implies that when the virus does access the T-cell compartment, some viral antigen expression is maintained (as judged by resultant cytokine production), yet the infection is not cleared by immune surveillance. It will be important to understand how this occurs, what the early events of T-cell infection are, and what cellular genetic changes are subsequently involved in the rapid evolution of these lymphomas. Almost certainly, tumorigenesis does not involve a simple transfer of the virus' physiologic growth-transforming program from a B-cell to a T-cell environment. These T-cell lymphomas, and indeed all available *in vitro* models of T-cell infection, do not express the EBNA2 and EBNA3 family proteins characteristic of B-cell growth transformation but display a more restricted form of latency.

In contrast, BL, HD, the NK/T-cell lymphomas, and the gastric and nasopharyngeal carcinomas all develop over much longer latent periods, more typical of tumors with a complex multistage pathogenesis. In each case, we still know relatively little about the mechanism whereby EBV contributes to tumor development or about the timing of viral action. In at least four tumor types (BL, HD, and the two carcinomas), different subtypes of the tumor distinguishable by histologic or geographic criteria show different strengths of association with the virus. However, the existence of an EBV-negative subset of tumors need not weaken the case for an etiologic role for the virus when present. The example of HD is particularly instructive here in that a virus-induced effect that is postulated to be important for tumor development in EBV-positive disease (constitutive NFkb activation) is indeed also a feature of EBV-negative disease, although there it is produced by a quite different, virus-independent, mechanism.

The tumors with long latency periods are also distinct in that they all arise in nonimmunocompromised patients who (where studied) have virus-specific CTL memory still intact. The same tumors also display restricted forms of virus latency characterized by Qp rather than Cp/Wp usage and hence by down-regulation of the immunodominant EBNA3A, 3B, 3C proteins. This might be interpreted as indicating immunologic pressure for selection of a cell lacking the EBNA3 proteins, perhaps as a final rate-limiting step in tumor evolution. In fact, this is unlikely to be the case, not least because (with the possible exception of HD) these tumors show no evidence of increased incidence in T-cell–immunocompromised patients. It is much more likely that the resident form of virus latency is imposed by the tumor cell phenotype per se. Thus, the restricted forms of latent gene expression in B-cell malignancies such as BL and HD seem to reflect forms transiently adopted by EBV at particular times during the normal life history of an infected B cell. Likewise, the non–B-cell tumors appear to arise from the (relatively rare) entry of the virus into an atypical cell lineage in which Cp/Wp usage is not naturally activated or at least is not sustainable.

PREVENTION AND CONTROL OF DISEASE

The sheer range of EBV-associated diseases emphasizes the importance of developing either prophylactic vaccines to reduce disease burden or therapeutic strategies that specifically target virus-positive lesions. A number of approaches are currently being pursued towards these goals.

Prophylactic Vaccination to Modify Primary Infection

Identifying the major viral envelope glycoprotein gp350 as the dominant target of the neutralizing antibody response (199,465) was the initial spur to the development of a prophylactic EBV vaccine. However, it is now evident that neutralizing antibodies alone, or the combination of antibody and cell-mediated responses to a single envelope component, are unlikely to offer long-lasting sterile immunity against an orally transmitted agent such as EBV (504,511). Nevertheless, a gp350-based vaccine could reduce the dose of infectious virus acquired orally and, particularly if combined with other vaccine antigens eliciting appropriate CD8+ T-cell responses, could limit virus replication at the initial site of infection. The consequent reduction in virus load may therefore be sufficient to prevent primary infections leading either to the symptoms of acute IM or, in immunocompromised patients, to PTLD.

Prophylactic Vaccination in Animal Models

Certain species of New World primate, although carrying their own LCVs, do not have cross-reactive antibodies against EBV and remain susceptible to experimental infection. The common marmoset can be infected by submucosal injection of EBV at oropharyngeal sites, leading in some cases to mild mononucleosis-like symptoms followed by viral persistence in the lymphoid system (95). By contrast, cotton-top tamarins (421) and owl monkeys (125) are susceptible not just to EBV infection but also to an EBV-driven B-lymphoproliferative disease, which in histologic appearance, oligoclonality, and viral gene expression, mirrors PTLD. However, disease induction requires direct intraperitoneal injection of relatively large doses of virus rather than infection by the natural oral route. Despite these limitations, studies with cotton-top tamarins have clearly demonstrated disease protection both by subunit gp350-based vaccines in various adjuvant formulations and by recombinant vaccinia and adenovirus vectors expressing gp350 (310,311,365). Interestingly, protective immunity in these and other studies did not always correlate with the presence of virus neutralizing antibodies, implying a role for gp350-specific cell-mediated responses in disease protection (311).

Access to a more physiologic animal model of EBV infection has become important not just for testing vaccination strategies but also for studying more closely the biology of the virus *in vivo*. The LCVs of Old World primates are interesting in this regard because they share extensive genome technology with EBV, have similar B-cell–transforming activity *in vitro* and, as shown by the LCV of cynomologus macaques, can induce B-lymphoproliferative disease or lymphoma in their natural hosts when T-cell immunity is impaired (134). Recently, experimental infection of young rhesus macaques with rhesus LCV has been shown to induce a transient IM-like illness with oropharyngeal virus replication, lymphocytosis, and sequential antibody responses to lytic and then latent cycle antigens. This was followed by the establishment of a carrier state with apparent immunity to a second exogenous viral challenge (307). Such a model has a number of important potential applications.

Prophylactic Vaccination in Humans

The first clinical testing of a gp350-expressing recombinant viral vaccine, based on the Chinese Tien Tan strain of vaccinia, was carried out on small groups of EBV-seronegative and EBV-seropositive children in Southern China.

Antibody responses to gp350 were induced in the former group and elevated in the latter, and six of nine vaccinees who were EBV-seronegative at the beginning of the trial remained virus free for at least the following 3 years (167). More recently, a gp350 subunit vaccine preparation has been administered to young adults and neutralizing antibody responses induced; the efficacy and duration of vaccine-induced protection from natural EBV infection remains to be determined (114).

Recognition of the importance of CD8+ T-cell responses in controlling primary EBV infection opens up the possibility of an alternative vaccine strategy based around virally encoded T-cell epitopes. Thus, it may be possible to prime the CD8+ T-cell response in naive individuals by vaccinating either with the synthetic epitope peptides themselves or with vectors expressing polyepitope constructs carrying epitopes for different HLA alleles in linear sequence (316). Such a strategy would again be aiming to limit lytic virus replication or the proliferation of latently infected cells within the initial period after oropharyngeal EBV transmission, rather than to prevent infection per se. First-generation vaccines, using synthetic lytic and latent cycle epitope peptides restricted through the HLA-B8 and HLA-A2.01 alleles, are now being tested in seronegative young adults at risk for IM (316). It is possible that maintenance of CD8+ T-cell immunity requires virus-specific CD4+ T-cell help *in vivo*, and the identification of immunodominant CD4+ T-cell epitopes in EBV antigens of the lytic and latent cycles is an important focus of current research.

Therapeutic Intervention

The involvement of the virus in so many proliferative or frankly malignant diseases offers a number of novel therapeutic possibilities. One gene therapeutic approach is to exploit the presence within tumor cells of viral transactivators such as EBNA1 (220) or EBNA2 (138) in order to drive expression of a suicide gene. Alternatively, EBV-positive tumor cell growth might be reversed by targeting EBNA1 (206) or LMP1 (229,298) transcription using ribozymes or antisense oligonucleotides. Many of these strategies remain at the “proof of principle” stage, however, whereas considerably more progress has been made toward targeting tumors by immunotherapeutic approaches.

Immunotherapy of PTLD-like Lesions in SCID Mice

Attempts to reconstitute the human immune system by xenografting in the severe combined immunodeficient (SCID) mouse, which lacks mature B or T cells, provided an unexpected animal model of EBV-induced lymphomagenesis. Reconstitution with more than 5×10^7 PBMCs from EBV-seropositive donors frequently leads to the appearance within 8 to 16 weeks of EBV-positive human B lymphomas, which in terms of histologic appearance, oligoclonality, and EBV gene expression, closely resemble the early-onset PTLD lesions seen in transplant patients (312; reviewed 218). Interestingly, tumor development requires the presence of autologous T cells (preferentially the CD4+ subset) in the original inoculum. This suggests that T-cell–derived cytokines enhance the early survival and growth of EBV-infected B cells in the SCID mouse environment at a time when autocrine B-cell growth factors are limiting. Thereafter, established tumors can be cured, or their growth severely impaired, by infusions of EBV-specific CTLs generated from the autologous donor by LCL stimulation *in vitro* (50,56,263), whereas lymphokine-activated killer cells and NK cell clones had little if any effect in the same assay (56,336).

Immunotherapy of PTLD in Humans

While the above work was in progress, an exactly analogous therapeutic strategy was being developed and tested in the clinic (reviewed in 195 and 336). This involved bone marrow transplant recipients, who can be at high risk of PTLD immediately after transplantation and in whom the disease arises in bone marrow-derived donor B cells. A first report indicated that PTLD growth could be reversed by a single infusion of small numbers of fresh PBMCs from the healthy EBV-seropositive bone marrow donor (346). This was associated with a dramatic and sustained increase in the EBV-specific CTL precursor frequencies in the patient's blood over several weeks after infusion (288), but was also accompanied by a high incidence of graft-versus-host disease (336,346). A second report showed that polyclonal preparations of EBV latent antigen-specific CTLs, reactivated from donor PBMCs by LCL stimulation *in vitro*, achieved equally effective tumor control without graft-versus-host disease and also could be used prophylactically to reduce high EBV genome loads in the blood of patients at risk for PTLD (383). Again, in many patients, there was a marked increase in EBV-specific CTL precursor frequency in the blood after a few weeks of infusion, and gene marking showed persistence of the infused cells for at least the next 3 years, during which time all infused patients remained tumor free (194,195,384). Several observations imply an effector role for EBV-specific T cells in this situation: first, the inability of nonspecific T-cell preparations to reduce viral load (169); second, the specific infiltration of infused cells at the site of the tumor (384); and third, the finding that a rare tumor that grew out in the face of T-cell therapy carried an EBV strain that had lost the two CD8+ epitopes against which the infused T cells were predominantly directed (155). Although CD8+ T cells recognizing latent cycle epitopes are thought to be the major effectors against PTLD, CD4+ T cells are present within all infused preparations (usually as a minor but occasionally as the major component) and may be important either in facilitating the CD8+ T-cell expansion *in vivo* or as effectors in their own right.

Extending this approach to the treatment of PTLD in solid organ transplant recipients is logistically more difficult because these tumors are usually derived from host rather than donor B cells. In most cases, therefore, preparations of autologous EBV-specific T cells have to be made from posttransplantation bleeds when the patient is already immunocompromised. A recent study has nevertheless shown that active CTL preparations can indeed by generated from such individuals by a modification of the *in vitro* LCL stimulation protocol, and that infusing such T cells can efficiently target PTLD lesions (234). Nevertheless, the above logistic difficulties have prompted some laboratories to attempt adoptive therapy using EBV-specific T-cell preparations from allogenic but partially HLA-matched donors (176,201,336). Although such effectors are unlikely to persist *in vivo*, they may nevertheless provide an immediate means of targeting PTLD lesions, especially in patients who have undergone primary EBV infection at the time of transplantation and in whom the virus-specific T-cell response has not yet developed.

Immunotherapy for Other EBV-associated Tumors

The fact that most EBV-positive malignancies other than PTLD show highly restricted latent antigen expression, with loss in particular of the immunodominant EBNA3A, 3B, 3C proteins, emphasizes the difficulties inherent in trying to target these tumors by immunologic means. Unless it proves possible to activate expression of these immunodominant EBNA3 targets in tumor cells, for instance, by using a demethylating agent such as 5'-azacytidine to rescue Cp transcription (378), immunotherapeutic approaches are likely to have to rely on subdominant components of the CD8+ T-cell response. Most interest to date has focused on HD, in which two subdominant target antigens, LMP1 and LMP2, are expressed in the malignant cells. Conventional LCL-stimulated CTL preparations can be generated *in vitro* from the blood of HD patients and, although predominantly reactive to EBNA3 antigens, sometimes contain weak reactivities to LMP2 or, rarely, to LMP1 (81,140, 385,425). Infusing such T-cell preparations back into the patients has so far shown persistence of the cells for several months and a corresponding reduction in EBV genome load in PBMCs (385); more studies will be required to determine whether there is any effect on tumor growth.

A further step will be to generate CTL preparations that are enriched for LMP reactivities at the expense of the usually dominant EBNA3 response. Selective *in vitro* reactivation of LMP-specific CTLs from memory can be achieved by stimulating PBMCs with epitope peptides when these sequences have been identified (237,371) or with monocytes and dendritic cells expressing whole antigen from recombinant viral vectors (368,425). It is encouraging in the context of HD therapy that both LMP1 (237) and LMP2 (268) epitopes are known that are weakly immunogenic and restricted through HLA-A2.01, a frequent allele in Western populations. Similarly, in the context of NPC, a tumor in which LMP2 appears to be more frequently expressed than LMP1, there are LMP2 epitopes that are restricted through the HLA-A11.01, HLA-A24.02, and HLA-B40.01 alleles, all of which are relatively common in Southeast Asian populations (268). Their existence offers the chance of targeting these EBV-positive malignancies either with combinations of epitope-specific CTL clones reactivated and expanded *in vitro* before reinfusion, or through boosting the patient's endogenous response to these epitopes by vaccinating with vectors expressing whole antigen or polyepitope constructs.

SUMMARY

Considerable progress has been made in our understanding of the biology of EBV infections and in our appreciation of the full extent of EBV-associated disease. A series of experiments on isolated B-cell subpopulations, now being complemented by the analysis of individual microdissected cells, is finally opening up the study of EBV infections within the human B-cell system *in vivo*. This is showing that EBV has evolved sophisticated mechanisms first for colonizing the B-cell system of the naive host, then for persisting within that system in the face of immune surveillance, and finally for rescuing infectious virus from latently infected cells within the persistent pool. Progress has also been made in identifying the full range of CD8+ T-cell responses that control EBV infection, in the process revealing the unexpectedly large size of the lytic cycle-specific response, particularly in IM patients. An equally thorough analysis of CD4+ T-cell, and perhaps also NK cell, responses is now required. An improved understanding of the immune response to EBV infection, combined with the lessons being learned from primary infections in XLP and VAHS patients, has the potential to unravel the pathogenesis of IM. There is, however, still much to learn about the biology of EBV infections, and an animal model that faithfully reproduces this biology will be essential for hypothesis testing, in particular for the analysis of individual viral gene functions *in vivo*. The recently developed rhesus LCV model holds considerable potential in that regard.

The existence of atypical primary infections, leading in the case of immunocompromised patients to PTLD lesions and in the case of VAHS patients to T-cell lymphoma, provides an important opportunity to study accelerated examples of EBV-positive tumor development at the molecular level. At the same time, the range of other EBV-associated tumors goes on increasing, the most significant recent additions being the two histologic subtypes of gastric carcinoma and the smooth muscle cell tumors of immunosuppressed patients. The number of tumors now linked to EBV is unexpectedly large, but in each case, the consistency and specificity of the association are impressive, and the circumstantial evidence for a viral involvement in etiology is correspondingly strong. This presents students of this virus with two challenges. The first is to explain at a mechanistic level how EBV contributes to the development of so many distinct malignancies. The pace of recent work analyzing the biochemistry and effector functions of EBV latent proteins (reviewed in Chapter 74 [245]) suggests that this is an achievable goal in the near future, especially as host cell pathways of growth control are characterized in ever-greater detail. The seminal work identifying HD as a tumor of B-cell origin illustrates how advances outside the immediate EBV field can profoundly affect our understanding of the virus' role in tumor pathogenesis. The second major challenge is to exploit our increased understanding of EBV biology in designing new ways to prevent or treat virus-associated disease. It should be possible to develop an effective prophylactic vaccine that, although not protective against infection per se, nevertheless reduces the chances of primary infection leading to acute disease (acute IM, VAHS, or PTLD). Whether such a vaccine would alter the long-term risk for malignancy is debatable. However, with respect to established EBV-positive malignancies, the continued expression of viral proteins in tumor cells offers the prospect of at least two therapeutic interventions: pharmacologic targeting to interfere with the viral effector mechanisms that promote tumor growth, and immunologic targeting exploiting the immune system's capacity to recognize viral antigens as foreign. In this latter regard, the success of adoptive T-cell therapy for PTLD represents an important proof of principle and illustrates how effective an immunotherapeutic approach can be in the right circumstances. The extension of this strategy to other EBV-associated malignancies is awaited with interest and not a little uncertainty. EBV, the first human tumor virus to be discovered, therefore continues to provide a fascinating series of challenges to both basic and clinical scientists working in an area of human medicine in which virology, immunology, and oncology meet.

CHAPTER 76 Cytomegaloviruses and Their Replication

Edward S. Mocarski, Jr. and Charmain Tan Courcelle

The cytomegaloviruses (CMVs) are a distinct, widely distributed subgroup of herpesviruses that share common growth characteristics and induce a cytopathology involving characteristic nuclear and cytoplasmic inclusions (432,499,500). Viruses in this group were generally known as salivary gland viruses until the common name cytomegalovirus was proposed by Weller et al. (595) to reflect both virus-induced cytopathic effects and the virus's role in congenitally acquired cytomegalic inclusion disease.

Cytomegaloviruses are the principal members of the betaherpesvirus subgroup, and they share several characteristics with other herpesviruses, including virion structure and the ability to establish persistent and latent infections. The CMVs exhibit a number of distinguishing biologic characteristics common to the betaherpesviruses, including salivary gland tropism, strict species specificity, and slow growth in cultured cells, all of which have been reviewed (216,378,461). Mammals each have a characteristic CMV (216,432,522). Based on genome nucleotide sequence comparisons of human CMV (92) and murine CMV (446), or human CMV and human betaherpesvirus HHV-6 (188), members of the betaherpesviruses have diverged markedly in different animal species as well as within the same animal species. Despite this divergence, significant predicted amino acid sequence homology in a core set of 70 to 80 betaherpesvirus-common open reading frames (ORFs) permits all of these viruses to be classified in the same subfamily (92,188,402,446,577) (see Chapter 80 and Chapter 81). In a similar way, amino acid sequence homology in as many as 46 viral ORFs controlling DNA replication, genome packaging, and virion morphogenesis shows that betaherpesviruses are related to all mammalian herpesviruses (see Chapter 71). Such standard sequence comparisons as well as more elaborate approaches (251) provide evidence that betaherpesviruses are more closely related to each other than they are to other herpesviruses.

In most areas of the world, human CMV spreads at an early age and infects a large majority of the population. This pattern has been altered by increased hygiene in developed countries, where this virus may reach only 40% to 60% of the population. Thus, in the developed world, a large proportion of the adult population remains susceptible to primary infection, increasing the risk of congenital transmission and subsequent disease (see Chapter 77). The importance of human CMV as a pathogen has also risen over the past three decades with the increase in organ allografting and immunosuppressive posttransplant therapies and the increase in acquired immunodeficiency syndrome (AIDS). These conditions predispose individuals to a primary CMV infection or to reactivation of latent infection, which may lead to fulminant, life-threatening disease that can be difficult to treat despite available antiviral drugs (141,379) (see Chapter 77).

VIRUS STRUCTURE AND GENOME ORGANIZATION

The virion of human CMV consists of an icosahedral capsid encasing a 235-kbp linear genome, surrounded by a tegument or matrix (354,617) and enveloped in a lipid bilayer carrying a large number of virus-encoded glycoproteins (66,511). By cryoelectron microscopy, the capsid appears similar to, though larger than, the herpes simplex virus (HSV)-1 capsid (95). In thin sections of infected cells (Fig. 1A,Fig. 1B) or by negative staining, the CMV envelope appears more pleiomorphic than the envelope of other herpesviruses (617), allowing intact CMV virions to be distinguished from other herpesviruses based on morphology. The genomes of the characterized CMVs are all linear DNA molecules ranging in size from 200 to 240 kbp (Table 1), which is significantly larger than those of other herpesviruses. The human CMV genome also exhibits a pattern of terminal and inverted repeats that vary in size depending on the virus strain and passage history (see Fig. 1C).

