volumes are consistently less than 100 mL. If a patient is unable to learn or is uncomfortable performing self-catheterization, she can be discharged home with a Foley catheter and return for a trial of void in the office. At time of discharge, patients are instructed to avoid heavy lifting or straining and to observe pelvic rest (i.e., no intercourse, no tampons) for 6 weeks postoperatively.

Patients are seen for follow-up at 1 week, 6 weeks, 6 months, 12 months, and yearly thereafter. Evaluation consists of urinalysis, postvoid residual urine measurement, and physical examination. Patients are administered the confidential Rectocele Symptom Inventory preoperatively and at 6-month intervals postoperatively, the results of which are entered into a prospective database (see Table 75-1).

## RESULTS

### Prolapse Outcomes

Rectocele repair with cadaveric fascia has been performed on a total of 53 patients between the ages of 31 and 86 years (mean, 59.7 years). Forty patients (75%) had at least 6 months' follow-up (range, 6 to 54 months; mean, 19.6 months). All patients had symptomatic grade 2 to 4 rectoceles preoperatively. For 29 (72.5%) of 40 patients, rectoceles were grade 3; for 7 (17.5%) of 40 patients, rectoceles were grade 4; and for 4 (10%) of 40 patients, rectoceles were grade 2. Only 2 (50%) of 40 patients

have had symptomatic rectocele recurrences (one grade 2 rectocele and one grade 3 rectocele).

### Symptom Outcomes

Thirty-nine patients (74%) have at least 6 months of questionnaire follow-up (range, 6 to 50 months; mean, 25.1 months). A comparison of preoperative to postoperative symptoms based on questionnaire responses is provided in Figure 75-8. Specifically, 33 (85%) of 39 patients complained of significant symptoms of stool trapping preoperatively, and 13 (33%) of 39 complained of the need to perform vaginal or perineal splinting or postural changes to facilitate defecation preoperatively. Postoperatively, only 11 (28%) of 39 and 6 (15.4%) of 39 described stool trapping or need to splint, respectively. In regard to overall bowel function, 15 (38%) of 39 patients described their bowel function as "significantly improved," and 10 (25.6%) of 39 stated that they continued to have trouble with their bowel function.

Twenty-six patients were sexually active before the procedure. In regard to overall sexual function, 106 (38%) of 26 stated their sexual function was "significantly improved," and 12 (46%) of 26 stated their sexual function was "unchanged, not a problem," resulting in 22 (85%) of 26 of patients having stable or improved sexual function. Nine patients complained of significant dyspareunia preoperatively, which improved in 5 (55.6%) of the 9 patients. Only 2 (7.7%) of 26 developed de novo dyspareunia.

Overall, patient satisfaction with the procedure has been excellent, with 32 (82%) of 39 patients giving a satisfaction rating of 50% or more and 33 (85%) of 39 stating they would undergo the procedure again.

## COMPLICATIONS

Most complications have been minor. Seven patients developed wound separation or granulation tissue, which healed with observation. Fecal urgency developed in one patient and was successfully treated with biofeedback. One patient suffered a mild cerebrovascular accident postoperatively and subsequently required transfer to a rehabilitation center. One patient had a rectotomy recognized intraoperatively that was repaired primarily. Despite intraoperative repair, the patient developed a postoperative rectovaginal fistula, which healed spontaneously with close observation and did not require operative intervention.

## CONCLUSIONS

Rectocele repair with cadaveric fascia, using nonfrozen cadaveric fascia lata for posterior vaginal wall reconstruction, offers several advantages over traditional posterior colporrhaphy. Incorporation of durable graft tissue prevents a reliance on the patient's own tissue, which has an established propensity for weakness. By

avoiding tissue plication and obliteration of the tissue in the midline, the degree of vaginal narrowing is minimal after rectocele repair with cadaveric fascia. In this way, complaints of postoperative dyspareunia are minimized, and patient satisfaction has been excellent. The avoidance of synthetic materials prevents subsequent graft erosion and wound infection associated with their use.

# PERINEAL HERNIA AND PERINEOCELE

*Christian Twiss and Nirit Rosenblum*

Perineal hernia is an uncommon condition that was once thought to be incurable because of the difficulty in closing the hernia defect and the high recurrence rate.<sup>1</sup> The past century witnessed the development of a plethora of techniques to repair perineal hernias and an improved understanding of the anatomic defects, leading to their classification. Despite the knowledge gained, much remains to be discovered about perineal hernias. There are no controlled studies to guide the clinician in the choice of optimal therapy. Perineocele is an even less studied and less well-defined clinical problem. Both conditions are discussed in this chapter.

## PERINEAL HERNIA

### Definition and Classification

Perineal hernias occur through focal defects within the pelvic floor, and they are classified by primary cause and by anatomic region. Primary perineal hernias are focal, acquired defects within the pelvic floor that typically occur in women as a result of pelvic relaxation associated with vaginal parity or chronic conditions involving increased abdominal pressure (e.g., chronic cough, constipation, ascites). Secondary perineal hernias are true incisional hernias within the pelvic floor that result from prior pelvic (typically exenterative) surgery.

Herniation can occur through the anterior or posterior compartments of the pelvic floor. Anterior perineal hernias (i.e., pudendal hernias, pudendal enteroceles, or levator hernias) occur within the urogenital triangle anterior to the superficial transverse perineal muscles, and they occur exclusively in women; no confirmed cases in men have been reported. Anterior perineal hernias occur through the urogenital diaphragm within the triangular regions lateral to each side of the vaginal vestibule defined by the medial border of the ischiocavernosus muscle, the lateral border of the bulbocavernosus muscle, and the anterior border of the superficial transverse perineal muscle (Fig. 76-1). Posterior perineal hernias occur in within the anal triangle posterior to the superficial transverse perineal muscles and anterior to the ventral borders of the gluteus maximus muscles. They typically occur midway between the anus and the ischial tuberosity within a levator ani defect, in the space between the pubococcygeus and iliococcygeus portions of the levator ani muscle, or in the space between the levator ani and coccygeus muscles (see Fig. 76-1).

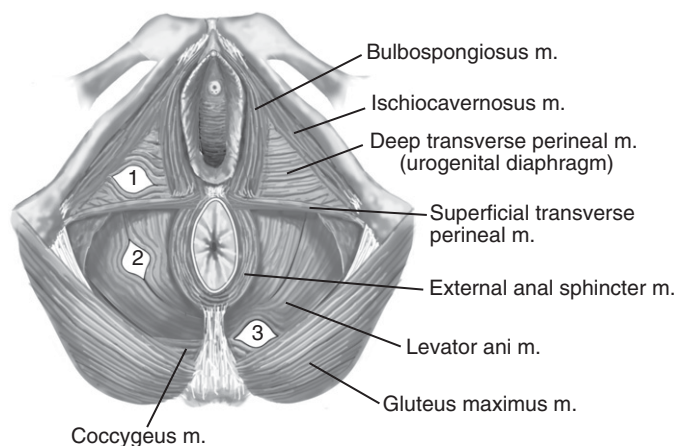

Translevator and supralelevator hernias are anatomically distinct.<sup>2</sup> A translevator perineal hernia sac passes through the focal defect within the levator ani musculature, whereas a supralelevator hernia sac remains superior to the levator ani but exists as a focal outpouching of the weakened levator ani muscle that extends beyond the plane of the levator plate. Despite the anatomic difference, the principles of hernia repair remain the same.

The hernia sac of a perineal hernia may be empty (i.e., peritoneum) or may contain one or more of the abdominopelvic viscera, including small or large bowel, bladder, omentum, ovary, and fallopian tube. Because intraperitoneal and extraperitoneal structures may herniate, a true hernia sac may not always be present.<sup>1</sup>

### Etiology and Epidemiology

Anterior perineal hernias can be primary or secondary (i.e., after surgery or obstetric procedures). Anterior perineal hernias are rare, with fewer than 17 well-described cases in the English literature.<sup>1,3-6</sup> Most reported perineal hernias are posterior perineal hernias. The largest reported series of anterior perineal hernias is that of Chase in 1922, reporting 13 cases.<sup>1</sup> However, only 10 of these 13 cases were described in enough detail to be confirmed cases of anterior perineal hernia. All of the well-described cases of anterior perineal hernia appear to have occurred in the setting of multiple prior pelvic operations for pelvic prolapse or urinary incontinence or of difficult and prolonged labor, often requiring forceps delivery. Both causes involve direct trauma to the pelvic floor musculature, which is thought to be the primary cause of anterior perineal hernias. Most anterior perineal hernias are secondary.

Posterior perineal hernias may be primary or secondary. Primary perineal hernias are rare, and their true incidence is unknown. They typically occur between the ages of 40 and 60 years, and they occur more commonly in women, with a female preponderance of threefold to fivefold higher than for men.<sup>7,8</sup> This female preponderance is attributed to female pelvic floor trauma encountered during childbirth<sup>9</sup> and the phenomenon

**Figure 76-1** Anatomy of perineum and typical locations of perineal hernias. (Modified from Cali RL, Pitsch RM, Blatchford GJ, et al: Rare pelvic floor hernias. *Dis Colon Rectum* 35:604, 1992.)

**Table 76-1 Risk Factors for Perineal Hernias****Primary perineal hernia**

Female gender  
 Vaginal childbirth  
 Prolonged or difficult labor  
 Pelvic organ prolapse or pelvic floor descent  
 Recurrent infections of pelvic floor  
 Chronic cough  
 Chronic constipation  
 Obesity  
 Abdominal ascites

**Secondary perineal hernia**

Female gender  
 Abdominoperineal resection  
 Open postoperative perineal wound  
 Pelvic exenteration  
 Radical cystourethrectomy  
 Coccygectomy  
 Anti-incontinence surgery  
 Hysterectomy  
 Pelvic organ prolapse surgery  
 Perineal prostatectomy  
 Pelvic irradiation  
 Excessive length of small bowel mesentery

of pelvic relaxation.<sup>10</sup> A study by Gearhart and colleagues<sup>10</sup> demonstrated a 15% incidence of levator ani hernia in a group of 80 patients who underwent dynamic pelvic magnetic resonance imaging (MRI) for the evaluation of symptomatic pelvic organ prolapse. Forty-two percent of these patients had undergone prior pelvic surgery, and approximately 60% (or 9% of the entire group) are presumed to be primary levator ani hernias associated with symptomatic pelvic organ prolapse. Other conditions are also thought to contribute to the formation of primary perineal hernia, including recurrent pelvic floor infections and conditions involving increased abdominal pressure such as chronic cough, chronic constipation, obesity, and ascites (Table 76-1).<sup>8,11,12</sup>

Secondary posterior perineal hernias occur through defects in the pelvic floor resulting from surgery, and they usually manifest within 1 year after the initial surgery.<sup>9</sup> Most secondary perineal hernias occur after pelvic exenterative surgery, requiring corrective surgery after approximately 0.7% of abdominoperineal resections<sup>13</sup> and 3% of pelvic exenterations.<sup>14</sup> The true incidence of perineal hernia after these procedures is likely higher, and most are asymptomatic. Hullsiek<sup>15</sup> found a 7% incidence of perineal hernia after abdominoperineal resection by means of barium x-ray films, and most were asymptomatic.

Secondary posterior<sup>16</sup> and anterior<sup>3,5,6</sup> perineal hernias have been reported after surgery for pelvic prolapse and urinary incontinence. However, their overall incidence after prolapse and incontinence surgery is unknown. It is difficult to determine whether these hernias result from the prolapse surgery or the pathophysiologic process of pelvic prolapse itself. Presumably, it is a combination of both because a significant proportion (42%) of perineal hernias associated with symptomatic pelvic prolapse occur in the absence of a history of pelvic surgery.<sup>10</sup>

Table 76-1 summarizes the types of operations associated with secondary perineal hernias. Poor perineal tissue quality and

**Table 76-2 Differential Diagnosis of Perineal Hernia**

Diagnosis	Clinical Features
<b>Anterior perineal masses</b>	
Anterior perineal hernia	Labial mass reduces into pelvic floor medial to pubic ramus
Inguinal hernia	Labial mass reduces into inguinal canal across pubic ramus
Bartholin gland abscess	Labial mass irreducible, fluctuant, signs of inflammation
Lipoma or sarcoma	Labial mass, irreducible
Hematoma	Labial mass, irreducible, history or signs of perineal trauma
Cystocele, rectocele, enterocele	Introital mass, associated urinary or fecal symptoms
<b>Posterior perineal masses</b>	
Posterior perineal hernia	Soft, reducible, posterior to perineum
Sciatic hernia	Emerges on inferior border of gluteus maximus
Rectal prolapse	Emerges from anus, associated constipation or fecal incontinence
Perineocele	Pelvic descent, increased anovaginal distance

factors that hinder wound healing such as diabetes and pelvic irradiation also predispose to perineal hernia. One of the most significant predisposing factors for perineal hernia after abdominoperineal resection was found to be a partial or complete open perineal wound in the postoperative period.<sup>17</sup>

### Symptoms and Clinical Findings

Anterior perineal hernia typically manifests as a reducible labial mass, usually in the posterior aspect of the labia majora. This may be accompanied by a heavy sensation within the perineum.<sup>4</sup> The mass is characteristically covered with vaginal mucosa on its medial border and the labial integument on its lateral border. An anterior perineal hernia is also characteristically reducible into the pelvic floor medial and inferior to the pubic ramus, whereas an inguinal hernia within the labia reduces into the inguinal canal by crossing over the pubic ramus. The reducibility of the hernia also distinguishes it from irreducible labial masses such as Bartholin's gland abscesses or cysts, benign labial cysts, labial lipomas and sarcomas, and labial hematomas (Table 76-2). Careful vaginal and perineal examination is needed to avoid inadvertent incision into a perineal hernia that many contain bladder or bowel.

It is not uncommon for anterior perineal hernias to contain bladder because defects within the anterior pelvic floor more often contain bladder.<sup>3</sup> This can result in urinary sequelae, including urinary incontinence, weak urinary stream, and incomplete bladder emptying with high postvoid residual volumes.<sup>4,6</sup> Patients with concurrent urinary symptoms should undergo diagnostic cystoscopy and imaging of the lower urinary tract.

Posterior perineal hernias typically manifest as soft, reducible masses within the posterior perineum (posterior to the perineal

body), usually occurring in the region between the anus and ischial tuberosity, but they may also emerge just ventral to the gluteus maximus, in which case they must be distinguished from a sciatic hernia, which is rare.<sup>12</sup> They are often asymptomatic,<sup>10</sup> but they may be accompanied by a heavy or dragging feeling within the perineal region and pain with sitting.

Perineal hernias usually do not incarcerate or strangulate because the pelvic floor defect is often large and the hernia remains easily reducible. However, there are reports of postoperative perineal hernia that have been accompanied by bowel obstruction and perineal skin breakdown.<sup>18,19</sup> Often, the bowel obstruction is intermittent and occurs because of bowel compression when the patient is sitting.

### Evaluation

There is no consensus on the workup of perineal hernias beyond a careful history and vaginal, perineal, and rectal examinations. The examination should focus on diagnosing the hernia and evaluate the possibility of cystocele, rectocele, or rectal prolapse, because some perineal hernias occur in the setting of pelvic organ prolapse.

In suspected cases of anterior perineal hernia with accompanying urinary symptoms, cystourethrography and cystoscopy are recommended to confirm the presence of bladder within the hernia and to determine whether the trigone is involved in the hernia. This seems reasonable because the bladder is more commonly involved in anterior perineal hernias. If cystourethrography is performed solely to confirm presence of bladder within the perineal hernia, other modalities such as computed tomography (CT) or pelvic MRI could derive the same information.

Further imaging of the suspected hernia is warranted to confirm the diagnosis and to provide additional information for surgical planning, such as which pelvic contents are present within the hernia, where the hernia emerges from the pelvic floor, and an estimation of the size of the defect. It is arguable whether a careful physical examination can derive all this information except for the exact contents of the hernia sac. However, the most conservative approach is to obtain the most information about the hernia through careful examination and pelvic imaging before its repair.

Plain radiographs of the pelvis and barium enema are able to demonstrate bowel within the hernia sac.<sup>20</sup> Dynamic proctography, typically used to evaluate defecatory dysfunction, is able to demonstrate the extent and involved segment of perineal rectal herniation.<sup>7</sup> The presumed advantage over barium enema is applicable for cases in which the perineal herniation occurs only during straining and defecation. CT evaluation of the pelvic floor is more definitively able to identify the contents of the hernia sac and the location and extent of the associated pelvic floor defect.<sup>11</sup>

MRI is gaining acceptance as a preferred method of evaluation of the pelvic floor because of its excellent resolution of pelvic floor<sup>21,22</sup> and perianal<sup>23</sup> structures and the ability to visualize the prolapsing pelvic organs in real time by dynamic pelvic MRI. In addition to its utility in visualizing pelvic organ prolapse with an anatomic staging system,<sup>24</sup> dynamic pelvic MRI was able to detect unsuspected levator ani hernias in 15% of patients undergoing evaluation for symptomatic pelvic organ prolapse.<sup>10</sup> Pelvic MRI was also able to preoperatively detect a large unsuspected posterior perineal hernia associated with recurrent vaginal vault

prolapse, thereby changing operative management.<sup>2</sup> These two studies highlight some important considerations. They confirm that perineal hernias occur in conjunction with pelvic organ prolapse and that clinicians treating these patients should maintain a degree of clinical suspicion about the diagnosis. As MRI evaluation of pelvic organ prolapse increases, the number of unsuspected perineal hernias can also be expected to increase. This ultimately presents a need and an opportunity to create patient cohorts to study and further define a protocol for the management of perineal hernia that occurs in the setting of pelvic organ prolapse.

### Treatment

The treatment for perineal hernias is surgical, but there is no clearly defined protocol for their management. Because they rarely incarcerate and strangulate, the primary indication for the repair of perineal hernias is patient discomfort. The general principles remain the same as for any hernia: exposure of the sac and the musculofascial defect, opening of the sac with reduction of its contents, and high ligation of the sac followed by closure of the musculofascial defect. There remain two important caveats. First, there is not always a clearly defined sac, because not all pelvic contents (especially bladder) are completely covered by peritoneum. Second, the fascial defect encountered can be quite extensive, especially in post-exenterative perineal hernias requiring advanced reconstructive maneuvers.

There are three basic approaches to repair: perineal, abdominal, and a combined perineal and abdominal approach. Two reports described a laparoscopic mesh repair technique.<sup>25,26</sup> There are no controlled studies demonstrating the superiority of any one approach. However, the combined experience of several surgeons demonstrates the applicability of each approach to management.

A key concept that determines the goals and techniques of repair is whether the hernia has occurred after pelvic exenterative surgery (i.e., pelvic exenteration or abdominoperineal resection). The repair of perineal hernias in this setting typically involves the repair of a large pelvic floor defect requiring an extensive reconstruction of the pelvic floor (Table 76-3). Cancer recurrence and bowel adhesions are additional considerations that affect the operative goals at the time of repair. Perineal hernias after non-exenterative surgery are typically more localized defects in the pelvic floor that do not require advanced reconstructive techniques. Because the pelvic organs are still in place, most pelvic reconstructive techniques described for the repair of post-exenterative perineal hernias are not feasible in the absence of prior pelvic exenterative surgery. However, because pelvic relaxation and pelvic organ prolapse are predisposing factors of perineal hernias, their surgical correction needs to be considered at the time of repair.

The perineal approach (or translabial approach in the case of anterior perineal hernias) remains the least invasive one with the advantages of less morbidity and success in most cases.<sup>17</sup> The perineal approach also allows resection of residual perineal skin that may accompany sizable perineal hernias.<sup>27</sup> However, the exposure is limited, allowing less access to sac contents, adhesions, recurrent cancer, or injured viscera or vasculature.<sup>28</sup> Recurrences have also been reported with the perineal approach.<sup>6,17,28</sup> In the small series of postoperative perineal hernias reported by So and coworkers,<sup>17</sup> the perineal approach carried a 23% recurrence rate, compared with no recurrences after repairs using the

Modified from Abdul Jabbar AS: Postoperative perineal hernia. *Hernia* 6:188, 2002.

abdominal or combined approach. Perineal repairs have been performed with<sup>4,27,29,30</sup> and without<sup>5,6,17</sup> mesh repair of the hernia defect. Because of its simplicity, the perineal approach has been recommended as the best initial approach for straightforward cases,<sup>4,17,27</sup> reserving the abdominal and abdominoperineal approach for recurrent cases, cases of strangulation of the hernia contents, or situations in which primary closure of the defect is complex.

The perineal technique involves a skin incision over the site of the hernia defect after sterile preparation of the perineum. In the case of anterior perineal hernias, this is directly over or alongside the involved major labium. If bladder (especially trigonal) involvement is suspected, prophylactic ureteral stents also may be placed. This is followed by careful dissection of the sac from the skin and then the margins of the hernia defect itself. In the case of post-exenterative hernias, the dissection during this step must be meticulous because it is a frequent source of bowel injuries.<sup>18</sup>

In cases of small hernia defects in which there is a clearly defined sac, the hernia sac is opened, the contents are reduced, and the sac is ligated and excised. Any additional nonperitonealized hernia contents, such as bladder, are also reduced. This is followed by repair of the hernia defect using a simple layered closure with or without mesh reinforcement on the pelvic side of the hernia defect.

When the pelvic viscera are in place, larger defects that cannot be closed primarily require mesh repair. Interposition of uterus has been reported.<sup>31</sup> In cases of large post-exenterative hernias, simple closure of the levator ani defect is usually not possible, and pelvic floor reconstruction is required using synthetic mesh, free fascial grafts, or pedicled flaps (see Table 76-3).<sup>27-29,32-35</sup>

The abdominal approach has been recommended as the best first approach by some surgeons,<sup>3,8,9,12,28</sup> primarily because of better exposure of the anatomic defect and hernia sac. This is especially true in the cases of large pelvic floor defects requiring

mesh reconstruction of the pelvic floor.<sup>9,27,28</sup> The abdominal approach facilitates proper fixation of the mesh to the pelvic and sacral support structures, and it assists simultaneous treatment of bowel adhesions and cancer recurrence after exenterative surgery.<sup>28</sup> The abdominal approach also facilitates sacral resuspension of pelvic contents such as herniated rectum<sup>36</sup> or prolapsed vaginal vault,<sup>2</sup> and it permits closure of the cul-de-sac to prevent abdominal contents from accessing the area of the repaired hernia defect.<sup>6</sup> In cases of strangulation of the hernia contents, the abdominal approach is required to address the need for possible resection or repair of the hernia contents.

For the abdominal approach, the patient should be placed in the modified lithotomy position to allow simultaneous access to the perineum. This enables perineal traction to be applied to assist in the dissection and allows vaginal access to assist in identification of the vaginal cuff. It also permits conversion to a combined approach and possible placement of ureteral stents.<sup>28</sup>

Access is obtained through a lower midline incision, followed by possible exploration for recurrent cancer in post-exenterative cases. The hernia sac is identified, and the sac is dissected free from the margins of the defect. A small defect can be repaired with layered closure or mesh, whereas larger post-exenterative defects typically require more complex reconstruction of the pelvic floor as previously discussed.

The abdominoperineal or combined approach provides maximal exposure of the hernia sac and hernia defect. It is especially useful in cases in which the pelvic floor defect is difficult to access by the abdominal route<sup>3</sup> and in cases of large perineal hernias in which the redundant skin of the perineum must be resected.<sup>36,37</sup> A laparoscopic combined approach has also been described<sup>25</sup> in which the hernia contents are mobilized by a laparoscopic intraperitoneal approach, followed by open perineal repair of the levator defect and subsequent laparoscopic reinforcement of the repair with polypropylene mesh on the pelvic side of the repair.

The list of methods that have been used to address the hernia defect is extensive (see Table 76-3), but there are no controlled trials demonstrating the superiority of any approach. In general, small defects with healthy tissue can be addressed by closing the levator defect primarily with nonabsorbable sutures. This can also be reinforced with mesh. When this is not possible or simple closure has failed, the use of synthetic mesh has produced durable repairs regardless of the surgical approach.<sup>6,25,28,36,37</sup> However, when the tissue is infected, the tissue quality is poor, or the mesh has failed, the transposition of healthy, well-vascularized tissue by flap reconstruction is often required.<sup>17</sup> Flap repairs using gracilis,<sup>33,34</sup> fascia lata,<sup>18</sup> rectus abdominis,<sup>38</sup> and gluteus maximus<sup>35</sup> have been described.

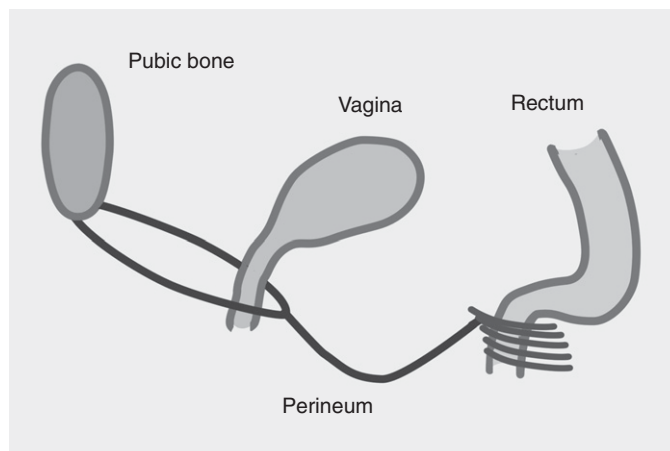

There is no single correct approach to the repair of a perineal hernia. The choice ultimately depends on the size of the defect, the patient's surgical history, the condition of the tissues, the condition and extent of the hernia sac contents, and the comfort level of the surgeon.