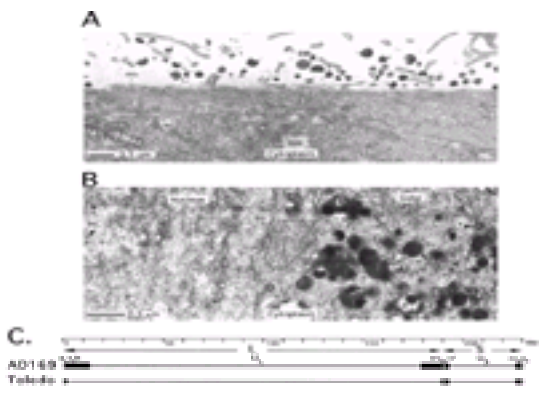

FIG. 1. Virus particles, replication, and genome structure. **A:** Surface of a cell onto which virions (*V*) and dense bodies (*DB*) of human CMV (Towne strain) have attached. This illustrates the size and approximate ratio of these two types of particles in a virus preparation, and the ability of both to attach to the cell surface. **B:** Productively infected cell with nucleocapsids (*NC*) in the nucleus and maturing virus (*V*) and dense bodies (*DB*) in the enlarged Golgi region of the cytoplasm, which forms the characteristic cytoplasmic inclusion of CMV. Many capsids lacking a dense core of nucleic acid can be observed in abundance in the nucleus, where, along with nucleocapsids, they form a characteristic nuclear inclusion of CMV (giving an “owl's eye” appearance to cells) (216). Envelopment of nucleocapsids (and capsids) occurs at the inner nuclear membrane, where thickened patches of modified membrane develop, as well as in the cytoplasm, whereas dense body envelopment occurs exclusively at cytoplasmic membranes. The *bar* represents 0.5 µm. (Micrographs similar to these were first published in ref. 387.) **C:** Human CMV genome structure. The *top line* is a size scale in kbp. The *second line* delineates the L and S components of the genome by *arrows.* The completely sequenced AD169*var*UK strain genome structure (92,124,386) is shown on the *third line* with unique sequences (*thin lines*) flanked by inverted repeats (*boxed areas*). The predicted genome structure of a low-passage level strain is depicted on the *fourth line* based on limited sequence analysis (82). Note that the leftward *b* sequence is present as a unique sequence, and the rightward *b* sequence repeat is truncated in clinical strains and is replaced by an additional unique (U_L) sequence . The lettering above the genome depicts the following features: The L-terminal *a* sequence repeat (a_L), zero to several (*n*) additional copies of the *a* sequence (a_n), the L-terminal *b* sequence repeat of the L component, the unique sequences of the L component (U_L), the L-S junction *b* sequence inverted repeat (*b*'), one to several (*m*) additional copies of the *a* sequence inverted repeats at the L-S junction (a'_m), the L-S junction *c* sequence inverted repeat (*c*'), the unique sequences of the S component (U_S), the S-terminal *c* sequence repeat, and the S-terminal *a* sequence repeat (a_S) with a variable number of additional copies of the *a* sequence (a_n). The *b* and *b*' repeats are also called TR_L and IR_L, respectively, and *cs*' and *c* repeats are also called IR_S and TR_S, respectively (92). In different strains of CMVs, including clinical isolates, the *a* sequence ranges in size from 700 to 900 bp (506).

Virus	Size (kbp)	Isomers (N)	Class[a]	Refs.
Human	229–235	4	E	92,170,200,536
Simian	208–220	1	F	206, Hayward (unpublished)
Rat (Wistar/ATCC)	230	1	F	35,266,577
Rat (Maryland)	230	1	F	74
Murine	230	1	F	144,302,360,362,445
Guinea pig	230	1	F	164,359

[a] E, genome with two components with direct and inverted repeat elements that isomerize to give four sequence arrangements; F, genome with small or no repeat elements. (See Chapter 7.)

TABLE 1. *Size and isomerization of cytomegalovirus genomes*

Simian and human CMV-infected cells contain several capsid forms (called A, B, and C capsids) that are characteristic of herpesvirus replication and represent stages in virion morphogenesis (176,228,315,565). Type A capsids lack DNA and accumulate because of a failure to stably package the viral genome; type B capsids are found predominantly in the nucleus as precursors of mature capsids that lack DNA but contain the viral scaffolding/assembly protein (75,315); and type C capsids are fully mature nucleocapsids. B capsids and virion nucleocapsids are composed of 12 pentons, hexons, and triplexes linking adjacent capsomeres at threefold symmetry positions in a T=16 icosahedral lattice (75,95,565). In addition, cryoelectron microscopy suggests that the overlying tegument in CMV virions is highly ordered in the region immediately proximal to the capsid, distinct from HSV-1 (95). CMV also exhibits a more compact interhelix DNA packing distance than HSV-1 (26 Å versus 30 Å), which explains how its larger genome is accommodated (40).

Three types of virus particles are produced in human CMV-infected cells: virions, noninfectious enveloped particles, and dense bodies; these three types can be separated based on physical differences (176,228,477). Virions contain a 130-nm nucleocapsid that is 5% larger than HSV (HSV) and results in a 17% increase in capsid volume (75,95,56). The noninfectious enveloped particles are readily differentiated from virions in electron micrographs because they lack an electron-dense DNA core (176,228,498,617). They appear to be an enveloped B capsid precursor. Together with dense bodies, they contribute to the relatively high particle-to-PFU (plaque-forming units) ratios (ª100) observed in virus stocks (536). Similar detailed observations have been made in ultrastructural studies of African green monkey (Colburn strain) CMV (565). Dense bodies (see Fig. 1A), which are present in virus preparations in numbers approximately equal to those of virions, are composed of several tegument proteins, predominantly pp65 (ppUL83), enclosed in an envelope derived from cytoplasmic me5)mbranes (117,477). These abundant particles completely lack both a nucleocapsid and viral DNA

(228,271,307,477).

Virion Proteins

Purified virus particles of human CMV have been estimated to contain 30 to 40 polypeptides with molecular weights ranging in size from 20 to over 300 kd (26,175,268,531). The capsid is composed of seven proteins, all of which are homologous to those identified in HSV (see Chapter 72). The major capsid protein (MCP) is encoded by UL86 and forms both hexons and pentons. Minor capsid protein (mCP) encoded by UL85, minor capsid binding protein (mC-BP) encoded by UL46, the smallest capsid protein (SCP) encoded by UL48.5 (also called UL48/49), and three distinct assemblin/assembly protein (AP)-related proteins encoded by UL80, UL80a, and UL80.5 associate with capsids (26,95,176,177 and 178,565). The genes for these proteins are distributed on the viral genome within the herpesvirus-common set of genes (Table 2).

TABLE 2. *"Composite" human CMV genome ORFs, proteins, and characteristics*

The virion envelope carries two prominent herpesvirus-conserved glycoprotein complexes (66,511). One is composed of covalently linked, proteolytically processed dimers of glycoprotein B (gB) encoded by UL55 (118,420,515), and the other is composed of the products of the UL75, UL115, and UL74 genes—gH, gL, and gO, respectively (224,514). These glycoprotein complexes play critical, but as yet incompletely understood, roles in entry that may be common to all herpesviruses. Glycoprotein B is one of the most highly conserved herpesvirus-common proteins (91). Unlike the alpha- and gammaherpesviruses, which have subgroup-specific envelope glycoproteins such as gD and gp220/350 that are central to entry, the only prominent envelope glycoproteins on CMV are members of the herpesvirus-common set. The CMV genome also carries a large number of ORFs with characteristics of integral membrane glycoproteins (see Table 2) that have not been studied in any detail but may encode minor envelope constituents that play roles in attachment and entry.

Between the capsid shell and envelope is a tegument that contains as many as 25 proteins, many of which are phosphorylated as denoted by the prefix *pp.* The most prominent are ppUL83 (pp65), ppUL32 (pp150), ppUL99 (pp28), ppUL82 (pp71), and ppUL48 (huge tegument protein) (63,175,176). Although several transcriptional transactivators (ppUL82, ppUL69, pTRS1, pIRS1) have been localized to the tegument (323,462,609), the functions of most tegument proteins remain uncharacterized. Tegument proteins are conserved among betaherpesviruses but are not herpesvirus-common.

Capsid Proteins

Initial characterization of the protein constituents of different types of CMV capsids (176) highlighted the overall similarity to other herpesviruses; however, the CMV capsid is larger than most and accommodates a significantly larger genome (75,95,565). The MCP in human CMV is a 1,370-amino-acid protein (pUL86) that is one of the most highly conserved herpesvirus-common proteins (91) and forms the major constituent of capsid pentamers and hexamers. Two smaller, less abundant capsid proteins, the 306-amino-acid mCP (pUL85) and the 290-amino-acid mC-BP (pUL46), associate in a 2:1 ratio to form triplexes, major surface structures that interdigitate hexons and pentons (75,95,565). The 75-amino-acid SCP (pUL48.5 or pUL48/49) has not been resolved in cryoelectron microscopic analyses (75), but it is thought to decorate hexon tips and direct tegumentation in a manner similar to its HSV homolog, VP35 (558).

A 708-amino-acid protein encoded by UL80 gives rise to at least three different proteins that carry out distinct functions in capsid assembly. These multiple UL80-derived capsid proteins generate two different-sized scaffolding proteins by posttranslational processing. The most abundant is denoted assembly protein (AP) and is derived from the carboxyl portion (UL80.5) by autocatalytic cleavage events mediated by a 30-kd serine-like maturational protease, assemblin (176,594). Assemblin is itself embedded in the amino-terminal portion of this ORF (30,179,592). The detailed structure of the protease (96,442,487,563) reveals a unique fold and novel type of catalytic triad composed of Ser-132, His-63, and His-157 in contrast with the Ser-His-Asp triads of other serine proteases. In addition, a fourth residue, Arg-166 (320), and dimerization of the protease seem to be necessary for activity. These characteristics make this protein a candidate target for antiviral agents (176).

Assemblin (UL80a) cleaves UL80 products made from a family of 3' co-terminal transcripts encoded in this region (592) into AP (176). The largest UL80 precursor is autocatalytically cleaved a minimum of three times. The first two cleavage events are involved in the maturation and release of the 45-kd human CMV AP, and the third appears to inactivate the protease (30,593). The AP is a major constituent of capsid intermediates and forms a recognizable electron-dense core ring in B capsids that accumulate prior to encapsidation of DNA (75,95,565). This protein directs formation of the capsid shell, a function similar to that of bacteriophage scaffolding protein (176). In addition to its role in maturation, the CMV

assembly protein remains associated with an alternative capsid form that matures as noninfectious enveloped particles (176,228) but appears to be absent from mature virions (565).

Envelope Glycoproteins

CMV is unusual among herpesviruses because it encodes as many as 60 putative glycoproteins, some or all of which could be present on the virion envelope. The envelope of human CMV contains viral proteins embedded in a host lipid bilayer and is derived from intracellular membranes. The acquisition of the envelope and its associated glycoproteins occurs at both nuclear and cytoplasmic sites. Envelope glycoproteins are important targets of the host antibody-mediated immune clearance mechanisms, and many reviews have been written about the synthesis, mapping, function, and immunogenicity of the more prominent envelope glycoproteins (66,378,511). Early studies revealed approximately eight major glycoprotein species in the human CMV envelope (175,531), with one, gB (gpUL55), being recognized as the major envelope constituent (66,175).

As the most highly conserved glycoprotein in mammalian and avian herpesviruses, gB is a type I integral membrane protein that influences virus binding to and entry into cells, cell-to-cell transmission, fusion of adjacent cells, and targeting of progeny virus to apical membranes for release from polarized cells (52,114,398,423,567,568 and 569). Glycoprotein B is the major heparan sulfate proteoglycan-binding glycoprotein (114), and it binds to a 30- to 36-kd cellular protein that is a suspected receptor (7,551). As homologs of gB play an essential role in attachment and penetration in other herpesviruses, it is likely that CMV gB is required for CMV entry (66).

Human CMV gB exhibits important distinguishing characteristics compared to gB from other herpesviruses (reviewed in refs. 66 and 511). Like homologs in most other herpesviruses (but unlike gB from HSV-1), the 906- to 907-amino-acid (150 kd) precursor of human CMV gB is cleaved between amino acids 460 and 461 by a host cell Golgi-localized furin protease (515,575) into two cleavage products of 93 and 55 kd. These proteins remain complexed and appear as a heterodimer on the virion envelope (68). Both N- and O-linked carbohydrates are added to gB, and at least a proportion of this protein is phosphorylated (405) in a manner that may regulate cellular distribution (154). Glycoprotein B is found on all membranes of infected cells and becomes incorporated into virions as they undergo envelopment at different sites (473). Because it is abundant, highly conserved, and the most immunogenic and best studied envelope glycoprotein, gB has been the principle candidate of subunit vaccine initiatives (6,415,515).

As the principal target of neutralizing antibodies detected in human sera (67,120,397), gB has been the subject of many monoclonal antibody epitope mapping studies (28,66,397,515,573). The 55-kd C-terminal cleavage product is immunodominant and contains many neutralizing epitopes (28,515,573); the 93-kd N-terminal cleavage product has fewer neutralizing determinants, and these vary among strains (28,397,515). Polyclonal antisera to the 55-kd component, as well as antisera raised against the intact gB heterodimeric complex, are generally capable of neutralizing viral infectivity (66,420). Although overall strain-to-strain sequence variation in gB is quite low (118,286,515), DNA sequence analysis has revealed that four distinct gB genotypes are in circulation (105). The existence of these genotypes has proven useful in epidemiologic studies (159).

Human CMV gH, or gpUL75, is a 742- to 743-amino-acid envelope glycoprotein (411) forming part of a second, relatively abundant glycoprotein complex to which neutralizing antibodies may be directed (445). Although highly divergent, gH is considered to be a herpesvirus-common glycoprotein because homologs share a pattern of cysteine residues, the presence of a conserved asparagine-glycine-threonine-valine glycosylation signal adjacent to a transmembrane region, and an unusually short carboxyl-terminal cytoplasmic domain (119). The gH complexes with at least one other herpesvirus-common glycoprotein, denoted gL, which facilitates transport to the cell surface (253,514). CMV gL is encoded by UL115 (see Table 2) and is a 278-amino-acid (32-kd) glycoprotein modified by N-linked and possibly O-linked carbohydrates. In CMV, a 145-kd protein (192), the likely product of the UL74 gene, called gpUL74 or gO, also joins with gH/gL to form a heterotrimeric envelope glycoprotein complex (gH/gL/gO) (224). In the gammaherpesvirus Epstein-Barr virus (EBV), viral proteins that complex with gH/gL influence cell tropism (586), and CMV gO may function in a similar role.

CMV gH is a target for complement-independent neutralizing antibodies (445), and it exhibits even less overall variation than gB (101), suggesting that evolutionary constraints have preserved protein conformation (514). Anti-gH antibody can prevent cell-to-cell transmission of virus (445), consistent with a role for this protein in membrane fusion. Antibodies that mimic the gH/gL complex block virus penetration of cells (254,256) and have implicated a cellular 92-kd phosphorylated glycoprotein as a possible receptor (255,256). Thus all three components of the gH/gL/gO complex are likely to be essential for viral entry.

A third herpesvirus-conserved glycoprotein complex is likely to be associated with the CMV envelope. One protein, encoded by UL100, initially referred to as the integral membrane protein (317), is part of this complex (250). UL100 and UL73 are the positional homologs of alphaherpesvirus UL10 (gM) and UL49.5 (gN), respectively. CMV UL73 also exhibits sequence homology with EBV BLRF1 (gN) (92). A gM/gN glycoprotein complex has been characterized in EBV and alphaherpesviruses (see Chapter 72 and Chapter 74), and, by analogy, a similar complex between human CMV pUL73 and pUL100 has been observed (Britt and Mach, personal communication, 2000). In fact, this gM/gN complex is probably the CMV envelope glycoprotein gcII complex (250). In other herpesviruses, both gM and gN are dispensable for growth in cell culture.

Several additional viral glycoproteins are likely to be minor envelope constituents but are not apparently associated with any major glycoprotein complexes. The glycoprotein gp48, or gpUL4 (86), is synthesized at both early and late times, with protein accumulating to highest levels at late times via complex transcriptional and translational controls. The 48-kd size of gpUL4 is the result of heavy modification of the 152-amino-acid polypeptide by both N-linked and O-linked carbohydrates. Glycoprotein UL4 is dispensable for growth in cell culture (455,547).

The products of one (UL33) of the four ORFs (UL33, UL78, US27, US28) that exhibit amino acid sequence similarity to

seven-transmembrane-spanning (7TM) receptors (94,188) have been detected in purified virions (347), suggesting that this class of protein is likely to be carried in the virion envelope. The presence of over 60 ORFs with sequence characteristics of integral membrane proteins (82,92) strongly suggests that additional functions will continue to emerge for less abundant envelope glycoprotein constituents.

Tegument Proteins

At least 25 proteins are located in the tegument layer between the virion capsid and envelope (176). The products of 11 ORFs (UL25, UL26, UL32, UL47, UL48, UL48.5, UL82, UL83, UL85, UL88, UL99) have been detected when virion/dense body polypeptides are electrophoretically separated (26,176), and all appear to be both phosphorylated (175,458) and highly immunogenic (303). These ORFs are all conserved in the betaherpesviruses (188,402,446,577), although only a small number are herpesvirus-common (see Table 2). Two tegument proteins, pp150 (ppUL32 or basic phosphoprotein), a 1,048-amino-acid (150- to 155-kd) protein, and pp65 (ppUL83 or lower matrix protein), a 561-amino-acid (65- to 68-kd) protein, are the most abundant proteins made during replication (175,531).

The large amount of pp65 produced by laboratory strains of virus is associated with abundant dense body production. Less pp65 is present in virions made from fresh clinical isolates (271). The target antigen in antigenemia assays that are used for rapid diagnosis of CMV clinical infection is pp65 (see Chapter 77). Although all tegument proteins are phosphorylated, pp65 is a major phosphate acceptor in infected cells as well as a primary target for phosphorylation *in vitro* by the virion-associated protein kinase (458,508). Protein kinase activity attributed to pp65 itself is probably caused by the interaction of pp65 with a host-derived kinase (162,458). Given its abundance, it is surprising that pp65 is completely dispensable for replication in cell culture (481).

The other major tegument phosphoprotein, pp150 (ppUL32 or basic phosphoprotein) (175,458), is the product of UL32 (234). It is incorporated preferentially into virions rather than dense bodies, and it is estimated to make up 20% of the virion mass (37). The pp150 is also a target for phosphorylation by the virion-associated protein kinase (458). This protein contains 19% serine or threonine and has a single O-linked N-acetylglucosamine addition (37), a modification that has also been observed on cellular proteins localizing to nuclear membranes. Also, pp150 is a broadly recognized viral antigen that is detected by 85% to 90% of CMV-seropositive human sera (303), resulting in its inclusion in recombinant protein-based serologic assays (456).

A number of additional proteins have been identified as known or likely tegument constituents. One abundant phosphoprotein, called pp71 (ppUL82 or upper matrix protein), functions as a transactivator of gene expression (323). A second, ppUL69, is also a virion tegument-associated transactivator (610). This protein exhibits limited sequence similarity to HSV ICP27, a nonstructural a gene product with a role in regulating late posttranscriptional events in replication. Mutations disrupting the UL82 or UL69 genes have shown that both are dispensable for high multiplicity of infection (MOI) of cultured fibroblasts (Greaves, personal communication, 1999) (204). Additional viral proteins have been localized to the tegument of partially purified virus particles using resistance to protease digestion as a criterion for being contained within enveloped particles. These include the viral DNA polymerase (345), the UL97 kinase (574,611), a late protein encoded by UL94 (607), the transactivator pTRS1/IRS1 (462), and pUL36 (417); however, none is sufficiently abundant to be directly detected as a protein species in purified virus particles (26,176).

The tegument also contains a number of functionally uncharacterized proteins, including one relatively abundant phosphoprotein denoted pp28 or ppUL99, a 190-amino-acid (28-kd), highly immunogenic glycoprotein (303) that localizes near the capsid surface in virions (307). A protein implicated in genome encapsidation, pp130 (ppUL56) is virion associated (51,63). Based on drug resistance studies (290), pp130 may complex with the CMV terminase (ppUL89) to package viral DNA during virion maturation. One additional protein, pp67, which includes some UL65 sequence (125), has not been consistently observed in characterized virus strains. The association of UL25, UL26, UL47, and UL88 products with the tegument has been determined by sequencing proteins directly isolated from virus particles (26).

Additional tegument proteins may be predicted from the nucleotide sequence of the human CMV genome because they are arranged in blocks with positional similarity to known or suspected herpesvirus tegument proteins (378). The human CMV UL47–UL53 cluster may serve functions similar to that of HSV UL37–UL31; CMV UL56 is likely to serve the same function as HSV UL28; CMV UL76 and UL77 may be analogous to HSV UL24 and UL25; CMV UL87 may be analogous to HSV-1 UL21; and the CMV UL89–UL104 cluster contains functions similar to those of HSV-1 UL15–UL6 (see Table 2). Discussions of the various homologs is presented in reports that deal with betaherpesvirus genome sequence analyses (92,188,402,446,577).

Host Proteins

A number of abundant host cell proteins, including b $_2$-microglobulin, actin, and various cellular enzymes, have been observed to associate with purified virions (26,162,194,371). The association of these host proteins with virus particles raises several interesting implications. Reports have identified proteins with size characteristics (183,371) of candidate cellular receptors for this virus (7,256,502,551), suggesting that the virus may mature carrying away receptors bound to its surface. Adherence of b $_2$-microglobulin suggests a way that CMV attaches to cells (194), and a report of a host cell actin-related protein suggests a means of cytoplasmic transport (26). Kinase activity associated with pp65 in virions (458) appears to be a host cell enzyme (162).

Other Virion Constituents

The virion of CMV, unlike that of other DNA viruses, contains two classes of RNA in addition to the DNA. One type of RNA forms hybrid structures within the origin of replication (*ori*Lyt) in packaged genomes (440), and the other type of RNA appears to be within the tegument and to be expressed after entry into cells (65). Except for a single copy of the tightly packed DNA with RNA at *ori*Lyt (40), the core of the human CMV virion contains only spermine and spermidine, at a ratio of approximately 2:1 (181), which probably counteracts the negative charge of packaged DNA. CMV replication is

sensitive to chemical agents that disrupt polyamine synthesis (181,570).