## PERINEOCELE

### Definition

Perineocele is typically synonymous with perineal hernia.<sup>39</sup> However, perineal hernia is a misnomer because many perineal hernias occur as labial swellings or swellings close to the buttocks and not on the perineum. Although perineal hernias remain focal defects within the pelvic floor, there is a related but separate clinical entity involving a diffuse weakening and bulging of the entire perineum itself due to an acquired attenuation of the perineal central tendon (Figs. 76-2 and 76-3).<sup>40,41</sup> This has a symptom complex and treatment strategy that differs from the perineal hernias previously described. We think that *perineocele* is the term most appropriate for this condition because it is a pelvic floor herniation of the perineum itself and a clinical entity that differs from a classic perineal hernia.

The two anatomic defects associated with perineoceles are convex deformity plus descent of the perineum with abdominal straining and widening of the distance between the posterior

**Figure 76-2** Schematic diagram of the anatomic defect of a perineocele. (Modified from Raz S: Repair of perineal hernia. In Atlas of Transvaginal Surgery, 2nd ed. Philadelphia, WB Saunders, 2002.)

**Figure 76-3** Physical examination for perineocele. (From Raz S: Repair of perineal hernia. In Atlas of Transvaginal Surgery, 2nd ed. Philadelphia, WB Saunders, 2002.)

vaginal fourchette and the anus.<sup>40,41</sup> Whereas the typical distance between the posterior fourchette and anus is 3 cm,<sup>42</sup> this distance can increase to as much as 8 to 14 cm in large perineoceles.<sup>40,41</sup> These defects are caused by a musculofascial disruption of the perineal body itself.

### Etiology and Epidemiology

The true incidence of perineocele has not been reported. Perineocele is thought to result from the process of pelvic floor relaxation, which is associated with the pelvic floor damage that occurs during childbirth. Lacerations to the perineum occur when the pelvic floor and perineum are stretched excessively during the second stage of labor.<sup>43,44</sup> Childbirth also lowers the position of the perineum,<sup>45</sup> which can take up to 5 years to return to its normal position.<sup>46</sup> It is unclear whether perineocele results from direct pelvic floor damage from childbirth or from the condition of abnormal perineal descent, or both.

### Symptoms and Clinical Features

In addition to having a perineal bulge between the anus and vagina, patients with perineoceles present with additional symptoms distinct from perineal hernias. They have a feeling of perineal pressure, and they typically present with chronic constipation and a possible need to apply perineal pressure to defecate.<sup>40,41</sup> The descending perineum syndrome, first described by Parks and associates,<sup>47</sup> is characterized by downward descent of the perineum during straining efforts and is associated with chronic constipation hallmarked by excessive straining with bowel movements and perineal pain. Fecal or urinary incontinence and vaginal prolapse may also be associated. The continued downward displacement of the perineum in descending perineum syndrome causes chronic stretching of the pudendal

**Figure 76-4** The goal of standard perineorrhaphy is to lengthen the perineum and shorten a widened genital hiatus. (Modified from Nichols DH: Posterior colporrhaphy and perineorrhaphy: Separate and distinct operations. *Am J Obstet Gynecol* 164:714, 1991.)

nerve, leading to worsening of the pelvic floor tone and anal tone.<sup>48-50</sup>

Perineocele and the descending perineum syndrome share some of the same clinical features, and it is interesting to postulate that they are in the same clinical spectrum. However, further investigation is required to determine whether perineoceles are perineal hernias with a distinct location and distinct features or are dynamic defects in the pelvic floor that lead to progressive pelvic floor neuropathy and the descending perineal syndrome.

### Treatment

The treatment of perineocele is surgical. Because there is no focal defect within the pelvic floor through which to reduce the sac and repair, the surgical technique differs from that of a typical perineal hernia. The goal of repair is to reconstruct the perineal body such that distance between the posterior vaginal fourchette and the anus, the perineal body length, is returned to its normal length of approximately 3 cm. This differs from the goal of standard perineorrhaphy, which is to repair the perineum in such a manner as to lengthen the attenuated perineal body while simultaneously reducing the anteroposterior length of the widened genital hiatus (Fig. 76-4).<sup>51</sup>

There is scant literature on the repair of perineoceles because it remains a relatively understudied clinical entity. Raz<sup>41</sup> has described a perineal site-specific technique for the repair of perineocele in which the levator musculature anterior to the anal sphincter is reapproximated to the transverse perineal muscles using a series of interrupted horizontal mattress sutures (Fig. 76-5). This technique is used to repair the anatomic defect and its associated symptoms, including constipation. There are no long-term data on the durability of this repair. Other investiga-

tors have made efforts to specifically address the perineum and perineal descent in the repair of pelvic floor prolapse by affixing the perineum to the sacrum with synthetic mesh while repairing vaginal vault prolapse.<sup>52,53</sup> However, it is not clear whether these techniques are applicable to the repair of perineocele because they correct perineal descent and its symptoms but do not address the condition of the widened perineum itself.

Perineocele, although a poorly studied condition, is a clearly defined anatomic defect of the pelvic floor that is distinct from classically described anterior and posterior perineal hernias. It is typically associated with chronic constipation, and it remains unclear whether it also carries the pelvic neuropathic sequelae of abnormal perineal descent. The study of a large group of these patients with respect to risk factors, possible associated pelvic floor defects and neuropathy, and durability of repair is needed.

### CONCLUSIONS

The anatomic defects of perineal hernia and perineocele are well defined, and a careful history, clinical suspicion, and physical examination remain tantamount to their diagnosis. Modern imaging techniques such as CT and MRI provide excellent and precise visualization of perineal hernias to assist in preoperative planning. Although there are few surgical repairs described for perineocele, there are several surgical approaches and repair techniques described for perineal hernia repair. However, there are no controlled trials directing clinicians to the optimal surgical approach or repair technique. Surgical treatment remains individualized, depending on the size and nature of the hernia defect, the condition of the tissues, and the comfort level and judgment of the surgeon.

**Figure 76-5** The goal of a perineocele repair is to shorten and strengthen the widened perineum by reapproximating the anal sphincter toward the superficial transverse perineal muscles. **A**, A 5-cm perineocele. **B**, Inverted Y incision to expose the defect. **C**, Suturing of the levator ani just anterior to the anus to the transverse perineal muscles. **D**, Repaired perineocele.

# COMPLICATIONS OF VAGINAL SURGERY

*Raymond T. Foster, Sr., Cindy L. Amundsen,  
and George D. Webster*

Urologists and gynecologists use the vaginal approach to surgically correct many of the pelvic organ problems of women, including urinary incontinence, uterine and vaginal prolapse, vesicovaginal fistula, and urethral diverticulum. As surgeons continue to seek new ways to surgically treat women without laparotomy, it is important that vaginal surgeons remain informed about potential surgical complications, some of which are unique to this route of surgery.

In this chapter, we review the potential complications of vaginal surgery, highlight patient characteristics and specific techniques that may be associated with a higher frequency of surgical complications, and outline strategies that may reduce the likelihood of a serious intraoperative or postoperative complication. Because this textbook is dedicated to a readership interested in female urology, we focus our discussion on complications related to urologic and pelvic reconstructive procedures.

### BLEEDING

Problematic bleeding is undoubtedly the most feared problem that a surgeon encounters during or immediately after a surgical procedure. During the procedure, intraoperative bleeding compromises the surgeon's ability to adequately complete the task at hand. The reported incidence of bleeding during vaginal surgery varies by specific procedure, and to some degree, reported rates of hemorrhage depend on the investigator's definition of excessive blood loss. Most surgeons consider the need for blood transfusion a reliable definition of excessive surgical bleeding, but less blood loss can still interfere with surgical outcome and prolong hospitalization. Reported rates of such intraoperative hemorrhage are between 0% and 2% for most vaginal procedures, but these rates likely underestimate the incidence of problematic bleeding.

Several investigators have reported low transfusion rates even when multiple vaginal reconstructive repairs, including hysterectomy and pubovaginal slings, are performed during the same operation. One of the largest series of patients undergoing multiple vaginal prolapse and incontinence procedures was reported by Shull and colleagues.<sup>1</sup> Three hundred and two patients underwent a uterosacral vault suspension in combination with other support defects involving the urethra, bladder, posterior cul-de-sac, or rectum. The mean intraoperative blood loss for all patients in this study was 243 mL, and the blood transfusion rate was 1%. Other studies have reported similarly low rates of blood transfusion and blood loss between 200 and 350 mL when performing multiple vaginal prolapse repairs with a uterosacral vault suspension.<sup>2-5</sup> In one report looking at a series of patients undergoing vaginal reconstructive procedures, each of which included uterosacral vault suspension, the investigator found that when he com-

pared blood loss between those having a hysterectomy at the time of repair with patients having only reconstructive procedures, hysterectomy did not significantly increase operative blood loss or the risk of significant bleeding.<sup>3</sup> One of the attractive features of the uterosacral vault suspension for apical prolapse is its low incidence of troublesome bleeding. However, most published data are reported by experts in the field and may not accurately reflect the experience of the generalist surgeon.

Although the reports cited found major intraoperative blood loss to be uncommon even when an apical prolapse procedure was performed, correction of the vaginal apex with a sacrospinous ligament fixation has been often associated with the potential for increased bleeding. This procedure, originally described by Richter,<sup>6</sup> has been studied repeatedly in the past decade with regard to surgical complications in general and bleeding in particular. The incidence of excessive bleeding reported in most series has been between 0.5% and 3.5%.<sup>7-9</sup> An important aspect of these statistics, however, is that maneuvers to control bleeding in this area have been reported to promote injury to adjacent structures, including the rectum and nerves. Nieminen and Heinonen<sup>9</sup> reported a higher transfusion rate (28% of 25 women) when performing a sacrospinous ligament fixation in a population of patients older than 80 years.

In an attempt to define the optimal surgical strategy for controlling intraoperative hemorrhage associated with sacrospinous ligament fixation, Barksdale and coworkers<sup>10</sup> conducted an anatomic study with 10 female cadavers to map the vascularity in the region of the sacrospinous ligament and propose surgical strategies for controlling hemorrhage. Their report detailed various combinations and permutations of vascular anastomoses in the area of the sacrospinous ligament (i.e., superior gluteal, inferior gluteal, internal pudendal, vertebral, middle sacral, lateral sacral, and external iliac by way of the circumflex femoral artery system). They concluded that because of the vascular anastomoses, the heroic approach of laparotomy with surgical ligation of the internal iliac artery was unlikely to be of significant benefit. They also determined the inferior gluteal artery to be the most likely artery responsible for hemorrhage related to the sacrospinous ligament fixation. Based on anatomic considerations, bleeding from the inferior gluteal artery is optimally controlled by any combination of packing and vascular clips by means of the vaginal approach or arterial embolization by invasive radiology techniques. We have become less hesitant to employ surface hemostatic factors, such as FloSeal (Baxter International, Deerfield, IL).

Very few studies have evaluated factors associated with increased blood loss during vaginal surgery, such as surgeon skill level, surgical techniques, obesity, and the impact of prior pelvic surgery. Coates and associates<sup>11</sup> reported surgical outcomes in 289 women undergoing a vaginal prolapse repair. In 154 of these operations, the senior staff member was the primary surgeon

(mean blood loss, 248 mL), and in the remaining 135 procedures, a senior gynecology resident was the primary surgeon (mean blood loss, 234 mL). The difference in operative bleeding between the senior staff surgeon and the surgical trainee was not clinically or statistically significant. One retrospective review of surgical outcomes in obese women (i.e., body mass index [BMI] > 30 kg/m<sup>2</sup>) compared surgical complications in 189 subjects undergoing abdominal hysterectomy and in 180 women having a vaginal hysterectomy.<sup>12</sup> Both groups of obese women had a mean change in hemoglobin of 1.7 g and a 13% transfusion rate, which established obesity as risk factor for hemorrhage in female pelvic surgery, regardless of the chosen surgical approach.

Besides patient characteristics and surgical experience, surgical equipment may also impact the occurrence of unacceptable bleeding. Good surgical exposure and lighting is paramount to achieving surgical goals and avoiding and controlling bleeding. The Lonestar retractor (Lone Star Medical Products, Stafford, TX) is invaluable in this regard because it retains an open introitus and allows the surgeon to maintain visualization of the vaginal apex. The use of a surgical headlight or a cool lighting system that is adherent to the retractor and placed within the pelvis (Light-Mat, Lumitex, Strongsville, OH) provides sufficient light for operating in a deep body cavity.

In addition to the traditional ways of controlling bleeding, such as suture ligation and electrocautery, other user-friendly techniques have been introduced. In the United Kingdom, Hefni and colleagues<sup>13</sup> randomized 116 patients to vaginal hysterectomy with traditional suture ligation ( $n = 59$ ) or to vaginal hysterectomy with the LigaSure (Valleylab, Boulder, CO) vessel sealing system ( $n = 57$ ).<sup>13</sup> Mean intraoperative blood loss was 100 mL in both groups, but perioperative bleeding complications in the suture ligation group neared statistical significance ( $P = .0571$ ).

More than other approaches to surgery, the transvaginal approach may be technically challenging in the setting of previous surgery. Boukerrou and coworkers<sup>14</sup> reported surgical outcomes of 741 women undergoing vaginal hysterectomy. Seventy-one (9.58%) of their subjects had undergone previous cesarean section, and the remaining 670 (90.41%) had not. Mean blood loss was 181.69 mL in the group of patients with previous cesarean section and 145.96 mL in the control group ( $P = .05$ ). Among women with a history of cesarean section, 11.3% had intraoperative hemorrhage (i.e., blood loss in excess of 500 mL), compared with only 2.5% of women without a history of previous cesarean section. It is intuitive to surgeons that prior procedures in the same area render subsequent operations more difficult and prone to complications such as bleeding, but few articles report this conclusion.

In addition to vaginal prolapse procedures, transvaginal incontinence procedures, such as pubovaginal slings, may also cause intraoperative bleeding. Even though the traditional bladder neck pubovaginal slings required more extensive transvaginal surgical dissection, including digital and usually blind dissection of the retropubic space, several large pubovaginal sling series have demonstrated rare intraoperative bleeding complications.<sup>15-18</sup> The increasingly popular minimally invasive or midurethral sling is placed by passing a trocar blindly through the retropubic or obturator space. Although there are rare reports of iliac artery injuries published on the MAUDE database, most case series report a 1% to 3% increased bleeding rate resulting in pelvic or perineal hematomas. Abouassaly and associates<sup>19</sup> reviewed 241 patients who had undergone placement of a tension-

free vaginal tape. These patients, recruited from six medical centers, had an intraoperative hemorrhage rate of 2.5% (16 patients). Four patients (1.9%) developed a pelvic hematoma within the first 24 hours after surgery. In another series, Krauth and colleagues<sup>20</sup> described 604 patients undergoing placement of a minimally invasive suburethral sling by the transobturator approach. They reported a 0.8% incidence of intraoperative hemorrhage and postoperative development of two (0.33%) perineal hematomas, one of which resolved without intervention, and the other, believed to be associated with a concomitant prolapse repair (not the transobturator sling), required revision surgery.

In summary, surgeons are wise to consider each patient's individual risk factors for operative bleeding before surgery. Intuitively, obese women and women with a history of prior pelvic surgery may have an elevated risk for excessive surgical bleeding, and extra precautions should be taken in the operating room (e.g., good surgical assistants and exposure, blood products available on short notice). We evaluate bleeding time and platelet function for patients who provide us a history of prior intraoperative or postoperative hemorrhage. Any medication that can affect bleeding should be stopped 7 to 10 days before surgery when this can be safely accomplished. Surgeons who are managing patients who require some level of anticoagulation, such as a patient with a history of heart valve replacement or atrial fibrillation, are wise to obtain hematologic advice for the perioperative management of anticoagulation agents.

## INJURY TO THE URINARY TRACT

Operating in the vagina places the surgeon close to the urinary tract, and great care must be taken to avoid its injury. As with any effort to avoid surgical complication, a sound surgical plan and good exposure are important, as is a thorough understanding of the anatomy within the surgical field. It is encouraging to consider that most injuries to the urinary tract during vaginal surgery are problematic only if unrecognized.

Injuries to the urethra, bladder, or ureters that are identified at the time of surgery and primarily repaired most often heal without incident or further significant consequence to the patient.<sup>21</sup> For this reason, we rarely perform vaginal surgery without a cystoscopic evaluation of the lower urinary tract and confirmation of bilateral ureteral spill after the administration of intravenous indigo carmine. In addition to absent ureteral spill, other abnormalities sought are suture transfixation or sling penetration of the bladder and surgical entry to the bladder, each of which would necessitate re-exploration for removal or repair. We also look for bladder wall ecchymosis, which may suggest the need for a longer period of postoperative catheterization. Several published studies have confirmed the importance of intraoperative cystoscopy when pelvic reconstructive procedures, including incontinence procedures, are performed. Harris and associates<sup>22</sup> reviewed the records of 224 consecutive patients undergoing urogynecologic and reconstructive pelvic surgery. Based on a 4% rate of injury to the urinary tract, which would have been unrecognized without intraoperative cystoscopy, they concluded that cystoscopy should be included in all incontinence and pelvic reconstructive procedures. Another large, prospective study, in which intraoperative cystourethroscopy was performed universally on 471 women undergoing hysterectomy, documented a 7.6% rate of injury to the urinary tract.<sup>23</sup> Of the patients in this

report, 144 (31%) had a vaginal hysterectomy. Among those patients having vaginal hysterectomy, 11 (7.6%) experienced an injury to their urinary collecting system; 6 of the 11 had concurrent prolapse surgery. Of the 11 injuries, 2 were ligated ureters, 7 were cystotomies, 1 was a suture in the bladder, and 1 was bladder abrasion. Concurrent prolapse surgery was therefore found to be an independent risk factor for injury to the urinary system. When controlling for prolapse and incontinence surgery, there was not a significant increase in the risk of urinary tract injury based on route of hysterectomy, age, BMI, race, blood loss, uterine size, and history of previous cesarean section. However, the standard of care in community practice is to not routinely perform cystoscopy at the end of hysterectomy or pelvic organ prolapse surgery.

Transvaginal vault suspensions, specifically uterosacral vault suspensions, have been associated with urinary tract injuries, especially injuries involving one or both ureters. Because this vault suspension involves placement of sutures intraperitoneally above the level of the ischial spines, the ureter is near the suture placement. A cadaveric study by Buller and colleagues<sup>24</sup> demonstrated the strength of the uterosacral ligament at various locations in the pelvis and its proximity to the ureter at the site of customary suture placement. Based on their findings after necropsy of 11 female cadavers, the ureter is, on average,  $2.3 \pm 0.9$  cm from the uterosacral ligament at the level of the ischial spine. This finding led Buller and his colleagues to claim, "The proximity of the ureter to the distal uterosacral ligament warrants concern during vaginal vault repairs that use the ligament."<sup>24</sup>

Several surgical series of uterosacral vault suspension have reported a 0% to 11% incidence of injury to the ureter.<sup>1-5</sup> In each of these series, the injuries were identified at the time of surgery after confirming an absence of ureteral spill on cystoscopic evaluation. Management usually involved removal of the uterosacral suspensory sutures with or without ureteral stent placement; however, some injuries, presumably transections, required ureteroneocystotomy. In these reports, all injuries were detected by intraoperative cystoscopy at the time of surgery, and as a result, none of the patients had permanent or long-term urinary tract sequelae. In addition to ureteral injury, cystotomy may occur during transvaginal surgical entry into the peritoneal cavity and may be repaired and the operation continued in most circumstances.<sup>4</sup>

Aronson and colleagues<sup>25</sup> reported the ureteral injury rate using a modified "deep" Mayo-McCall uterosacral ligament plication for vaginal vault suspension. The technique for placement of suture through the uterosacral ligament described by the investigators resulted in a uterosacral anchoring point much more dorsal and posterior than previously described. In this retrospective report of 411 consecutive patients, they observed three ureteral injuries, only one of which was attributable to the vault suspension procedure (0.24% [range, 0.01% to 1.35%]).

Injury to the lower urinary tract is not uncommon in vaginal procedures designed to treat stress urinary incontinence, and the data depend on the procedure used. Factors such as anesthetic technique (i.e., regional or local versus general anesthesia) and the use of hydrodissection in the retropubic space were previously thought to affect bladder injury rate, but a report from Ghezzi and coworkers<sup>26</sup> disputes these assumptions.

The minimally invasive techniques for placement of midurethral slings are associated with the highest rate of bladder injury,

with some articles describing cystotomy rates greater than 10%.<sup>27-29</sup> However, in one study that surveyed members of the American Urogynecologic Society and members of the Society for Urodynamics and Female Urology, only 10% to 15% of those surveyed from both groups admitted to cystotomy rates higher than 5%. More than 90% of the members in both societies would replace the trocar at the time of surgery, and more than 80% of the members in both societies would drain the bladder transurethraly for at least 24 hours if a cystotomy was made with the trocar.<sup>30</sup>

Some investigators have described risk factors associated with inadvertent cystotomy. Bodelsson and associates<sup>27</sup>, in their series of 177 patients undergoing a tension-free vaginal tape procedure, were able to show a statistically and clinically significant difference in the occurrence of cystotomy and urethrotomy among surgeons with different levels of experience. Another potential contributing factor to operative morbidity, including urinary tract injury, is obesity. However, Rafii and colleagues<sup>29</sup> performed a midurethral sling in 38 consecutive patients with a BMI greater than 30 and compared outcomes with 149 age- and parity-matched controls with a BMI of 30 or less.<sup>29</sup> They found no difference in estimated blood loss, operative times, bladder injuries, postoperative urgency, and voiding disorders. This study also found no difference between the two groups in objective and subjective cure rates. Lovatsis and coworkers<sup>28</sup> studied 35 patient pairs (BMI = 35 kg/m<sup>2</sup> versus BMI = 30 kg/m<sup>2</sup>) undergoing placement of tension-free vaginal tape. The patients were matched according to age and history of previous incontinence surgery. In this series, obesity was protective against injury to the lower urinary tract (0% versus 14%,  $P = .03$ ). It may be that although obesity complicates vaginal access, it protects the bladder by virtue of the fat separation of the bladder from the symphysis pubis. Rardin and associates<sup>31</sup> looked at surgical complications related to placement of tension-free vaginal tape as a primary procedure ( $n = 157$ ) or as a secondary procedure for recurrent stress urinary incontinence ( $n = 88$ ). The cystotomy rates were similar (3.2% versus 3.4%).

In summary, surgical experience appears to be related to the occurrence of injury to the urinary tract during placement of retropubic midurethral slings. However, obesity and prior incontinence surgery do not appear to increase the risk of cystotomy or urethrotomy.

We prefer to use a 70-degree cystoscope to evaluate the bladder and a 30-degree cystoscope to visualize the urethra after passing the trocars through the retropubic space but before the sling is placed. During cystoscopy, we are careful to fully expand the bladder with 400 to 500 mL of clear fluid, and we pay particular attention to the 11- and 8-o'clock and the 1- and 4-o'clock positions, which are the most likely areas to be penetrated during trocar passage. We are encouraged by failure to visualize a perforation with a fully expanded bladder and by the absence of hematuria. If a bladder perforation is identified, we remove the offending trocar and replace it, with an exaggerated emphasis on "hugging" the pubic bone during passage of the trocar. Cystoscopy is repeated to ensure adequate trocar placement is obtained on the second passage. After cystotomy, we leave a catheter for 24 to 72 hours postoperatively.

Recognizing the need for a safer suburethral sling system that may not obligate the surgeon to cystoscopy, Delorme<sup>32</sup> introduced a transobturator midurethral sling in 2001. Although there are few safety and efficacy data on this relatively new approach for sling placement, Cindolo and colleagues<sup>33</sup> experienced a single

bladder neck laceration, which was repaired intraoperatively, and no occurrence of bladder perforation after placing a midurethral sling in 80 women. However, cystoscopy was not used to definitively document the absence of bladder injury. In a similar series of 71 patients, Dargent and coworkers<sup>34</sup> reported no instance of bladder perforation with the transobturator technique, despite cystoscopic examination at the time of surgery. Conversely, Minaglia and associates<sup>35</sup> reported three bladder perforations in 61 patients and concluded that “routine intraoperative cystoscopy is therefore recommended for the identification of bladder injuries during the transobturator sling procedure.” Anecdotally, we have also seen a patient with an intraurethral sling after this approach.

Vesicovaginal fistula (VVF) may occur after vaginal surgery, most commonly after hysterectomy (0.5% to 2% of cases).<sup>36,37</sup> Examination of this occurrence shows that it more commonly follows the abdominal rather than the vaginal approach. The symptoms of continuous urinary leakage, usually developing between 1 and 6 weeks after surgery, are ominous and should lead to evaluation for fistula by vaginal examination, tampon test, and cystoscopy. Less commonly, the ureter is the source of a postoperative vaginal fistula. When suspecting a ureterovaginal fistula, usually heralded by urinary leakage emanating from the vaginal cuff, the physician should pursue further investigation with an excretory urogram.

The intraoperative events that lead to VVF remain unknown, and the fact that the cervix must be dissected from the bladder adds to the inherent risk because the bladder wall may be thinned. Inadvertent entry into the bladder during this maneuver must be carefully repaired in layers, and a Foley catheter is left for sufficient time to allow healing. This area is close to the vaginal cuff closure, and any breakdown will promote fistula formation. Suture transfixation of the bladder by the cuff closure sutures has been suggested as a factor in the genesis of fistula, although animal experiments cast doubt on this theory. The proximity of the cuff and bladder at this location make this event almost unavoidable on some occasions, particularly when the patient is obese, hemostasis is poor, or exposure, lighting, and assistance are suboptimal. Cystoscopy may help identify the bladder injury that may lead to fistula formation, but it is not performed in most cases of hysterectomy.