Viral DNA

The genome of human CMV (235 kbp) contains internal repeats in a class E genome structure (see Table 1 and Fig. 1C) and undergoes inversion of two genome components similar to HSV-1 (see Chapter 71). The genomes of all other characterized betaherpesviruses, including all the animal CMVs, are linear and lack internal repeats (see Table 1). The human CMV genome has two unique components, U_L and U_S, flanked by inverted repeats *b* (TR_L/IR_L) and *c* (IR_S/TR_S) (see Fig. 1C). A directly repeated *a* sequence is found at the genome termini (383) and is also present in inverted orientation at the L-S junction. This arrangement of *a* sequences promotes genome inversion. The *a* sequence carries cis-signals, called *pac*-1 and *pac*-2, for cleavage and packaging of the viral genome (260,360,383,512). The *pac*-1 and *pac*-2 sequence elements are conserved in all herpesvirus genomes (361,383); however, their location relative to the cleavage site varies. In human CMV, cleavage occurs to one side of the *pac*-1 and *pac*-2 elements (260), whereas in other herpesvirus genomes that have been examined, including rodent and guinea pig CMVs (349,359,578), cleavage occurs between these elements. DNA cleavage varies by a few nucleotides in some strains but always leaves ends with 3' overhanging nucleotides (383,550).

The human CMV genome is G+C rich and contains a significant number of direct and inverted repeats, exhibiting a greater density of genomic repeats than other herpesviruses. Aside from the *a* sequence that contains a large array of short degenerate repeats (512), three regions show an extremely high density of closely spaced inverted and direct repeats—the DNA replication origin, *ori*Lyt, and two transcriptional enhancers, *ie*1/*ie*2 and US3 (350).

Following serial undiluted passage, human CMV generates defective viruses carrying DNA molecules that are shorter than genome length (444,536). These defective DNA molecules are approximately one-third smaller than intact viral genomes, or roughly 150 kbp rather than 235 kbp, which is the size packaged in other herpesviruses. The structure of defective DNA has not been evaluated further except to show that CMV does not generate the head-to-tail concatemeric repeats observed for other herpesviruses. Novel restriction fragments are found in defective CMV DNA, suggesting that specific deletions or rearrangements occur relative to standard viral DNA.

Genome Organization

The only human CMV strain that has been completely sequenced is a laboratory-adapted strain, AD169 (465). This 230,283-bp sequence (accession number X17403) with 208 nonoverlapping ORFs of greater than 80 codons originally reported (92) is among the largest and most complex animal virus genomes. ORFs are numbered sequentially and designated by their location within the unique (U_L, U_S) and repeated (TRL/IRL, TRS/IRS) regions of the viral genome, and a nomenclature for naming viral genes and proteins has evolved (511). The ORFs initially identified in strain AD169 did not represent a full set of viral genes, however; thus all known human CMV ORFs are listed in Table 2. Gene functions of the 213 known genes are assigned based on direct study as well as on information from sequence homologs in other herpesviruses. As in all herpesviruses, the genes encoding different human CMV temporal classes and functions are interspersed across the genome. For example, the earliest genes to be expressed during viral replication, the a or immediate-early (IE) genes, map to diverse locations in both the L and S components.

The AD169 strain of human CMV chosen for genome sequence analysis (92) is a variant (AD169*var*UK) that was propagated under growth conditions to attenuate virulence for its use as a live attenuated vaccine (146). Its genome was plasmid cloned following 25 years of serial passage in various laboratories (409). The reported sequence contains errors requiring correction (497) as well as omissions that complicate its use as a prototype. For example, the report misses a 929-bp sequence in the UL42–UL43 region that is carried by all strains of CMV, including AD169 (124,386) (accession number AF01963), and a large, approximately 15-kbp region with 19 ORFs that is absent from AD169 but present in the Toledo strain and clinical isolates of CMV (82). Furthermore, when portions of clonal isolates of Towne (passage 125) and Toledo (passage 9) (accession number U33331) strains were subjected to nucleotide sequence analysis, a large U_L-*b*8' region that is absent from AD169 but present in fresh clinical isolates of CMV was identified (82). By combining all of this information, Table 2 approximates the expected genome organization of a wild strain of CMV.

Families of ORFs that result from gene duplication events during evolution are present in all betaherpesviruses (92,188,378,402,446,577). DNA sequence comparisons of the genomes of various animal betaherpesviruses to human betaherpesviruses reveal a remarkable level of sequence divergence, such that the viral DNAs do not cross-hybridize to any extent, and only short stretches of nucleotide sequence are conserved. These regions include the *pac* sequences (for cleavage and packaging of viral genomes, as discussed in the preceding section), as well as some transcription factor binding sites, most notably in the major immediate-early enhancer (61,140). In contrast to the relatively low level of DNA sequence conservation, betaherpesvirus genomes retain significant amino acid sequence homology in approximately 80 ORFs in the UL24 to UL116 region (188,402,446,577) (see Table 2). By an adopted convention, nomenclature of animal CMV ORFs follows that set in place for human CMV ORFs, so murine or rat CMV ORFs that retain sequence similarity to human CMV ORFs are designated with upper-case letters (e.g., M44, R44) whereas those not conserved in human CMV are represented by lower-case letters (m144, r144). ORFs found in U_S or the repeated regions of the human CMV genome are not well conserved in other betaherpesviruses.

Although genome sequence analysis confirms the relationship of all betaherpesviruses, this subgroup is the most divergent and ancient of the herpesvirus subgroups (187,251,355). The presence of as many as 46 herpesvirus-common ORFs provides strong evidence of a common origin for all herpesviruses (see Table 2). Using information largely from studies characterizing HSV-1 mutants, approximately one quarter of these ORFs appear to encode DNA replication and metabolism functions, and three quarters are predicted to play roles in virion maturation and structure (see Table 2) (92,378). All betaherpesviruses exhibit a characteristic genome organization distinct from either alpha- or gammaherpesviruses. If the human CMV U_L ORFs are arranged into seven conserved blocks denoted ABCDEFG, the arrangement in HSV-1 and EBV would be depicted GF'EDBA'C' and A'CGF'EDB, respectively. A prime (') indicates an inverted orientation. Thus, these conserved sequence blocks have a characteristic order in each of the herpesvirus

subgroups. These sequence features suggest that general characteristics of DNA replication, virion maturation, and virion organization are likely to be conserved in all mammalian herpesviruses.

Although analysis of individual gene functions in human or other animal CMVs is still incomplete, nearly 70 ORFs are known to be dispensable for productive replication in cultured fibroblasts, indicating that a large proportion of the genetic complexity of CMV is committed to optimizing growth, dissemination, tissue tropism, immune evasion, and pathogenesis in the host. A total of 46 genes are known to be dispensable for growth as a result of spontaneous deletions arising during passage in cell culture (82,278,389,546), including UL1–UL10, UL36, UL42–UL43, UL133–UL153, US1–US15, and one copy of the TRL4/IRL4–TRL14/IRL14 gene cluster. In addition, targeted mutagenesis shows that UL16, UL18, UL20, UL33, UL36, UL83, UL124–UL128, US27, US28, TRL4/IRL4, IRS1 and US2–US11 are all dispensable for growth (49,71,190,243,252,347,365,417,513,576) (Browne and Minson, personal communication, 1994; Duke and Mocarski, unpublished). Consistent with their nonessential role for replication in cell culture, four of these genes (US2, US3, US6, US11) have been shown to function in immune evasion (429). Though difficult to assess in human CMV, several gene products needed for infection in the host animal have been identified in murine CMV (127,152,155,343,468). Finally, several regulatory gene mutants (UL69, UL82, UL123) (190,204,382) (Greaves, personal communication, 1999) and an *ie*1*ie*2 enhancer utant (363) replicate to normal levels after passage at high MOI but are unable to replicate at low MOIs. In addition, two DNA replication/metabolism gene mutants (UL97, UL114) grow slowly at any MOI (438,439).

Strain Polymorphism

Various lines of evidence suggest that all human CMV strains are closely related. DNA:DNA reassociation reveals an overall 90% to 95% DNA sequence homology (220,441). Electrophoretic patterns of virion or infected-cell proteins from different strains are similar (197), to the extent that variation in electrophoretic mobility of viral proteins is too rare to differentiate strains (103,174). Antibodies raised against one strain of CMV generally react with other strains, although several strain-specific epitopes have been identified on different viral proteins (66,421). Restriction site polymorphism of viral DNA (84,142) or sequence analyses of polymerase chain reaction (PCR) amplified DNA fragments (104) of laboratory-adapted and clinical strains are used to differentiate strains. DNA sequence-based analyses are, of course, the most sensitive means to differentiate strains, and they demonstrate that a large number of different CMV strains are in circulation worldwide.

One type of genome variation is the deletion of U_L sequences and the expansion of the *b* sequence repeats that have arisen independently within viral strains following high MOI serial passage in cell culture. All currently propagated AD169 strain variants, including AD169*var*UK and AD169*var*ATCC have replaced approximately 15,000 bp of nucleotide sequence and 19 to 21 ORFs (UL133–UL153) with a large, 11-kbp *b*' region (82), as depicted in Figure 1C. AD169*var*UK differs from other AD169 variants (e.g., AD169*var*ATCC) in growth properties (69) as well as in genome sequence. The 929-bp deletion that removes portions of UL42 and UL43 in AD169*var*UK is retained in AD169*var*ATCC and all other strains of CMV examined (124,386). AD169*var*ATCC also exhibits distinct properties, such as a UL36 gene product with altered localization and stability relative to other strains (417), suggesting that this variant also carries distinct mutations relative to wild strains. Although the AD169 strain was isolated almost half a century ago (465) and became a widely used strain because of its efficient replication in cultured cells, little care has been taken to ensure that a single, uniform stock was distributed to laboratories interested in studying CMV, or to ensure use of low MOI passage. The existence of large deletions relative to clinical strains and multiple strain variants call into question its de facto role as a prototype. Towne (passage 125), a vaccine candidate that has become a common laboratory strain (430), also has variants generated as a result of passage, and it carries a deletion affecting the U_L-*b*' region that is different from that observed in strain AD169*var*UK (82). In the case of Towne, however, an earlier passage was preserved that exhibits patterns of gene expression and a restriction map that is distinguishable from Towne (125,184). Some preparations of the Towne strain, including those available from ATCC, are a mixture of at least two variants, one of which carries a U_L-*b*' deletion (82) and the other of which appears to be intact based on sequence analysis (Kemble and Duke, personal communication, 1999), even though all of these variants show an attenuated phenotype when looked at as vaccine candidates (5). As yet, there has been only limited study of CMV genome stability during long-term serial passage in cell culture or in different cell types; however, the genome of a particular strain appears to be stable during limited passage at low MOI in cell culture (69,103,105), and biologic properties of low-passage strains are not readily lost during limited passage or plaque purification (431). Virus strains that are propagated on a particular cell type, such as endothelial cells or fibroblasts, retain tropism for that cell type and often fail to replicate efficiently on other cell types (583), suggesting that adaptive mutations may accumulate with prolonged passage. The significance of adaption in cell culture to the biology of CMV in the host remains unclear, although it seems likely that high-MOI serial passage carried out in an attempt to attenuate virulence (146,430) may have contributed to deletions similar to what is suggested to have occurred in defective virus genomes (536), as well as in spontaneous mutants that carry large deletions in other regions of the genome (278).

VIRUS GROWTH

General Considerations

Human CMV exhibits a highly restricted host range in cell culture. Primary differentiated human fibroblasts (HFs) from skin or lung show the greatest susceptibility to viral infection. During natural infection, fibroblastic, epithelial, macrophage, smooth muscle, and endothelial cell types support productive replication (491). Although HFs are commonly used to isolate and propagate CMV in culture, studies have clearly shown that freshly isolated human CMV replicates preferentially on endothelial cell types (454,493,583,613). The genetic alterations that underlie virus adaptation to different cell types remain unknown. Undifferentiated, transformed, or aneuploid human cells, including almost all cell lines, are nonpermissive (297,465). Fibroblasts from chimpanzees are permissive (422), but cells from more distantly related primate species are not. The host cell restriction to human CMV replication observed in nonpermissive cells is the result of a postpenetration block in viral gene expression and not to a failure to enter cells; virus has never been adapted to replicate in any completely nonpermissive cell type. CMV replication in an epithelial cell line (CaCo-2) has been associated with this host's undifferentiated state (235), and virus strain differences or other factors may also contribute (149). Certain astrocytoma cell lines, such as U373MG, although fully permissive (143), do not support viral replication to

the high levels observed with fibroblasts. HFs that have been immortalized with the human papillomavirus type 16 E6/E7 genes are just as permissive as primary HFs (112,189), and such cells have proved to be invaluable as a basis for the construction of complementing cell lines to isolate viral mutants (190,382).

The initial events in the replication cycle are only partially understood. Attachment and penetration at the cell surface (113) is rapid and efficient in permissive as well as in nonpermissive cell types, suggesting that cellular receptors for CMV are widely distributed. Addition of exogenous heparin, or treatment of cells with heparinase, blocks viral attachment and implicates the major cell surface proteoglycan heparan sulfate in the initial interaction between virus and cell (114,270,401), as is the case for other herpesviruses. Initial interaction with heparan sulfate is followed quickly by heparin-independent adsorption and penetration steps that employ widely distributed but poorly characterized receptors (7,256,551). The efficiency of penetration depends on the presence of these receptors (407). Initial interest in a 30- to 36-kd gB-binding cell surface protein (7,551), appearing to be annexin II, has been tempered by the observation that annexin II does not have to be present on cells for entry (423). Interest in a gH-binding phosphoprotein (255,256), which may be important in penetration (254), has led to the partial cloning of a CMV fusion receptor (CMVFR) (27), although its full characterization remains to be completed.

A number of mechanisms for entry have been proposed for cellular and viral functions that may influence the efficiency of entry into cells (46,71,576). A b_2-microglobulin bridge model (194,356) suggests an interaction between major histocompatibility complex (MHC) class I on target cells and the viral MHC class I homolog pUL18, but UL18-deficient virus replicates normally (71). CMV US28 chemokine receptor is a coreceptor for human immunodeficiency virus (HIV) entry (428) and increases fusion activity of other viral envelope proteins (427), but US28 itself is completely dispensable to CMV (46,576). Cellular CD13 influences entry (183), but cells devoid of this protein are nonetheless susceptible. Thus, many proposed CMV entry mechanisms may influence the behavior of virus in specific tissues or cell types, but none has been assigned a central role in entry.

Attachment to the cell surface is followed by penetration, mediated by fusion of the virion envelope and the cell surface in a pH-independent manner (113), a process that probably involves the gH/gL complex (254). Viral nucleocapsids rapidly make their way to the nucleus, so the tegument protein ppUL83 (122) can be detected within 20 to 30 minutes following exposure to a virus inoculum, and expression of *ie*1/*ie*2 gene products follows shortly thereafter (370). Several studies have shown that CMV (or CMV glycoprotein) binding to cells is sufficient to initiate a signalling cascade even in the absence of viral penetration (54,62,627,633). Viral attachment may therefore stimulate specific cellular processes that facilitate viral replication, or they may be part of some other host cell response to viral infection. Low-speed centrifugation (centrifugal enhancement) increases the efficiency of adsorption and penetration of murine or human CMV (8,410,614) by stabilizing weak interactions or encouraging fusion (217).

Productive replication in permissive HFs follows a pattern of coordinate expression with viral genes assigned to different kinetic classes depending on time of expression and sensitivity to inhibition of protein synthesis or viral DNA synthesis. These classes have been referred to as a or immediate early (IE), b or early, and g or late. Expression of a genes immediately follows entry and does not depend on the expression of any viral genes. Expression of b genes depends on the expression of functional a gene products. The b genes may be further divided into b_1 and b_2, which differ in timing and shutoff characteristics. Expression of g genes occurs last and may be divided into g_1 and g_2 based on the timing and dependence on viral DNA replication (378). The relative lack of dependence of g gene expression on viral DNA replication, and the existence of subclasses of b and g genes are major reasons for employing a, b, and g terminology in defining gene classes (see Chapter 72). Although the replication cycle of human CMV is slow, requiring 48 to 72 hours to begin the release of progeny (534), the expression of a gene products starts immediately after viral entry. In ways that are not well understood, virion tegument proteins influence this earliest phase of infection, and viral functions expressed early play regulatory roles later in infection. The switch from early phases to late phases is delayed until 24 to 36 hours postinfection (hpi), with maximal levels of virus release starting 72 to 96 hpi. Once maturation starts, infected fibroblasts continue to produce virus at peak levels for several days.

During productive infection in HFs, a gradual increase in human CMV DNA synthesis is observed starting as early as 14 to 16 hpi and is accompanied by a stimulation of host cell metabolism (378). Viral replication and maturation parallel accumulation of viral DNA replication functions, features suggesting that the prolonged replication cycle of this virus may result from this slow accumulation of essential gene products. CMV infection does not inhibit general cellular metabolism but rather stimulates both RNA and protein synthesis (378). Early work suggested that stimulation of host cell DNA synthesis might be a prerequisite to CMV DNA replication, but more recent studies have established that resting (G_0) HFs do not progress into the S phase of the cell cycle but rather give the appearance of a G_1/S block when productively infected with CMV (64,138). HFs already in S or G_2 may proceed to a later, G_2/M block (327), although expression of viral gene products is either delayed (470) or aborted (131) in such cells. These observations, all carried out at relatively uniform, high MOIs (>3), do not explain why CMV replicates best in serum-stimulated, actively dividing fibroblast cultures when infection is carried out at low (<0.1) MOIs (532).

Regulation of Gene Expression

Host cell RNA polymerase II and associated basal transcription machinery direct the transcription of CMV genes, which have promoters and may be spliced in ways that resemble cellular genes (377,535). Host cell transcription factors are influenced by virus-encoded transactivators that modulate expression of viral as well as host genes during infection. The cellular basis of permissiveness for human CMV replication depends more on the efficiency of early viral gene expression and subsequent DNA replication and less on entry into cells. The transcriptional enhancer controlling *ie*1/*ie*2 expression, in particular, functions in a cell type– and differentiation state–dependent fashion (364). It is also activated by signalling through cell surface receptors (62) and may be modulated by virion and other viral regulatory proteins (109,364,489,516,529).

P>Control of expression within the viral genome is complex and relies on promoters that produce 3' co-terminal mRNA transcripts encoding different gene products from a single region. For example, the *ie*1/*ie*2 region encodes productive

phase transcripts immediately after infection that differ from those produced late in productive infection (529) or during latent infection (281). Many regions of the viral genome produce more than one class of productive phase transcript and more than one species of protein through selective promoter usage as well as by alternative mRNA splicing.

Transcriptional Enhancers and Modulators

There are two loci in the human CMV genome whose expression is controlled by prominent transcriptional enhancer-modulators with many functional similarities. One is the *ie*1/*ie*2 gene, which encodes a family of MIE regulatory proteins from differentially spliced transcripts (516,529) using one of the strongest transcriptional enhancers yet identified in mammalian biology [mapping at 174,000 nucleotides (nt)] (61). The other is the US3 gene (mapping at 195,000 nt), which encodes an immunomodulatory protein (12,245) using a second viral enhancer (597).

The MIE (*ie*1/*ie*2) promoter-enhancer was initially identified by its ability to promote high level *in vitro* transcription (559) and to rescue replication of enhancerless simian virus 40 (61). Its impact on transcription is attributed to a dense collection of host transcription factor binding sites (403,404), including sites for CREB/ATF, NF-kB/Rel, Sp1, AP1, NF-1, retinoic acid receptor, serum response factor, ELK-1, C/EBP, p53, and Gfi-1, that span a genomic region approximately 500 bp upstream of the promoter (173,364). Shortly after infection, several transcription factors, such as NF-kB, AP-1, Sp1, and CREB/ATF are induced and activate expression from the *ie*1/*ie*2 promoter-enhancer by binding to repetitious elements, referred to by their sizes as 16-, 18-, 19-, and 21-bp repeats (61,559). As infection proceeds, expression is repressed by an IE2-dependent process (337) that acts via a specific signal, the cis-repression sequence (*crs*) near the transcription start site (529). Expression and repression are completely independent of the upstream modulator region (363,365).

The 19-bp repeats contain a cAMP response element (CRE, also called an ATF-binding site) (88,403,524) that contributes in a major way to strong basal enhancer activity (226) and that is also responsive to the virion transactivator ppUL82 (pp71) (323). The 18-bp repeats, which contain consensus binding sites for NF-kB (99,472), confer responsiveness to signal transduction resulting from virus binding (62,627,633), to autoregulation by the viral IE1 regulatory protein (99), and to inducers of *rel* family transcription factors such as phorbol esters (472) and cytokines (295). The 21-bp repeats carry both Sp1 and YY1 binding sites that may be involved in activation or repression of the enhancer (324), and one report suggests that the 16-bp repeats bind NF-1 (404).

An analogous enhancer, which conserves both 18- and 19-bp elements of the *ie*1/*ie*2 promoter-enhancer but little other nucleotide sequence identity, has been found upstream of the major regulatory gene locus in both murine and simian CMVs (87,140). The human CMV enhancer has been used in place of its murine CMV counterpart to support full replication in cell culture (21) as well as in lethally irradiated mice (195), suggesting that these diverse enhancers function in a similar fashion, although each probably contributes to cell tropism differences.

The enhancer-promoter shows extreme tissue and cell type specificity in expression, as illustrated by the activity of various promoter-enhancer constructs in cultured cells (364) and by the dramatic cell type specificity of expression in transgenic mice (29,274). Its activity depends on the presence of appropriate transcription factors in cells and is influenced by the adjacent modulator region that confers cell type and differentiation state dependence (173,364). This distal regulatory region extends from approximately 500 bp to approximately 1,000 bp upstream of the *ie*1/*ie*2 start site and contains cellular factor binding sites (285,490), including YY1 sites, which may repress the promoter-enhancer in undifferentiated cells (324).

Considerable experimental evidence from transient expression systems suggests that the modulator is dispensable for maximal expression of *ie*1/*ie*2 in many different common cell lines (173), but that it represses expression in undifferentiated teratocarcinoma NTera-2 cells and in myelomonocytic THP-1 and U937 cells. In these settings, efficient expression depends on cell differentiation state (173). Regions overlapping with or upstream of the enhancer appear to bind proteins that affect activation of enhancer function in differentiated cells (223,324,489). However, when assayed in recombinant virus constructs, the modulator has little role in cell type or differentiation state–dependent expression (363,365). Viruses with mutations that remove only the modulator region replicate and express the *ie*1/*ie*2 products as well as parental viruses, whether assayed in differentiated or nondifferentiated cells (365). The differences between results obtained in transient expression assays and infected cells draw into question the value of the transient assays to evaluate such processes.

The region upstream of US3 has also been shown to have the characteristics of a complex transcriptional enhancer (597), and it carries two types of repetitious sequences that bind host transcription factors. One (R_2) contains NF-kB sites and is very likely involved in enhancer responsiveness to phorbol esters, cytokines, virus binding, and the viral IE1 $_{491aa}$ regulatory protein. The other (R_1) is not yet fully characterized but is probably involved in modulating the enhancer (83,560). This promoter-enhancer is most likely regulated in a manner similar to that observed for the better-studied MIE promoter-enhancer (42,310). Unlike the regulatory proteins encoded from the *ie*1/*ie*2 locus, whose expression is necessary for efficient replication (190,363,382), the US3 gene and associated enhancer is dispensable for replication in cultured cells (243,278). The US3 enhancer contains a modulator (or silencer) region upstream of the enhancer, as well as a *crs* element between the TATA element and the start site that is analogous to the *ie*1/*ie*2 promoter-enhancer (83,310). Evaluation of the US3 regulatory elements within the context of the viral genome (310) reveals the importance of IE2-mediated repression via the *crs* element. Expression of the US3 enhancer is also subject to negative regulation in permissive fibroblasts because of a distal silencer region consisting of seven copies of the R_1 repeat, as first demonstrated by transient assays (83,560) and confirmed directly using viral mutants (310). Thus, US3 expression is down-modulated by both a silencer and a *crs* element, so that maximal levels of this gene product are never fully achieved in permissive cells. Although IE2-mediated repression of US3 expression has been best characterized, CMV mutants that accumulate lower levels of *ie*1/*ie*2 gene products as a result of an enhancer mutation have also been observed to accumulate reduced amounts of US3 (363), suggesting that activation by *ie*1/*ie*2 products may dominate over repression in a way that still needs to be clarified.

Virion Transactivators

The virion carries several proteins localized to the tegument that carry out regulatory activities. One of the abundant tegument proteins, ppUL82 (also called pp71 or upper matrix protein), is able to activate the *ie*1/*ie*2 promoter-enhancer in transient transfection assays (323). Its effect is mediated through the binding sites for the cellular transcription factors CREB/ATF or AP-1 found in the 19-bp enhancer repeats. UL82 expression starts early but peaks at late times in the infection (175). Deletion of UL82 from the viral genome results in a multiplicity-dependent growth phenotype correlated with poor expression of the *ie*1/*ie*2 locus (Greaves, personal communication, 1999), suggesting that optimal activation of MIE gene expression depends on adequate ppUL82. When expressed in an HSV recombinant devoid of its own transactivators (VP16, ICP0, and ICP4), ppUL82 transactivates HSV gene expression as well as expression of a human CMV *ie*1/*ie*2 indicator gene (218). In addition, transiently expressed ppUL82 increases the infectivity of transfected viral DNA in a manner that appears independent of a role for *ie*1/*ie*2 expression (25). Taken together, these studies suggest that ppUL82 functions as a more general transactivator of gene expression rather than as a specific activator of *ie*1/*ie*2 gene expression.

Additional transactivators of viral gene expression that are present in the virion as minor tegument proteins may play regulatory roles following entry. One phosphorylated subform of the viral protein ppUL69 associates with the virion tegument (610) and transactivates expression from the *ie*1/*ie*2 promoter-enhancer, particularly when used in combination with ppUL82 (608). Unexpectedly, UL69 mutant virus growth is delayed under high MOI conditions due to an impact on DNA replication rather than on *ie*1/*ie*2 gene expression (204). At low MOI, growth of this mutant is severely compromised, although the point of inhibition has not been established. The viral pIRS1 and pTRS1 transactivators, a gene products that cooperate with other viral regulatory proteins (231,463,527), are also associated with virions and dense bodies (462), suggesting that they may contribute to virion transactivation. In addition to regulatory proteins, the virion may carry host protein kinases (162) and phosphatases (372) that might modulate the activity of viral regulatory proteins following entry. Finally, virus particles also contain mRNAs that may contribute to regulatory processes following entry (65).

a (Immediate-Early) Gene Expression and Gene Products

Four regions of a gene expression have been mapped on the human CMV genome, UL36–38, *ie*1/*ie*2 (UL122–123), TRS1–IRS1, and US3 (109,516,529), with one additional region (UL115–119) that may also fit into this class (109,538). The expression of a genes begins within one hpi and peaks between 4 and 8 hpi, independent of *de novo* protein synthesis.

The overwhelming majority of expression immediately after viral entry arises from a single major locus, the so-called MIE locus, located between 169 and 175 kbp on the human CMV genome (see Table 2) (92,535). Transcription from the *ie*1/*ie*2 promoter-enhancer gives rise to differentially spliced and polyadenylated transcripts encoding the two major products $IE1_{491aa}$ and $IE2_{579aa}$, which share a common 85-amino-acid amino-terminal domain but splice either to UL123 for $IE1_{491aa}$, or to UL122 for $IE2_{579aa}$ (516,529). In addition to an important role for the MIE products in viral replication, ancillary a genes play roles in regulation (TRS1/IRS1) (231,527), inhibition of apoptosis (UL36 and UL37) (185,186), and modulation of host cell MHC class I expression (US3) (12,245). All animal CMVs examined have an analogous MIE locus, but they vary with respect to the presence of ancillary a genes.

$IE1_{491aa}$ (or IE1p72) and $IE2_{579aa}$ (or IE2p86) are nuclear phosphoproteins that have apparent sizes of 68 to 72 kd and 80 to 86, kd respectively. $IE2_{579aa}$ is likely to be the major regulatory protein encoded by this virus (516,529,530). In addition to the abundant 579-amino-acid *ie*2 product, a less abundant rotein, called $IE2_{425aa}$ (or IE2p55), shares the same 85 amino-terminal amino acid with $IE1_{491aa}$ and $IE2_{579aa}$. $IE2_{425aa}$ is encoded from an mRNA with an additional spliced intron, resulting in an in-frame deletion within UL122 (265,516,529). Even more complex UL122 splice variants arise in granulocyte-monocyte-macrophage lineage cells (265,281). The *ie*1/*ie*2 gene products accumulate differentially during infection, depending on infection conditions and host cell type. $IE1_{491aa}$ expression continues throughout infection, whereas $IE2_{579aa}$ expression decreases during the early phase of infection and rises again late in infection (525,530). Whereas $IE2_{579aa}$ and several additional minor IE2-related proteins are made from splice variants immediately after infection, the most abundant *ie*1/*ie*2 gene product is a true late (g2) protein called $gIE2_{338aa}$, encoded from a distinct, unspliced late transcript expressed from a promoter within UL122 (238,529).

Evidence from a wide range of transient assay experiments using promoter targets from both heterologous sources and CMV genes shows that the *ie*1/*ie*2 gene products are positive and negative regulators of viral as well as host cell gene expression (516,529). The major a gene products, $IE1_{491aa}$ and $IE2_{579aa}$, autoregulate *ie*1/*ie*2 and US3 expression by activating via NF-kB binding sites ($IE1_{491aa}$) and repressing via IE2 cis-repression signals (*crs*) in these promoter-enhancers. The major role of $IE2_{579aa}$ discerned from transient assays appears to be activation of viral b and g gene expression, with $IE1_{491aa}$ functioning as an accessory protein in this process. The MIE gene locus in other animal CMV genomes retains a remarkable level of mRNA splicing-pattern similarity but encodes proteins that share limited amino acid sequence identity with those of human CMV. Where assayed, these have thus far all functioned similarly.

Regulatory Activities of Human CMV IE1

Two predicted roles of $IE1_{491aa}$ have been substantiated by studies using UL123 null ($IE1_{491aa}$-deficient) viruses, including a role in activation of *ie*1/*ie*2 promoter-enhancer expression (382) and a role in efficient expression of viral b and g genes (190). In transient assays, transactivation by $IE2_{579aa}$ alone or in combination with ancillary regulators such as pTRS1/pIRS1 is influenced by the presence of $IE1_{491aa}$ (231). Consistent with this role, viral mutants lacking the ability to express any $IE1_{491aa}$ because of a complete deletion of UL123 replicate well at high MOIs but exhibit growth deficiency at low MOIs (190,382). Given the fact that $IE1_{491aa}$-null mutants do not exhibit single-hit infectivity (190), some or all of the

known $IE1_{491aa}$ activities must be crucial to the viral replication cycle under conditions where a single virion initiates infection.

In addition to its ability to cooperate with $IE2_{579aa}$, $IE1_{491aa}$ has been observed under idealized transfection conditions to directly influence gene expression via a number of different transcription factors, including NF-kB (44,380,584), CCAAT box–binding protein (205), and E2F (23). $IE1_{491aa}$ appears to increase the levels of NF-kB activity without engaging in a stable association with this transcription factor or with DNA (289,380). The impact of $IE1_{491aa}$ on a TATA-less promoter with E2F sites (23) and the presence of this viral protein in complexes with E2F family members (346) led to studies showing that $IE1_{491aa}$ binds to the amino terminus of retinoblastoma (Rb) family member p107, in a region distinct from the "pocket" normally associated with E2F binding. $IE1_{491aa}$ binding is sufficient to overcome p107-mediated cell growth suppression (240,436). $IE1_{491aa}$ may also induce AP1-dependent gene expression via a protein kinase cascade involving mitogen-activated protein kinase/ extracellular signal-regulated kinase pathway (269).

Like the ancillary regulatory functions of other herpesviruses (ICP0) and adenoviruses (E4) (229,352), $IE1_{491aa}$ associates with nuclear domain 10 structures (PML bodies) and disrupts their integrity (10,230,257,282,603). Interaction between $IE1_{491aa}$ and PML bodies is direct and relies on $IE1_{491aa}$ domains distinct from those involved in transactivation and association with chromatin (9,603). SUMO-1-modification of PML protein itself is blocked while $IE1_{491aa}$ becomes SUMOylated (394). PML body reorganization does not appear to contribute to viral replication in cultured cells because $IE1_{491aa}$-deficient virus fails to rearrange PML bodies under high MOI conditions where this virus replicates as well as parental virus (9). Thus, disruption of PML nuclear bodies is not required for these domains to function as sites of organization for viral transcription (230) and DNA replication (11,353), at least under conditions of high MOI.

An additional activity long associated with $IE1_{491aa}$ is the ability to bind to cellular chromatin (249,298) although this protein fails to bind DNA directly. The extremely acidic carboxyl terminus is necessary for this association (603). Chromatin binding is not a component of activation of gene expression, even though the same acidic carboxyl terminus appears to be required for $IE1_{491aa}$ to function as a transactivator (Greaves, personal communication, 1999). Finally, $IE1_{491aa}$ has been expressed in a variety of bacterial and mammalian cells, including a line of HFs used for propagation of $IE1_{491aa}$-deficient mutants (190), without any evidence that expression interferes with cell growth. One report suggests that this protein is mutagenic under certain conditions (486), although it is not responsible for chromosome breaks observed during infection of human cells (157).

Regulatory Activities of Human CMV IE2

$IE2_{579aa}$ is the predominant viral regulatory protein with two established core functions: (a) controlling the switch from a to b and g gene expression during productive infection, and (b) as the infection proceeds to the late phase, ensuring down-modulation of the two a genes, *ie*1/*ie*2, and possibly US3, via binding to a *crs* located near the start site of transcription of either gene. Viral $IE2_{579aa}$-deficient mutants have not yet been used for studies on this protein, so that functional evaluation has relied on introduction of $IE2_{579aa}$ into cells to reveal functions implicated in the control of replication (364,516,529). This protein has been introduced either transiently or stably into established human as well as nonhuman cells where many of its broad activation and repression characteristics are preserved. Evidence has accumulated that stable $IE2_{579aa}$ expression is toxic to cells. Experimental observations comparing stable versus transient expression systems include inconsistent reports showing failure (59) or success (600) of an IE2-mediated block to G_1 progression, as well as either success (634) or failure (185) in demonstrating an IE2-mediated block in apoptosis. These contradictory results may be explained by analysis of $IE2_{579aa}$ cDNA in stable cell lines used to derive some of these phenotypes, which reveals that nonfunctional mutants are selected because they are less cytotoxic than wild-type $IE2_{579aa}$ (Greaves, personal communication, 2000). Although most attention has been focused on the prominent a gene product, alternative forms of $IE2_{579aa}$ that arise as a splice variant, $IE2_{425aa}$, or as the highly abundant product of a late transcript, $gIE2_{338aa}$, retain different subsets of activation and repression functions (238,529).

$IE2_{579aa}$ and $gIE2_{338aa}$ function directly in the shutoff of a gene expression by binding to at least two specific sites between the TATA box and the transcription initiation sites of the *ie*1/*ie*2 gene (98,322,424) denoted the cis-repression signal, or *crs*. A similar mechanism has been suggested for regulation of the US3 gene (310). The *crs*-specific repression requires only the carboxyl-terminal dimerization (amino acids 346 to 579), metal-binding and *crs*-specific DNA binding domains (160,338,581) of these proteins. Given that $IE2_{579aa}$ is expressed early as well as late, and $gIE2_{338aa}$ is expressed abundantly at late times, a reduction in a gene expression at late times of infection appears to be the reason for this function. The *crs* is a 14- to 15-bp DNA sequence element with a twofold axis of symmetry (the underlined portions) just upstream of the transcription start sites ($^{+1}$) in the *ie*1/*ie*2 (CGTTTAGTGAACCG^{+1}) and US3 [CGT(G/T)CAGTCCACACG^{+1} (41,310) genes. The *crs* functions in either orientation, can repress basal or activated promoter-enhancer expression, and will confer IE2-dependent repression on heterologous promoters independent of a complex upstream enhancer as long as it is positioned near the transcription start site (98,322,424). Recombinant IE2 species purified from prokaryotic expression clones have long been known to bind to *crs* (308,338) and to block *in vitro* transcription by altering RNA polymerase II preinitiation complex formation (338,618) when assays are carried out with high protein levels. Recombinant IE2 (309) or dephosphorylated mammalian cell–derived $IE2_{579aa}$ binds to *crs* as a dimer using minor groove contacts (581). The phosphorylation state of $IE2_{579aa}$ dictates its ability to bind DNA such that the mammalian cell–derived native protein is inactive as a result of phosphorylation at Ser or Thr (581). Unfortunately, these data are not entirely consistent with direct mapping of major phosphorylation sites on $IE2_{579aa}$ from infected cells (202), which suggested that host serum–stimulated MAP kinases phosphorylate this protein in regions distinct from the protein kinase A sites controlling DNA binding activity (581). These data are most consistent with a model of different phosphorylation pathways controlling transactivation and DNA binding properties of this protein. Thus, $IE2_{579aa}$ appears to inhibit transcription of *crs*-bearing a genes as a dimeric or oligomeric Ser/Thr phosphorylation-sensitive DNA-binding protein that physically blocks recruitment of RNA polymerase (pol) II to the preinitiation complex without impacting on the

binding of other basal transcription factors (314).

$IE2_{579aa}$ is a promiscuous transactivator that acts more efficiently in the presence of $IE1_{491aa}$ (reviewed in refs. 516 and 529). $IE2_{579aa}$ alone or with $IE1_{491aa}$ regulates different promoters via a variety of unrelated cellular transcription factors that include a potential common effect on the basal transcription factor $TF_{II}D$ (330,331). $IE2_{579aa}$-mediated transactivation has a long-recognized similarity to adenovirus E1A (see Chapter 67), in that no single common target sequence or transcription factor is involved in transactivation (331,516,529). CMV $IE2_{579aa}$ plus $IE1_{491aa}$ are able to complement an E1A mutant (518,555). $IE2_{579aa}$ contains two transactivation domains (an amino-terminal 51-amino-acid domain and a carboxyl-terminal 33-amino-acid domain) and two nuclear localization signals (529). A range of mutations has been introduced into $IE2_{579aa}$ that interfere with transactivation (80,100,529,624), supporting a role for most of the protein in this process.

An appealing model for $IE2_{579aa}$-mediated transactivation suggests that its role is that of an adapter-like protein stabilizing $TF_{II}D$-associated factors on the promoter (330). The model is supported by the ability of this protein and $IE1_{491aa}$ to contact a subset of $TF_{II}D$-associated factors, including $TAF_{II}130$ and $TAF_{II}110$ (266,330), possibly with $IE1_{491aa}$ as a coadapter with $IE2_{579aa}$ binding simultaneously to the transcription machinery via $TAF_{II}130$ (330). Consistent with this model, three regions of $IE2_{579aa}$ interact with the carboxyl terminus of TBP and with $TF_{II}B$ (80,248,331,507). Bridging interactions between $IE1_{491aa}$ and $IE2_{579aa}$ are also consistent with the observations that $IE1_{491aa}$ can be replaced by host cell Sp1 transcription factor in transactivation assays (267).

Regulatory Activities of Other a Gene Products

Over the past couple of years, a significant number of mechanistic studies have clarified the role of ancillary a gene products, extending most of them beyond a role in transactivation of gene expression, although some may certainly be involved at this level as reviewed in (109). The US3 region encodes a number of related, differentially spliced products that have characteristics of integral membrane glycoproteins (554). These are glycosylated proteins dispensable for viral growth in HFs (243,278) and epithelial cells (189). US3 encodes endoplasmic reticulum (ER)-targeted proteins that block egress of peptide-loaded MHC class I proteins and therefore represents the earliest of several viral gene products that down-modulate MHC class I expression (12,241,245). This property is discussed in the section, Immune Evasion and Piracy.

Differential splicing in the UL36 to UL38 region of the viral genome gives rise to a number of mRNAs capable of expressing proteins whose individual functions have not yet been fully characterized (109). The predominant UL37 product in CMV strain AD169-infected cells is gpUL37, which, like US3, attracted significant attention as a glycoprotein expressed from a spliced transcript immediately after infection. Both gpUL37 and pUL37x1, a nonglycosylated amino-terminal form of this protein expressed from an unspliced transcript (554), are localized to the cytoplasm of infected cells. Despite their localization pattern, these proteins are suspected of having regulatory functions because the genomic region (UL36 to UL38) cooperates in transactivation (109,231) in ways that implicate one or more of these functions in the regulatory cascade leading to DNA replication (231,413). Recently, UL37 cDNAs were isolated when CMV-encoded functions that block apoptosis were sought by expression-cloning strategies (185). This gene encodes a novel viral mitochondria-localized inhibitor of apoptosis (vMIA) distinct from Bcl-2 family members (185). Three related proteins, pUL37x1, gpUL37, and another multiply spliced form denoted $gpUL37_{M}$, have been expression-cloned and shown to be functional. The pUL37x1 (vMIA), which is the smallest fully active UL37 gene product and which resides at the mitochondrial surface in association with the adenine nucleoside transporter, is the only UL37 gene product expressed during infections with the Towne strain, suggesting that this gene product is sufficient for UL37 function. Despite the complete lack of any structural hallmarks of known Bcl-2 family members, vMIA blocks apoptosis at a point downstream of caspase 8 but prior to cytochrome c release from mitochondria in a Bcl-2-like manner. This work suggests that the long-established role of UL37 as a transactivator (109) in transient gene expression assays may result from its ability to block apoptosis.

UL36 encodes a singly spliced transcript that encodes a nonglycosylated cytoplasmic protein (417). pUL36, the only other known a gene in the UL36-38 cluster implicated in regulation (109,231), is also antiapoptotic, inhibiting at a central point in the caspase cascade. This inhibitor can block at a pre-caspase 8 step despite the absence of sequence hallmarks of known signalling or inhibitory molecules, including the Fas-associated death domain (FADD) or FADD-like interleukin (IL)-1b-converting enzyme inhibitory protein (FLIP) functions (186). Expression patterns of UL36 suggest unusual strain variability in function (417), consistent with observations that this protein is already mutated in many commonly used laboratory strains (186) and is inactive as a result of a point mutation (Cys-131) in AD169 *var*ATCC used for many experiments (417). Laboratory strains of virus may rely more directly on pUL37x1 than on either gpUL37 or pUL36 to prevent apoptosis during productive replication in cultured cells.