The timing of VVF repair has been reported to be successful at all intervals after discovery, and some advocate immediate surgical repair. However, a more judicious approach includes a period of catheterization, hoping for spontaneous healing. The size of the fistula affects the likelihood of success with this approach and how long it should be pursued. We time our intervention based on the status of the vaginal cuff tissue, and our preference is to monitor inflamed and edematous tissue at weekly intervals until the cuff reveals a healthy, mature fistulous tract. Vaginal repair usually can be performed by 6 weeks after hysterectomy.

In summary, transvaginal surgical treatment of prolapse and incontinence is a significant risk factor for injuring the urinary tract in women. We believe that careful surgical planning and intraoperative cystoscopy is an advisable element for most vaginal surgeries that seek to correct these problems. We recognize that patients experience poor long-term outcomes after urinary tract injury when the problem is undetected at the time of occurrence. However, patients are likely to recover from surgery without incident when the urinary system is repaired at the time of the primary surgery.

## BOWEL INJURY

Complications involving the bowels most commonly occur during rectocele repair, although the high rectum is vulnerable during all varieties of vaginal vault suspension. For this reason, we prefer a low bowel preparation preoperatively and the placement of a rectal pack at the commencement of some procedures to aid in the identification of surgical landmarks.

Injury to the bowel is a relatively uncommon occurrence during vaginal surgery. Hoffman and coworkers,<sup>38</sup> at the University of South Florida, reported nine rectal injuries (0.7%) from their database of 1346 patients who underwent vaginal surgery between 1987 and 1998.<sup>38</sup> Of the nine, six were being treated for prolapse, one for cervical dysplasia, one for fibroid uterus, and one for gender dysphoria. In another large study from a vaginal surgery database, Mathevet and colleagues<sup>39</sup> reported 14 (0.45%) rectal injuries in 3076 patients undergoing vaginal surgery. Most (62.5%) of the 14 patients were undergoing surgery for the primary indication of genital prolapse. In the study of Isik-Akbay and associates<sup>12</sup> comparing abdominal and vaginal routes of surgery in obese women undergoing hysterectomy, the investigators found five bowel injuries in the abdominal group (2.7%) and none among women having vaginal surgery. Although the difference was not statistically significant, this report suggests fewer rectal injuries in obese patients when surgery was performed vaginally.<sup>12</sup>

During rectocele repair, injury is most likely to occur in women undergoing repeat surgery. When the rectum is prepared before surgery and injury occurs, it is generally appropriate to repair the defect primarily. Even though the published rate of rectal injuries is low, we routinely perform a digital rectal examination at the conclusion of vaginal prolapse procedures that involve some risk of rectal injury to ensure that there is no blood on the examining finger and that there has been no suture transfixation. As with urinary tract injury, the best time to identify injury is at the time of the primary surgery. If a rectovaginal fistula does occur postoperatively, as with vesicovaginal fistula, the timing of repair is individualized and is dictated primarily by the status of the tissues. If the fistula is large, a temporary diverting colostomy is required to afford the patient the highest probability of a successful repair. Such decisions are individualized based on severity.

## INFECTION

The hallmark clinical sign of postoperative infection is fever, and in surgical training, we are taught to investigate the cause of fever with physical examination, radiographic images, and laboratory studies. Historically, surgeons have treated postoperative fever with antibiotics even in the absence of an obvious cause after a comprehensive evaluation. More contemporary evidence, however, calls into question the medical necessity of treating an unidentified postoperative infection in most patients. In 1983, Freischlag and Busuttill<sup>40</sup> reported their experience following 464 patients after abdominal surgery. They defined postoperative fever as a rectal temperature of 38.5°C or higher in the first 6 postoperative days. Seventy-one patients (15%) had postoperative fever. Only 19 (27%) of these 71 patients had an identifiable source of infection after a radiographic and laboratory evaluation. They concluded that routine evaluations of fever do not alter the outcome most patients and are not cost-effective.

Shackleford and associates<sup>41</sup> examined the predictive value of postoperative fever for infection in patients recovering from vaginal surgery. Febrile morbidity was defined in their series as an oral temperature greater than 38.0°C on two separate occasions, excluding the first 24 hours after surgery. They retrospectively examined outcomes of 431 vaginal surgery patients. Forty-three percent of these patients had vaginal hysterectomy alone, and the remaining 57% had a procedure for prolapse with (27%) or without (30%) vaginal hysterectomy. Fifty-four women (12.5%) had postoperative febrile morbidity. Thirty-five infections were definitively identified (8.1%), but only 13 of these infections occurred in the 54 patients with postoperative fever. Among the identified infections were 20 urinary tract infections (4.6%), five infections at the suprapubic catheter site (1.2%), three cases of vaginal cuff cellulites (0.7%), three “pelvic infections” (0.7%), and two cases of *Clostridium difficile* colitis. Two women had infection unrelated to their vaginal surgery; one was diagnosed with sinusitis and the other with bronchitis. Based on their findings, the investigators calculated the sensitivity of febrile morbidity for postoperative infection to be 40%, with a specificity of 98%, a positive predictive value of 26%, and a negative predictive value of 94%. Univariate analysis was performed, and they found that women with febrile morbidity were older, had longer procedures, lost more blood, were higher parity, and had lower uterine weights and longer hospital stays than women without febrile morbidity. Their data also demonstrated that women with proven infection had prolonged surgery, weighed less, had lower uterine weights, and stayed in the hospital longer than women without infections. Women who had hysterectomy done at the time of prolapse surgery were the most likely to have postoperative infection compared with women who had vaginal hysterectomy alone or prolapse surgery without hysterectomy.

Vaginal surgery is a clean-contaminated procedure. Some investigators have become interested in the vaginal flora at the time of surgery. The assumption of these clinical scientists is that an understanding of how to manipulate the vaginal flora at the time of surgery (e.g., decrease the bacterial colony count) would aid in the prevention of postoperative infection for patients undergoing vaginal procedures. Culligan and colleagues<sup>42</sup> published an observational study in 2003 that reported the rate of vaginal contamination (defined as an aerobic or anaerobic culture result of 5000 colony-forming units/mL) at given time intervals during vaginal reconstructive surgery. All patients in their study had preoperative antibiotic prophylaxis and a standard 5-minute surgical scrub with povidone iodine. The first set of cultures, obtained 30 minutes after the surgical scrub, revealed a 52% contamination rate in the surgical field, whereas the cultures collected at 90 minutes only had a 41% contamination rate. After this initial study that defined vaginal contamination as a surrogate end point for postoperative infection, Culligan and his group<sup>43</sup> published their results of a randomized trial that evaluated povidone iodine and chlorhexidine gluconate as surgical scrub solutions for vaginal surgery. Fifty patients were enrolled in the study that demonstrated a clinically and statistically significant difference between the contamination rates of surgical fields prepared with povidone iodine (63% contaminated) and chlorhexidine gluconate (22% contaminated) at 30 minutes ( $P = .003$ ; relative risk = 6.12; 95% CI: 1.7 to 21.6).

Surgical infection is a problem that is often easier to prevent than to treat. In an era of prophylactic, broad-spectrum antibiot-

ics, we are rarely confronted with wound infections at the surgical site after vaginal procedures. Postoperative febrile morbidity and postoperative infections at sites remote from the vagina remain areas of some concern, especially in elderly patients, those with above-average blood loss, and patients who undergo prolonged surgical procedures.

#### COMPLICATIONS RELATED TO GRAFT MATERIALS USED IN THE VAGINA

Reported rates of recurrent or de novo vaginal wall prolapse range from 15% to 30%<sup>44</sup> and for this reason, many clinicians implant synthetic or organic (allograft or xenograft) material to address this problem. This position is supported by the fact that surgeons have known for a long time that the efficacy and durability of hernia repair is improved by the use of a graft material. However, long-term data associated with the use of the various graft materials, including complications and success rates for prolapse repair, are limited. Vaginal surgery is performed in a clean-contaminated field, and this adds the potential risk of infection and erosion when synthetic material is used. There are also concerns about whether the inclusion of grafts or synthetics in vaginal repairs may compromise vaginal caliber or elasticity and thereby compromise sexual function. There have been few well-designed studies to provide evidence that the risks of placing the mesh are balanced by a longer durability of the vaginal repair, but this continues to be the trend.

Synthetic material may be absorbable or permanent. Two randomized studies evaluated the use of an absorbable synthetic graft to reinforce the vaginal prolapse repair, and they had opposing views on the success of the material. Neither, however, reported significant complications associated with the material. Sand and colleagues<sup>45</sup> randomized women to polyglactin 910 mesh (with anterior colporrhaphy) or to anterior colporrhaphy alone. Thirty women (43%) without mesh and 18 women (25%) with mesh had recurrent cystocele beyond the mid-vaginal plane ( $P = .02$ ). The study authors concluded that polyglactin mesh was useful in the prevention of recurrent cystoceles. In 2001, Weber and coworkers<sup>46</sup> compared standard colporrhaphy, standard colporrhaphy with polyglactin 910 mesh, and ultralateral anterior colporrhaphy. They analyzed 109 patients randomized to one of the three treatment arms, with a mean follow-up of 23.3 months (range, 4.5 to 44.4 months) and found no difference in the three groups with respect to the anterior vaginal wall. A single vaginal mesh erosion was the only mesh-related complication in this study. There seems not to be widespread interest in absorbable mesh to enhance prolapse repair.

The most commonly reported permanent synthetic mesh used for vaginal prolapse has been polypropylene. Randomized, controlled studies are lacking, but several published case series using polypropylene mesh report a rate of recurrent prolapse not exceeding 6%.<sup>47-49</sup> The same reports document mesh erosion rates between 7% and 13%, and postoperative, new-onset dyspareunia in 14% to 63% of patients. Management of vaginal exposure of the mesh should begin with conservative therapy such as intravaginal conjugated equine estrogen cream, but surgical resection of the exposed portion of mesh is commonly required.

Organic materials such as cadaveric dermal or fascia lata grafts have also been used for vaginal prolapse reinforcement. In a

randomized study evaluating the success of solvent-dehydrated fascia lata versus a standard anterior colporrhaphy, 21% of the allograft-reinforced group had recurrent prolapse, compared with 29% in the control group. This finding did not reach statistical significance. No vaginal erosions were reported among the 76 patients in the allograft group.<sup>50</sup> We notice a surprising lack of literature to document the erosion rate of allograft material when used in transvaginal prolapse surgery, and there seems to be little evidence to guide management strategies when erosion does occur. In our own experience (69 women), we have found a 10.9% vaginal exposure rate of dermal allograft material when used in anterior or posterior repairs.<sup>51</sup> We also documented a 100% rate of resolution of this problem with vaginal conjugated equine estrogen cream. The median time to complete healing in our series was 13 weeks.

Xenograft material has been marketed for use in prolapse repair. Available materials include porcine dermis and porcine small intestinal submucosa. As with the materials discussed previously, there have been variable results, with recurrent prolapse reported in 8% to 39% of patients.<sup>52,53</sup> Vaginal exposure of the graft appears to be relatively common, similar to that seen with cadaveric dermis, with a reported incidence of 15% and a healing time of up to 3 months with conservative therapy. Porcine dermis has several suggested beneficial characteristics, including the fact that it is 95% homologous to human collagen, possibly providing a nonallergenic scaffold for human tissue ingrowth.

When considering complications such as vaginal graft erosion, infection, and postoperative dyspareunia, the physician may be wise to consider that the graft itself is not always the determining cause for these suboptimal outcomes. Surgical techniques of graft placement must always be considered, and it is inappropriate to always blame the product for a bad outcome; however, we have no way to control for the surgeon's performance.

Minimally invasive techniques used to place the material may produce complications related to blind passage of a trocar. Although the techniques are new with infrequent reports of complications, placement of augmented synthetic mesh using a trocar approach could cause rectal and bladder injury with the potential for rectovaginal fistula and vesicovaginal fistula.<sup>54</sup> We await development of this field, which promises to simplify the repair of vaginal organ prolapse if the techniques can achieve good functional results and prove to be safe.<sup>55</sup>

### INJURY TO THE PERIPHERAL NERVOUS SYSTEM

Peripheral nerve injury resulting from vaginal surgery is an unexpected but reported complication after pelvic surgery. It is a potentially debilitating problem for the patient and a great concern for the surgeon. Most neuropathies that occur in reconstructive pelvic surgery are neurapraxic, and they heal with time. Physical therapy and neuroleptic medications plays a role in managing these patients, and rarely is surgery required for relief of symptoms.

The nerve injuries most commonly reported have been sciatic nerve injuries and are largely thought to be caused by positioning in free-hanging stirrups.<sup>56-58</sup> Injury to the sciatic nerve has been reported after sacrospinous ligament fixation in which the nerve was thought to be entrapped by the suture.<sup>8</sup> Symptoms are usually buttock pain radiating down the posterior thigh, and if the cause is related to sacrospinous ligament fixation, removal of the suture often resolves the pain.

We have managed patients with temporary postoperative sciatic pain after undergoing transvaginal uterosacral cuff suspension by removal of the suture or expectant management with analgesics, anti-inflammatory agents, and neuroleptic medication. Recovery time for expectant management may be several months. Use of padded Allen stirrups with an extended padded lower leg support provides a secure and stable positioning for the patient's legs, and we believe this added precaution reduces the risk of lower extremity neural injuries. Symptoms of femoral nerve injury include weakness with hip flexion, leg extension, and sensory loss over the anteromedial thigh and leg. These are uncommon but may follow prolonged lithotomy with the legs markedly abducted or a retractor blade compression injury after retropubic surgery.<sup>59</sup> Injury to the common peroneal nerve may occur if pressure is placed on the lateral part of the lower part of leg where the nerve wraps around the fibular head or if there is hyperflexion of the thigh. The almost routine use of sequential compression hose, which raise the lower leg from the stirrup periodically, probably reduces this complication. Common symptoms of peroneal nerve injury are footdrop and sensory loss to the anterior leg and dorsal foot.

In pelvic surgery, injury may occur to branches of the ilioinguinal and iliohypogastric nerves in the suprapubic location. These branches are susceptible to injury where the nerve runs on the undersurface of the external and internal abdominal oblique fascia above the symphysis, where they may become entrapped or involved by the fixation of pubovaginal slings. Patients present with sharp or burning pain and paresthesia in the suprapubic region that may radiate to the groin, and it can be quite problematic. Treatment may be by local injection of the trigger point, and occasionally, the site must be explored surgically to release the suture, lyse the fibrosis, or excise a neuroma.

Obturator nerve injury may occur during vaginal, paravaginal, or transobturator prolapse surgery. The patient has difficulty adducting the leg (and therefore complains about problems walking) and may have sensory loss to the medial thigh. Injury to branches of the pudendal nerve, including the dorsal genital nerve to the clitoris and the perineal branch to the urethral sphincter, perineal skin, and anal sphincter, may occur during any anterior vaginal dissection. These unfortunate injuries therefore may occur during incontinence or prolapse surgery. Common symptoms of these uncommon injuries include sharp, burning pain to the perineal area or worsening of urinary and fecal incontinence.

Important measures to reduce the incidence of neural injury include proper patient positioning, surgical technique to avoid known nerve locations, careful use of retractors and, avoidance of prolonged surgery. Even when all these preventative strategies are followed, neuropathies will occur. Postoperatively, clinical symptoms and physical examination allows the physician to make the diagnosis. If motor deficits are identified, a neurology consultation may be obtained for baseline testing and management options.

### CONCLUSIONS

The possible complications associated with vaginal surgery are numerous and tend to be underestimated. Reducing complications is probably largely a product of the technical skills of the surgeon and the application of good surgical principles, but some events remain unavoidable. Variables contributing to the occur-

rence of adverse events in vaginal surgery that are beyond the immediate control of the surgeon include obesity, medical comorbidities, and undiagnosed bleeding dyscrasias. However, by good surgical planning and execution, the surgeon may reduce

the occurrence of complications. Vaginal surgery, when performed correctly and safely, remains one of the most rewarding aspects of surgical practice for female urologists and gynecologists.

# PATHOPHYSIOLOGY, DIAGNOSIS, AND TREATMENT OF DEFECATORY DYSFUNCTION

*Tracy Hull and Massarat Zutshi*

The domain of defecatory disorders is vast, and their treatment can be frustrating for the surgeon and the patient. Except for straightforward surgically correctible disorders, most diseases in this category have many causes and need treatment that encompass medical, behavioral, and surgical modalities. These patients often go from physician to physician seeking a cure for these complex disorders.

### ANATOMY

Pathogenesis of the defecatory disorders can be a function of abnormal anatomy at the outlet. The anal sphincter complex is composed of the puborectalis, the internal anal sphincter, and the external anal sphincter. The puborectalis and the external anal sphincter are striated muscles that are primarily responsible for the process of defecation by voluntary relaxation. They are innervated by the S3 and S4 nerves. The internal anal sphincter accounts for about two thirds of the resting tone and is composed of smooth muscle. It is innervated by the autonomous nervous system. The external anal sphincter accounts for one third of the resting tone. Any process that causes a change in this normal physiology can lead to defecatory disorders.

### MECHANISM OF DEFECATION

Storage is a function of the transverse colon. When the sigmoid colon is filled, the process of defecation commences with the propagation of stool into the rectum. Defecation occurs in response to the sensory stimulus generated by rectal distention that is received by receptors in the pelvic floor and anal transition zone; the rectum itself is not richly innervated by sensory nerves. The sensation of filling is normally perceived at a volume of 50 mL, and the maximum tolerated volume normally is about 200 mL. Rectal pressures should be more than the anal pressures for evacuation to take place, which is usually achieved by increasing the intra-abdominal pressure. The external anal sphincter and puborectalis relax, allowing fecal contents to be evacuated. If it is socially unacceptable at that time, the external anal sphincter contracts, and the sensation of the need to evacuate disappears.

### DIAGNOSIS

#### History and Physical Examination

A detailed history and physical examination is the first step in diagnosing any defecatory disorder. The history should be tai-

lored to the patient's presenting symptoms. All patients should be asked about their current medications, and a history should be sought for all medical problems, especially diabetes, thyroid disorders, scleroderma, multiple sclerosis, stroke, dementia, food intolerance, and inflammatory bowel disease. The evaluation of a female patient with fecal incontinence should include a detailed obstetric history, including the number of vaginal deliveries, tears and episiotomies, unusual presentations, and prolonged labor. Other pertinent points are pad usage and number of accidents, symptoms of urinary incontinence, previous perineal surgery, back injuries, irradiation, and effect of symptoms on sexual behavior. Patients undergoing evaluation for constipation should be specifically asked about the duration of symptoms, the use of digitation to relieve symptoms, and factors that relieve or alleviate symptoms.

Physical examination of a patient with fecal incontinence should focus on the sphincters and pelvic floor. Scars are looked for, and the anal opening is assessed for any gaping. The anocutaneous reflex can be evaluated, providing a crude assessment of the nerves. The patient may then be asked to strain. Perineal descent and prolapsed hemorrhoids or prolapsed rectum should be looked for. A digital rectal examination with the patient squeezing assesses the tone, obvious defects, and muscle fatigue.

For a patient with constipation, the digital rectal examination evaluates increased tone with paradoxical contractions when straining and the presence of an internal intussusception and rectocele. In cases of rectal prolapse, inspection is important to differentiate a true rectal prolapse from prolapsing hemorrhoids, mucosal prolapse, or an anal or rectal polyp.

#### Enema

A tap-water enema in the office is a good and simple test to evaluate the sphincter tone in an incontinent patient. After administering the enema, the nurse documents the time the patient can hold the 100 mL of water. A patient with a suspected rectal prolapse is examined on the commode after the enema is given. The rectal prolapse may be seen while the patient strains on the commode. In a patient with irritable bowel syndrome, it may demonstrate urgency in the presence of normal tone.

#### Anal Physiology Testing

Anal physiology testing has two parts. The first is manometry, which records resting and squeeze pressures and evaluates rectal sensation by documenting the time of first sensation of rectal filling and maximum tolerated volume. Rectal compliance also can be calculated. Paradoxical pressures in the rectum can be

**Figure 78-1** Normal anal ultrasound. EAS, external anal sphincter; IAS, internal anal sphincter.

**Figure 78-3** Defect in the internal and external anal sphincters.

**Figure 78-2** Defect in the external anal sphincter.

recorded during squeeze and strain, and they also can be demonstrated on electromyography by identifying the external anal sphincter contraction. Balloon expulsion tests can demonstrate rectal inertia or loss of coordination among the rectum, pelvic floor, and anal sphincters.

The second part of the test evaluates pudendal nerve terminal motor latency. The test uses the St. Marks electrode and records electrical impulses when the pudendal nerve is stimulated. The amplitude of the wave reflects the voltage, which is low or absent in neurologic disorders.

### Anorectal Ultrasound

Endoluminal ultrasound is the single most important test to demonstrate sphincter defects. The normal sphincter is shown in Figure 78-1. Sphincter defects may be those of the internal anal sphincter or external anal sphincter (Fig. 78-2), or both (Fig. 78-3). Thinning of the internal anal sphincter is easily

demonstrable. After sphincteroplasty, the repaired sphincter can be evaluated with this test.

### Colon Transit Study

Transit studies specifically demonstrate slow-transit constipation. This assessment reflects motility of the colon but not the rectum. The patient swallows capsules with radiopaque markers. The markers are followed on day 1, 2, 4, and 7. Demonstration of markers in the right and left colon on day 7 indicates slow transit of the fecal matter on the right side, supporting a diagnosis of colonic inertia. If markers are aggregated on the left side, the problem may be redundancy of the left colon or outlet obstruction.

### Defecating Proctogram

Patients with constipation and symptoms suggesting obstructive defecation syndrome are subjected to a test in which contrast is instilled in the rectum, small bowel, vagina, and bladder. Patients defecate in a radiolucent commode, and serial radiographs are taken to demonstrate perineal descent, cystocele, enterocele, internal intussusception, and rectal prolapse.

### Dynamic Magnetic Resonance Imaging

Dynamic magnetic resonance imaging (MRI) is a test that replaces the defecating proctogram. Contrast is instilled in the vagina and rectum, and serial MR images are taken with the patient straining. Newer imaging techniques use upright MRI scans with the patient seated and evacuating in the sitting position. This test can evaluate pelvic descent, rectal diameter before and during straining, the width of the pelvic hiatus, presence of enteroceles and sigmoidoceles, and prolapse of the uterus and bladder.<sup>1</sup> It may become the confirmatory test for obstructive defecation. Cine radiography can give a dynamic picture of the process of evacuation, and it can demonstrate prolapse of the anterior wall of the rectum.

## Colonoscopy

All colonic pathology must be excluded before undertaking formal treatment of any defecatory disorder. Colonoscopy should be part of the workup of all patients older than 50 years and patients with any suspicion of mucosal pathology.

## Barium Enema

A barium enema is warranted when the anatomy of the colon needs to be defined. It may be of use in cases of rectal prolapse to demonstrate a redundant sigmoid colon, necessitating a sigmoid colectomy.

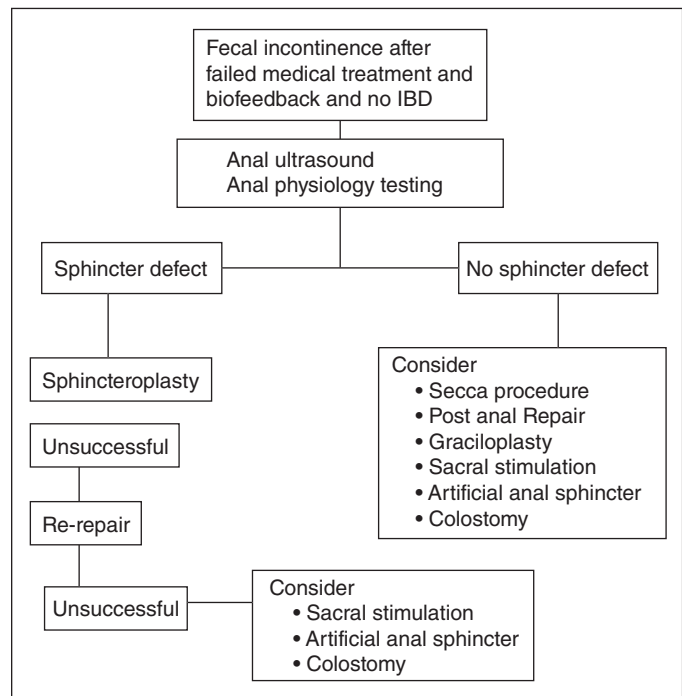

## FECAL INCONTINENCE

### Pathophysiology

Injury to the muscle complex or the nerves that supply them can result in a loss of continence. The most common etiologic factor is childbirth injury. Other causative factors are listed in Table 78-1.

### Treatment of Fecal Incontinence

The treatment of fecal incontinence is based on the severity of symptoms, the anatomy of the sphincter mechanism, and the presence of nerve damage. An algorithm for management is provided in Figure 78-4, but treatment options depend on

**Figure 78-4** Algorithm for the management of fecal incontinence. Sacral stimulation has been used successfully in some centers. Although listed, graciloplasty no longer available in the United States. IBD, irritable bowel disease. \*Sacral stimulation has been used successfully in some centers. \*\*Not available in the US.

the availability of certain procedures and on the patient's comorbidities.

### Treatment of Minor Incontinence

A thorough history and physical examination are the first step in treatment to rule out inflammatory bowel disease, irritable bowel disease, and neurologic disorders. Minor incontinence can be treated with medical management<sup>2</sup> using bulking agents, which can change the consistency of stool and lead to evacuation as a mass movement. They are started in small doses to prevent abdominal distention and bloating, and they are gradually increased to achieve the desired effect. Other agents that are used slow the gastrointestinal motility. They tend to constipate the patients because they decrease the bulk of the stool during the increased transit time. Loperamide hydrochloride (Imodium) is the commonly used medication, and it may be started in doses of 2 mg before breakfast and advanced to a maximum of 16 mg daily as warranted. Diphenoxylate hydrochloride (Lomotil) is another drug that may be used, especially if diarrhea is the main symptom. It is started in doses of 1 tablet once or twice daily and may be advanced to 1 or 2 tablets three or four times daily.

Amitriptyline<sup>3</sup> has been used for idiopathic fecal incontinence. It acts through an anticholinergic mechanism, increasing intrarectal pressures. Phenylephrine cream is an  $\alpha_1$ -adrenergic blocker that has not been approved by the U.S. Food and Drug Administration (FDA). Used in some studies in strengths of 10% to 40%, it has been shown to increase resting pressures for 1 to 2 hours.<sup>4</sup>

Other treatment modalities include the use of regular (even daily) enemas, which evacuate the rectum until it fills again. Bulking agents may be used in conjunction to prevent seepage between enemas.

**Table 78-1** Causes of Fecal Incontinence

#### Sphincter injury

Diarrhea  
Myopathy

### Biofeedback and Kegel Exercises

Kegel exercises are an integral part of the treatment of fecal incontinence, but they are ineffective as the sole treatment. They may benefit to patients with very mild incontinence and those with easy fatigability of the sphincter and no sphincter defect.

Biofeedback training consists of retraining the patient's response using visual, auditory, and sensory stimuli. It consists of strength training of the external sphincter, retraining the sphincter to coordinate rectal distention with external anal sphincter contraction, and sensory training of the rectal mucosa to be able to sense earlier when the rectum receives contents. It is done in the office by a trained therapist using the electromyographic apparatus to retrain and strengthen the sphincter, and a rectal balloon is used for sensory stimulation training. Some studies have shown improvement after biofeedback therapy.<sup>5</sup> Biofeedback has been shown to benefit patients after sphincter repair.<sup>6</sup>

### *Treatment of Moderate Fecal Incontinence with an Intact Sphincter*

#### Secca Procedure

The Secca procedure involves radiofrequency stimulation of the muscular layer of the anal canal and lower rectum. It has been hypothesized that the procedure causes stimulation of collagen deposition and remodeling over time, which can improve symptoms of fecal incontinence.

The procedure is done under conscious sedation. After local anesthesia is injected, radiofrequency is delivered by means of a specialized probe that contains needles that pierce the mucosa and submucosa. In about 64 separate punctures, the radiofrequency is applied beneath the mucosal surface. Contraindications to this procedure include inflammatory bowel disease, a history of depression, collagen vascular disease, acute infections, pudendal neuropathy, and a history of pelvic irradiation.<sup>7</sup>

#### Sacral Stimulation

Sacral nerve stimulation is FDA approved in the United States for stress urinary incontinence, and it is being evaluated under a research protocol for fecal incontinence. It produces constant stimulation of the sacral nerves, resulting in an increase in resting tone and squeeze pressures. In this procedure, a temporary stimulator is implanted as a first step, and if the patient improves, a permanent device is implanted. It has gained popularity in Europe, where it has been available for many years.<sup>8</sup>

#### Perianal Bulking Agents

Bulking agents instilled in the perianal area are being studied.<sup>9</sup> They work by increasing the internal bulk of the sphincter, preventing seepage of stool. An optimal bulking agent should be nonbiodegradable, should not migrate, and should be removable if the need arises.

### *Treatment of Moderate to Severe Fecal Incontinence due to a Defect in the Sphincter Mechanism*

#### Overlapping Sphincter Repair: Sphincteroplasty

Any fixable defect of the sphincter complex should be considered for repair. Because it is difficult to determine which patient will benefit, consideration should be given to all those with a defect.

The technique involves a semicircular incision about 1 to 1.5 cm beyond the anal verge. For obstetric injuries, this arc spans about 200 degrees in a semicircular fashion, mirroring the anus. The branches of the pudendal nerves that innervate the external

sphincter approach the muscle from the posterolateral position. To avoid nerve injury, the arc of the incision should not extend to the extreme posterolateral position. The rectovaginal septum is dissected, and care is taken to avoid making buttonhole defects in the anal canal or rectum. Occasionally, the only part of the perineal body that remains is the vaginal and anal mucosa, and dissection in this situation can be difficult.

The dissection is carried laterally to the ischioanal fat. A finger placed in the vagina or rectum and dissecting from lateral to medial may facilitate the dissection. Any tears in the anal mucosa are repaired with 4-0 chromic suture. The ends of the sphincter are usually dissected with scar in the midline (or mid-portion of the injury). This scar is divided in the middle, leaving two ends of sphincter with scar attached. It is important to divide the scar but to not trim it from the ends of the sphincter, because this will provide tensile strength when the repair is done. If the internal and external muscles are injured, it is preferable to repair them as one unit. If the internal sphincter is intact, divide and repair only the external sphincter.

The levator ani muscles may be plicated at this point using 1-0 or 2-0 delayed absorbable sutures. This may lengthen the anal canal. The vagina should be checked after the levator plication to ensure that a ridge or narrowing did not occur with levator plication, because this may contribute to dyspareunia. If the internal anal sphincter was intact, plication can be done before the sphincteroplasty if there is redundant internal sphincter.

The sphincter ends that have been sufficiently mobilized to allow overlapping of the muscle are grasped. Some authorities<sup>10,11</sup> advocate merely approximating the muscles, but if possible, overlapping the muscle ends is preferred using 2-0 polyglactin sutures, placing mattress sutures for the sphincteroplasty. Approximately six sutures (three on each side) are used. The repair tightens the anal canal such that only an index finger may be admitted. During the procedure, the wound may be irrigated with antibiotic solution. The skin edges are closed in a V-Y fashion, starting laterally and leaving the center open for drainage. If there is a significant amount of dead space, a 0.5-inch Penrose drain can be inserted and then removed postoperatively.

Postoperatively, we keep patients on intravenous antibiotics for 2 to 3 days and withhold oral intake. Because sitz baths macerate the skin edges, they are avoided, but showers are permitted. We do not use constipating drugs. The Foley catheter is removed on postoperative day 2, and the patient is allowed a high-fiber diet just before discharge. At discharge, patients are placed on Metamucil, Citrucel, or Konsyl daily. Additionally, they take 1 ounce of mineral oil each morning. If they do not move their bowels by postoperative day 7, they take 1 ounce of milk of magnesia twice daily until their bowels begin to function. Because they undergo a complete bowel cleansing before surgery, patients may not move their bowels for several days after surgery.

A diverting stoma is used at the discretion of the surgeon. Preoperatively, this should be discussed with patients who have had previous failed repairs, have concomitant inflammatory bowel disease, have severe diarrhea, or need an extremely complicated repair. A stoma does not ensure success but may aid a successful outcome in such patients.<sup>12</sup>

Initial functional improvement can be anticipated in 80% to 90%<sup>13-15</sup> of patients. Pudendal nerve damage is associated with suboptimal results.<sup>13</sup> Age does not seem to significantly affect results,<sup>12</sup> although erratic bowel problems such as urgency and diarrhea may lead to continued incontinence. Wound infection occurs in up to a fourth of patients<sup>15</sup> but does not usually adversely

affect the outcome unless the sphincter repair sutures become disrupted. Complete disruption of the skin sutures usually heals by secondary intention with adequate wound care.

Long-term follow-up suggests that about 40% of patients undergoing a repair are expected to be continent without further surgery.<sup>16</sup> In patients needing a repeat overlapping sphincter repair due to disruption of the initial repair, evidence suggests that satisfactory outcome can be achieved.<sup>17</sup>

### Dynamic Graciloplasty

Graciloplasty is no longer available in the United States, because the stimulator is no longer supplied by the manufacturer. Indications for this procedure include sphincter defects from obstetric or traumatic injury, congenital defects, and idiopathic incontinence. Contraindications are diseases with a neurologic basis, such as multiple sclerosis. Dynamic graciloplasty has been an excellent choice for patients who have no alternative but to have a stoma. Success has been reported in about 40% to 65% of patients undergoing this procedure.<sup>18,19</sup>

### *Treatment of Moderate to Severe Incontinence with an Intact Sphincter and No Neurologic Deficit*

#### Postanal Repair

Postanal surgical repair is indicated in patients with an intact sphincter but no neurologic incontinence.<sup>20</sup> The aim of this procedure is to increase the length of the anal canal, reestablish the anorectal angle, and tighten the anal canal.

The operation is done through an inverted-V-shaped incision made 5 to 6 cm from the anal verge posteriorly. Flaps are raised, and the intersphincteric plane is identified. Dissection is carried in this plane cephalad to Waldeyer's fascia, which is divided to expose the mesorectal fat. Figure-of-eight, 2-0 polypropylene sutures are placed to draw the two sides of the iliococcygeus muscle together. The sides do not approximate because of the distance, and the sutures are tied with minimal tension to form a lattice. The pubococcygeus muscle is the next muscle encountered. Sutures are placed and tied to again to form a lattice, especially posteriorly, although anteriorly, the ends may be approximated. The last layer plicated is the puborectalis and external sphincter. The skin is closed with absorbable suture in a V-Y fashion. Postoperative care is similar to that for sphincteroplasty. Postanal repair has lost popularity because of poor overall improvement results.

### *Treatment of Severe Fecal Incontinence due to Failed Repairs or Neurologic Causes*

#### Artificial Anal Sphincter

The artificial anal sphincter evolved from the artificial urinary sphincter. The device has three parts. The first is an inflatable cuff that encircles the anal orifice. The second is a pump with a valve that controls the fluid entering and exiting the cuff. It is placed in the labia or the scrotum. The third part a balloon that is placed in the space of Retzius. When the valve is activated, fluid flows from the cuff to the balloon, allowing defecation. Over the next 7 minutes, reverse flow from the storage balloon to the anal cuff produces occlusion of the anus. If evacuation is incomplete, the valve can be activated again.

Continence is restored completely in the immediate postoperative period. The main problems associated with this procedure are the rate of infections and device malfunction. These problems can affect as many as 33% of patients, even after a period of learning how to operate the device.<sup>21,22</sup>

### Colostomy or Ileostomy

When the symptoms are severe, the quality of life is greatly affected, and all other avenues have been unsuccessfully explored, a colostomy or ileostomy is a viable option. Although this procedure may sound drastic, it improves the quality of life for these patients, who otherwise become prisoners in their homes.

## CONSTIPATION

### Pathophysiology

It is difficult to define constipation. It often is defined by reference to bowel frequency, because this is the most convenient way to assess and document the condition. Bowel frequency of less than three movements per week is considered to be constipation, but this is not the only criterion. Excessive straining at stools and hard stools are other symptoms that should be considered.

The pathophysiology of constipation is disordered motility of the colon and rectum rather than delayed motility. The transit time may not be vastly delayed, but the patient may be still be constipated.

The many causes of constipation are listed in Table 78-2. It is important to differentiate constipation from obstructive defeca-

**Table 78-2 Causes of Constipation**

#### Idiopathic causes

##### Drugs

- Antidepressants
- Anticholinergics
- Antispasmodics
- Antipsychotics
- Iron supplements
- Calcium
- Antacids
- Opiates
- Antihypertensives
- Anticonvulsants

#### Metabolic causes

- Diabetes mellitus
- Hypothyroid
- Hypercalcemia
- Pregnancy

#### Neurogenic causes

- Hirschsprung's disease
- Neurofibromatosis
- Hypoganglionosis
- Intestinal pseudo-obstruction
- Ganglioneuromatosis

#### Neurologic causes

- Spinal cord lesions
- Parkinson's disease
- Trauma to nervi erigentes
- Multiple sclerosis

#### Collagen and vascular disorders

- Dermatomyositis
- Systemic sclerosis
- Amyloidosis

tion syndrome because this changes the workup and treatment of these patients. A thorough history should include associated symptoms such as cramping, bloating, straining, use of digitation and pressure around the anus or in the vagina during evacuation, medications, presence of metabolic disorders, and cerebral and neurologic causes. The physical examination should include a digital rectal examination, which assesses prolapse of the anterior rectal wall, paradoxical contractions of the anal muscles, and rectal lesions.

Most patients are referred to a surgeon after exhausting all medical treatments. A full workup includes excluding all metabolic causes listed in Table 78-2. Colon transit studies using radiopaque markers (i.e., sitz markers) are ordered for all patients with long-standing constipation not responding to medical treatment. Anal manometry is ordered for patients in whom an outlet obstruction is suspected. Manometry can demonstrate paradoxical contractions of the anal muscles, which may respond to biofeedback training. For patients suspected of having rectal prolapse or obstructive defecation syndrome, a defecating proctogram or dynamic MRI may be helpful. These studies provide valuable information regarding rectal dilatation during straining, pelvic descent, and the presence of obstructing sigmoidoceles or enteroceles. In patients with suspected adult Hirschsprung's disease, a full-thickness biopsy is indicated for diagnosis if a rectal anal inhibitory reflex is not helpful (done as a part of anal manometry).

### Medical Management

Recent-onset constipation may be treated with diet modification; increasing fiber with bulk laxatives (containing psyllium); saline laxatives such as magnesium citrate, magnesium sulfate, and hyperosmolar laxatives such as lactulose, sorbitol, and polyethylene glycol. Emollient laxatives such as mineral oil, docusate salts, stimulant laxatives such as castor oil, anthraquinones (e.g., senna, cascara sagrada, phenolphthalein, and bisacodyl) are avoided for long-term use. Patients who have paradoxical contractions can be treated with biofeedback sessions<sup>23</sup> and can be taught to use the right muscles to be able to initiate the process of defecation.

### Surgical Management

For patients who have exhausted medical treatment, surgical treatment requires defining the problem as colonic inertia or obstructive defecation. The algorithm for treatment is provided in Table 78-2. Long-standing constipation due to colonic inertia is treated with a total colectomy with an ileorectal anastomosis or occasionally with a cecorectal anastomosis. Because preservation of the sigmoid colon is associated with postoperative constipation,<sup>24,25</sup> an ileosigmoid anastomosis is not considered a good option. Laparoscopic colectomy is gaining popularity because of the decreased morbidity, shorter hospital stay, and better cosmetic result.<sup>26,27</sup> Patients who undergo colectomy with ileorectal anastomosis have increased number of bowel movements, although many patients complain of incontinence and persistent symptoms of abdominal pain and bloating.<sup>28</sup> Quality-of-life scores are usually not elevated although the symptoms of constipation are successfully treated.<sup>29,30</sup>

A less popular procedure is the antegrade continent enema (ACE) described by Malone in 1990. This procedure was described for children and later used in adults.<sup>31</sup> Through a surgically con-

structed retrograde appendicostomy, washout of the colon is accomplished, although it can also induce high-amplitude waves and mass movement. Although this procedure has good results, it is marred by complications such as intestinal obstruction and perforation, and it may require many surgical revisions.

A newer technique that is showing potential in treating constipation is neuromodulation. Sacral nerve stimulation, which is unavailable in the United States, has produced some promising results in studies conducted in Europe.<sup>32</sup> Further research and newer techniques in neuromodulation may be the future treatment of choice for colonic inertia.

Patients with obstructive defecation may respond to biofeedback,<sup>33</sup> relaxation therapy, and retraining. This requires a dedicated therapist and a motivated patient. Results of biofeedback therapy are encouraging in carefully selected patients.<sup>23</sup> Those with symptoms that do not respond to biofeedback have been improved with the stapled transanal rectal resection (STARR) procedure.<sup>34</sup> This is widely used in Europe and uses a circular stapler to excise a full thickness of the rectal wall at a distance of about 6 to 9 cm from the anal verge.

Surgery for constipation is appropriate for only selective patients and in patients with severe symptoms. Patients usually dictate the timing of the surgery, but they should be warned that not all preoperative symptoms are relieved. Usually, bowel frequency is a symptom that does improve.<sup>30</sup> Figure 78-5 is an algorithm for management of patients with chronic constipation.

## IRRITABLE BOWEL SYNDROME

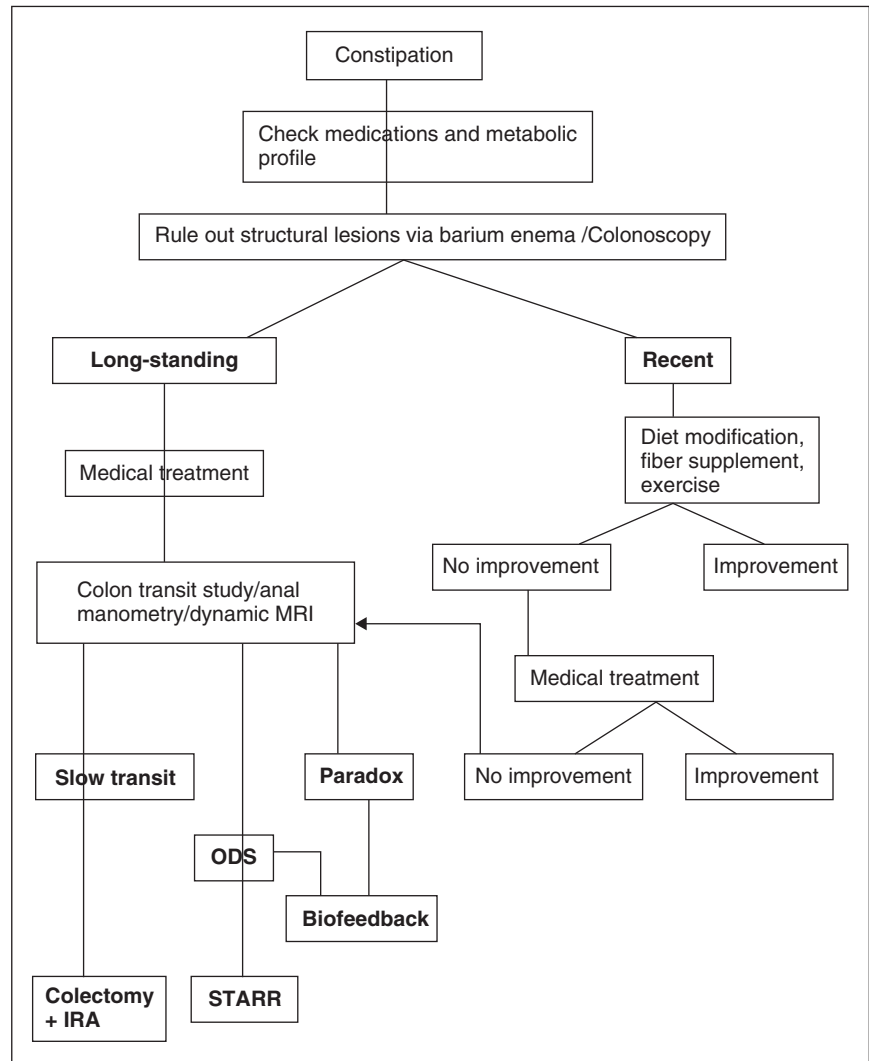

### Pathophysiology

Irritable bowel syndrome (IBS) is a disease of symptoms with no single pathologic entity. The prevalence has been estimated at 10% to 15% in the Western population,<sup>35,36</sup> with only 3.3% being medically diagnosed.<sup>37</sup> The Rome II criteria are commonly used (Table 78-3).<sup>38</sup> The common symptoms are abdominal pain and altered bowel habits. Patients can develop symptoms with diarrhea (IBS-D) or constipation (IBS-C) as a predominant symptom or have a combination of diarrhea and constipation. There have been no studies that demonstrate a change in myoelectric activity in the colon and small intestine. Current studies are focusing on the role of visceral sensory abnormalities in IBS.<sup>39</sup>

This disease has been associated with various emotional disorders, and this has led to the speculation of being associated with a disorder of the central nervous system. However, it is uncertain whether this is a primary central nervous system disorder that affects gut motility or a primary gut disorder with inappropriate input from the central nervous system.<sup>40</sup> Associations between sexual and physical abuse,<sup>41</sup> abnormal psychiatric features,<sup>42</sup> and IBS have been reported. Other factors are a history of prior gastrointestinal infection, malabsorption, and food intolerance.

### Treatment of Irritable Bowel Syndrome

The diagnosis of IBS is essentially one of exclusion of organic causes. A workup should include a thorough history and physical examination, a complete blood cell count, sedimentation rate, thyroid profile, and stool analysis for parasites. For patients with diarrhea-predominant symptoms, a hydrogen breath test to rule out lactose intolerance is considered. IBS has been known to remit spontaneously.

**Figure 78-5** Algorithm for the management of chronic constipation. IRA, ileorectal anastomosis; MRI, magnetic resonance imaging; ODS, obstructive defecation syndrome; STARR, stapled transanal rectal resection.

### Diet

The treatment of IBS is frustrating for the physician and the patient because it consists of a trial-and-error approach. The initial management is dietary guidance and counseling. It is important to have an in-depth dietary history that rules out food allergies, lactose intolerance, foods that cause increased gas production, and foods that induce an immune response, which contribute to mucosal inflammation.

Diet is modified in accordance with symptoms. Fiber may help constipation-prone patients, and limiting fiber, salads, fresh fruit, and some vegetables may help those that are diarrhea prone. However, most patients with IBS rarely adhere to a strict dietary or supplementary regimen.<sup>43</sup> Foods commonly found to help patients when excluded from the diet are milk, eggs, and wheat and, less commonly, coffee, nuts, and peas. Exclusion of wheat, potatoes, onions, and dairy products has been shown to decrease the amount of gas production. Lactose-free diets have not had any benefit in adult patients, except in selected groups of patients or cultures<sup>44</sup> (e.g., Norwegian) in which the lactose intake is high.

### Drugs Causing Decreased Bowel Motility

Antidiarrheal agents have been widely used in IBS-D patients. They delay transit time, increase anal pressures, and decrease rectal sensation, causing the stool to be dehydrated. Loperamide

is the most commonly used antidiarrheal and has been shown to decrease fecal urgency, borborygmi, and diarrhea.<sup>45</sup> Other agents commonly used are cholestyramine, which is a resin that binds bile acids, and ondansetron,<sup>46</sup> which is a serotonin receptor antagonist.

Antispasmodic agents have a wide application in IBS. They range from anticholinergics such as dicyclomine to calcium channel blockers and peppermint oil, which is a naturally occurring carminative.

### Drugs for Irritable Bowel Syndrome with Constipation

The 5-hydroxytryptamine type 4 (5-HT<sub>4</sub>) receptor agonist tegaserod stimulates peristaltic activity and increases small and large intestinal transit time. The dosage used has been (6 mg twice daily) has provided significant improvement of bloating, abdominal discomfort, and constipation (during first and repeated symptoms).<sup>47,48</sup> The common side effects are diarrhea and headaches.

### Antidepressants

Amitriptyline has been used in the IBS-D patients. In addition to its mood-lifting activity, it has a physiologic effect by inhibiting the motor activity of the gut. These effects are particularly helpful in patients with pain-predominant symptoms.

**Table 78-3 ROME II Criteria for the Diagnosis of Irritable Bowel Syndrome**

For at least 12 weeks (which need not be consecutive) of the preceding 12 months, abdominal discomfort or pain that has two of three of the following features\* †

1. Pain relieved with defecation
2. Onset of pain associated with a change in frequency of stool
3. Onset of pain associated with a change in form (appearance) of stool

Symptoms that cumulatively support the diagnosis of IBS

1. Abnormal stool frequency (more than three bowel movements per day; less than three bowel movements per week)
2. Abnormal stool form (lumpy or hard; loose or watery)
3. Abnormal stool passage (straining, urgency, or feeling of incomplete evacuation)
4. Bloating or feeling of abdominal distention

Symptoms are *not* typical of IBS

1. Pain that awakens or interferes with sleep
2. Diarrhea that awakens or interferes with sleep
3. Blood in the stool (visible or occult)
4. Weight loss
5. Fever

Symptoms that further aid the diagnosis of IBS

- A. Fewer than three bowel movements a week
- B. More than three bowel movements a day
- C. Hard or lumpy stools
- D. Loose or watery stools
- E. Straining during a bowel movement
- F. Urgency
- G. Feeling of incomplete bowel movement
- H. Passing mucus during a bowel movement
- I. Abdominal fullness, bloating, or swelling

Categorization of IBS based on symptoms‡

Diarrhea-predominant IBS: At least one of B, D, and F but none of A, C, and E, or at least two of B, D, and F plus one of A or E

Constipation-predominant IBS: At least one of A, C, and E but none of B, D, and F, or at least two of A, C, and E plus one of B, D, and F

\*Rome I criteria not included in this algorithm. The diagnosis of IBS relies on meeting Rome II inclusion criteria (updated by Rome III criteria) and excluding other illnesses based on the history, physical examination, and laboratory testing.

†In addition to meeting these positive criteria, patients have initial laboratory testing with a complete blood cell count, basic chemistry panel, and an erythrocyte sedimentation rate. The diagnostic accuracy for IBS is more than 95% when the Rome II criteria are met, the history and physical examination results do not suggest any other cause, and initial laboratory test results are negative.

‡An update to these criteria was issued at the Rome III conference and published in May 2006. The preferred terms were changed to IBS with diarrhea (from diarrhea-predominant IBS) and to IBS with constipation (from constipation-predominant IBS). In this categorical system, many people whose features place them close to a subtype boundary (e.g., IBS with alternating stool pattern) can change pattern without a major change in pathophysiology.