TRS1 and IRS1, two members of the US22 family (92), transactivate in cooperation with $IE1_{491aa}$ plus $IE2_{579aa}$ (231,463,527) by a poorly understood mechanism. TRS1 and IRS1 appear to be distributed in both the cytoplasm and the nucleus of infected cells. Both are expressed immediately after infection and are detected in virion preparations (462), although a truncated form representing the carboxyl terminus of IRS1 ($IRS1_{263aa}$) is not virion associated. TRS1 consistently displays stronger transactivation than IRS1, and IRS1 is dispensable for replication so long as TRS1 is retained (243). The presence of TRS1 or IRS1 together with ppUL82 and/or pUL69 dramatically increases the transactivation of the TRS1 or IRS1 promoters themselves, and the truncated form, $IRS1_{263aa}$, blocks TRS1- or IRS1-enhanced transactivation (463). TRS1 or IRS1 cooperates with $IE1_{491aa}$ and $IE2_{579aa}$ to transactivate b genes that have been tested (231,463,527), which suggests that their role may be to increase expression of DNA replication functions (413).

b and g (Delayed Early and Late) Gene Expression: General Considerations

The designation of viral genes into the b or g class depends on timing of expression as well as sensitivity to inhibitors of viral DNA synthesis, such as phosphonoformate (582), or 9-(1,3-dihydroxy-2-propoxymethyl)guanine (DHPG, ganciclovir) (344). A conditional DNA polymerase mutant has also been employed to evaluate sensitivity of gene expression to viral DNA synthesis (134). Both classes of genes are believed to be activated by a ene products targeting the TATA and initiator elements as well as upstream promoter elements located within 100 to 200 bp of transcription start sites. Many nonstructural CMV genes expressed early during infection are transcribed to their highest levels at late times in infection, and transcription of structural genes begins early in the infection even in the presence of viral DNA synthesis inhibitors. Although a genes are active immediately after entry, b and g gene expression is delayed and parallels the very slow synthesis of viral DNA, structural proteins, and progeny. Transcription of b (delayed early) genes starts by 24 hpi (most starting at 4 to 12 hpi) and can be divided into b_1 (early) and b_2 (early late) transcript classes based on the timing of peak protein expression, impact of viral DNA synthesis inhibitors, and changes in expression levels at late times. g (late) gene transcription starts later than 24 hpi and can also be divided into two classes, g_1 (leaky late), where transcripts are made at reduced levels but are not blocked by inhibition of viral DNA synthesis, and g_2 (true late) transcription, which is completely blocked by inhibition of viral DNA synthesis. Both b and g gene expression requires prior expression of a gene products (533). The timing and expression of transcriptionally active viral genes are further modulated by (a) translational and other posttranscriptional controls that dictate appearance of proteins (17,77,262,377), (b) sensitivity of viral replication to the physiologic state of the host cell, and (c) other events, such as activation of host cell protein degradation machinery, that influence the accumulation of b and g gene products during infection.

Although the kinetic class of each gene is dictated by transcriptional activation events and activation of transcription is a major regulatory step, most b and g transcripts have a polycistronic structure. This correlates with the relatively few polyadenylation signals on the viral genome, such that many 3'-co-terminal families of transcripts are generated from a series of promoters, each controlling a separate gene. In addition, many regions of the genome, including the *ie*1/*ie*2 locus, the UL36-38 locus, and the UL115-119 locus, produce both a and g transcripts, whereas other regions such as UL4, UL112-113, US6, and UL44 produce both b and g transcripts from multiple promoters. Thus, the same or related gene products are encoded at different times through the differential activation of transcription in concert with mRNA splicing signals and choice of polyadenylation sites. Once made, transcripts are subject to regulation of transport and translation. At early times, mRNA from selected regions of the viral genome is preferentially associated with polysomes. Most polyadenylated RNA is retained in the nucleus, to be found on polysomes only at late times (377). Two specific types of posttranscriptional regulation have been studied: (a) alterations in the timing or accumulation of cytoplasmic transcripts, possibly caused by differential splicing or 3'-end processing, either one controlling the expression of alternative proteins (313,530,615), and (b) delay in translation (166), one type of which has been ascribed to short ORFs in the 5' leader region of certain transcripts (17,76,77 and 78,167,168).

b (Delayed Early) Gene Expression and Gene Products

Two abundantly expressed b genes, encoding 1.2-kb ($b_{1.2}$) and 2.7-kb ($b_{2.7}$) transcripts, remain prototypes for studies on gene regulation despite the fact that their translation products have not been studied (516). Additional genes whose regulation and gene products have been studied in some detail are involved in DNA replication (UL112–UL113, UL54/DNA polymerase, UL44/DNA processivity factor), immunomodulation (US11), and an early glycoprotein expressed from multiple promoters employing transcriptional and posttranscriptional controls, UL4 (gp48).

$b_{1.2}$ and $b_{2.7}$ map to adjacent positions near the L-component terminus and have been studied solely because they represent 20% to 40% of total viral transcription from early times during infection (378,516). These are located within the *b* repeats of popular laboratory strains such as AD169 (191); however, only single copies of these genes are present in low-passage strains (82) (see section, Strain Polymorphism). The 1.2-kb gene has a biphasic pattern of expression starting very early during infection, and transient assays suggest that the upstream transcription factor binding sites for early activation are less important late in infection so long as plasmids used in transient assays contain a CMV DNA replication origin (516). The $b_{2.7}$ gene encodes the single most abundant viral b or g transcript in infected cells (191,589). This transcript steadily accumulates during infection and accounts for more than 20% of the viral mRNA. When used to drive indicator gene expression, the $b_{2.7}$ promoter confers abundant expression throughout the infection, which is not influenced by the site of insertion in the viral genome (388). Although difficult to detect in infected cells, the conserved TRL4 ORF on this transcript encodes a nucleolar-targeted protein (38) whose expression is subject to translational down-modulation (38,43,167,168,273). Both copies of this abundantly expressed $b_{2.7}$ gene have been deleted from a virus without altering its ability to replicate in cultured cells (Duke and Mocarski, unpublished).

US11 is a b_1 gene encoding an ER-resident protein that directs degradation of MHC class I protein by the proteasome and helps the virus evade immune detection (12,212,485,601) (see section, Immune Evasion and Piracy). Its expression peaks within the first 24 hpi and depends on two separate upstream CRE and ATF binding sites that together contribute to maximal activation in both transient assays and in the context of the viral genome (90). Thus, for this b_1 gene, regulation in transient assays mirrors that observed in the context of the viral genome and implicates specific host transcription factors known to be responsive to viral transactivators.

The UL112-113 (also called 2.2-kb) gene encodes a family of early phosphoproteins (233,616) that regulate expression of core DNA replication genes (231,413) and organizes viral DNA replication compartments as they begin to form during infection (11,419) (see section, DNA Replication). Differentially spliced transcripts of 2.1, 2.2, 2.5, and 2.65 kb in size arise from a single promoter and represent splice variants that express four phosphoproteins of 50, 43, 84, and 34 kd, respectively (516). Although these transcripts are all made very early in infection, the proteins appear in cells as if they represent two temporal classes. The 34-, 43-, and 84-kd species exhibit b_1 kinetics and accumulate from 8 hpi, whereas the 50-kd species exhibits b_2 kinetics and appears later in infection. The transcription start site used early in infection shuts down and shifts 62 nt upstream at late times, although this switch in transcription start site does not drive the late expression of the 50-kd protein. Transient assay analysis of the UL112-113 promoter has indicated that both the TATA box and an upstream CRE/ATF site contribute toward responsiveness to the viral transactivator $IE2_{579aa}$, but that

activation is independent of four IE2 binding sites in the promoter (22,483,484). When studied in the context of the viral genome, expression at early times shows dependence on a CRE/ATF site, but this site is unnecessary for maximal expression at late times (459). The most proximal $IE2_{579aa}$ binding site contributes to full activation at late times.

Transcript from the DNA polymerase (UL54) gene is first detected at 8 hpi but is classified as a b_2-class gene, because levels of transcript and enzyme increase dramatically to maximal levels late in infection. In transient assays, this promoter exhibits much greater response to $IE1_{491aa}$ acting in concert with $IE2_{579aa}$ than to $IE2_{579aa}$ alone, even when introduced into cells with accessory transactivators TRS1 and UL112-113 (261,264). Maximal expression in transient assays is most strongly affected by an upstream inverted repeat element (IR1) (261,264)—that is, a nonconsensus Sp1 site (333)—and binds a complex that includes both $IE2_{579aa}$ and Sp1 in infected cells (619). When evaluated in recombinant viruses, UL54 regulatory elements that are important for early activation are the same as those identified in transient assays, and they implicate IR1 in the activation. In contrast, late expression is not significantly affected by the presence or absence of this site (261), reminiscent of the UL112-113 promoter (459). When the UL54 promoter is evaluated in the context of the viral genome, mutations in the CRE/ATF binding site severely reduce overall expression levels early as well as late during infection (263), arguing strongly that this transcription factor is important for authentic regulation at late times. Together, these experiments suggest that CREB/ATF may provide distinct roles for different genes involving mechanisms that will need further analysis in virus-infected cells.

The polymerase processivity factor (UL44) gene, often referred to as a late gene because its accumulation in cells is to such strikingly high levels at late times of infection (166,175,533), may be operationally considered in the b_2 gene class even though it has three spatially distinct transcription start sites that are activated at different times during infection (312). Two of the three are b promoters that are active at 8 hpi, and the third is a g promoter that is not active until 36 hpi. These three promoters are independently regulated in transient assays (527). Although initially characterized as needing both $IE1_{491aa}$ and $IE2_{579aa}$ to impact on UL44 expression, promoter substitutions demonstrated that TRS1 gives maximal stimulation together with $IE2_{579aa}$, without any requirement for other viral regulatory proteins (463). Although the mechanism of TRS1 function remains to be determined, preliminary analysis suggests that regions bracketing any of the three UL44 gene TATA boxes may be sufficient for TRS1-enhanced $IE1_{491aa}$ plus $IE2_{579aa}$ transactivation (Stasiak and Mocarski, unpublished), which would be consistent with a co-modulator role much like that discussed for $IE1_{491aa}$.

The gpUL4 gene, which encodes an early structural glycoprotein (gp48), appears to be directly responsive to $IE2_{579aa}$ without a requirement for $IE1_{491aa}$ in transient assays (342). UL4 has three transcription start sites that are differentially regulated during viral infection (85,86). Two of the three are b promoters and one of the three is a g promoter. All three promoters are independently responsive to viral infection, but only one of the b promoters is responsive to $IE1_{491aa}$ plus $IE2_{579aa}$ or $IE2_{579aa}$ alone when tested in transient assays (342). UL4 provides the best-characterized example of regulation by posttranscriptional mechanisms, here manifested as translational control by short ORFs in the 5' leader of an mRNA that block progression of ribosomes to downstream ORFs (17,43,76,77 and 78,129,479). The mRNA encoding the UL4 ORF contains three additional short ORFs upstream of UL4, the second of which, uORF2, encodes a 22-amino-acid nascent peptide that stalls the translation machinery by blocking the release step of the last tRNA ($tRNA^{Pro}$). The extent to which other CMV genes are subject to such regulation remains to be determined. A recent evaluation of uORF2 from UL4 genes of a few clinical isolates showed variable ability to stall ribosomes (17).

The ultimate understanding of the regulatory cascade leading to expression of the array of b and g gene products during CMV replication will require dissection of cis-acting as well as trans-acting viral functions acting at many levels. An understanding of the importance of transcriptional regulation by *ie*1/*ie*2 gene products, acting either alone or in combination as transactivators and repressors, will require further detailed study of a range of individual a and b promoters. Transient assay analysis that provides mechanistic insights must be accompanied by studies in the context of the viral genome and viral infection. Only through such studies will the physiologic significance of transcriptional and posttranscriptional regulatory activities become clear.

g (Late) Gene Expression and Gene Products

Even from the limited number of investigations in this area, regulation of g_1 (leaky late) and g_2 (true late) genes appears to differ markedly. From the little that is known, g_1 genes are regulated in a fashion analogous to the b_2 class described earlier, although less detailed characterization of promoter elements is available, and very little has been undertaken in the context of the viral genome. UL83, a g_1 gene encoding the major tegument protein pp65, is transactivated in transient assays by the combination of $IE1_{491aa}$ plus $IE2_{579aa}$, and an upstream octamer sequence contributes to responsiveness (134). When introduced into the viral genome, however, the level of activation of this promoter at early times and dependence on the octamer were not dramatic, suggesting that other regulatory events provide a more dominant influence on expression (277). Additional studies are needed to address g_1 gene class regulation.

The only major g_2 gene whose regulation has been dissected in some detail is UL99, which encodes the tegument protein pp28 (135) from either of two g_2 class transcripts under separate promoter control. The more abundant of these transcripts contains a portion of the UL98 ORF upstream of UL99 (2,135,369). This UL99 promoter is not very responsive to transient transactivation and does not rely on particular upstream elements (135). Indeed, when examined in the context of the virus, sequences upstream of –40 relative to the transcription start site are not required for authentic expression (277). Maximal authentic expression occurs when a small promoter fragment containing little more than a TATA element (–40 to +6 relative to the start site) is placed in the context of the virus, although expression is a balance between slightly reduced transcript levels and dramatically increased indicator gene expression, because of the disruption of a G:C-rich hairpin structure involving the first 25 nt of the transcript (262). Evaluation of the adjacent UL94 gene by transient assay has suggested that full activation can be achieved with a similar promoter fragment containing little more than a TATA element (–45 to +1 relative to the start site) (606). The balance of transcriptional and translational controls appears important, but additional studies need to be completed on the less-abundant UL99 transcript as well as

more detailed studies on other g_2 genes before a complete picture of regulation can emerge.

Effects on the Host Cell

Host cell transcription and translation increase during CMV infection (533). Virus binding and/or entry results in the elaboration of cellular signalling responses (15) as well as the induction of host immediate and interferon response genes (53,55,56,399,626,628,632,633). This behavior indicates that activation via cell surface receptors, delivery of tegument proteins, or some other virus particle-mediated process plays a predominant role in stimulating host cell gene expression. Binding of ultraviolet-inactivated virions to cellular receptors initiates cellular signalling cascades (53,56,626,628,632,633), with soluble forms of gB or gH able to stimulate cells on their own, presumably via their interaction with cellular receptors (62,627). As yet there is no experimental distinction between the stimulation by virus binding and the introduction of particular virion transactivators as a result of viral entry; however, the combined impact of these events on cellular gene expression is broad under experimental conditions (587,632). A majority of host genes whose expression is stimulated within the first 24 hours after infection appear to respond to virion-mediated events preceding expression of viral regulatory genes.

Viral regulatory proteins expressed after penetration further regulate cellular signalling pathways and gene expression as infection proceeds (14,232,460,475,532). The viral $IE1_{491aa}$ gene product, in particular, contributes to both stimulation and suppression patterns of host cell gene expression (587). Optimal virus replication depends on host gene expression (161,305), possibly of genes that are specifically stimulated, such as host DNA metabolism enzymes, DNA polymerase a and proliferating cell nuclear antigen (PCNA) (138,215); cell cycle functions cyclin E, cyclin B, pRB, and p53 (138,236,470,488); and transcription factors (53,472,629), some or all of which require viral gene expression to be adequately induced.

Co-infection studies with other viruses also reveal the striking impact of human CMV infection on cellular metabolism. HSV-1, adenovirus, adeno-associated virus, human T-cell lymphoma virus (HTLV)-1, and papovavirus replication have been shown to be activated by human CMV infection (110,357,414,518). Both activation and suppression of HIV and HTLV-1 have been observed, apparently dependent on cell type (237,288,311,545).

Despite a pattern of cellular gene expression consistent with cell cycle progression (236,470), productive infection of permissive HF cells does not induce either cellular DNA synthesis or cell division (14,64,131,132,138,327). When serum-stimulated at the time of or just prior to infection, resting HFs fail to synthesize host cell DNA and exhibit a profile consistent with a G_1/S arrest (64,138). Permissive HFs that have already entered S or later phases at the time of infection may arrest at different points (236,327) and exhibit a delay in viral gene expression as well as replication (470). A very different series of events may occur in abortively infected cell types, where virus-induced stimulation of host cell DNA synthesis is readily observed (16) and stimulation of DNA synthesis may prevail under certain conditions in particular differentiated cell types that are permissive for viral replication (488). Although the response varies considerably, depending on many different experimental factors, the reasons and implications for such contrasts in the cell response to viral infection remain to be fully elucidated.

Two viral functions may contribute to the G_1/S arrest phenotype in HFs, the virion tegument protein ppUL69 and the major regulatory protein $IE2_{579aa}$. Virion-associated ppUL69 has been shown to contribute to cell cycle dysregulation during CMV infection (328) because deletion of this gene from the viral genome results in reduced G_1/S arrest that can be reversed when ppUL69 is incorporated into mutant virions (204). $IE2_{579aa}$ is able to induce cell cycle arrest following transient expression (600), and it interacts with a number of cell cycle regulated proteins, including p53 (393,521,566), pRB (199,507), and $p21^{cip1}$ (488), suggesting mechanisms of cell cycle regulation that may include physical interactions with cell cycle regulatory functions.

The observation that human CMV infection stimulates host cell metabolism underlies possible involvement in chronic proliferative diseases, ranging from cancers, adenocarcinoma, or Kaposi's sarcoma (464,517), to vascular diseases such as atherosclerosis and restenosis after angioplasty (147). Although epidemiologic associations are complicated by the ubiquitous distribution of human CMV in the adult population, the difficulty of using molecular detection methods to unambiguously associate small amounts of viral nucleic acids with a chronic disease and controversy regarding the epidemiologic methods used, these areas remain of active interest. Three “morphologic transforming regions” on the human CMV genome, called *mtr*I, *mtr*II, and *mtr*III, mapped near 156,000 bp, 159,000 bp, and 174,000 bp, respectively, have been characterized for their ability to growth-transform rodent fibroblasts (139). CMV-induced growth transformation of rodent cells follows a hit-and-run paradigm (339), complicating assignment of a role for any CMV genetic element in transformation. A 79-amino-acid ORF related to UL111A within *mtr*II (395,557) that appears to encode the amino terminus of a CMV IL-10 homolog (284,326) is the only region that is retained in transformed cells. The ability of human CMV $IE1_{491aa}$ or $IE2_{579aa}$ to increase adenovirus E1A-mediated transformation (486) can be related to a potential antiapoptotic activity (634), but neither of the CMV gene products is retained in outgrowing E1A-transformed cells and neither exhibits transforming activity on its own. This area of research is complicated by several contrasting observations, such as reports that constitutive expression of $IE1_{491aa}$ does not alter either growth or permissiveness of HFs (190,382), whereas expression of $IE2_{579aa}$ is toxic and induces cell cycle arrest (600).

The mutagenic effects of human CMV virion binding/penetration events are readily scored (1). Recent evidence for breaks introduced specifically into chromosome 1 when permissive HFs are exposed to virus particles (157) opens a host of questions about how much of a role is played by signalling cascades induced by virion binding or by structural proteins delivered to cells through the entry process.

DNA Replication

CMV replication is believed to follow a productive replication scheme that is common to other herpesviruses. The definition of CMV DNA replication has been derived predominantly from transient DNA replication assays employing viral

genes (20), with only limited investigations using viral mutants (134,438). The roles of some viral gene products are relatively well understood by analogy to other herpesviruses, whereas others are still poorly understood because they appear to be betaherpesvirus specific. Six herpesvirus-conserved CMV replication-fork proteins—a DNA polymerase (pUL54) and its associated processivity factor (ppUL44), a single-stranded DNA binding protein (ppUL57), and a three-subunit helicase-primase complex (pUL70, pUL102, and pUL105)—are required for viral origin (*ori*Lyt)-dependent DNA synthesis. In some assays, the products of additional CMV genes (UL84, UL112-113, UL114) also appear necessary for optimal replication (20,438,476). Importantly, UL84 may play a key function in initiation of *ori*Lyt-specific replication (476).

Human CMV DNA replication begins at approximately 16 hpi and peaks at 60 to 80 hpi (533) with the production of several thousand genome copies per infected cell (536) that mature and are released from cells over a 24- to 48-hour period (419). The CMV genome circularizes in the nucleus of permissive cells within 4 hpi, and replication produces concatemers late in infection. Most replicating viral DNA is larger than unit genome length and lacks terminal fragments. This is consistent with a directional rolling-circle mode of replication (296,358) that may require cellular replication proteins in addition to viral functions. Host cells are stimulated in such a way that they have the appearance of transiting the S phase (236,391) but are actually blocked from S phase progression when supporting viral replication (64,132,133,138,327,470). These conditions appear to favor viral DNA synthesis, although this remains a slow process even under optimal conditions.