### Other Drugs

Prokinetic drugs such as cisapride (which has been taken off the market) have been used in IBS-C patients.<sup>49</sup> Other drugs that have been used are anxiolytics, antispasmodics, and mast cell degranulation inhibitors such as disodium cromoglycolate. Probiotics have been studied, and the results are conflicting.<sup>50</sup> The probiotic commonly used is *Lactobacillus plantarum*.

Alosetron (Lotronex), a 5-HT<sub>3</sub> receptor antagonist, decreases small and large intestine motility and transit time. It has been used to treat severe IBS-D patients for control of diarrhea and abdominal discomfort.<sup>51,52</sup> The use of alosetron has been limited because of its association with ischemic colitis<sup>53</sup> and serious complication of constipation.<sup>54</sup>

### Other Therapies

Other treatment modalities that have been helpful are relaxation therapy,<sup>55</sup> psychotherapy,<sup>56</sup> and hypnotherapy.<sup>57</sup> Patients with IBS frequently present with symptoms of constipation or fecal incontinence. These patients most often fail surgical corrections unless the symptoms of IBS are brought under control first.

## RECTAL PROLAPSE

Overt rectal prolapse is the prolapse of the entire thickness of the rectal wall through the anal orifice. This is usually a problem seen in older women. A multitude of treatment modalities have been described, highlighting the fact that treatment is controversial and that no one treatment or surgery is entirely successful.

### Etiopathology

The cause of rectal prolapse is unknown, but several theories have been postulated. The first of these, described by Moschowitz,<sup>58</sup> attributes rectal prolapse to a sliding hernia through a defect in the pelvic fascia. The second theory by Brodin and Snellman<sup>59</sup> postulates that rectal prolapse is an intussusception of the rectum starting about 3 inches above the anal verge. Radiologic findings that the prolapse starts well above the pelvic floor rules out the possibility of this being a sphincter disorder. Predisposing factors are intractable constipation, chronic diarrhea, neurologic diseases, anatomic defect due to pregnancies, previous surgeries, and psychiatric illness.

Rectal prolapse has been categorized as complete or full-thickness (Fig. 78-6) wall prolapse through the sphincters or intussusception that has not protruded beyond the sphincter complex. It should be differentiated from mucosal prolapse (Fig. 78-7).

### Workup

The confirmatory test is a clinical demonstration of a rectal prolapse and the exclusion of prolapsing hemorrhoids. Other tests are done for associated symptoms and to rule out colonic pathology. These tests may include a barium enema to look for a redundant colon, anorectal manometry and dynamic MRI (when obstructive defecation is suspected), transit studies in patients with constipation, and a colonoscopy.

### Treatment of Rectal Prolapse

The earliest operation for rectal prolapse was described by Thiersch in 1891. It involved encircling the anus with a silver

Figure 78-6 Complete rectal prolapse.

Figure 78-7 Mucosal prolapse of rectum.

wire, thereby decreasing the anal opening. This procedure has largely been abandoned.

The current operative procedures are divided into abdominal and perineal procedures. The abdominal procedures are based on fixing the rectum to the sacrum; the perineal procedures aim at excision of the prolapsed rectum.

### Abdominal Procedures

The principles of abdominal procedures are based on rectal mobilization and fixation, with or without resection of the sigmoid colon based on the patient's symptoms. Rectal mobilization is described subsequently, and the various methods of rectal fixation are discussed.

#### Abdominal Mobilization of the Rectum

Rectal mobilization is carried out through a Pfannenstiel or midline incision. The extent varies among surgeons but usually involves posterior mobilization to the coccyx and incision anteriorly to the upper third of the vagina. Lateral mobilization is controversial, and at least one lateral stalk may be preserved to avoid new evacuation problems.

#### Rectal Fixation

Rectal fixation can be achieved by using mesh (i.e., Ripstein's procedure) or a foreign material (i.e., Ivalon sponge repair) or suture rectopexy.

Ripstein's procedure is more frequently done outside the United States. Ripstein and Lante<sup>60</sup> thought that the rectal prolapse was caused by loss of attachment of the rectum, which makes it lose its posterior curvature and become a straight tube. Massive straining causes the rectal walls to intussuscept, which begins at the rectosigmoid junction and finally protrudes through the anus. They did not believe that the pelvic defects were the primary cause and did not see the need to repair them. Rectal fixation was achieved initially by fascia lata and later changed to Marlex mesh<sup>61</sup> and Gore-Tex mesh.<sup>62</sup>

In this procedure, the rectum is mobilized to the tip of the coccyx posteriorly. The lateral stalks may be divided. The free end of a 5-cm Marlex or Gore-Tex mesh is fixed to the sacrum with nonabsorbable sutures, which are placed 1 cm from the midline, taking care to avoid any presacral bleeding. The mesh is wrapped around the rectum anteriorly, and the free end is sutured to the other side in a similar fashion. The sling should be loose enough to admit two fingers. The peritoneum is then closed over the sling.

Intraoperative complications of this procedure include presacral bleeding. Postoperative complications include hemorrhage and pelvic abscesses.<sup>63</sup> Late complications include persistent constipation, new onset of constipation, recurrence, erosion of the mesh, and strictures. The recurrence rate has been cited as 2% to 10%.<sup>64,65</sup> Some investigators<sup>66</sup> have recommended this procedure be performed with a sigmoid resection in patients with a long-standing history of constipation. However, others are hesitant to resect large intestine in the face of introducing mesh at the same procedure.<sup>63</sup>

Ivalon sponge repair was described by Wells<sup>67</sup> in 1959 and was popular in Europe. After rectal mobilization, a rectangular piece of Ivalon sponge is moistened and fixed to the sacrum in the midline using nonabsorbable sutures. The mobilized rectum is then pulled upward in front of the sponge, and the sponge is wrapped around the rectum and sutured to the anterior wall, leaving one third of the circumference free anteriorly. The sponge is then buried under the peritoneum.

The predominant complication is pelvic abscess, which occurs in about 16% of the patients.<sup>68</sup> Even though an abscess usually necessitated removal of the sponge, inflammatory scarring of the rectum on many occasions fixes the rectum to the sacrum, thereby curing the prolapse. This procedure is not performed in the United States.

Suture rectopexy was first described by Pemberton and Stalker.<sup>69</sup> It fixes the rectum to the sacrum posteriorly. After mobilization of the rectum posteriorly, proctopexy is achieved using two or three nonabsorbable sutures on either side to fix the rectum to the presacral fascia, taking care to avoid the presacral vessels, which can result in bleeding.

Suture rectopexy has been associated with a mortality rate of 0% to 6.7% and a recurrence rate of 0% to 20%.<sup>70</sup> In many, the incontinence decreases in time after rectopexy.<sup>71</sup>

#### Abdominal Rectopexy with or without Resection of the Sigmoid Colon

Sigmoid resection alone has not been popular for rectal prolapse. However, resection of the sigmoid colon has been advocated when constipation is a predominant symptom preoperatively

and a redundant sigmoid colon has been demonstrated by imaging studies. In some cases, this improves after sigmoid resection.<sup>72</sup> Resection and the subsequent fibrosis that occurs in the area of the anastomosis may add to the fibrosis that occurs with a rectopexy.

### Laparoscopic Rectopexy

The laparoscopic approach is theoretically similar to the open procedure, and results should be comparable, but the technique is still evolving. The advantage of the laparoscopic technique is a reduction in pain at the incision site and hospital stay.<sup>73</sup> Laparoscopically assisted rectopexy has acceptable results, with a morbidity rate of 9%, leak rate of less than 1%, and a recurrence rate of 2.5% for a full-thickness and 18% for a mucosal prolapse.<sup>74</sup> Studies have demonstrated that laparoscopic resection has a short-term benefit in the length of stay and is comparable to open prolapse surgery in the long term for continence and constipation and recurrence rates.<sup>14</sup>

### Perineal Procedures

#### Perineal Rectosigmoidectomy

Perineal rectosigmoidectomy was initially described in 1889 and popularized by Miles<sup>75</sup> in 1933. Subsequently, Altemeier<sup>76</sup> championed its use in the United States. The indication for surgery is the high-risk individual who may not tolerate the anesthesia needed for an abdominal approach. Some institutions have advocated this approach for young men in whom the abdominal procedures may carry a higher risk of sexual dysfunction.<sup>77</sup>

It can be done under local, regional, or general anesthesia in the lithotomy position. The anastomosis can be hand-sewn or stapled. A circumferential incision is carried out 1 to 2 cm above the dentate line, and of the rectum is mobilized. The mesentery of the rectum is clamped and divided until the bowel cannot be pulled down anymore. The bowel is then transected and anastomosed to the distal cut end. Before the anastomosis, the levator muscles may be plicated in an effort to lengthen the anal canal to improve continence.

Complications include bleeding from the suture line, dehiscence of the suture line, anastomotic stricture, injury to the small bowel, and an increase in morbidity due to pulmonary and cardiac complications in fragile patients.<sup>78</sup>

#### Delorme Procedure

The Delorme<sup>79</sup> procedure is another perineal procedure. It has become more popular in recent years. A circular incision is made in the mucosa about 1 cm above the dentate line, and the mucosa is carefully lifted away, taking care to cauterize any bleeding vessels on the way. This continues until there exists no further redundancy. The redundant mucosa is amputated, and the

mucosal ends are then brought together and sutured. Recurrence rates vary from 5% to 20%.<sup>80</sup>

### Abdominal versus Perineal Procedures

The abdominal procedure is the procedure of choice for the medically fit patient in most institutions because of the lower recurrence rates. Perineal procedures are usually offered to frail patients with comorbidities. The choice of perineal procedure usually rests with the surgeon and depends on his or her level of experience. The perineal rectosigmoidectomy has a lower recurrence rate than the Delorme procedure.<sup>81</sup> The Delorme procedure may be a choice when there is insufficient length to do a perineal rectosigmoidectomy. Concomitant levatoroplasty after a perineal rectosigmoidectomy has been shown to improve continence.<sup>81</sup>

The most common abdominal procedure is rectopexy with or without resection. The abdominal procedures are associated with better continence than the perineal procedures.<sup>82</sup> Suture rectopexy has acceptable results, and the addition of mesh posteriorly does not seem to offer any distinct advantage. The addition of a sigmoid resection is of value in patients with a redundant colon and symptoms of constipation. The Ivalon sponge has been associated with an increase in infection and has been abandoned. The Ripstein's procedure has been associated with new-onset constipation due to the mesh configuration. Laparoscopic rectopexy is gaining popularity, and with time and development of new instruments, it will be performed more.<sup>73</sup>

Emphasizing the mental algorithm in approaching patients with rectal prolapse Kim and colleagues<sup>83</sup> reviewed 188 perineal rectosigmoidectomy and 160 abdominal rectopexy patients. They found no significant differences in morbidity but found a higher recurrence rate with perineal procedures.

Recurrent rectal prolapse is treated by a repeat repair, and both abdominal and perineal repairs have been advocated. However, care should be taken to delineate the previous anastomosis. It is important to consider all previous operations in an attempt to avoid rendering a section of bowel ischemic due to division of blood vessels at the previous repair.

## CONCLUSIONS

Evaluation of the individual patient is the key to treating defecatory disorders and fecal incontinence. There is no perfect cure for these ailments, and much patience and time goes into making a diagnosis and reaching an individual treatment plan that can help these patients. Newer treatment options are emerging, and the modalities of treatment may change in the future.

# URETHROVAGINAL FISTULA

*Jason P. Gilleran and Philippe E. Zimmern*

Urethrovaginal fistula (UVF) presents a challenging diagnostic and therapeutic dilemma for the reconstructive surgeon. Because of its uncommon occurrence, much of what is known about this entity is derived from small series and case reports. Consequently, most UVFs are seen and treated in specialized centers, whether they manifest alone or in combination with a vesicovaginal fistula. The underlying cause, number of prior repairs, and damage to the continence mechanism are key factors in approaching the patient with a UVF. This chapter reviews the common causes, diagnostic modalities, and therapeutic options for UVFs.

### ETIOLOGY

#### Postoperative Iatrogenic Factors

Traumatic fistulas resulting from obstetric deliveries account for most UVFs in underdeveloped nations, whereas in industrialized nations,<sup>1</sup> UVFs occur as a complication of urethral diverticulectomy, anterior colporrhaphy, or other periurethral procedures. Some direct injuries are recognized at the time of the original surgery. In this instance, closure of the urethral lumen without verifying water-tightness, overlapping suture lines, lack of consideration for tissue interposition, insufficient bladder drainage, or a combination of these factors can contribute to the secondary formation of a UVF. Indirect mechanisms are less common but have been reported after periurethral collagen injection<sup>2</sup> and an anterior colporrhaphy during which tight suburethral plication resulted in tissue necrosis and secondary fistula formation.<sup>3</sup> An unrecognized urethral injury, which can occur during urethrolisis and particularly in the setting of dense periurethral scar tissue after a sling procedure, is another indirect mechanism. Most contemporary series on synthetic slings using tension-free vaginal tape or transobturator tape report a low incidence of urethral injuries and secondary urethral erosions, which can result in UVFs.<sup>4-6</sup>

#### Radiation Therapy

Although the incidence of vaginal fistulas occurring after irradiation for pelvic malignancies is significantly lower than in the past because of technical advances in radiation delivery, the profound long-term effects of radiation on surrounding tissues can promote fistula formation. Repair with flap interposition should be considered, but a supravescical diversion may be the only remaining option for heavily radiated tissues.

#### Other Causes

Vaginal lacerations after pelvic trauma, if ignored or inadequately repaired, can lead to UVF formation. Primary closure of vaginal

lacerations is advocated to prevent fistula formation; regardless of the approach, these lacerations are susceptible to wound dehiscence if not properly débrided before repair.<sup>1</sup> Although rare, a neoplasm arising from a urethral diverticulum<sup>7</sup> can extend locally and manifest as a UVF. Likewise, radiation therapy for urethral cancer can lead to tumor necrosis and a secondary UVF.

### DIAGNOSIS

#### History and Physical Examination

Presenting symptoms may provide some insight as to the location and size of a UVF. Fistulas distal to the urethral continence mechanism may be entirely asymptomatic, or they may manifest as a split urinary stream or vaginal voiding. Occasionally, recurrent urinary tract infections are the main presenting symptoms. Women with larger fistulas or with fistulas involving the proximal urethra and bladder neck region present with continuous incontinence. It is important to review the prior operative notes, evaluate tissue quality (i.e., multi-operated, densely scarred, or atrophic tissues), and look for risk factors for deficient healing (e.g., immunosuppression, malnutrition, irradiation). Physical examination should identify the size and location of the fistula and any other associated fistulas or tissue changes. However, smaller tracts may be challenging to recognize, requiring endoscopy and imaging for exact determination. In some cases, a high index of suspicion despite thorough negative investigations may lead to urethrocytoscopy under anesthesia to establish the diagnosis.

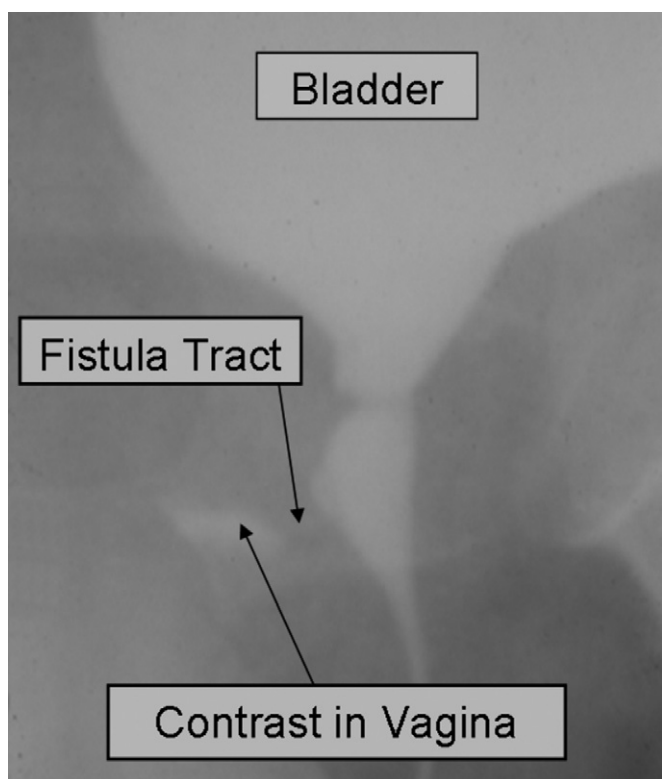

#### Imaging

Visualization of the fistula tract may be accomplished by voiding cystourethrography<sup>8,9</sup> or by double-balloon urethrography, but these techniques require high resolution to see the tract and true lateral views (Fig. 79-1). Upper tract imaging may be necessary for large or multiple fistulas to exclude ureteral obstruction or an associated ureterovaginal fistula. Urethral magnetic resonance imaging is of limited benefit to identify a fistula tract and is occasionally helpful in case of suspected residual diverticulum pocket associated with a UVF after urethral diverticulectomy.

#### Endoscopy

Direct visualization of the fistula opening on the floor of the urethral lumen with a short-beaked female urethroscope or a flexible scope can confirm the diagnosis.<sup>10</sup> It is important to document the size of the opening and its location in the urethra in relation to the continence mechanism. The status of the bladder neck, trigone, and ureteric orifices should be observed, as well as the condition of the surrounding tissues for changes

**Figure 79-1** Lateral view from voiding cystourethrography (VCUG) of a woman with a urethrovaginal fistula at the mid-urethra demonstrates a fistula tract, with contrast seen in the vagina. Good resolution and true lateral voiding films are important in visualizing the tract on VCUG.

suggesting inflammation or neoplasm. A biopsy may be indicated for friable and irregular fistula edges or in case of a palpable induration around the fistula site. After vaginal laceration or urethral tear, the urethra may be completely strictured and the UVF located proximal to the site of urethral injury. Transvaginal endoscopy can help accessing the fistula tract and possibly the bladder by advancing a small flexible scope through the tract.

## MANAGEMENT

The decision on how and when to best manage a UVF largely depends on the cause of the fistula, the quality of the surrounding tissues, the correction of risk factors for poor tissue healing whenever possible, and the number of prior repairs. Experience with urethral reconstruction procedures is paramount to achieving a good technical outcome. A large armamentarium of additional procedures to secure continence and prevent fistula recurrence should be available to the repairing surgeon.

## Observation

Small fistulas in the distal urethra may be discovered incidentally and observed if minimally or asymptomatic. Spontaneous resolution of UVF with short-term catheter drainage has been reported.<sup>11</sup> Most patients, however, choose surgical repair.

## Table 79-1 Perioperative Checklist

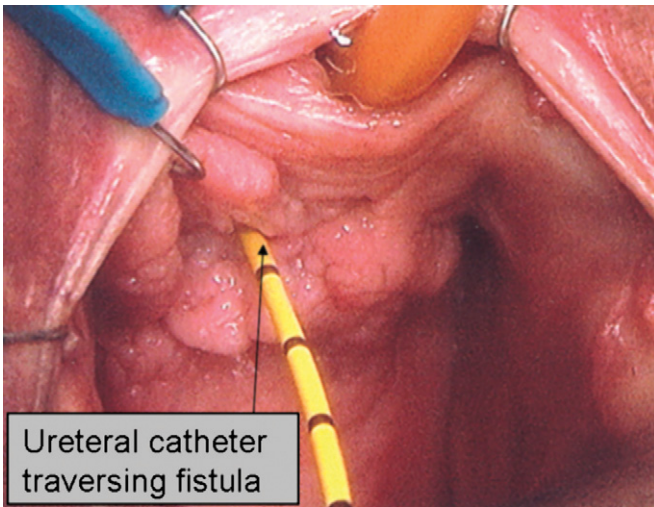

High lithotomy (or prone) position	Fine urethral instruments and sutures
Short-beaked female cystourethroscope (consider guidewire and open-ended ureteral catheter)	Access to autologous sling harvest (rectus fascia, fascia lata)
Suprapubic tube placement (Lowsley retractor or percutaneous kit)	Interposing graft (Martius labial fat pad, gracilis muscle)
Headlight	Soft urethral catheter
Vaginal retractor (Scott Lone Star, Turner-Warwick)	Magnifying loupes (optional)
Injectable saline and marking pen	Vaginal pack, antibiotics and anticholinergic medications (belladonna and opium suppository)

## Surgical Repair

The goals of UVF repair are to close the tract, prevent recurrence of the fistula, and restore continence as indicated. In the case of a small distal fistula tract producing a split urinary stream with minimal or no incontinence, a simple marsupialization procedure to create a hypospadiac opening (i.e., Spence procedure) may correct the problem.<sup>12</sup> We review two scenarios for transvaginal repair of a UVF, one involving a simple primary closure for a small nonirradiated UVF and the other a larger UVF necessitating more advanced techniques of urethral reconstruction and flap interposition for continence and closure.

### Primary Closure with a Vaginal Flap

A primary repair using layered closure was first described by Collis,<sup>13</sup> and it is ideal in the setting of a small to medium-sized UVF in nonirradiated tissues. Sterile urine must be obtained preoperatively, and antibiotic administration must be continued perioperatively. Several elements are necessary to facilitate a successful repair, as listed in Table 79-1. Patient positioning varies between advocates of the prone position<sup>14</sup> and those preferring a high lithotomy position. Maximum perioperative urinary drainage is best achieved with a urethral and a suprapubic catheter. Exposure is facilitated by a Lonestar retractor (Lone Star Medical Products, Stafford, TX) or other self-retaining retractor, a weighted vaginal speculum, a headlight, and even magnifying glasses if available. Passage of a Teflon guidewire over a 5-Fr open-ended ureteral catheter through the tract can facilitate the dissection of the tract (Fig. 79-2). Hydrodissection with normal saline can aid in separating the vagina from the urethral wall. A broad-base, inverted-U-shaped incision is made in the anterior vaginal wall. This broad-base flap permits secondary tissue interposition (e.g., autologous sling, Martius labial fat pad graft<sup>15</sup>) (Fig. 79-3). After raising the anterior vaginal flap, the fistula opening on the vaginal wall is closed with fine absorbable sutures. In our experience, which follows the principles recommended by Raz for a vaginal repair of a vesicovaginal fistula, the well-circumscribed UVF tract is not excised. This decision prevents enlarging the fistula site and creating further bleeding and urethral compromise. Closure of the tract is performed with two running absorbable sutures started at each corner of the fistula

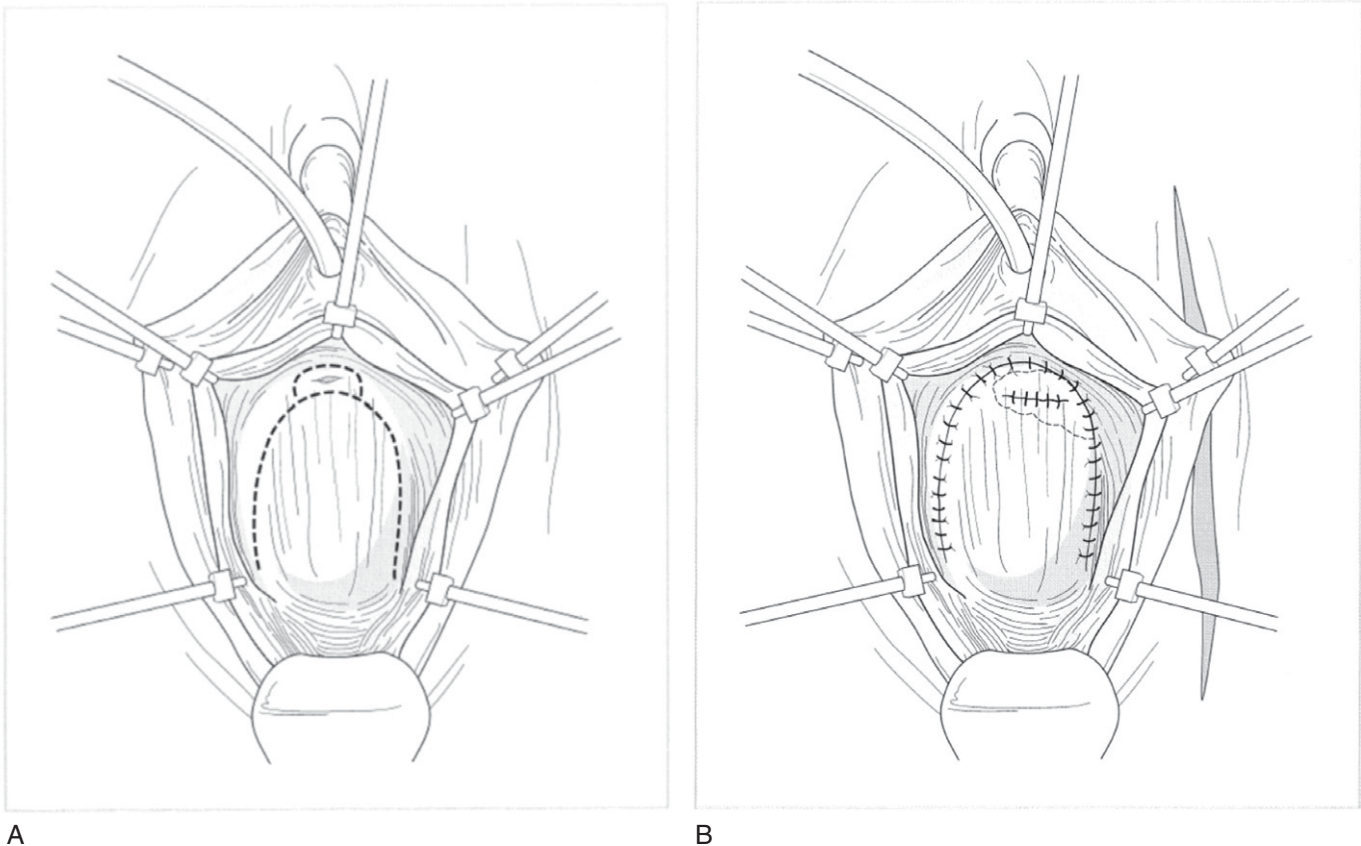

**Figure 79-2** Passage of a 5-Fr ureteral catheter over a Teflon guidewire facilitates identification of the fistula tract during dissection. Additional hooks as part of the self-retaining retractor (lateral) are important to adequately visualize the surgical field.

tract and run toward the midpoint. After water-tightness of the repair is verified,<sup>16</sup> it is frequently necessary to interpose a layer over the urethral repair to minimize the risk of recurrence. We routinely use an autologous sling (i.e., rectus or fascia lata) interposition, which serves the dual purpose of restoring continence and minimizing recurrence. After the sling is secured in place at the undersurface of the urethra and over the UVF closed site, the initially raised anterior vaginal wall flap is advanced to complete the vaginal closure. Use of a fibrin adhesive as a protective layer between suture lines has been reported.<sup>17</sup> A vaginal pack with antibiotic ointment is placed for 24 hours, and anticholinergic medications are administered to avoid secondary bladder spasms.

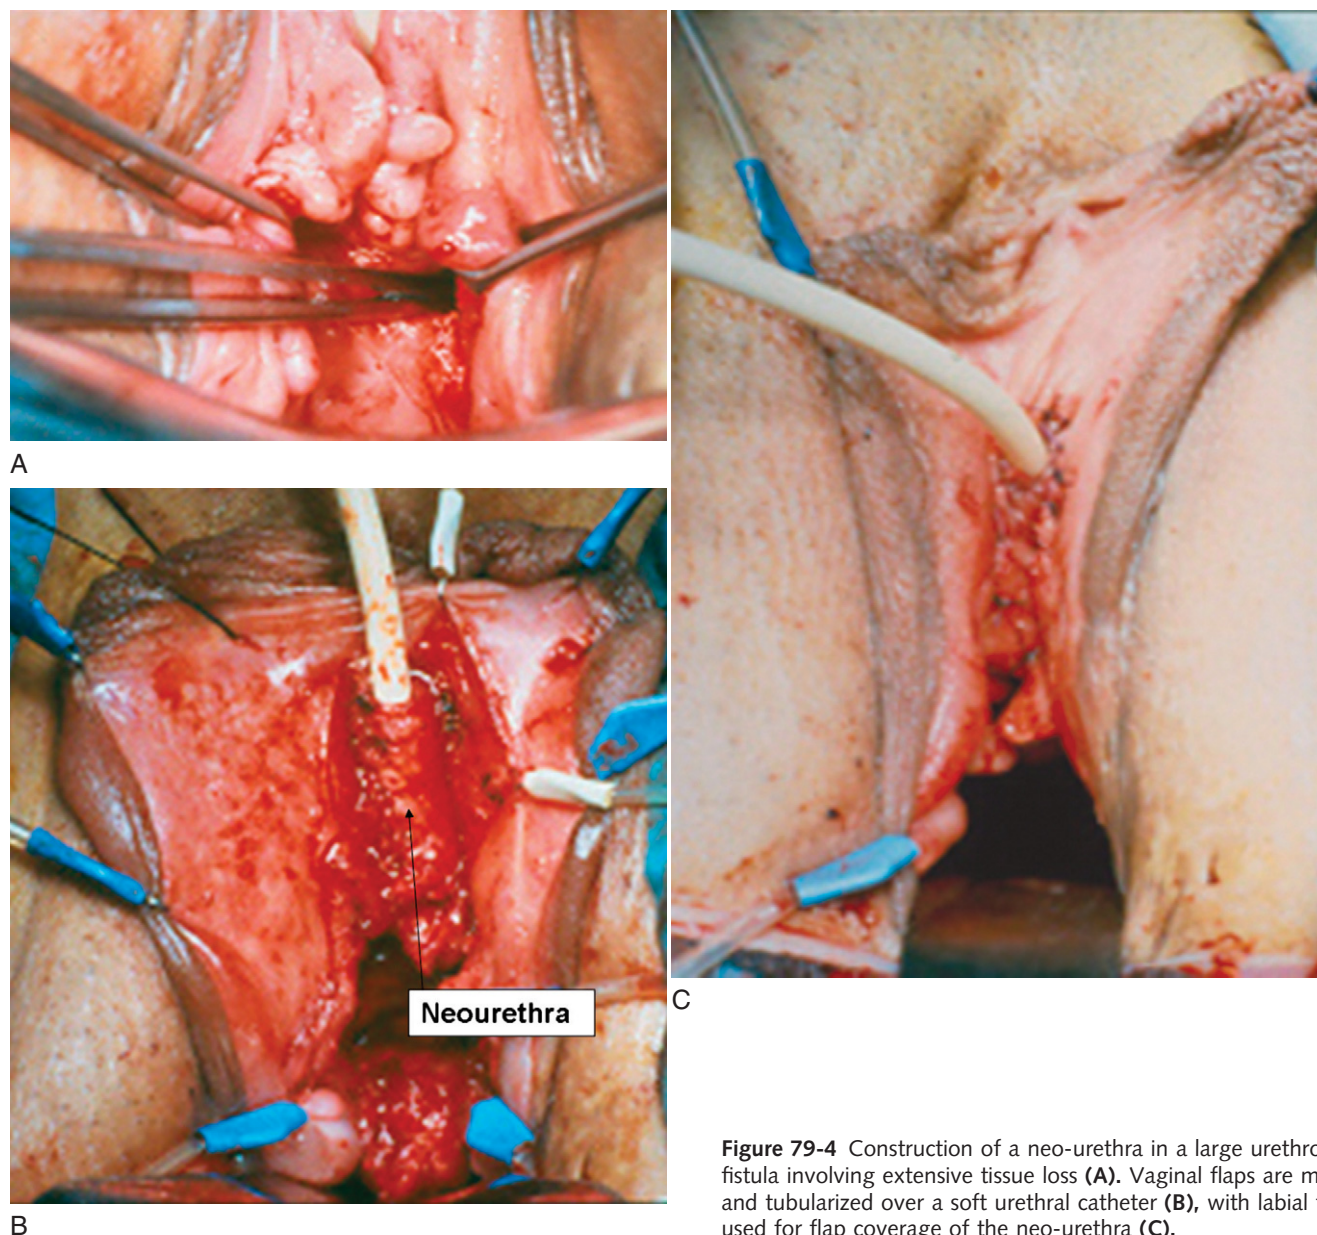

#### *Urethral Reconstruction*

In advanced cases involving a severely damaged urethra from many previous urethral procedures, a more complex surgical repair may be necessary. At the time of consent, it is essential to explain to the patient and her family the challenges posed by repairing a large urethral defect with often scarred, thin, and poorly vascularized tissues or making a neo-urethra. A large defect always compromises the continence mechanism; closing

**Figure 79-3** **A**, An inverted-U-shaped anterior vaginal wall flap incision is made, with the fistula outlined. Creating a broad vaginal flap is essential to avoid flap necrosis and allow for adequate mobilization. **B**, The flap is advanced and the fistula tract closed, with tissue interposition between the two (transparent) to prevent recurrence.

**Figure 79-4** Construction of a neo-urethra in a large urethrovaginal fistula involving extensive tissue loss (A). Vaginal flaps are mobilized and tubularized over a soft urethral catheter (B), with labial tissue used for flap coverage of the neo-urethra (C).

the defect alone will lead to an incontinent pipe-stem urethra, and urethral support with a nonsynthetic sling can aid in restoring continence. Despite these precautions, a secondary UVF fistula can occur, and even after a technically successful repair, various degrees of stress or urge incontinence, secondary urethral narrowing, or even voiding dysfunction can remain challenging issues to manage.

Before deciding which technique to employ, a careful examination under anesthesia is needed to determine the precise location and extent of the urethral loss, the quality and length of the anterior vaginal wall, and the condition of the labia minora and the labia majora. Traditionally, the options for repair are limited to the creation of an anterior vaginal wall flap or a tube graft from the labia minora. When the defect extends into the bladder neck and trigone, placement of ureteral stents is recommended. After the tissues are adequately mobilized, our preference to create a neo-urethra or a segmental inferior urethral plate is to roll labia

minora flaps medially and suture them with invagination of the mucosal layer<sup>18</sup> around a 14- or 16-Fr, soft, Silastic urethral catheter (Fig. 79-4). Then a second layer of tissue (i.e., Martius or sling, or both) is interposed before vaginal closure. Using the vagina to create a urethra usually is our second choice, and it can be considered when the anterior vaginal wall is long enough or the risk of foreshortening is not a concern in a patient who is not sexually active.

Beyond these two scenarios are a multitude of complex reconstructions involving poor-quality tissues, occasionally damage from radiation exposure, total or near-total urethral loss, or refractory UVFs, for which other techniques may need to be considered, including an anterior bladder wall flap, other interposition tissues (e.g., gracilis, rectus muscle,<sup>19</sup> omental flap), or vaginal wall closure with an island of bulbocavernosus musculocutaneous flap<sup>20</sup> with attached skin. However, in such advanced cases, consideration should be given to transvaginal or abdomi-

nal<sup>21</sup> bladder neck closure or a continent or noncontinent urinary diversion.<sup>22</sup>

### Postoperative Care

Broad-spectrum antibiotic coverage is continued, and the vaginal pack is removed after 24 to 48 hours. Uninterrupted postoperative bladder drainage with urethral and suprapubic catheters is imperative. Anticholinergic medications are administered during this period to limit bladder spasms and to prevent catheter expulsion. After approximately 3 to 4 weeks, voiding cystourethrography should be used to document urethral integrity and exclude a fistula recurrence. Return to sexual activity is delayed until complete healing of the vagina has occurred.

### RESULTS

Because of the rarity of UVF, no large case-control series or randomized trials are available. Most case series consist of heterogeneous UVFs managed with different techniques. One series divided 34 women into three groups based on the degree of urethral damage and type of surgical repair. In women with intact urethras who underwent a primary, transvaginal, layered closure, 23 (88%) of 26 experienced a successful anatomic and functional outcome.<sup>12</sup> Five women with destruction of the posterior urethra underwent extensive reconstruction, with all having successful anatomic outcomes, but only two of five were continent postoperatively. In another series of nine women with UVF, there was a 100% anatomic success rate after primary repair with a Martius labial graft interposition, with no cases of recurrent fistula or stricture.<sup>18</sup> However, two patients required additional surgery for stress incontinence. Similar success rates were reported in a series of 24 patients who underwent UVF repair using a Martius fat pad for reinforcement.<sup>11</sup>

The systematic use of a Martius labial fat pad interposition for all UVF repairs is arguable. In a report of 11 women with UVF, 7 who had undergone primary or vaginal flap closure without a Martius procedure had recurrences and subsequently underwent secondary repair with a labial fat pad.<sup>1</sup> The four remaining patients who underwent a Martius procedure had excellent anatomic results. In another retrospective study of 12 women with UVF, 3 of 4 patients who were repaired primarily alone had recurrences, compared with only 1 of 8 whose closures were reinforced with a Martius labial fat pad.<sup>23</sup> Women in this series who had multiple or recurrent UVFs and underwent Martius along with UVF repair fared better than those women repaired without a Martius flap.

Repair with a rectus abdominis muscle flap was reported for six women with refractory and complex UVFs. In this series, no patient had fistula recurrence at a mean follow-up of 23 months, and five of six women were continent and voiding to completion.<sup>19</sup> Similarly, a series of four “giant” vesicourethrovaginal fistulas were repaired by a suprapubic approach with fistula excision and omental interposition or a modified Tanagho bladder wall flap urethral reconstruction.<sup>24</sup> Two of these patients remained totally incontinent due to deficient sphincteric mechanism.

### PREVENTION

“An ounce of prevention is worth a pound of cure” is applicable to urethral surgery and UVF formation. Technical considerations

to help avoid this complication altogether are addressed in the following sections.

### Urethral Diverticulectomy

Beyond patient positioning, adequate visualization of the tissues during urethral diverticulectomy can be facilitated by the use of a headlight and magnifying glasses. Careful dissection to limit the size of the urethral defect after complete excision of the diverticulum pocket, particularly along the inside wall of the diverticulum adjacent to the urethral lumen, can decrease the risk of fistula formation.<sup>25</sup> After the urethral defect is closed with fine absorbable sutures, the integrity of the closure is tested with a 5-Fr feeding tube or ureteral catheter in the lumen, occluding the distal outlet and bladder neck. Any visual leak should be further controlled with absorbable sutures. For a large defect, strong consideration should be given to tissue interposition (i.e., Martius or sling).

### Pubovaginal Sling and Urethrolisis Procedures

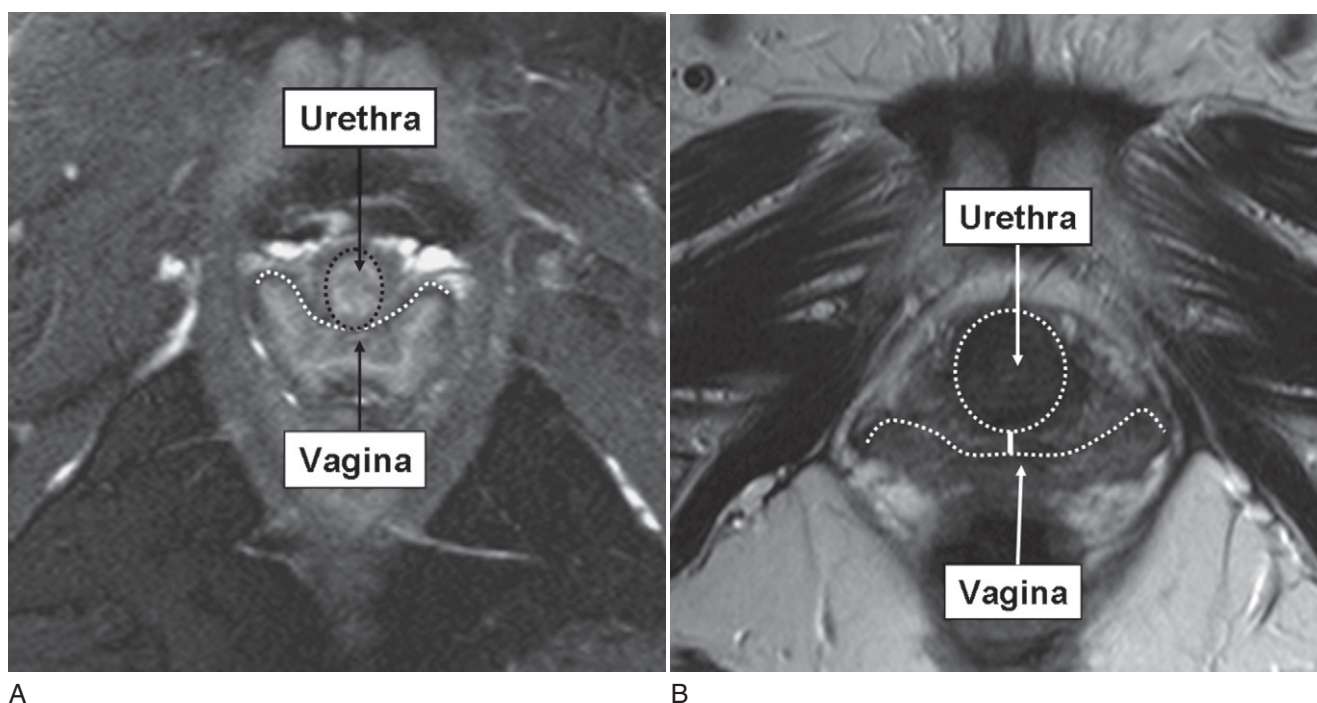

The risk of urethral injury is of particular concern in the mid-urethra because the plane between urethra and vagina (Fig. 79-5A) is thinner compared with that in the proximal urethra (see Fig. 79-5B). Hydrodissection can aid in discerning this fairly avascular plane; venous bleeding from the urethral side may suggest an otherwise subtle urethral injury. Urethroscopy at the end of the vaginal dissection may be useful to identify such an injury, which should be repaired before sling placement. With a midline longitudinal incision common to many of the synthetic sling procedures, there is a risk of lateral urethral injury early in the dissection. The tips of the scissors should be pointed laterally and away from the undersurface of the urethra. In case of obstruction from a synthetic sling, it is preferable to stay lateral rather than just underneath the urethra to incise the sling.<sup>26</sup> Sling excision exposes the patients to urethral injury, especially when the sling is under tension and encroaches on the suburethral tissues.

### Anterior Colporrhaphy

Early reports described UVF formation caused by overplication of tissues around a urethral catheter using silk sutures.<sup>11</sup> Although the use of permanent suture material or distal urethral plication has been abandoned for the most part, plication at the bladder neck or proximal urethra can still result in fistula formation. Palpation through the vaginal wall to identify the location of the Foley catheter balloon at the bladder neck is an important step to avoid extending the dissection underneath the urethra.

### CONCLUSIONS

UVFs have different causes, locations, sizes, and associated factors. These aspects and the patient’s symptoms dictate the selection of a surgical technique. Each repair is unique and challenging, and it is best performed by an experienced reconstructive surgeon. Adherence to time-honored principles of fistula repair can help ensure satisfactory anatomic results in most instances. Patients should be counseled that functional results are not always perfect in regard to continence and voiding function postoperatively.

**Figure 79-5** **A**, Transverse view on T2-weighted magnetic resonance imaging(MRI) at the mid-urethra demonstrates the proximity of the urethral and vaginal tissue (*outlined*), with no discernible gap between the two. Dissection here is more likely to result in urethral injury and contribute to urethrovaginal fistula formation. **B**, Similar transverse MRI at the proximal urethra (one cut distal to the bladder neck) shows an identifiable gap between the urethra and vaginal tissue (*outlined*).

# RECONSTRUCTION OF THE ABSENT OR DAMAGED URETHRA

*Jerry G. Blaivas and Jaspreet S. Sandhu*

Damage to the female urethra requiring surgical intervention is rare. It is most commonly seen in underdeveloped countries where obstetric injuries predominate because of prolonged labor, particularly when there is maternal-fetal disproportion. It is postulated that the fetal head compresses the bladder neck and urethra against the undersurface of the pubis, causing pressure necrosis.<sup>1</sup> With the advent of modern obstetric techniques, the most common causes of urethral injury are shearing injuries from scarring that occurs between the urethra and cervix in response to cerclage sutures, prior cesarean section, or other sources.

In industrialized countries, surgical trauma from anti-incontinence surgery is the most common cause. Less common causes include damage from urethral diverticula, pressure necrosis from long-term indwelling catheters, pelvic fracture injury, and invasion from adjacent malignancies. Iatrogenic injuries may occur during urethral diverticulectomy, anti-incontinence surgery, anterior colporrhaphy, and vaginal hysterectomy. Erosions of synthetic slings and sutures from anti-incontinence surgery are seen with increasing frequency and may manifest years after the original surgery. This is fast becoming the most common reason for damage to the urethra, requiring various degrees of urethral reconstruction.<sup>2-6</sup> The most likely cause is the increased use of synthetic materials and technical issues, such as dissecting too close to the urethra or tying the sling too tightly. In our experience, urethral diverticulectomy continues to be the most common cause of extensive urethral damage.<sup>7,8</sup> This most likely results from failure to obtain a tension-free closure of the urethral defect that results from excision of the diverticulum. During bladder neck suspension, an inadvertent (and unrecognized) injury to the bladder or urethra may occur, or an errant suture may result in fistula formation or tissue necrosis. We have also seen several patients who sustained extensive tissue loss after a seemingly simple Kelly plication. It is postulated that the plication sutures were tied too tightly around a urethral catheter, resulting in pressure necrosis.

Long-term indwelling urethral catheters may cause pressure necrosis of the urethra, and less commonly, trauma to the pelvis may result in fracture or separation of the symphysis pubis, which lacerates the urethra or vesical neck, or both. There may be local invasion of the urethra or bladder neck from carcinoma of vagina or cervix. There can be extensive fibrosis or fistula of the urethra as a consequence of radiation treatment of adjacent cancers.

Regardless of the cause of urethral damage, the diagnostic and therapeutic challenges are considerable. The goals of surgical correction are to create a continent urethra that permits the volitional, painless, and unobstructed passage of urine. It should be of appropriate length to ensure that the patient does not void into

the vagina or over the toilet bowl, which can occur if the urethra is too long. We think these goals can almost always be accomplished with a single transvaginal procedure.

### DIAGNOSIS

Although urethral damage is rare, it should be suspected in certain clinical scenarios: 1) urinary incontinence after pelvic surgery, particularly urethral diverticular surgery, incontinence surgery, anterior colporrhaphy, and Kelly plication; 2) large urethral diverticula; 3) urinary incontinence or other lower urinary tract symptoms after pelvic fracture; 4) urinary incontinence that occurs around an indwelling urethral catheter; and 5) urinary incontinence or lower urinary tract symptoms in patients who have undergone pelvic irradiation. Most patients with significant damage to the urethra have urinary incontinence, but they occasionally present with overactive bladder or voiding symptoms. In patients who have undergone recent synthetic sling placement, urethral erosion should be suspected when the patient has intractable vaginal or urethral pain, recurrent urinary tract infections, vaginal discharge, or hematuria.

For patients with incontinence, the first step in diagnosis is physical examination with a comfortably full bladder; the physician should witness urethral leakage of urine with his or her own eyes before a definitive diagnosis of sphincteric incontinence is made. On more than one occasion, we have diagnosed a urethra-vagina fistula in a woman already scheduled for anti-incontinence surgery because the fistula was misdiagnosed as sphincteric incontinence. When incontinence is observed from the urethral meatus and there is reason to suspect a fistula, the examination should be repeated with a finger obstructing the meatus to observe for leakage more proximally from the fistula itself. Conversely, some women with urethrovaginal fistula have no symptoms, particularly when the fistula is in the distal half of the urethra and the vesical neck remains intact. These fistulas usually are discovered incidentally on physical examination and need no treatment. For examination, we find it best to use the posterior blade of a vaginal retractor to depress the posterior vaginal wall downward. In many instances, the anatomic deformity is obvious, or urinary leakage may be seen proximal to the urethral meatus.

The next step in diagnosis is cystourethroscopy to evaluate the extent of the fistula and to assess the remainder of the urethra, particularly the length, viability, and sphincteric function of the proximal urethra. Visualization of the urethra is best accomplished with a 0- or 30-degree lens and a cystoscope with a 90-degree beak or flexible cystoscope. Cystourethroscopy is the

modality of choice for diagnosing urethral erosions after sling placement.

When a urethral injury is diagnosed, an equally high index of suspicion should be maintained for concomitant abnormalities such as vesicovaginal or ureterovaginal fistula, ureteral obstruction, vesicoureteral reflux, and sphincteric deficiency. A careful evaluation to exclude each of these conditions should be undertaken before surgery. Detrusor function may be compromised in the form of low bladder compliance, impaired detrusor contractility, or detrusor overactivity. However, it is difficult to diagnose these conditions preoperatively, and even when present, they should not be surgically treated when the damaged urethra is repaired because most subside spontaneously after successful repair of the urethra.

Urethral stricture is a rare complication of pelvic fracture or other trauma, multiple urethral dilations, prior surgery, and pelvic irradiation. This condition is usually diagnosed by cystoscopy, but it is occasionally found by urodynamic study.

## MANAGEMENT

### Indications for Surgery

The mere presence of extensive urethral damage is not an indication for surgery. The two main indications for reconstruction are sphincteric incontinence and urethral obstruction, but neither is an absolute indication. Urethral erosions after urethral synthetic sling surgery are a definite indication for surgery because of the presence of foreign material in contact with the urinary tract. If there is an associated condition such as a vesicovaginal fistula, it should be repaired at the same time.

Urethral reconstruction is technically demanding and requires a considerable degree of experience and skill. In inexperienced hands, the risks may be prohibitive, and when there is insufficient local tissue for reconstruction, it may be more prudent to consider urinary diversion than urethral reconstruction, particularly when complications of radiation therapy are suspected.

When sphincteric incontinence is present preoperatively, we believe that it should be surgically corrected at the time of urethral reconstruction. We prefer to construct an autologous fascial pubovaginal sling<sup>9,10</sup> with an interposed labial fat pad flap<sup>7,9,11,12</sup> between the sling and the reconstructed vesical neck. Others have recommended transvaginal bladder neck suspension,<sup>13</sup> but in our experience, this has a failure rate of about 50%.<sup>9</sup> Although it is tempting to use a synthetic sling, we do not recommend it because of the possibility of infection or erosion. It may be prudent to use allograft or xenograft tissue for the sling, but because of lack of long-term follow-up and some early failures, we have chosen these kinds of tissue grafts very selectively.<sup>4,8</sup>

There are three general approaches to urethral reconstruction: anterior bladder flaps,<sup>13,14</sup> posterior bladder flaps,<sup>15</sup> and vaginal wall flaps.<sup>1,7,12,16-18</sup> These techniques appear to be comparable with respect to creation of a neo-urethra. However, when the vesical neck and proximal urethra are involved, which is usually the case, postoperative incontinence rates of about 50% are to be expected unless a concomitant anti-incontinence procedure is performed.<sup>13-15</sup> We believe that vaginal reconstruction is considerably easier and faster, is much more amenable to concomitant anti-incontinence surgery, and is associated with much less morbidity than the bladder flap operations.