Origin/Replicator

Human, murine, and simian CMV genomes contain a single *ori*Lyt located within the U_L region and adjacent to the ORF encoding the single stranded DNA binding protein, ppUL57 (19,201,350,351). This relative position is preserved in all betaherpesviruses and is analogous to the arrangement observed for HSV-1 ori_L (510). Human CMV DNA replication proceeds bi-directionally from *ori*Lyt, based on chain termination assays (201), which fulfills functional requirements of an authentic productive DNA synthesis initiation site. Although CMV enters latency with retention of the viral genome as an extrachromosomal circle (57) in cells with the potential to divide, a genome maintenance origin has not yet been identified. In addition, genes corresponding to the origin-binding proteins of alphaherpesviruses (see Chapter 72) or the related functions in the betaherpesviruses HHV-6 and HHV-7 (see Chapter 80) are not encoded by any CMV, limiting understanding of the initiation of CMV DNA synthesis.

The minimal *ori*Lyt maps to a large region between 91,751 and 93,299 nt on the AD169 genome (19,350,635); however, an even larger region spanning 90,500 to 93,930 nt is required for full replicator function. The minimal *ori*Lyt sequence contains clustered and dispersed repeats and binding sites for various transcription factors (19,201,350,588), the precise function of which awaits further study. Human CMV encodes a number of short transcripts within the *ori*Lyt region (222,440) and virions carry stable *ori*Lyt-specific RNA–DNA hybrid species (440), suggesting that transcription may play some role in the initiation of viral DNA synthesis. A 189-bp repeat sequence present in varying copy numbers in the origins of human CMV strains AD169 (93,337 to 93,525 nt) and Towne has been shown to be dispensable for DNA replication (97,258). Introduction of heterologous DNA at this location abolishes DNA replication, implicating a role for at least one copy of this sequence in CMV DNA synthesis. One origin sequence element, a 31-nt homopyrimidine (Y block), has been shown to be absolutely essential for replication (222). In addition, scanning mutagenesis of this entire region revealed that many mutations within and adjacent to the minimal origin reduce replication efficiency from 50- to 100-fold to undetectable levels (635). Two absolutely essential regions were confirmed in this screen, one overlapping the Y block between 92,209 and 92,573 bp and the other, between 92,979 and 93,145 bp, overlapping an RNA species arising within the *ori*Lyt region.

DNA Replication Enzymes and Sites of CMV Replication

Human CMV DNA polymerase (pol) enzymatic activity is readily measured (219). A DNA pol mutant that fails to make viral DNA has been described (134) but has not been subjected to detailed study. Conservation of a high level of sequence similarity and enzymatic properties of CMV DNA pol with similar enzymes encoded by other herpesviruses indicates that this protein functions as a key replication-fork protein responsible for resistance to high salt concentrations and sensitivity to particular deoxyribonucleoside and pyrophosphate analog antiviral agents (158,219,582). Conserved structural domains present in other cellular and viral DNA polymerases are also conserved in the CMV DNA polymerase (107). CMV DNA polymerase is dependent on an associated polymerase processivity factor, ppUL44 in human CMV (148,591). This protein is conserved in function, but not sequence, in all herpesviruses.

The product of UL44 was initially referred to as the major late DNA binding protein (175,180) because it binds to double-stranded DNA (175,180,385), an activity that underlies its role as the DNA polymerase processivity factor that prevents dissociation of the polymerase from the DNA template (148,591). Thus, ppUL44 shares biochemical characteristics with the processivity factor encoded by HSV-1 UL42, but it does not exhibit significant sequence conservation (92,446). The other DNA binding protein is encoded by UL57 and has similar size and biochemical activities to the HSV-1 single-stranded DNA binding protein (18,259). By analogy to HSV-1, the product of UL57 is predicted to prevent reannealing of DNA strands following unwinding by the putative human CMV helicase–primase complex, UL105–UL102–UL70, which is analogous to the HSV-1 UL5–UL8–UL52 helicase–primase (see Chapter 72). This process has received little direct study in CMV.

Current antiviral therapies, including ganciclovir (158), cidofovir (620), and foscarnet (582), target the CMV DNA polymerase. Though CMV does not encode a specific deoxynucleoside (or thymidine) kinase, the phosphorylated active form of ganciclovir accumulates within infected cells through the action of the CMV gene UL97 (48,543). UL97 appears to encode a kinase (93) that is the homolog of a herpesvirus-conserved serine/threonine protein kinase responsible for autophosphorylation as well as for phosphorylation of other viral proteins (208). UL97 is unusual in appearing to use the nucleoside ganciclovir as a substrate (321,543). One recent study suggests that UL97 is also able to phosphorylate acyclovir but to a lesser extent (548), which may explain this drug's lower activity against CMV compared to HSV-1. Point mutations in either the CMV DNA polymerase (24,106,542) or UL97 (102,495) confer resistance to these therapies. Although CMV does not encode a gene for thymidylate synthase, it appears to require this cellular enzyme for efficient

DNA replication. Treatment of human or murine CMV–infected cells with inhibitors of thymidylate synthase results in inhibition of viral DNA synthesis (108,193).

In addition to these core replication proteins, four viral gene loci are known to influence replication as presumed regulatory proteins—*ie*1/*ie*2, TRS1/IRS1, UL112-113, and UL36-38 (231,412,413). The *ie*1/*ie*2 and TRS1/IRS1 genes may function to activate gene expression (see section, Regulation of Gene Expression), but the key functions of the UL36 and UL37 genes appear to be prevention of apoptosis (see section, Regulatory Activities of Other a Gene Products) (185,186). Furthermore, two loci (UL84, UL112-113) needed for viral DNA synthesis (412,413) may be more directly involved in the process. The ppUL84, a 75-kd protein, stably interacts with IE2 $_{579aa}$ in infected cells (471,519); however, it is still unclear how this property relates to the evidence that this is an origin-specific initiator protein, which was based on the ability of this protein to facilitate human CMV *ori*Lyt-dependent replication using the six EBV replication-fork proteins (476). The ppUL84 is unable to initiate *ori*Lyt-dependent replication with the human CMV replication-fork proteins in the same assay. The ppUL84 interaction with IE2$_{579aa}$ inhibits transient transactivation (169), but the impact of this complex on replication requires further analysis. Finally, the four phosphoproteins encoded by the UL112-113 region (233,616) appear to orchestrate recruitment of replication-fork proteins to nuclear sites associated with viral transcription and DNA synthesis (11,419).

Human CMV DNA synthesis proceeds in distinct subnuclear regions within the infected cell. The viral replication functions, ppUL44 and ppUL57, follow an ordered progression of localization patterns, leading eventually to the formation of large globular intranuclear structures that bear resemblance to HSV-1 replication compartments (419,572). These subnuclear domains are sites of human CMV DNA replication based on bromodeoxyuridine incorporation (419). The products of UL112-113 localize into replication compartment precursors earlier than any of the known replication-fork proteins and appear to function as recruiting proteins for these enzymes (11). Based on bromodeoxyuridine pulse-chase experiments, the early precursors of CMV replication compartments are sites of both cellular and viral DNA synthesis (419). Interestingly, small amounts of viral DNA are still synthesized in the presence of viral DNA polymerase inhibitors (391,419). This, together with the localization of viral DNA replication to known sites of cellular DNA synthesis, suggests that early phase viral DNA amplification may depend on cellular replication enzymes.

The human CMV genome also carries a number of enzymes involved in nucleotide metabolism and DNA repair. These include the large subunit of ribonucleotide reductase, deoxyuridine triphosphatase, deoxyribonuclease, and uracil DNA glycosylase (92). At least one of these proteins, the human CMV uracil DNA glycosylase encoded by UL114, is required for efficient DNA replication, based on analysis of a viral mutant (438). UL114 does not score as necessary in transient replication assays, but a human CMV mutant in UL114 exhibits a prolonged growth cycle corresponding to a restriction prior to viral DNA synthesis. Further analysis of this mutant has revealed that it is able to synthesize DNA to 10% of the level of wild-type virus, suggesting that UL114 is required for the transition to high-level, late-phase DNA replication (Courcelle and Mocarski, unpublished data).

Genome Inversion and Maturation

Genome inversion and maturation occur in the nucleus of infected cells, with most newly replicated DNA maturing into virions that are released over a period of 2 days after synthesis (419). Inversion results in progeny genomes appearing as any one of four isomers differing only with respect to the orientation of L and S components (see Fig. 1C). This process occurs at late times in infection, during or following replication, and possibly within concatemeric intermediates found prior to DNA cleavage and packaging (358). Human CMV is the only member of the betaherpesviruses that undergoes inversion of two genome components. As is the case in other herpesviruses, inversion of the human CMV genome is dispensable for replication in cultured cells (Duke and Mocarski, unpublished observation). The recombination that drives inversion requires inverted repeat sequences located at the ends of each genomic component. The genomic *a* sequence is necessary and sufficient for inversion, because deletion of the L-S junction *a* sequence without disruption of either *b* or *c* repeats freezes the viral genome in one isomer (Duke and Mocarski, unpublished observation), and duplicating an *a* sequence segment results in additional inversion events (260). When murine CMV is engineered to carry an additional copy of the joined termini in inverted orientation, the viral genome uses these sequences to support inversion as well as cleavage/packaging progeny genomes in a new register (362). When the same fragment is inserted in direct orientation, only packaging occurs (360). The biologic role of inversion in those herpesviruses that carry out this process remains a mystery.

Like other herpesviruses, human CMV packages its genome into preformed B capsids composed of MCP, mCP, mC-BP, and SCP together with the AP precursor (pUL80.5) (176). The functions that are likely to play some role in this process are all tegument proteins, and they include UL56, UL89, and UL104, as indicated by antiviral resistance mapping (290,571) (Rubsamen-Waigmann, personal communication, 2000), as well as UL51, UL52, UL77, UL47, and UL48 based on sequence similarity to most functions known to be important in HSV genome maturation (see Chapter 72). Resistance to 2-bromo-5,6-dichloro-1-(b-D-ribofuranosyl)-benzimidazole (BDCRB) and 2,5,6-trichloro-1-(b-D-ribofuranosyl)-benzimidazole (TCRB) maps to UL89 and UL56 (290,571), and resistance to BAY 38-4766 maps to UL89 and UL104 (Rubsamen-Waigmann, personal communication, 2000), directly implicating these genes in the cleavage/packaging process inhibited by these different compounds. The importance of UL89, a homolog of the terminase, and UL56, a DNA binding protein, is also suggested by studies that show that these proteins associate into a complex (50) (Bogner, personal communication, 2000) in a manner similar to their HSV homologs (see Chapter 72).

The signals used to direct cleavage and packaging of CMV genomes, denoted *pac*1 and *pac*2, are highly conserved short sequence elements found near the genomic termini in all mammalian herpesviruses. Human, murine, and rat CMVs contain elements that are homologous to both *pac*1 and *pac*2 elements (348,349,383,512,549,578). These elements are essential cleavage/packaging signals (260,360) and can allow HSV-1 to recognize and package plasmids bearing a CMV *a* sequence (512). In most herpesviruses that have been examined, including murine and rat CMVs that lack an *a* sequence, *pac*1 and *pac*2 are positioned on opposite sides on the cleavage site, whereas in human CMV both appear to be carried on the S-component proximal side of the *a* sequence (260). Cleavage leaves a *pac*2 element near a free

S-terminal fragment that is present on concatemers. The packaging machinery preferentially inserts termini derived from the S rather than the L component into maturing capsids (358). This *pac*2-leading directional packaging from concatemers appears to be a common theme and occurs in murine CMV and guinea pig CMV, as well as in HSV-1 (361). Although the precise cleavage site appears to vary slightly from strain to strain in human CMV, the two strains that have been examined (Towne and AD169) have a single 3' nucleotide extension on both termini (383,550). Even when the terminal direct repeat is extremely small, such as in murine CMV where *pac*1 and *pac*2 lie outside the 30-bp terminal repeat, both elements are essential for the genome maturation process (360). The cleavage/packaging process results in a variable number of *a* sequences at human CMV genomic termini and the L-S junction (383), with a single *a* sequence predominating at all positions. A poorly studied process of *a* sequence duplication and amplification occurs at some step during replication. Studies in murine CMV suggest that the duplication of an inserted terminal repeat only occurs at the same time the additional junction is recognized for cleavage. Anywhere from one to eight directly repeated *a* sequence copies may be detected at the L or S terminus and L-S junction, and a small proportion of genomes lack an *a* sequence altogether at the S terminus (260,383,550). The sequence within a 220-bp region that carries both *pac*1 and *pac*2 is sufficient to convey a site for cleavage/packaging as well as inversion on a recombinant human CMV (260).

Little is known about the cellular proteins that might contribute to genome inversion or maturation events. A cellular protein has been detected, partially purified, and shown to bind to the human CMV *pac*-2 sequence elements (260), but characterization of its role in replication, genome inversion, or genome maturation has yet to be completed. Human CMV expresses several functions with similarity to suspected HSV-1 maturation functions. Based on direct studies of protein function, the human CMV UL46 product (mCP) appears to be a homolog of HSV-1 19C (92,175), a protein involved in anchoring DNA into HSV-1 nucleocapsids. Human CMV UL48, the homolog of the huge virion protein (VP1) of HSV-1, and CMV UL98, the homolog of the HSV-1 deoxyribonuclease, are conserved genes and may play roles in genome maturation.

Virion Morphogenesis

Ultrastructural studies (354,498) show nucleocapsids accumulate in the nucleus (see Fig. 1B) and form a nuclear inclusion that is readily observed by light microscopy as the typical “owl's eye” cytopathic effect. Maturation starts in uclear inclusions, where nucleocapsids mature within a nuclear fibrillar network consisting of viral structural proteins adjacent to a DNA replication compartment (156,419). Particles with and without electron-dense DNA cores mature (see Fig. 1B). Formation of capsids is controlled by MCP–AP (1:1) precursor complexes that initially associate via an AP precursor conserved carboxyl-terminal domain following synthesis at cytoplasmic sites (408,612). This interaction is responsible for both translocating the MCP to the nucleus (426) and initiating capsid assembly (176,306). In the nucleus, a conserved amino-terminal AP precursor domain facilitates oligomerization that drives the formation of hexons, pentons, and higher-order structures. A triplex of mCP–mc-bp (2:1) complexes interdigitate hexons and pentons on oligomerized AP precursors as they form an internal scaffold, which is structurally observed as a dense core ring in B capsids (75,95,565). The association of SCP on the outer capsid surface and a series of assemblin-mediated protease cleavage steps separate AP from the MCP and inactivate the protease itself. This completes the formation of B capsids, into which viral DNA is packaged. The insertion of DNA displaces AP. The process is dependent on the viral UL97 kinase (610a). Progeny nucleocapsids locate to thickened concave patches in the inner nuclear membrane, where they bud into the perinuclear cisternae (176). The nuclear membrane is modified with viral glycoproteins that are also present on the mature viral envelope (443,537). Thus, the initial site of virion envelopment is at the inner nuclear membrane (378), but the site of final envelopment has not been unambiguously determined and may occur at cytoplasmic membranes through a process of deenvelopment/reenvelopment best characterized in HSV-1 (599). Evidence that the human CMV envelope has the lipid composition of early endosomal membranes (564) has been complemented by studies that suggest cytoplasmic maturation sites are where some tegument proteins exclusively reside (473,474). Electron micrographs support the removal and re-acquisition of the envelope during egress (498). Dense bodies, consisting solely of tegument material surrounded by an envelope, mature exclusively at cytoplasmic sites, and nonenveloped nucleocapsids have been observed free in the cytoplasm as well as budding into cytoplasmic vesicles. The virion is transported in vesicles via the Golgi apparatus to the cell surface, suggesting that egress from cells involves an exocytic pathway sensitive to brefeldin A (145). This observation reinforces the need for glycosylation and transport of the virion through the Golgi apparatus prior to release. The characteristic cytoplasmic inclusion that develops in CMV-infected cells represents an expanded Golgi complex in which nucleocapsids and dense bodies accumulate (see Fig. 1B). This inclusion distorts the cell nucleus, giving it a characteristic kidney-bean appearance. Progeny virus is efficiently released from cells, with approximately half of the progeny virus at very late times after infection found in the culture fluid and half remaining associated with the cell.

PATHOGENESIS, PERSISTENCE, AND LATENCY

Human CMV exhibits a ubiquitous pattern of distribution and efficient transmission via direct contact in all areas of the world regardless of socioeconomic conditions (216) (see Chapter 77). The usually benign primary infection by this virus is controlled by a combination of innate and adaptive immune control functions, after which latent infection continues for life. Primary infection, lifelong latency, and intermittent shedding resulting from reactivation commonly occur without any marked disease consequences. These characteristics underscore the remarkable balance this pathogen has developed with its host.

Primary infection typically starts with replication in mucosal epithelium as a result of direct contact with infectious secretions from an infected individual. A high incidence of infection in the general population and accumulating evidence that hand-washing prevents acquisition of CMV from infants who shed high levels of virus in urine and saliva provide excellent evidence that this virus reaches a large proportion of the population because it is efficiently transmitted (3,4,523). A systemic phase of infection disseminates virus in the host via a leukocyte-associated viremia that may last for several months as assessed using assays for viral DNA or viral antigen (450,631). Cell-free infectious virus is not found in blood, although viral DNA, somehow protected from degradation, is detected in plasma from immunocompromised individuals (520). Peripheral blood (PB) neutrophils, monocytes, and endothelial cells have all been observed to carry infectious virus in immunocompromised hosts (171), but the role of particular leukocyte subsets as vehicles for dissemination during primary infection in the immunocompetent host is still unclear. The suggestion that

neutrophils act as vehicles to disseminate infectious virus and viral products has been supported by cell culture studies on transmission of clinical strains in the absence of full replication (172). PB monocytes are vehicles for dissemination of murine CMV (111,539), and this interaction is controlled by viral tropism determinants (468). The systemic phase of primary infection in adults is accompanied by persistent viral shedding in urine, saliva, breast milk, and genital secretions, which may be important sources for transmission between hosts. The distribution of virus during acute infection is best understood from studies in the immunocompromised host, but a range of endothelial, epithelial, and hematopoietic cells in tissues are also believed to be susceptible in immunocompetent individuals (425). Systemic replication leads to a well-documented (216) seeding of the ductal epithelia where replication releases virus into secretions. Myeloid-lineage hematopoietic cells become important targets for lifelong latency. Viremia continues for a long period of time after an adaptive immune response can first be detected, typically at least 6 months in adults (450,631) and several years in young children (416). This prolonged period of primary infection is surprising given the intensity and quality of the host immune response, although this pattern reinforces the balance that characterizes all aspects of CMV pathogenesis (216). Although an initial persistent infection is often observed, clearance of acute infection is the norm in all immunocompetent individuals (416,523), and it is correlated with a slow rise in cell-mediated immunity (631). The relatively long period of persistent shedding observed in infants correlates with their immune status and allows the virus an efficient means of transmission to uninfected individuals (4).

CMV is also transmitted as a result of transplantation of solid organs or bone marrow and transfusion of whole blood, where blood leukocytes are an important reservoir for transmission (128,623). PB mononuclear cells in the myeloid lineage support latent infection (281,489,503,505). Latently infected cells most likely originate from the bone marrow in healthy seropositive individuals (280,281,375) and virus has occasionally been recovered from PB leukocytes subjected to long-term co-culture (137,503). Latent virus is strongly suspected to play an important role as a source for transmission with transplanted solid organs or transfused blood products, although studies that correlate latent viral load with risk of transmission are still needed.

Pathogenesis of CMV disease is directly linked to the immune status of the host. Primary infection, as well as reactivation from latency, contributes to pathogenesis (see Chapter 77). Innate and adaptive immune mechanisms control acute virus infection, maintain latent infection, and modulate virus during reactivation. Clearance mechanisms are subjected to a range of viral immunomodulation that both thwart the effectiveness of the immune response and use the immune system to ends that benefit the virus. CMV infection directly perturbs immune functions, leaving the host open to disease, such as during transplant procedures, bone marrow or stem cell allografting (300), and PB stem cell autografting (45). This virus has been shown to down-regulate MHC class I protein expression to reduce the impact of cytotoxic T-lymphocyte (CTL) immunity (211,429).

Because of its strict species specificity, human CMV has never been successfully introduced into another animal, although human tissue implants carried in severe combined immunodeficient (SCID-hu) mice are permissive (69,381). Epithelial cells are prominent targets for replication in SCID-hu (thy-liv) mice, where variation in replication efficiency of different virus strains (69) has provided insights into genome variation (82). Murine, guinea pig, rat, and rhesus macaque CMVs have been employed as surrogate models of human CMV infection, latency, and disease (73,126,225,325,522,544), providing insights into CMV pathogenesis, including host immune control (283,452), mechanisms of dissemination, and tissue tropism (58,81,468,539,544), disease in the immunocompromised host (433,448,528), contribution to chronic disease (437,580), and mechanisms of congenital disease (325), latency (294), and immunomodulation (151,210). All of these areas are important contributors to viral pathogenesis.