### Timing of Surgery and Preoperative Management

In the past, much controversy surrounded the timing of surgical repair. For decades, it had been taught that surgery should be delayed for 3 to 6 months or even longer to allow adequate time for tissue inflammation and edema to subside. In our experience, surgery can be safely performed as soon as the vaginal wound is free of infection and inflammation and the tissues are reasonably pliable.

### Principles of Surgical Technique

In women with damaged urethras, the vaginal tissue is often scarred, fibrotic, and ischemic. Before surgery, careful examination of the vagina is necessary to determine the actual extent of urethral tissue loss and to assess the availability of local tissue for use in the reconstruction. In most instances, there is sufficient tissue in the anterior or lateral vaginal wall that can be mobilized and used for the reconstruction.<sup>1,7,9,12,13,16-18</sup> Occasionally, it may be necessary to use an adjacent labial<sup>16,19</sup> or thigh flap.<sup>20,21</sup> Alternatively, an anterior bladder flap can be used.<sup>13</sup>

In patients undergoing urethral reconstruction for urethral erosion after synthetic sling placement, attempts should be made to remove all synthetic material, including nonabsorbable mesh and sutures.<sup>2</sup> When infection is absent, bone anchors can be left in place because of the difficulty in retrieving them. However, if infection exists, it is advisable and usually straightforward to identify and remove bone anchors. The urethra usually can then be reconstructed primarily.

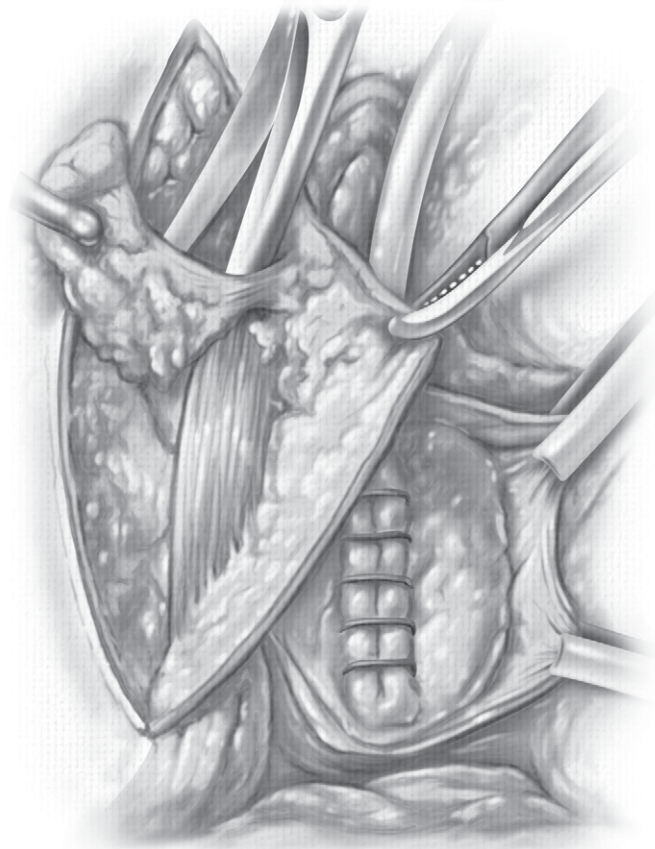

After reconstruction of the urethra, it is often advisable to interpose a well-vascularized pedicle flap over the site of the repair. Sources include labial,<sup>9,13,22</sup> rectus abdominal,<sup>17,23</sup> gracilis,<sup>7</sup> and thigh tissue.<sup>20,21</sup> In most patients, nothing more than a labial fat pad graft is necessary (Fig. 80-1).

The most important principles of surgical repair include clear visualization and exposure of the operative site; creation of a tension-free, multilayered closure; an adequate blood supply; and adequate bladder drainage. Bladder drainage is best accomplished with a suprapubic catheter, which should be placed at the beginning of the procedure to avoid damaging the reconstructed urethra. We use a urethral catheter as a stent postoperatively. The catheter must be sewn to the anterior abdominal wall in a gentle curve to avoid putting tension of the suture line.

### Surgical Technique

There are four basic techniques for urethral reconstruction: primary closure, laterally based (tube) flaps, advancement flaps, and labia minora pedicle grafts. The choice of incision depends on the local anatomy of the tissue loss and whether a pubovaginal sling or other anti-incontinence procedure is planned. If a pubovaginal sling is planned, it is best to complete the urethral reconstruction first; the sling then is completed. In our prior publications on urethral reconstruction, we made the opposite recommendation, but in subsequent operations, we encountered some instances in which the vaginal dissection for the sling interfered with subsequent incisions for the reconstruction.<sup>7,9</sup>

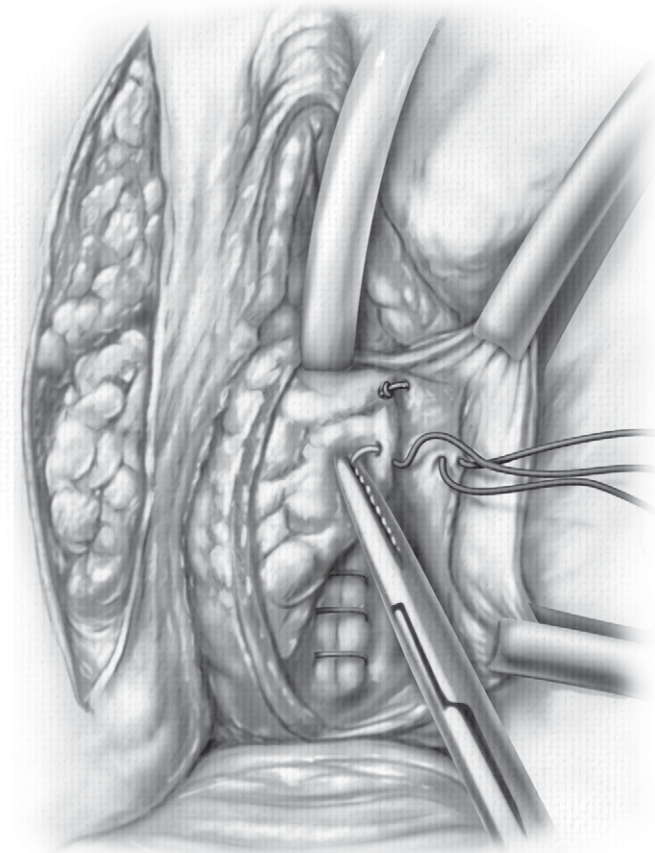

Before incising the vaginal wall for passage of the sling, it is important to select the site and shape of the initial incisions for vaginal reconstruction to be sure that no options are sacrificed. On several occasions, we inadvertently burned some bridges and hope others can learn from our mistakes. If an inverted-U-shaped

A

B

C

**Figure 80-1** Labial fat pad graft—a Martius flap. **A**, A vertical incision is made over the labia majora, and the fat pad is mobilized. The initial dissection should begin beneath Scarpa's fascia. If the plane is more superficial than that, troublesome bleeding may be encountered from thin, wide, flat veins that are difficult to visualize. The fat pad is mobilized anteriorly, suture ligated and divided, and the end of the suture is left long. **B**, A tunnel is made underneath the vaginal epithelium, and the fat pad is pulled into place with the long suture (*arrow*). **C**, It is sewn in place over the suture lines of the neo-urethra. (Modified from Mattingly RF, Thompson JD: Ch. 27. In Mattingly RF, Thompson JD [eds]: *TeLinde's Operative Gynecology*, 6th ed. Philadelphia, JB Lippincott, 1985, p 665.)

incision is made in the anterior vaginal wall in anticipation of advancing it to cover the reconstruction, that tissue can no longer be used as an advancement flap for urethral reconstruction if needed. Accordingly, an inverted-U-shaped incision should be made only after it is clear that an advancement flap will not be necessary. If two parallel incisions are made alongside the intended site of the urethra to roll the flaps into a tube graft, it is important to be sure that the distance between the two incisions is sufficient to allow the flaps to cover the entire circumference of the catheter and that they can be sutured together over the catheter without any tension. The tissue lateral to the incisions should not be undermined until it is clear that a laterally based flap will not be needed to cover the wound.

### Primary Closure

If the defect is small and the tissue pliable enough to achieve a loose, tension-free closure over a 16-Fr catheter, primary closure should be considered (Fig. 80-2). We prefer chromic catgut to longer-acting synthetic absorbable sutures for urethral closure because the latter often make subsequent voiding or urethral instrumentation painful. Only after the repair has been completed is the decision made about how to cover the wound. In some instances, it is possible to elevate laterally based flaps and suture them in the midline over the wound, but when this is not possible, a U-shaped or inverted-U-shaped flap usually suffices. If a Martius labial fat pad graft is needed, it is prepared before

closure of the wound (see Fig. 80-1); if a pubovaginal sling is also necessary, the fat pad graft is placed between the sling and urethra. The vaginal incision is closed with 2-0 or 3-0 chromic catgut (Fig. 80-3).

### Advancement Flap

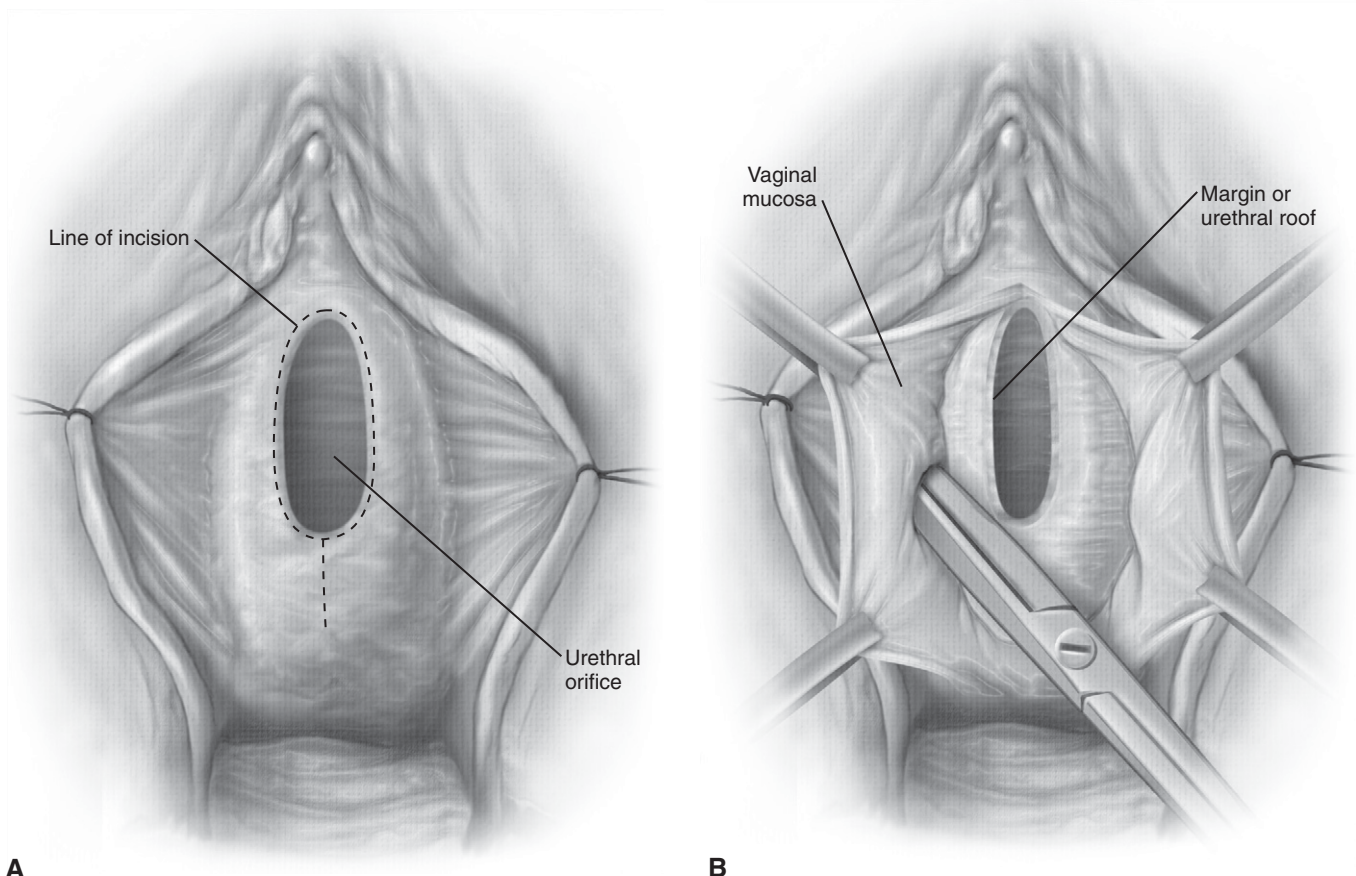

If there is insufficient tissue on the anterior vaginal wall at the site of the urethra to mobilize lateral flaps, it may be possible to repair the urethra and cover the repair with an advancement flap from the anterior vaginal wall cranial to the damaged urethra (see Fig. 80-3).

### Tube Graft

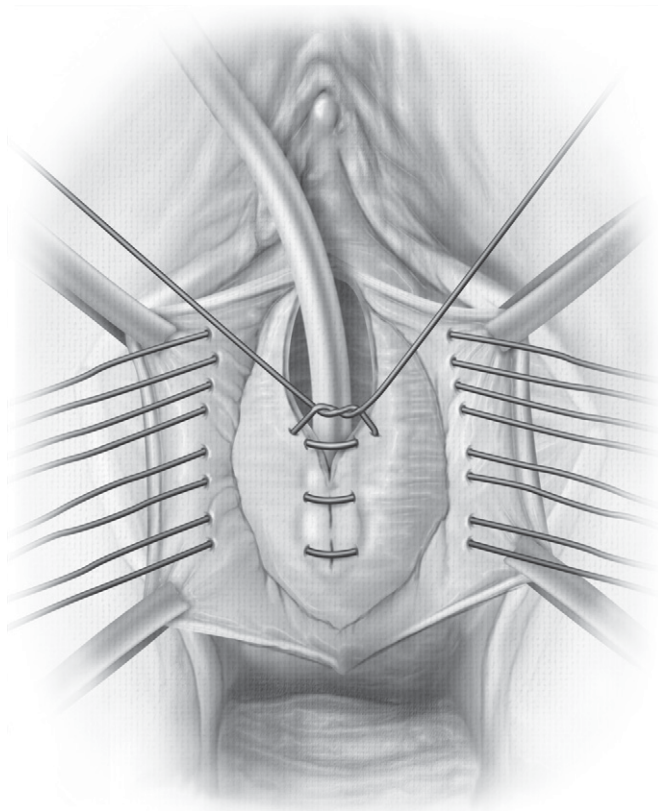

If there is circumferential loss of the urethra and sufficient vaginal wall tissue on the anterior vaginal wall, a tube graft should be considered (Fig. 80-4). Parallel incisions are made over the site of the neo-urethra, and tissue is loosely rolled into a tube over a 16-Fr urethral catheter and closed with interrupted sutures of 3-4 chromic catgut. If there is a urethral fistula, we prefer to retain the remaining bridge of urethral tissue and close the fistula primarily to preserve local blood supply.

### Labia Minora Pedicle Graft

When there is insufficient local vaginal wall tissue, a labia minora pedicle graft may be possible (Fig. 80-5). An oval incision is made in an adjacent hair-free portion of the labia minora as close to

**Figure 80-2** Primary closure of the urethra. **A**, The fistula is circumscribed. **B**, Lateral and cranial vaginal wall flaps are elevated, but the edges of the fistula are not excised because that would likely comprise the size of the reconstructed urethral lumen.

C

D

E

**Figure 80-2, cont'd** C, The urethra is closed primarily with interrupted sutures of 3-0 or 4-0 chromic catgut, and the vaginal wall is closed with lateral flaps. D and E, If there is insufficient mobility of the lateral tissue, an inverted-U-shaped graft of anterior vaginal wall (*arrow*) may be used. (Modified from Blaivas JG: Vaginal flap urethral reconstruction: An alternative to the bladder flap neo-urethra. *J Urol* 141:542-545, 1996.)

**Figure 80-3** Advancement flap. **A**, The vertical distance from the planned meatus to the base of the defect should be measured, and a U-shaped incision is made so that the apex of the U reaches the site of the new meatus without any tension. **B**, The U-shaped flap is mobilized and rotated 180 degrees. Its lateral edges are sutured to the vaginal wall over the catheter for form the neo-urethral tube using interrupted sutures of 3-0 or 4-0 chromic catgut. **C**, An inverted-U-shaped graft of anterior vaginal wall is made so that its tip reaches the new meatus without tension. **D**, The flap is undermined, advanced, and sutured in place with 3-0 chromic catgut. If there is insufficient tissue for this, a full labial graft may be used (see Fig. 80-6). (Modified from O'Connor VJ, Kropp KA: Ch. 13. In Glenn JF, Boyce WH [eds]: Urologic Surgery. New York, Hoeber Medical Division, Harper & Row, 1969, p 568.)

A

B

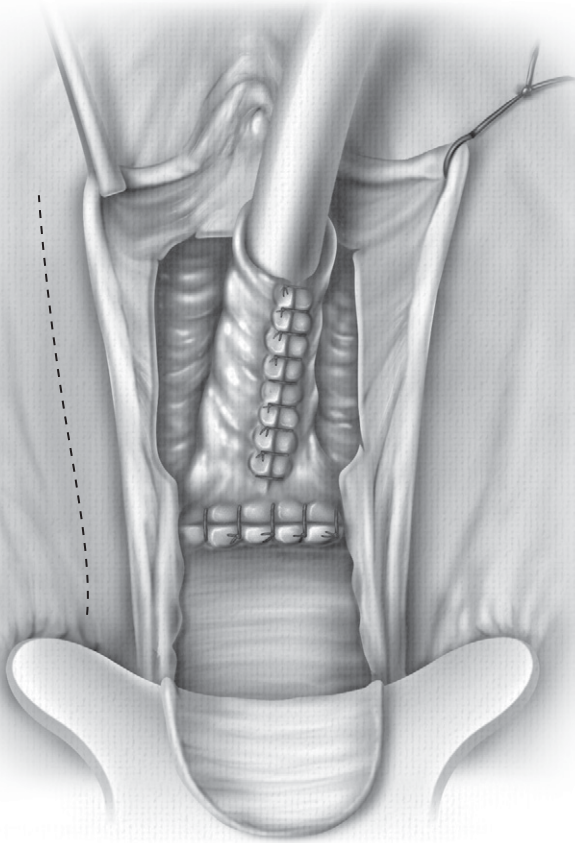

C

D

**Figure 80-4** Tube graft. **A**, A bridge of tissue separates the fistula into two openings. The proximal opening is circumscribed, and an inverted-U-shaped incision is made in the anterior vaginal wall with the apex of the U at the vesical neck, just proximal to first fistula. **B**, Full-thickness vaginal wall flaps are developed around the fistula. **C**, The proximal fistula is closed with interrupted sutures of 4-0 chromic catgut. **D**, A rectangular incision is made. The horizontal distance should be measured to be sure that it is wide enough to cover a 16-Fr Foley catheter. The vertical distance is defined by the site of the new urethral meatus.

E

F

**Figure 80-4** E, The lateral edges of the incision are undermined medially and laterally and then rolled over and approximated in the midline over the Foley catheter, creating the neo-urethra. If necessary, A vertical incision is made over the labia majora for access to the labial fat pad graft. F, The vaginal wall is closed by advancing a U-shaped flap, but if this is not possible, any of the other techniques previously discussed may be used. (Modified from Blaivas JG: Vaginal flap neo-urethra: An alternative to bladder flap urethral reconstruction. *J Urol* 141:542 -545, 1989.)

the site of the urethra as possible (Fig. 80-6). The size of the incision should be large enough to roll into a tube around a 16-Fr catheter or to be used as a patch graft over the catheter and allow loose approximation over the catheter. The incision is deepened around labial incision, and a pedicle graft is raised on an anteriorly or posteriorly based blood supply. The graft is passed beneath the vaginal wall and rotated so that the mucosal surface forms the inner wall of the reconstructed urethra. In some patients, it is not possible to create a tunnel for passage of the graft because of extensive scarring. In this instance, an incision is made in the vaginal wall between the site of the new urethra and the graft. It is usually possible to elevate flaps to cover the graft.

#### Alternative Closures

If it is not possible to close the vaginal incision primarily, there are several alternatives. The most straightforward is to create an inverted-U-shaped or lateral broad-based flap (Fig. 80-2(d&e)). If that is not feasible, a labia minora pedicle graft may be taken and rotated so that the skin is on the outside (Figure 80-5). Alternatively, a modification of the Martius flap using full-thickness vaginal wall can be used (see Fig. 80-6). Other techniques include gracilis myocutaneous, rectus pedicle, and Singapore flaps (19-

21), but in approximately 100 cases, we have found an alternative approach to be necessary only two times.

At the conclusion of the procedure using any technique, the Foley catheter is sutured to the anterior abdominal wall with a gentle loop to ensure that undue tension is not placed on the urethra. Failure to maintain a correct position of the catheter may result in necrosis of the urethra.

#### Postoperative Care

If a Martius flap is used, the Penrose drain is removed as soon as there is minimal drainage, which usually is on the first or second postoperative day. The urethral wound and catheter are checked frequently to be sure that there is no tension or pressure on the suture line. The urethral catheter is removed as soon as feasible, usually within the first 2 to 5 days, but always before discharge from the hospital. Voiding cystourethrography is performed through the suprapubic catheter at about day 14. If the patient voids satisfactorily and there is no extravasation, the suprapubic tube is removed. If not, the tube is left in place, and another voiding trial is undertaken in about 2 weeks.

## RESULTS

Because of the rarity of the condition, there have been few studies concerning reconstruction of the severely damaged urethra. Combining all the series we could find in the English language literature, there were fewer than 500 patients. Overall, successful anatomic reconstructions were reported in 67% to 100% of women (Table 80-1). Most study authors emphasized the need

for well-vascularized pedicle flaps to ensure a successful outcome. Continence, however, was achieved in only 55% to 92% after a single operation, and postoperative urethral obstruction was reported in 2% to 17% of patients. In most studies, the criteria for incontinence and urethral obstruction were not specified, and in view of lack of follow-up, the results cited should be considered overly optimistic. It does seem evident that an anti-incontinence procedure should be performed at the same time

**Figure 80-6** Technique of obtaining a full-thickness labial fibrofatty pedicle graft to cover the reconstructed urethra when there is insufficient local vaginal wall tissue. **A**, A U-shaped incision is made in the labia minora large enough to cover the defect. The incision is carried down through the labial fat pad (see Fig. 80-1), and the posterior end of the flap is suture ligated. **B**, The vaginal wall is closed primarily with running sutures of 3-0 or 400 chromic catgut. (Modified from Mattingly RF, Thompson JD: Ch. 27. In Mattingly RF, Thompson JD [eds]: *Telinde's Operative Gynecology*, 6th ed. Philadelphia, JB Lippincott, 1985, p 665.)

as the urethral reconstruction. Failure to do so resulted in incontinence rates ranging from 50% to 84%. The results of many series indicated that secondary procedures to correct incontinence were successful in most patients.

The first report of a large series was published in 1969 by Hamlin,<sup>12</sup> a dedicated pioneer of fistula repair who worked in West Africa. Excellent anatomic repair was achieved in 49 of the 50 childbirth injuries, but 8 (16%) had severe incontinence, and many more had lesser degrees of incontinence. The incontinence was usually cured after a second procedure. Symmonds<sup>22</sup> described 50 women undergoing neo-urethra procedures using tubularized vaginal wall. Follow-up ranged from 1 to 15 years, and using an independent examiner, he reported that 37 of 50 patients were dry (i.e., no pads and said they were cured) and that 7 of 50 patients considered the operation successful, even though they had “some” stress incontinence.

We have operated on more than 100 women with extensive anatomic vesical neck and urethral defects; results for 74 have been reported.<sup>8</sup> The causes of the injury are given in Table 80-2. All but one patient underwent a vaginal reconstruction (one patient had a Tanagho anterior bladder flap that failed). One patient with squamous cell carcinoma of the distal third of the urethra underwent wide excision and urethral reconstruction with adjacent local flaps. In the remainder, we used a Martius flap in all except three—one had a successful repair with a gracilis flap, and two women with childbirth injuries underwent cutaneous labial pedicle grafts. One of the latter patients was successful; the other failed because of wound necrosis and underwent con-

tinuous urinary diversion. A successful anatomic outcome was achieved in 93%, and continence was achieved in 87% of patients who had preoperative incontinence; no patient developed de novo incontinence. Early in our series,<sup>7</sup> we did not routinely perform concomitant pubovaginal slings, and 50% of the women who underwent a modified Pereyra procedure had persistent sphincteric incontinence; all were subsequently cured or improved by an autologous fascial pubovaginal sling. No patient required

intermittent catheterization except for the patients with anatomic failures, who underwent continent urinary diversion. One had a previously unrecognized vesicovaginal fistula.

Rovner and Wein<sup>24</sup> recommended that women with large, circumferential urethral diverticula undergo complete excision of the diverticulum and partial urethrectomy by transecting the urethra to gain access to its dorsal wall. Urethral continuity was restored by end-to-end urethroplasty or by tubularizing the anterior wall of the diverticulum to construct a neo-urethral segment. Autologous fascial slings were used selectively. With only short-term follow-up, they reported that six of the eight patients were dry (i.e., no pads), one was using two or three pads per day, and the remaining one reported urgency and the use of one pad each day. Complications included one distal fistula and one stricture.

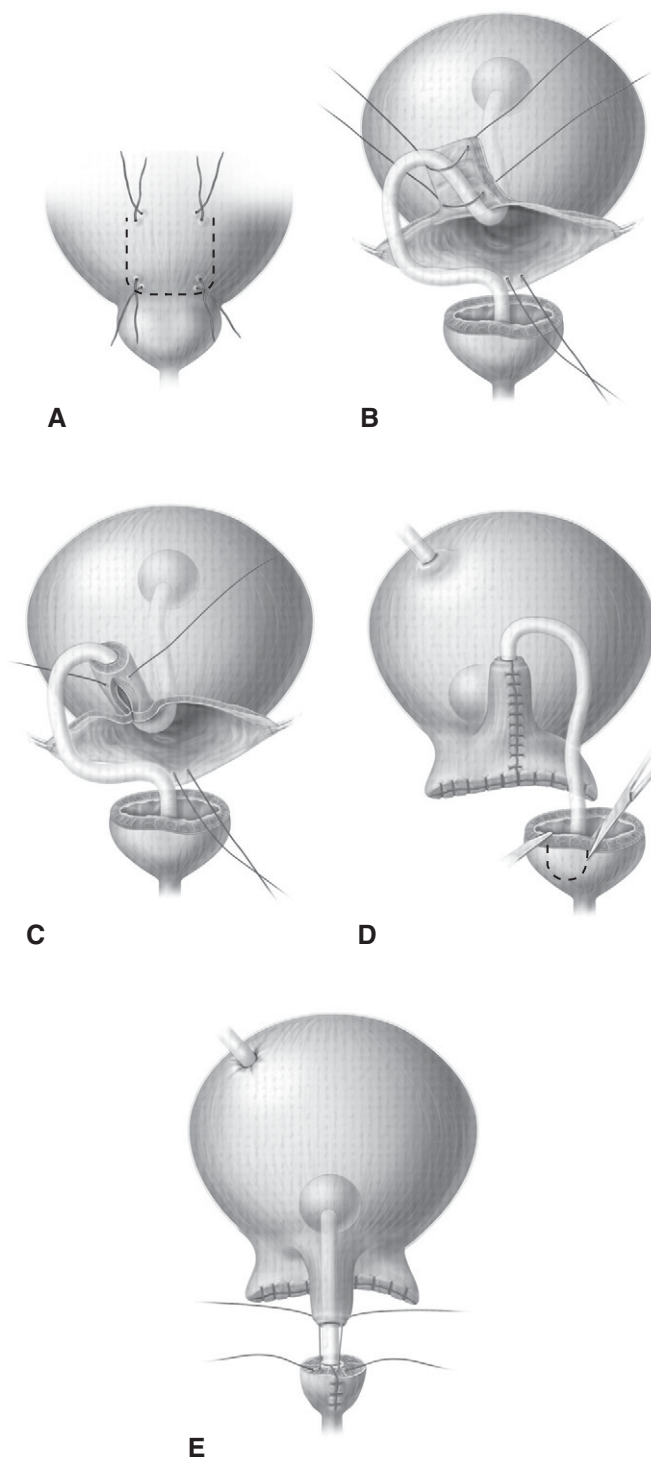

Tanello and colleagues<sup>16</sup> described two women undergoing urethral reconstruction using a pedicle skin flap from the labia minora. They cited a 2-year follow-up and reported that both patients were dry. Bruce and coworkers<sup>23</sup> described six women with multiple previous urethral operations who underwent reconstruction. The surgical technique used a pedicled rectus abdominis flap interposed between the fistula closure and the vaginal suture line. The follow-up period was 23 months. Five of six patients were dry and able to void; one had urge incontinence.

Many investigators have reported the results of urethral reconstruction after urethral erosion resulting from mid-urethral sling placement. Amundesen and colleagues<sup>2</sup> described nine patients who presented with urethral erosion. All were repaired primarily with a multilayered closure, followed by a Martius flap in two patients. All were repaired adequately, but 66% of patients with preoperative urge urinary incontinence or stress urinary incontinence had continued incontinence. Others have reported results with similar rates of incontinence, prompting some surgeons to perform concomitant anti-incontinence procedures with interposed vascularized tissue, such as a Martius flap.<sup>3,4</sup>

### BLADDER FLAP TECHNIQUES

We believe that bladder flap reconstructions are almost never necessary in these patients. The single patient in whom we performed this procedure failed because of refractory detrusor instability. There are two basic techniques: anterior and posterior bladder flaps. The anterior technique is depicted in Figure 80-7. More information is available in the original descriptions and the excellent work of the late Vincent O'Connor.<sup>25</sup>

In the latest and most extensive series, Elkins<sup>13</sup> and associates reported their experience with a Tanagho-like procedure in 20 West African women with extensive urethral damage after obstructed labor. These patients had large vesicovaginal fistulas, and because of extensive scarring, they were not suitable for vaginal flap techniques. The procedure was performed entirely through the vaginal approach. The anterior and lateral fistula edges are dissected sharply away from the pubic bone beneath the arch of the pubic ramus, and the retropubic space is entered from the vagina. The anterior bladder wall is then dissected free of surrounding tissues to the level of the peritoneal reflection. After the anterior bladder is mobilized, a 3 × 3 cm flap is raised and rolled into a tube over a 16-Fr catheter. The new urethra is sutured to the remaining distal urethra or at the site of the new meatus. The posterior edges of the vesicovaginal fistula are approximated and "fixation sutures are placed through the top portion of the neo-urethra to reattach the urethra to the base of

**Figure 80-7** Technique of performing anterior bladder flap urethroplasty (i.e., Tanagho procedure). **A**, An anterior bladder wall flap is selected, mobilized, and held with suspension sutures. **B**, The urethra is transected at site of fistula. **C**, The bladder flap is tubularized. **D**, The posterior bladder is closed. **E**, The neo-urethra is sutured to the distal urethra. (Modified from Tanagho EA: Bladder neck reconstruction for total urinary incontinence: 10 years of experience. *J Urol* 125:321, 1981.)

the pubic periosteum." In the last three patients in the series, a modified Pereyra procedure was performed instead. A Martius fat pad graft was then placed beneath the suture lines. Eighteen of the 20 women so treated had a satisfactory anatomic repair of the fistula, but 4 of the 18 had persistent stress incontinence that required further surgery. Two others had refractory detrusor instability or low bladder compliance.

## OTHER TECHNIQUES

Park and Hendren<sup>26</sup> reported a series of seven girls with severely fibrotic urethras. Urethral reconstruction was accomplished with a 2 × 4 cm full-thickness buccal mucosa graft after splitting the pubis and excising the fibrotic urethra. Causes of the urethral pathology included complications from operations for cloacal extrophy and other cloacal malformations. The investigators reported that five of seven patients were continent and that two were being treated with periurethral bulking agents. After the follow-up period of 12 to 58 months (mean, 34.7 months), all seven patients were continent, but two required bulking agents for continence.

## CONCLUSIONS

Reconstruction of the severely damaged urethra is a technically challenging undertaking that requires considerable surgical expertise and decision-making. Most women with traumatic injuries have sufficient vaginal tissue for a vaginal flap reconstruction, and we believe that the vaginal approach offers the best chance for a successful outcome. However, for those with extensive vaginal scarring that precludes a local tissue repair, bladder flap techniques or free grafts with or without gaining access by splitting the pubis may prove useful.

The most important principles to keep in mind are clear visualization and exposure of the operative site; careful selection of the initial vaginal incision to ensure that there is adequate blood supply if pedicle flaps become necessary; removal of all foreign material; creation of a tension-free, supple, multilayered closure; an adequate blood supply and soft tissue base with a Martius flap; a concomitant pubovaginal sling when anti-incontinence surgery is indicated; adequate bladder drainage; and suturing of the urethral catheter to the anterior abdominal wall and meticulous attention to catheter care to prevent pressure necrosis.

# VESICOVAGINAL FISTULA: VAGINAL APPROACH

*Matthew P. Rutman, Larissa V. Rodríguez,  
and Shlomo Raz*

Vesicovaginal fistula (VVF) is one of the most significant and distressing complications in female urology and urogynecology. A VVF is an abnormal communication between the bladder and vagina that results in continuous urine leakage from the vagina. VVFs have been recognized and described since ancient times, but successful repair was not documented until James Marion Sims' first paper in 1852.<sup>1</sup> He used a transvaginal technique to perform the repair, including the use of silver wire suture. Many principles he described are still applicable. Subsequent modifications and advances included the first layered repair by Mackenrodt<sup>2</sup> and the interposed labial fat graft of Martius<sup>3</sup> in the late 1920s.

In developing countries, birth trauma remains the most common cause of VVF. Prolonged and obstructed labor leads to pressure necrosis of the anterior vaginal wall and the underlying bladder neck and urethra. In industrialized nations, most fistulas result from complications of gynecologic and other pelvic surgery. Regardless of the cause, surgical repair remains the gold standard and primary treatment of VVF.

### ETIOLOGY

In the United States and other developed nations, VVFs occur as a result of surgical trauma, most commonly at the time of abdominal or vaginal hysterectomy. Unrecognized suture placement into the bladder during closure of the vaginal cuff results in tissue necrosis and subsequent fistula formation. Excessive blunt dissection of the bladder can result in ischemia or an unrecognized tear in the posterior bladder wall. Approximately 75% of VVFs are reported to occur after hysterectomy for benign disease.<sup>4</sup> The incidence of VVF after hysterectomy is between 0.5% and 1%.<sup>5</sup> VVFs also occur after anterior colporrhaphy, sling procedures for stress incontinence, cystocele repair, colposuspension procedures, and urethral or bladder diverticulectomy. Approximately 90% of VVFs in North America result from gynecologic procedures. The other 10% are caused by advanced local malignancy (i.e., cervical, vaginal, and endometrial), radiation therapy, inflammatory bowel disease, foreign bodies, and infectious processes of the urinary tract.

### PREVENTION

Recognizing that most VVFs are iatrogenic, it is paramount that the treating surgeon takes the necessary precautions to prevent their occurrence. Risk factors reported for fistula development

include prior cesarean section, endometriosis, previous cervical conization, and radiation treatment.<sup>6</sup> The bladder is most often injured during the dissection of the posterior bladder wall from the anterior surface of the uterus at the level of the vaginal cuff during abdominal hysterectomy. Placement of an indwelling Foley catheter and meticulous sharp dissection can minimize inadvertent injury. Iatrogenic injuries can be unavoidable in difficult reoperations and in patients with dense adhesions that obliterate normal surgical planes. Careful attention should be paid to diagnose and repair the injury intraoperatively. Filling the Foley catheter with methylene blue dye to check for leakage is a simple and effective method of checking bladder integrity. If a bladder injury is recognized, two-layer repair is required after adequate exposure is provided. A drain should be placed. The catheter should be left in longer than the usual 1 or 2 days after hysterectomy. An interposition flap can provide an additional layer of coverage.

### DIAGNOSIS

#### History

Patients typically present with continuous urinary drainage (day and night) from the vagina after gynecologic or pelvic surgery. Any patient with urinary incontinence immediately after pelvic surgery should be evaluated to rule out a VVF. The fistula may manifest immediately postoperatively, but it often becomes clinically apparent days to weeks later. Ureterovaginal fistulas tend to manifest later than VVFs. Ten percent of patients with a VVF have an associated ureterovaginal fistula.<sup>7</sup> Early in the postoperative course, patients may present with fevers, abdominal pain, hematuria, ileus, and lower urinary tract symptoms.

Patients with VVF related to prior radiation therapy may present 6 months to 20 years later.<sup>8</sup> Fluid draining from the vagina may be urine, lymph, peritoneal fluid, fallopian tube fluid, or vaginal secretions. Important considerations in the differential diagnosis of VVF include urethrovaginal fistula, ureterovaginal fistula, ectopic ureter, peritoneal fluid drainage, and vaginal cuff infection.

#### Diagnostic Tests

To confirm that the leaking fluid from the vagina is urine, the fluid can be sent for creatinine analysis. Elevated levels (relative to serum) establish the diagnosis of a communication between the vagina and urinary tract. Physical examination is paramount in the evaluation of a woman with a suspected fistula. The

diameter, depth, mobility, and mucosa of the vagina must all be assessed. Concomitant prolapse, urethral hypermobility, and stress incontinence should also be evaluated. Vaginal examination with a speculum can isolate the point of leakage. The most common location for VVF (after a hysterectomy) is at the level of the vaginal cuff. Pooling of urine at the apex and the fornices is commonly seen. Surrounding vaginal mucosa may appear edematous and erythematous, making it difficult to identify the opening. Placing a Foley catheter into the bladder can assist by visualizing the balloon. If all of these measures fail to identify a fistula, dye tests can be used for confirmation. Instilling methylene blue dye through the Foley catheter, with concomitant inspection of the vagina for leakage of blue fluid, can help identify a VVF. Requesting the patient to ambulate with a vaginal pack in place may stain the packing blue. If a VVF is still not identified, the patient should be given oral phenazopyridine, which stains the urine orange. The vagina is then packed, and orange staining confirms a fistula. A positive phenazopyridine test result with a negative methylene blue test result strongly suggests a ureterovaginal fistula.

All patients with a diagnosis of a urinary fistula should undergo upper tract evaluation and cystoscopy. Upper tract evaluation can be done with intravenous pyelography (IVU) or retrograde pyelography. Ureteral involvement can be demonstrated by hydronephrosis or extravasation on IVU, although the ipsilateral kidney can appear normal with prompt drainage. Retrograde pyelography remains the most sensitive test to evaluate ureteral involvement in the presence or absence of a VVF. Cystoscopy should identify the location and size of the fistula and determine its relation to the ureteral orifices. It is important to ascertain that there is adequate bladder capacity and to rule out foreign body as the source of the fistula. Surveillance for multiple fistulas is imperative, because this finding would alter operative repair. Patients with a radiation- or malignancy-associated fistula must undergo biopsy of the site before repair. A voiding cystourethrogram (VCUG) can help identify the presence and location of a fistula. Coexisting vesicoureteral reflux, urethral diverticulum, stress incontinence, and cystocele can also be identified, which may alter the surgical plan. VCUG can help elucidate fistulas involving the rectum or uterus, and vaginoscopy can assist in identifying the vaginal communication.

## TREATMENT

### Conservative Management

Small VVFs may close spontaneously with continuous Foley catheter drainage (up to 10% of cases). This has usually been attempted by the time patients have sought consultation with a specialist. Three weeks of drainage is a reasonable option if the fistula is discovered early in the postoperative period. Mature fistula tracts are unlikely to resolve with this technique. Prolonged catheter drainage requires coverage with antibiotics.

Another conservative treatment option includes fulgurating the lining of the fistula tract. This should not be attempted with large fistulous tracts. Stovsky and colleagues<sup>9</sup> reported closure in 11 of 17 patients with fulguration of fistulas less than 3 mm long and with 2 weeks of catheter drainage. Reports have shown success with fibrin therapy in treating small VVFs.<sup>10</sup> Most conservative measures ultimately fail in the attempt to cure VVFs. For larger, complex, and radiation-induced fistulas, there is no

role for conservative treatment, and formal repair remains the gold standard.

### Operative Management

#### Preoperative Considerations

Before formal repair of a VVF, many factors must be considered to optimize the chances of a successful repair. Historically, most surgeons advocated waiting 3 to 6 months before surgical repair to allow the fistula to completely mature.<sup>11,12</sup> They theorized that this allowed maximal healing during the post-hysterectomy inflammatory stage. However, patients with VVFs experience enormous social, physical, and psychological stress during this period that greatly hinders their quality of life. Contemporary surgeons have reported excellent results with early repair, and the strategy avoided patients' distress throughout a waiting period.<sup>13,14</sup> Typically, early transvaginal repair is performed 2 to 3 weeks after the time of injury. This is most commonly done in women with fistulas that form after hysterectomy using an abdominal approach. Patients with vaginal cuff infections or pelvic abscesses must be treated long-term with antibiotics before any repair attempt. Patients with previously failed repairs or radiation-related fistulas are not candidates for early intervention. They should wait a minimum of several months before repair. VVFs after traumatic delivery are ischemic in origin and require a longer period of conservative management.

The most appropriate approach to formal surgical repair of a VVF is the one most familiar to the surgeon. The choice between an abdominal or vaginal approach depends on the surgeon's experience, training, and comfort level with the procedure. The highest success rates are associated with the first operation, regardless of the approach. Traditionally, the fistula's location dictated the surgical approach. Infratrigoanal and bladder neck fistulas were repaired vaginally, whereas supratrigoanal fistulas were repaired transabdominally. Even complex high VVFs can be repaired using a transvaginal approach with adherence to good surgical technique and tissue interposition. The advantage of an abdominal approach is the ability to perform simultaneous procedures for coexisting intra-abdominal pathology, including augmentation cystoplasty, ureteral reimplantation, and repair of bowel fistulas. The vaginal approach avoids an abdominal incision and possible bladder bivalving. It is associated with decreased morbidity, shorter hospital stay, and quicker patient convalescence. We use the transvaginal approach for most VVFs.

Many principles are integral to fistula repair, regardless of the approach chosen. Excellent exposure with watertight, tension-free closure using multiple, nonoverlapping sutures lines provide an approximately 90% chance of cure on the first attempt. Continuous catheter drainage postoperatively is mandatory. Interpositional grafts optimize the chance for cure if the integrity of the repair is in question.

Preoperative preparation includes prescribing antibiotics to clear any infection and provide a sterile environment for repair. Urine culture should document absence of infection before surgery. Broad-spectrum, intravenous antibiotics are provided preoperatively. Preoperative estrogen-containing vaginal cream is used in the postmenopausal or post-hysterectomy patient to improve the quality of the vaginal tissues.

Traditional repair of VVF included excision of the tract to provide clean and vascular edges. This was thought to increase chances for cure. Raz and associates<sup>15,16</sup> demonstrated excellent results without excising the fistulous tract with no adverse effects.

Excising the fistula enlarges the tract, and it may cause iatrogenic bleeding, requiring hemostatic measures that may inhibit healing. Excising fistulous tracts located near the ureteral orifices may require ureteral reimplantation.

Before surgical repair, the surgeon should be familiar with several techniques for interposition of tissue. Although these grafts are often necessary in large, complex, post-radiation, and failed primary repairs, it is difficult to accurately predict which fistulas will require the additional layer of coverage to avoid a tenuous repair.

Preoperative evaluation should attempt to identify patients who have coexisting stress urinary incontinence. Simultaneous sling procedure or bladder neck suspension can be performed, avoiding the need for a second procedure. Concomitant repair for stress incontinence does not increase the fistula recurrence rate.<sup>17</sup> It is also important to consider the sexual function of the patient and ensure preservation of vaginal depth in the sexually active patient. This can require rotational flaps in patients with large fistulas and vaginal stenosis. Local estrogen replacement should be used in patients with vaginal atrophy.

### Vaginal Technique

We routinely repair VVFs by means of a vaginal approach and describe the technique for transvaginal repair of VVFs. The surgery is performed on an outpatient basis and avoids the morbidity of a laparotomy.

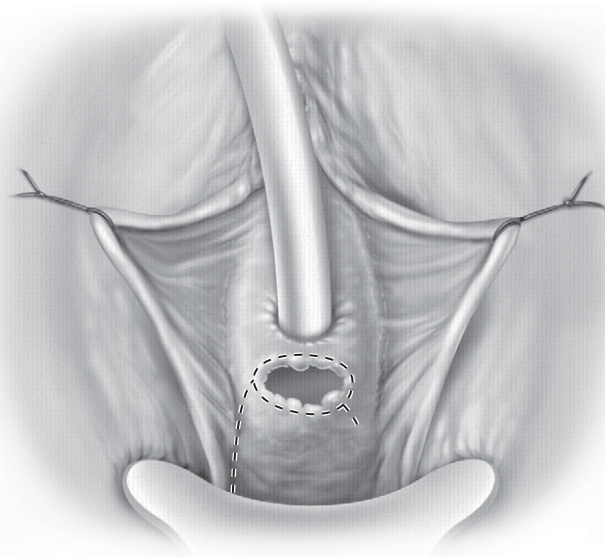

Step 1 is patient preparation. The patient is placed in the low lithotomy position and prepped in standard fashion. A headlight provides excellent visualization for the surgeon. Cystoscopy with ureteral catheterization is done when the fistula is located near the trigone and the ureteral orifices. A curved Lowsley retractor aids in placement of a 16-Fr suprapubic catheter through a small suprapubic incision. A posterolateral episiotomy (i.e., relaxing incision) may be necessary in a patient with a narrow vagina. The labia minora are sutured apart, and a ring retractor is positioned for optimal exposure. A urethral catheter is placed to ensure maximal urinary drainage. An Allis clamp is used to elevate the anterior vaginal wall, and a weighted speculum is placed posteriorly.

Step 2 is isolation of fistula. The fistulous tract is identified and catheterized with an 8- or 10-Fr Foley catheter. This aids retraction throughout the dissection. Metal sounds may be necessary to dilate the tract before catheter placement. An inverted-J incision is made with care taken to circumscribe the fistulous tract (Fig. 81-1). The long end of the J should extend to the apex of the vagina, which facilitates rotation and advancement of a posterior flap at the later stages of the procedure. Fistulas located high in the vaginal cuff may require an inverted incision, with the base of the flap facing the urethral meatus.

Step 3 is the creation of flaps. Anteriorly and posteriorly based vaginal flaps are dissected on each side of the fistulous tract, starting with healthy tissue located away from the fistula itself (Fig. 81-2). This usually provides a healthy plane of dissection and helps prevent enlargement of the fistulous tract or inadvertent bladder perforation. The ring of vaginal tissue at the opening of the fistula is left intact. The flaps should be developed at least 2 to 4 cm away from the fistulous tract, exposing the underlying perivesical fascia. The flaps are then retracted with the hooks of the ring retractor. Lateral dissection of the vaginal wall 2 to 4 cm from the fistulous tract allows complete exposure of the perivesical fascia.

**Figure 81-1** Inverted-J-shaped incision around the fistulous tract. (From Raz S, Little NA, Juma S: Female urology. In Walsh PC, Retik AB, Stamey TA, Vaughan ED Jr [eds]: Campbell's Urology, 6th ed. Philadelphia, WB Saunders, 1992, pp 2782-2828.)

**Figure 81-2** Development of vaginal flaps.

Step 4 is closure of the fistula. The standard VVF repair is done in three layers. The first layer closes the epithelialized edges of the fistula tract and a few millimeters of the surrounding tissue (including bladder wall) with interrupted, absorbable, 2-0 sutures (Vicryl or Dexon) in a transverse fashion (Fig. 81-3). The fistula catheter is removed, and the sutures are secured, closing the fistulous tract. The second layer of the repair incorporates the perivesical fascia and deep muscular bladder wall using the same suture material (Fig. 81-4). The sutures are placed at least 1 cm from the prior suture line and secured in a tension-free fashion. The sutures are placed in a line 90 degrees from the first suture

**Figure 81-3** First layer of repair: transverse closure of a fistulous tract without excision.

**Figure 81-4** Second layer of repair: imbricated first layer with perivesical fascia.

layer to minimize overlapping suture lines. The second layer of sutures completely covers the first layer of closure. The bladder is filled with indigo carmine diluted in saline to ensure repair integrity.

Step 5 is completion of the operation. In a standard VVF repair (without interposition), the procedure is completed. The previously raised posterior flap is rotated beyond the fistula closure site by at least 3 cm. The excess vaginal flap tissue is

**Figure 81-5** Third layer of repair: vaginal flap advancement.

excised. The vaginal wall is closed using a running, locking, absorbable, 3-0 suture (Vicryl or Dexon). This covers the tract with healthy vaginal tissue and provides a third layer of closure with no overlapping suture lines. (Fig. 81-5) An antibiotic-impregnated vaginal pack is placed, and the urethral and suprapubic catheters are left to dependent drainage.

Most cases of uncomplicated VVF require only a three-layer, tension-free repair. Complicating factors that mandate additional protection include prior irradiation, failed prior surgery, and poor tissue quality. These conditions require tissue interposition. In most cases of high VVF after hysterectomy, we perform the interposition of a peritoneal flap between the first two layers of fistula closure and the advancement of the vaginal wall flap. The tissue is readily available, requires minimal additional dissection, and creates a more secure closure of the fistulous tract.

#### *Other Techniques*

The abdominal approach is beyond the objectives of this chapter. We use the abdominal approach only in selected patients requiring concomitant abdominal procedures such as augmentation cystoplasty or ureteral reimplantation.

The Latzko operation, originally described in 1942, uses partial colpocleisis to treat the VVF.<sup>18</sup> The operation consists of denudement of the vaginal wall around the fistula without excising the fistulous tract. A separate layered closure is performed that includes the bladder, fistula, and vagina. A major concern with this procedure is vaginal shortening. However, success rates of 93% and 95% have been reported in two series of 43 and 20 patients, respectively, with no significant patient-reported vaginal shortening or sexual dysfunction.<sup>19,20</sup> Many gynecologists still use this technique because of its technical ease and minimal morbidity.

Transurethral suture cystorrhaphy without fistula tract excision has been described as a minimally invasive alternative for smaller fistulas (5 to 8 mm) located away from the ureteral orifices. The technique requires fulguration of the tract and surrounding bladder mucosa before combined transurethral and abdominal endoscopic suture placement. A minimum 2- to 3-

week period of bladder drainage is required. Eight (73%) of 11 patients treated with this technique were cured.<sup>21</sup>

With the recent upsurge in minimally invasive surgery, VVF repair also has been done laparoscopically.<sup>22</sup> The approach was first described in 1994 and has since undergone various modifications, including use of endostaplers, omental interposition, and layered closure.<sup>23</sup>

### Management of Complex Fistulas