Immunity

A central importance of cell mediated immunity to the control of CMV infection is reinforced by the observation that individuals with deficiencies in cellular immunity exhibit the highest risk for CMV disease. Resistance to CMV infection depends on successful collaboration between the innate and adaptive immune systems. Both natural killer (NK) cells (60) and CTLs (452), whose presence correlates with protection from CMV disease (47,319), play prominent roles in immune clearance. The humoral antibody response is critical in some settings such as neonatal disease (623) and solid organ transplant settings (501), although it is less clearly important in other settings such as bone marrow allografting. Adoptive transfer of CMV-specific CTL clones provides a benefit to the host, above and beyond antiviral therapy in bone marrow allograft recipients (452,585), and demonstrates that MHC class I restricted CTL response to a small set of structural protein determinants on ppUL83 and ppUL32 is sufficient for adoptive immunotherapy (585). CTL responses to CMV ppUL83 are evident over the life of the individual and remain a remarkably consistent percentage of the total immune repertoire (239,590).

Immune clearance in humans has focused on MHC-linked control, although in mice, resistance to CMV disease maps to MHC-linked as well as nonlinked determinants. These include one locus controlling the permissiveness of cells (203) and another, called *cmv*-1, influencing NK cell function (70,151,478). MHC-linked resistance in mice extends beyond CTL immunity and includes differences in interferon levels, macrophage function, and other cytokine-mediated immune response elements that control CD4+ as well as CD8+ T-cell clearance mechanisms (283,489). NK responses are important in human CMV infections (47), and studies using murine CMV reveal their central role in modulating virus in the earliest stages of infection. Specific adaptive immunity is responsible for clearance and survival (151,596). In murine CMV, in fact, the adaptive cellular immune response by CTLs is sufficient to clear infection from most tissues and is sufficient for survival (283). Clearance from particular organs, such as from salivary glands, is dependent on a CD4+ T-helper-cell response rather than on CTLs (329). It is likely that specific adaptive cellular immune mechanisms are most important for control of acute infection and maintenance of latency.

Immune Evasion and Piracy

Viral functions committed to evading the host immune response, optimizing viral growth, and promoting viral dissemination are encoded by many genes that are dispensable for productive replication in cultured cells. Initial insights into the roles of such genes came from murine CMV, where a viral gene (m133), denoted *sgg*1, was shown to be a determinant of replication in salivary glands (299,343) and from human CMV, where a cluster of dispensable genes

(US2–US11) has been shown to encode a function (gpUS9) that influences cell-to-cell spread of virus in polarized cells (341), as well as four functions (gpUS2, gpUS3, gpUS6, gpUS11) that down-modulate MHC class I expression to reduce the effectiveness of CTL immunity (241,429). MHC class I down-regulation is a theme common to human CMV (33,211,622) and murine CMV (130), although the modulation is carried out by a distinct, unrelated set of viral genes in each virus (210,429). In human CMV, MHC class I down-regulation occurs as a result of expression immediately after entry (12,212,241,601) of gpUS3, an a gene product that resides in the ER and prevents MHC class I transport to the cell surface (12,245). Subsequent down-modulation is by gpUS2 and gpUS11, two b_1 gene products residing in the ER (12,241,244,601) that direct the proteasomal degradation of newly transported MHC class I proteins by binding to MHC protein ectodomains while signalling degradation from the carboxyl-terminal, cytoplasmic tail (485,540). Even later in infection, MHC class I translocation is prevented by gpUS6, a g_1 gene product that targets the ER and binds to the lumenal side of the transporter of antigen processing (TAP) complex, inhibiting peptide translocation (13,213,316). One additional specialized mechanism may reduce MHC class I–dependent presentation of the nuclear protein IE1 $_{491aa}$ via a phosphorylation event controlled by tegument protein ppUL83 (182). In the host, these immunomodulatory processes probably reduce effectiveness of the CTL response enough to slow clearance and encourage persistence. Despite the elaboration of this myriad of immunomodulators, CTL-mediated immune clearance remains the most important component of the immune response contributing to viral clearance (452), providing evidence of the delicate balance between the virus and host. To avoid the impact of down-modulation, CTLs may recognize input structural proteins presented before viral immunomodulatory gene products have a chance to alter class I levels (453,604). Although MHC class I synthesis and processing are reduced by viral infection, sufficient levels of class I remain on the surface of infected cells to allow killing, but with altered sensitivity to CTLs (211). It remains unclear whether down-modulation of MHC class I plays a more important role during the induction phase of the immune response than during the elaboration of effector functions. In this regard, mutations in the murine CMV immunomodulatory functions (152,155,210) may play different roles in various phases of the immune response or infection.

CMV infection also modulates IFNg-induced MHC class II expression, with a likely impact on antigen presentation during either induction or effector phases of the CD4+ T-lymphocyte response (374). Human CMV infection inhibits cytokine-induced MHC class II expression by blocking the induction of transcription activator, CTA_{II}, a target of the Janus kinase 1 (Jak1) pathway (373). Although not yet as well studied as MHC class I down-modulation, multiple mechanisms appear to control MHC class II modulation during human CMV infection, with a US2-dependent degradation system also contributing to reduction in MHC class II levels (562). In murine CMV, down-regulation of IFNg-induced MHC class II expression reduces antigen presentation on infected macrophages (209). Induction of host IL-10 that occurs during murine CMV infection of macrophage-lineage cells suppresses even constitutive MHC class II expression (449). The discovery of a functional viral IL-10 in human CMV (284,326) suggests that both viral and cellular IL-10 may contribute to MHC class II down-regulation in addition to the impact of other viral gene products. Human and other primate CMVs encode a homolog of IL-10 from spliced mRNA that retains a subset of introns found in host IL-10 (326), including, in human CMV, an amino terminus derived from UL111A (92). The human CMV IL-10 signals via IL-10 receptors (284), indicating an antiinflammatory role first suggested for the EBV IL-10 homolog (390).

A number of other human CMV genes encode homologs of cellular gene products that probably play a role in pathogenesis. An MHC class I heavy-chain homolog (UL18) binds b_2 microglobulin (72) and peptides (150) as does host MHC class I (89), but it is dispensable for replication in cell culture (71). The pUL18 has been thought to prevent an effective NK cell response by replacing host cell MHC class I on the infected cell surface. The cellular receptor for pUL18 is related to killer cell inhibitory receptors (KIRs) found on NK cells, and it is denoted lymphocyte IR-1 (LIR-1) because of more prevalent distribution on lymphocytes and monocytes (115,116). The small populations of LIR-1-positive NK cells bind pUL18 as well as different MHC class I alleles, which is different from the pattern of allelic recognition in KIRs (579), and they function by contacting common structural features in pUL18 or MHC immunoglobulin domains (89). A proposed NK inhibitory role for pUL18 (451) has not been sustained in settings where expression of the viral protein can be followed (318); however, a comparison of LIR-1^+ and LIR-1^- NK cells may shed further light on the function of this protein. In mouse CMV, deletion of the MHC class I homolog (m144), which does not interact with LIRs, nonetheless specifically enhances virulence through a decrease in NK-mediated clearance (152). One additional event in human CMV–infected cells may be related to NK killing. Expression of HLA E, which is an inhibitor of NK cells in certain assays, is enhanced during infection (632), apparently because a leader peptide from CMV gpUL40 can enhance expression of this nonclassical MHC protein at the cell surface (561).

Four human CMV genes (UL33, UL78, US27, US28) encoding homologs of 7TM receptors (94) are expressed at early and late times during infection. Some encode virion envelope proteins (347). The best-studied and only known functional member of this family (US28) encodes a C-C chemokine G-protein-coupled receptor (GCR) (400), which binds both CC (163,291) and CX_3C chemokines (272), and signals in response to some. The pUS28 may function as a chemokine sink (49), mediate intracellular signalling (46), and control the level of host cell activation through inducing chemokinesis or chemotaxis (541). The outcome in any of these scenarios would be that the behavior of infected cells is altered. Chemokine receptors normally control migration of cells in chemokine gradients (i.e., chemotaxis); however, evidence for US28-mediated chemotaxis has been difficult to obtain. Recent studies using adenovirus vectors to efficiently direct expression in vascular smooth muscle cells suggest that this receptor might direct cell movement (541). Although any relationship to the pathogenesis of AIDS remains unclear, human CMV pUS28 also provides coreceptor function for HIV entry (428,466). Neither mouse nor rat CMV has a US28 homolog, but deletion of other 7TM homologs, including murine CMV m33 (127) and rat CMV r78 (34), results in altered growth patterns in the natural host. US28, US27, and UL33 are dispensable for replication in cell culture (49,347,576).

Virus-encoded chemokines also influence the behavior of leukocytes during infection. Two CMV genes (UL146, UL147) exhibit cysteine spacing and weak amino acid homology to CXC chemokines, with UL146 encoding a fully functional IL-8-like chemokine denoted vCXC-1 (418). The vCXC-1 is exported and found in a medium of infected cells. vCXC-1 induces chemotaxis of neutrophils but no other PB cell type via the human chemokine receptor CXCR2. Thus, vCXC-1 may play a role in attracting neutrophils or possibly other CXCR2-positive myeloid cells to sites of infection, where they may acquire virus or contribute to dissemination (172). This viral chemokine does not bind to the US28 chemokine receptor. Although neutrophils are attracted to sites of CMV replication, it is unclear whether vCXC-1 is

immunomodulatory or acts in some other way to orchestrate host leukocytes. A role for positively acting chemokines in viral infection can be gleaned from studies on the murine CMV CC chemokine, MCK (335,336), which signals to monocyte-macrophages (468) and influences dissemination in the host (155,468). MCK expression increases the level of monocyte-associated viremia during infection (468) by increasing the size and composition of the inflammatory response at sites of infection, attracting host monocytes that carry virus into the bloodstream.

Several additional viral functions have received less study but may also be immunomodulatory. A tissue necrosis factor (TNF) receptor sequence homolog is carried in the Toledo strain genome (UL144) (82) and recognized through its similarity to one of the cellular proteins that mediate HSV-1 entry, HveA (see Chapter 72). The gpUL144 itself does not bind any known TNF ligands (36) but may interfere with TNFa or Fas ligand–mediated killing of infected cells (Leong, Phillips, and Lanier, personal communication, 1999). The CMV T-cell gamma chain receptor sequence homolog (UL20) exhibits similarity to the variable and constant domains (31), but nothing more is known about its function. An IgG Fc receptor is induced in cells infected with human CMV (334) and is likely to be a virion envelope constituent (621), although a gene assignment has not yet been made. Murine CMV m138 encodes an Fc receptor (556), but this function plays an unexpected and unexplained antibody-response-independent role in virus infection (121).

Latent Infection

Evidence has accumulated that human CMV remains latent in lineage-committed myeloid cells, including progenitors that give rise to granulocytes, macrophages, and dendritic cells (200,489,505), and possibly endothelial cells (492). Viral DNA is present in mononuclear cells derived from PB or bone marrow of healthy seropositive individuals (39,367,494,526,553), but infectious virus is not present. Viral gene expression in latently infected progenitor cells is restricted to latency-associated transcripts that have been observed in both natural and experimental infection in cells with cell surface marker CD33 expressed together with lineage-specific markers (CD14, CD15, CD1a, or CD10) (200,280,281). The pattern of latent gene expression changes as these cells mature into monocytes or dendritic cells (200) and may become productive as a result of differentiation under proinflammatory conditions. Earlier investigations employing a variety of cell lines revealed a now well-accepted role for cell differentiation state in controlling permissiveness (173). Differentiation of primary PB monocytes to monocyte-derived macrophages in the presence of activated T cells promotes cell differentiation and supports reactivation of latent virus (503), although the precise factors that control this process are not yet clear (505).

Latently infected cells are very difficult to detect in PB or bone marrow–derived monocytes from latently infected individuals. Despite ready detection in PB leukocytes of immunocompromised individuals (123,198) and one report suggesting easy detection of viral IE transcripts in lymphocytes of healthy seropositive individuals (482), only a very small percentage (0.01%) of latently infected cells are present in bone marrow–derived mononuclear cell preparations. These are largely CMV IE transcript negative even when very sensitive, PCR-driven *in situ* hybridization is employed (494). Lymphocytes and other PB leukocyte subsets remain uniformly negative during lifelong latency (552,553).

Viral Genome and Gene Expression

The CMV genome is maintained as a covalently closed circle in the nucleus of CD14+ PB mononuclear cells (57). CMV latency-associated transcripts (CLTs) originating from both DNA strands in the *ie*1/*ie*2 region are the only viral gene products that have been associated with latent infection, with sense CLTs transcribed from the same strand as MIE gene products and antisense CLTs transcribed from the opposite DNA strand (281). Sense CLTs are oriented in the same direction as productive MIE transcripts, initiate at two unique transcription start sites that map in the MIE enhancer region, and are present in a subset of naturally or experimentally infected CD33+ myeloid progenitors (200,281,494). Four ORFs (ORF55, ORF42, ORF45, and ORF94) are predicted to be uniquely encoded by sense CLTs, and three ORFs (ORF59, ORF154, and ORF152/UL124) are present on antisense CLTs. Antibodies to these ORFs are recognized by sera from heathy CMV seropositive individuals (281,304), suggesting that they are expressed during natural infection. Only one, a 94-amino-acid basic protein encoded from sense CLTs, exhibits a nuclear localization pattern when expressed in mammalian cells, and only this ORF has been subjected to detailed study. Genetic analysis of a virus carrying an ORF94-specific mutation has not revealed a role for this gene product in either productive or latent infection (598). Mutations in the MIE modulator or enhancer region (363,365) or in other predicted sense or antisense gene products have not yet been evaluated for impact on latency. Thus, it is not yet clear that establishment or maintenance of latency requires specific viral gene expression.

Reactivation

Reactivation is believed to be more important than primary infection as a source of virus-causing disease in the immunocompromised host, and it is thought to occur as a result of at least three collaborating events: (a) cytokine stimulation of latently infected cells causing differentiation into a permissive cell type that supports viral replication (200,275,280,503,505), (b) viral amplification caused by reduced immune surveillance that leads to a widespread systemic infection with a readily detectable viremia (153,469,480) and virus in many tissues (396), and (c) disease states developing as a result of a poorly understood collaboration of immune-, organ-, and virus-specific determinants (see Chapter 72). These three stages of reactivation help illuminate an important interplay of the immune response in reactivation and pathogenesis. Immunocompetent individuals who support persistent infection or who frequently reactivate and shed virus may be predisposed to more rapid amplification and clinical disease because the first event is unnecessary. Most clinical manifestations of reactivation result from the second event, after virus replication reaches readily detectable levels. The consistency with which CMV reaches high systemic levels prior to and in the absence of disease is the basis of preemptive antiviral (630) or adoptive CMV-specific CTL therapies (452), as well as being the basis for the dramatic reduction in incidence of CMV retinitis and gastroenteritis resulting from immune reconstitution that follows highly active retroviral therapy in AIDS patients (136,279).

The earliest event in reactivation (the first event) is a fascinating area of virus biology. Cytokine-mediated differentiation of PB monocytes into macrophages under strongly proinflammatory conditions is undoubtedly key to this process

(364,503,505). Experimentally infected myeloid progenitor cells reactivate latent virus when cultured in the presence of IFNg or TNFa, which are part of a natural inflammatory response (200), but this signal is insufficient to reactivate naturally infected bone marrow–derived cells. Naturally infected PB monocyte-derived macrophages require the presence of allogeneically stimulated T cells to reactivate latent virus, and IFNg contributes important signals to this process (503,504). The accumulated data suggest that latency is preserved as most monocytes differentiate and that specific proinflammatory signals must be delivered to latently infected cells for reactivation to ensue (505). Such proinflammatory signals are likely to be generated during allograft transplant rejection, reinforcing a clear connection between inflammatory signals, allogeneic rejection, and reactivation. A low level of reactivation and replication of CMV itself may have an amplifying effect on inflammation that drives further reactivation. Investigation of murine CMV latency and reactivation suggests that latent virus is distributed widely in both endothelial and myeloid cells (276,292,376,434,435). Reactivation with immunosuppression alone is very difficult to achieve (79,246,447). Proinflammatory cytokines play a critical role in reactivation aside from the viral amplification that results in an immunocompromised host (275).

Given the prolonged, persistent nature of primary infection (450,631) and the sporadic shedding that occurs throughout life (509), persistent infection very likely contributes to transmission as well as pathogenesis. Low-level persistent infection, kept in check by effective immune surveillance, would amplify rapidly in the immunocompromised host and facilitate susceptibility to clinical disease. The relative importance of such amplification still needs to be addressed. In terms of the molecular basis of CMV disease, persistence and latency may exist side-by-side in different cell types or tissue, or as parts of a continuum in a particular lineage. The widely held view that latency and reactivation depend on the level of permissiveness of myeloid lineage cells (200,280,503,505) illustrates the difficulty in separating these phenomena in natural infection.

Latency is operationally defined as the ability to reactivate virus from cells of infected tissues following co-cultivation with permissive cells in culture without being able to detect virus directly in disrupted tissues (247). Using these criteria, murine CMV remains latent in epithelial, endothelial, and hematopoietic cells in a wide variety of tissues, including spleen, salivary gland, blood, skin, prostate, and testes (216,247,275,276,292,293,376,434,435). The tendency for persistent infection to depend on the age, immune status, and strain of mouse, and the evidence that latency extends to a number of cell types in different tissues rather than a single target, continue to complicate interpretation of studies on murine CMV latency. Because of ready access and reproducible reactivation, the most commonly studied sites of latency have been the spleen and lungs; however, the importance of bone marrow and salivary glands as sites of persistence and latency remains poorly characterized (380). Indeed, studies in this model have been complicated by a failure to recognize that latency cannot be studied as a cellular or organ-specific phenomenon while ignoring persistent infection at other sites within the same host. *In situ* methods of detecting latent viral genomes and distinguishing latent and persistent infection help (275,276,293), but the range of results that have been reported cannot yet be reconciled.

CHAPTER 77 Cytomegalovirus

Robert F. Pass

HISTORY

The medical and public health impact of cytomegalovirus (CMV) results largely from its role as the leading cause of congenital infection. The history of the discovery of CMV is closely linked to early 20th century studies of the pathology of fetuses and newborns who died from a multisystem disease characterized by prominent central nervous system, hepatic, and hematologic abnormalities. In 1904, Jesionek reported on the appearance of abnormal cells in the lungs, kidney, and liver of a premature fetus thought to have died from syphilis (147). Features consistent with CMV cytopathology were described, including an intranuclear inclusion surrounded by a clear zone, although the abnormal appearance of cells was considered suggestive of protozoal infection. In the same year, Ribbert reported having seen similar cells in 1881 in the kidneys of a stillborn infant (241). Within 3 years of these initial descriptions of distinctive pathology, similar cellular changes were reported in salivary glands of older infants and children (179). Other pathologists also reported finding intranuclear inclusions in salivary glands, liver, lungs, or kidneys from young infants (77,115). The similarity between this cytopathology and the inclusions seen in lesions produced by other herpesvirus infections such as varicella zoster and herpes genitalis was noted (115,174,297). Goodpasture and Talbot used the term *cytomegalia* in 1921 (115). Mueller suggested that the presence of this cytopathology in stillbirths implied a prenatal insult (192). Thus in addition to their descriptive contributions, early investigators provided evidence that the agent responsible for these cytomegalic cells could be acquired prenatally, affected multiple organs, was present in the salivary glands of children without systemic disease, and produced cytopathology similar to that produced by infectious diseases due to herpesviruses.

Continued study of infants with cytomegalic disease and of salivary gland pathology provided evidence that the fetal and infant disease was due to a common viral agent. Farber and Wolbach reported on cells with intranuclear and intracytoplasmic inclusions in 14% of salivary glands from 183 infant postmortem examinations (92), which indicated that the agent responsible for the cytopathology and organ dysfunction noted in stillbirths and infant deaths was more common than might be inferred from the occurrence of the multiorgan disease. In 1926, experiments with guinea pigs had shown that a filterable agent that was inactivated by heating at 54°C for 1 hour was transmissible and produced cytomegalic cells in salivary glands (71). In the early 1950s, the term *generalized cytomegalic inclusion disease* was used to describe the infants with multiorgan involvement (313). Fetterman described premortem detection of cytomegalic cells in the urine of a newborn who died shortly thereafter and was found on autopsy to have cytomegalic cells with inclusions in multiple organs (94). Not long after, the detection of inclusion-containing cells in urine was described as a diagnostic technique, and developmental delay and cerebral palsy were reported in a surviving infant (181,186). Using electron microscopy, Minder described apparent viral particles in the cytoplasm and in the clear zone around the intranuclear

inclusion in cytomegalic cells in the pancreas in 1953 (190).

However, tissue culture isolation of human CMV was not achieved until the mid 1950s, when three laboratories were successful at roughly the same time (244,260,302). Weller has reviewed the circumstances and chronology of the initial culture isolation of CMV (303). Margaret Smith isolated a mouse salivary gland virus in tissue culture in 1954 and at about the same time isolated and serially propagated human salivary gland virus and an isolate from the kidney of an infant who died from cytomegalic inclusion disease (259,260,303). The first isolation of CMV from tissues of a living human was made serendipitously in 1955 when Weller's laboratory was attempting to isolate *Toxoplasma* from a liver biopsy taken from an infant with hepatosplenomegaly, cerebral calcification, and chorioretinitis. The tissue culture (embryonic skin-muscle) developed foci of swollen cells with the cytopathology now associated with CMV. Continued study of this isolate, the Davis strain, led Weller and colleagues to conclude that they had recovered the agent of cytomegalic inclusion disease (302,303). Rowe and colleagues, studying adenoviruses from adenoids of children, came across cytopathology that differed from that expected from adenoviruses (303). Collaborating with Weller's laboratory, they were able to determine that their agent was similar to that isolated from cases of cytomegalic inclusion disease by Weller's group and by Margaret Smith (303). Rowe's group was able to prepare a complement fixation antigen, and their initial paper reporting isolation of a salivary gland virus-like cytopathogenic agent from human adenoids included data indicating that the majority of adults were infected by this agent (244). The ability to propagate CMV in tissue culture provided investigators with the means to use virus isolation diagnostically, to prepare antigens for serology, and to begin to study the virus *in vitro*.

INFECTIOUS AGENT

Propagation and Cytopathic Effect in Cell Culture

Although a variety of cell culture systems are permissive, human CMV is propagated best in fibroblasts of human origin. The growth of human CMV is characterized by a relatively prolonged replication cycle and distinctive focal cytopathic effect (CPE) with cell enlargement and rounding. Human foreskin fibroblasts and the human embryonic fibroblasts, WI-38 and MRC-5, are commonly used for propagation and isolation of CMV. Cell rounding and early cytoplasmic inclusions are visible by 5 hours postinfection (11). Nucleoli become distinctly defined in the centrally placed nucleus by 24 hours. The characteristic eosinophilic perinuclear inclusion appears and, with progression of the replication cycle, becomes more distinctly defined. By 48 to 72 hours postinfection, CPE is well developed with prominent cell enlargement, a basophilic nuclear inclusion, and a large, well-defined, eosinophilic perinuclear inclusion. The nuclear inclusion is an accumulation of nucleocapsids and the perinuclear inclusion is a complex of nucleocapsids, dense bodies, and Golgi apparatus. Progeny virus accumulates in the cytoplasm of infected cells, and about 96 to 120 hours postinfection, infectious virus appears in tissue culture fluids. Inoculum size, cell culture lineage, and CMV strain influence the appearance of CPE in a tissue culture monolayer. Spread of wild isolates of human CMV in the fibroblast monolayer appears to be principally by cell-to-cell contact, as they usually (unless the inoculum is very large) produce only scattered foci of CPE that often take 10 to 14 days to become easily seen (Fig. 1). In addition, wild isolates usually yield very little extracellular virus unless they have been adapted to cell culture growth by serial passage. In contrast, laboratory-adapted strains, such as AD169 or Towne, yield extracellular virus readily and can produce generalized CPE involving the entire cell monolayer in around 7 to 10 days postinoculation. Distinct patterns of CPE are expressed respectively by the two prototypic laboratory-adapted strains of human CMV, AD169 and Davis (12,240). Davis strain CPE is characterized by rounded cells with an eccentric, kidney-shaped nucleus. Fibroblasts infected by the AD169 strain recover from early cell rounding and retain their elongated shape. In addition, nuclear morphology is less distorted and perinuclear inclusions are less distinct (11). Clinical isolates usually exhibit the Davis-type CPE.

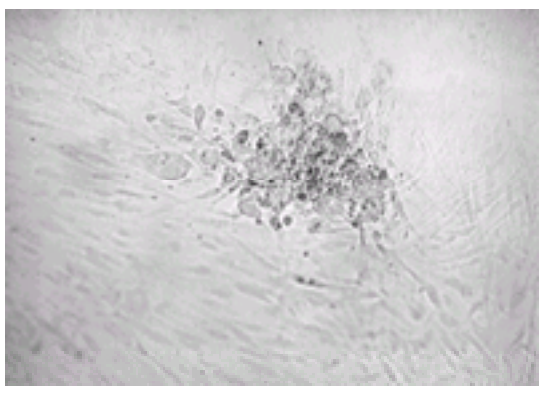

FIG. 1. Focal cytopathic effect of a clinical isolate of human cytomegalovirus in unstained fibroblast monolayer 14 days after inoculation.

In addition to fibroblasts, a number of other cell types of human origin are permissive, although CMV does not replicate as well in them; these include macrophages, smooth muscle cells, vascular endothelial cells, astrocytes, epithelial cells, and trophoblasts (131,132,141,219,226,257,299). Permissiveness of vascular endothelial cells for laboratory strains of CMV varies according to the origin of the endothelial cells and the virus. Infection of human umbilical artery endothelial cell cultures by laboratory strains of CMV propagated in fibroblasts (AD169 or Towne) is nonproductive, whereas low-passage, recent clinical isolates replicate in cultured endothelial cells (136,299). Transformed cell lines derived from fibroblasts, epithelial cells, glioblastomas, and malignancies of myelomonocytic origin can also be productively infected *in vitro*, although virus yields are generally much reduced compared with infection of fibroblasts (219).

Assay in Cell Culture

Quantitation of human CMV in the laboratory is best accomplished in monolayers of human fibroblasts. Assays typically use log_{10} dilutions of virus stock to estimate quantity of infectious virus in terms of tissue culture infective dose ($TCID_{50}$) or by enumeration of plaques. CMV is particularly well suited to the latter because CPE typically develops slowly and focally. Rapid plaque assays have been developed using centrifugation enhancement of infectivity and monoclonal antibodies to immediate-early proteins to identify infected cells (214).

PATHOGENESIS AND PATHOLOGY

Host Entry and Initial Replication

The cellular pathways that are used by CMV to gain entry into the host have not been proven experimentally, nor has it been possible to perform the type of observational or serial histopathologic studies that might delineate entry pathways during naturally acquired infection in humans. Epidemiologic evidence suggests that the entry of CMV follows contact between infectious virus and a mucosal surface. The sites of entry for CMV appear to be epithelium of the genitourinary tract, upper alimentary tract, or respiratory tract. Virus is often isolated from these sites and histopathologic and immunochemical studies on tissues obtained at autopsy have shown evidence of CMV in epithelial cells in each of these locations (257). However, initial infection of mucosal epithelial cells is not required, as CMV infection is readily established by blood transfusion and transplanted organs. For fetal CMV infection, virus most likely enters via the hematogenous route. Studies of placental cells have shown that the cytotrophoblasts, cells that form the barrier between maternal and fetal circulation, can be readily infected *in vitro* (122,132).

Spread Within the Host

Leukocytes and vascular endothelial cells appear to be important in spread of CMV within the host. The importance of leukocytes in dissemination of virus is suggested by early studies of viremia and of transfusion-acquired CMV infection. Among patients with CMV mononucleosis and in symptomatic immunocompromised patients, virus is frequently isolated from buffy coat but not from plasma (172,312). Transmission of CMV through blood products from seropositive donors can be prevented by removal of leukocytes (110). Virus-encoded chemokines could facilitate dissemination of CMV from the site of initial replication by attracting neutrophils and monocytes. Recently, CMV UL146 was shown to encode a late gene product with a chemokine activity; this viral CXC-1 was shown to be fully functional in neutrophil degranulation and chemotaxis (217). A murine CMV encoded b-chemokine was found with ability to promote trafficking of leukocytes with appropriate surface receptors to virus-infected cells, and viruses with deletions in the gene for this b-chemokine had significantly reduced levels of viremia (245). Although the key pathways for spread of human CMV from the initial site of replication are not clearly proven, circulating virus is usually found in leukocytes, and CMV appears to have evolved mechanisms for promoting leukocytic dissemination of virus.

When viewed in terms of the whole organism, human CMV infection in immunocompromised patients is a dynamic process, characterized by rapid turnover of virus in blood. Emery and colleagues assessed the dynamics of human CMV replication by serial quantitative polymerase chain reaction (PCR) for DNA in whole blood (90). They used the slope of the decline in viral DNA levels in ganciclovir-treated AIDS and marrow transplant patients to calculate the rate of CMV clearance, as others had done previously for human immunodeficiency virus (HIV). They found that the doubling time or half-life of CMV in blood was around 1 day, and that the rate of increase in viral load is an independent predictor of disease in immunocompromised patients (89).

Tissue Tropism

Studies of tissue obtained at autopsy show that CMV infects a wide range of tissues and often multiple cell types within an involved organ (reviewed in refs. 137,219, and 257). Cells exhibiting typical CMV cytopathology have been identified in salivary glands, lung, liver, pancreas, kidney, eye, ear, placenta, alimentary tract, heart, ovaries, pituitary, adrenals, thyroid, brain, and skin. The most common cell type exhibiting CMV cytopathology is the ductal epithelial cell. Cells with cytopathology typical of CMV have been described in the epithelium of salivary glands, bile duct epithelium, bronchial epithelium, islet cells, renal tubular epithelium, capillary endothelium, astrocytes, neurons, and epithelial cells of the inner ear (cochlea, stria vascularis, Reissner's membrane, limbus spiralis, saccule, utricle, and semicircular canals) (137). Studies using monoclonal antibody to immediate-early antigen and DNA hybridization techniques have expanded the number of cell types that are known to harbor CMV and reveal that normal-appearing cells are often positive for immediate-early antigen or viral DNA (137,196,257,292). Not surprisingly, most histopathologic studies have used tissue obtained from patients, usually infants with fatal cytomegalic inclusion disease or immunocompromised patients. However, tissues from subjects who died from trauma or other causes not linked to CMV infection have also been studied. Ho summarized the results of nine studies of salivary glands from children from 1907 to 1957 and noted that cytomegalic cells were reported in from 8% to 32% of salivary glands (137). Toorkey and Carrigan found CMV immediate-early antigens in apparently normal cells of kidney, lung, liver, spleen, and brain from seropositive patients who died from trauma (292).

The medical significance of congenital CMV infection is the ability of the virus to infect and damage the central nervous system (CNS). Animal experiments as well as classical pathologic study of brains indicate that CMV can infect a wide variety of cells within the CNS. In cases of fatal human congenital CMV infection, inclusion-bearing cells have been found in neurons, glia, ependyma, choroid plexus, meninges, and vascular endothelium (31). Lesions in the CNS are usually multiple, small, necrotic foci surrounded by an inflammatory infiltrate. Inclusion-bearing cells have also been detected in multiple locations within the ear, including epithelial cells in the semicircular canals, vestibular membrane, and cochleae (Fig. 2). Pathologic changes in the inner ear include inflammatory cell reaction and edema. In the eye, areas of focal retinal necrosis and inclusion-bearing cells have been described. Using immunofluorescence, CMV antigens have been found in the organ of Corti and in neurons of the 8th cranial nerve (278). Using a murine model, van den Pol et al. used recombinant murine CMV to introduce reporter genes into a variety of CNS cell types, including glia, neurons, endothelial cells, radial glia, ependymal cells, microglia, meningeal, and choroid cells (294). Their results

suggested that CMV infection could impair the developing brain by a number of mechanisms, including lytic infection of cells, interference with neuronal migration, loss of neuronal stem cells, and vascular compromise.

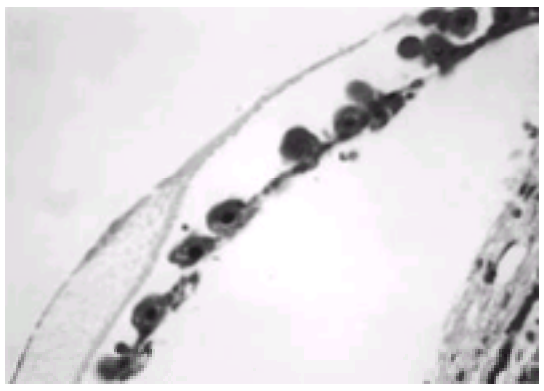

FIG. 2. Cytomegalovirus infection of the inner ear. Epithelial cells of Reissner's membrane show typical cytomegaly and inclusions.

Fatal cases of congenital CMV infection usually have evidence of damage to multiple organs and tissues outside the CNS as well (31). Inclusion-bearing cells in lungs of fatal cases of congenital CMV infection have been described, although inflammatory reaction is usually absent. The liver may exhibit inclusion-bearing cells in bile ducts, necrosis of parenchymal cells with giant cell transformation, evidence of bile stasis, and periportal lymphoid infiltration. Inclusion-bearing cells are also found in the kidney, especially in distal tubules; glomerular involvement is uncommon, as is evidence of renal damage. Cytomegalic cells are usually not seen at autopsy in the bone marrow or spleen, although congenital CMV infection clearly affects marrow function. Anemia and thrombocytopenia are common in symptomatic infections and leukopenia is occasionally seen. Extra-medullary hematopoiesis is sometimes seen in the skin, liver, spleen, and kidneys. Glandular epithelial cells of salivary glands, pancreas, and endocrine glands often have typical inclusions.

Benirschke et al. reported a wide spectrum of placental pathology in congenital CMV infection, ranging from no abnormalities to massive villous necrosis (34). Placental villitis was the most typical lesion, described as focal necrosis of villi with surrounding lymphocytic and plasma cellular infiltrate accompanied by capillary and venous thrombosis, with or without inclusion-bearing cells.

Immune Response

Natural Killer Cells

Evidence from animal experiments and from investigation of human infections shows that natural killer (NK) cells and specific cellular and humoral immunity all play important roles in control of CMV disease. A link between resistance to murine CMV infection and NK cell function was established by studies that showed that beige mice (genetically deficient in functional NK cells) have increased susceptibility to murine CMV (252), and that depletion of NK cells from mice led to more serious infections after challenge (56). It was also shown that spleen cells with NK cell phenotype conferred protection from a lethal murine CMV challenge (56,57). A case report of a patient with deficient NK cell responses and severe infection by CMV and other herpesviruses provides clinical evidence for a role for NK cells in initial control of CMV infection in humans (36). Borysiewicz et al. studied human NK responses to CMV *in vitro* and found that they were mediated by large granular lymphocytes, were independent of interferon, and were manifest at the time early viral proteins were expressed (50). Indirect evidence for the importance of NK cells in defense against CMV infection comes from the observation that the viral gene products that appear to be conserved can protect against NK cell–mediated lysis (290).

Antibody

Experimental and clinical evidence indicate that humoral immunity to CMV plays a key role in protecting the host from disease. In a murine CMV model, passive immunization and active immunization against the envelope glycoprotein B protected mice from lethal challenge (233). In the guinea pig model, immunization of pregnant dams with affinity purified guinea pig CMV envelope glycoprotein preparation decreased the rate of fetal loss and fetal CMV infection after challenge (125). Among solid organ transplant patients, CMV disease is more frequent and more severe when the transplant recipient is seronegative and the donor is seropositive. The severity of disease due to primary CMV infection in renal transplant patients was significantly reduced by pretransplant immunization with Towne strain live CMV vaccine (222) and by administration of a high-titer CMV immune globulin (261). Among very low-birth-weight newborns who acquire CMV from blood products, the principal determinant of protection from disease is the presence of maternal antibody to CMV prior to transfusion (315).

Antibodies to approximately two dozen immunogenic human CMV proteins can be detected in sera from seropositive humans (reviewed in refs. 53 and 163). Studies of infected cell lysates, purified virions, and mixtures of recombinant proteins have shown that immune human sera vary in their reactivity with these immunogenic proteins. The proteins to which immune human sera most consistently react are listed in Table 1. Nearly all immune human sera have antibody to envelope glycoproteins gB (UL55) and gH (UL75), to the tegument phosphoprotein pp150 (UL32), and to a nonstructural DNA binding phosphoprotein, pp52 (UL44) (119,250). Neutralizing antibody is directed principally against envelope glycoproteins gB and gH but also against other envelope glycoproteins (53). Experimental and clinical evidence indicates neutralizing antibody is associated with protection from infection and disease, but protective levels of neutralizing

antibody have not been defined (8,233,251). Although humoral immunity alone as provided by passive immunization cannot prevent CMV infection (in contrast with disease), the extent to which humoral immunity from naturally acquired infection or from active immunization contributes to the host's ability to prevent or limit reinfection is unknown.

Name (ORF)	Location	Immune response	Application
gB (UL55)	Envelope	Major target of neutralizing antibody	Subunit vaccines and serologic assays
gH (UL75)	Envelope	Major target of neutralizing antibody	Therapeutic hu-Mabs and serologic assays
pp150 (UL32)	Tegument	Nonneutralizing antibody and CD8+ CTL	Serologic assays
pp28 (UL99)	Tegument	Nonneutralizing antibody	Serologic assays
pp71 (UL82)	Matrix	Nonneutralizing antibody	Serologic assays
pp65 (UL83)	Matrix	Main target of CD8+ CTL and target of antibody	Component of recombinant vaccines and of serologic assays; the antigen of "antigenemia" assays for viremia
pp52 (UL44)	NS, DNA binding	Nonneutralizing antibody	Serologic assays
pp72 (UL123)	IE, NS, regulatory	Target of nonneutralizing antibody and CTL	IE antigen detected in rapid culture assays ("shell vial")

Note: These proteins were selected because of their current or investigational clinical applications. They are important targets of the immune response to CMV infection, and their immunogenicity is the basis for investigational immunotherapy and novel serologic assays. ORF, open reading frame; NS, nonstructural; IE, immediate-early; CTL, cytotoxic T lymphocyte; hu-Mabs, humanized monoclonal antibody.

TABLE 1. *Immunogenic proteins of human cytomegalovirus (CMV)*

Cell-Mediated Immunity

Although there is ample evidence of the importance of cellular immunity in control of CMV infection, perhaps none is more persuasive than the observation that severe CMV disease (excepting congenital infection) is seen almost exclusively in patients with profoundly impaired cell-mediated immunity, such as patients who are undergoing bone marrow transplantation or have AIDS. In fact, the severity of disease due to CMV infection parallels the degree of impairment of T-lymphocyte responses. Understanding the immune response to CMV infection in terms of the role of specific components of the immune response as well as specific viral proteins has been improved by the study of animal models and by the ability to assess human responses to recombinant CMV proteins. Early investigations using murine models showed that suppression of T-lymphocyte function led to reactivation and dissemination of natural infection (107), and the importance of murine CMV specific cytotoxic T-lymphocyte (CTL) responses in recovery from infection was demonstrated (229). Further studies with the murine model showed that adoptive transfer of CD8+ cytotoxic T cells protected mice from lethal challenge, independent of CD4+ helper T cells; murine CMV specific CD8+ T-cell clones specific for both structural and nonstructural proteins were identified (235,236). An important role for CD4+ T lymphocytes in g-interferon production was suggested (134).

In humans, lymphocyte proliferative responses to CMV preparations are consistently present in seropositive adults, but they appear to be markedly suppressed after CMV mononucleosis, in young children with congenital infection, in immunocompromised transplant patients with CMV disease, and even in normal adolescents after asymptomatic primary infection (172,207,227,319). In humans with naturally acquired CMV infection, CD4+ helper T-lymphocyte responses to multiple structural and nonstructural CMV proteins have been demonstrated. Although CD4+ T-lymphocyte responses to envelope glycoproteins gB and gH, to the lower matrix protein pp65, and to immediate-early proteins are most commonly detected, responses to other proteins have also been reported (14,33,76,98,126,175).

Quinnan et al. studied both lymphoproliferative responses and human leukocytic antigen (HLA) class I restricted CTL responses of peripheral blood lymphocytes from bone marrow transplant patients. CTL response to CMV was associated with clinical recovery from CMV disease (230). In humans, CD8+ CTL responses to a number of CMV proteins have been described also, including pp65 (UL83), pp150 (UL32), gB (UL55), and IE1 (UL123) (35,47,51,113,242). Comparison of precursor frequencies of CTL specific for gB (UL55) and the 72-kd IE protein (UL123) using vaccinia recombinants to infect target cells revealed a low frequency of gB-specific CTLs (£6% of CTL), whereas 18% to 58% of CTLs recognized vaccinia IE–infected targets (51). An assessment of CTL precursor frequencies to five CMV proteins, pp65 (UL83), gB (UL55), gH (UL75), pp50 (UL44), and pp28 (UL99), found that pp65 was immunodominant (47). Kern et al. used multiple, overlapping pentadecamer peptides spanning the entire 491 amino acid sequence of the 72-kd IE1 protein to identify CD8+ T-cell epitopes and to measure CTL frequencies (153). They found that the frequencies of IE1-specific and pp65-specific CTLs were similar in most donors; however, some donors had responses to IE1 or to pp65, but not to both. Although it is likely that more targets for CTL will be identified among CMV proteins, at the present time the pp65 (UL83) and IE1 (UL123) appear to be the major targets.

Based on the observed association between recovery of CTL responses to CMV and recovery from CMV pneumonia in bone marrow transplant patients (237), adoptive transfer of CMV-specific clones of CTL was evaluated as a therapeutic intervention (300). Marrow donor lymphocytes were stimulated *in vitro* by autologous, CMV-infected fibroblasts and clones of CD3+CD8+CD4– CTL were harvested and infused into the bone marrow recipients at intervals after transplant. The recipients had increasingly vigorous CMV-specific CTL responses with serial infusions of CTL. In addition, none of the 14 treated transplant patients had viremia or CMV disease, although nine were seronegative recipients of marrow from seropositive donors and the other five were seropositive before the transplant. Although the clinical role of this approach to adoptive immunotherapy in control of CMV disease is still being determined, this study provided *in vivo* evidence for the importance of CTLs in controlling human CMV infection, and it also showed that persistence of the CD8+ CTLs required CMV-specific CD4+ T-helper-cell function.

Immune Evasion

A characteristic feature of CMV infection in the normal host is the persistence of productive infection, viremia, and virus excretion for months or even years in the face of the host immune response. The ability of the virus to avoid elimination or termination of active infection by the host's immune system may be due at least in part to CMV gene products that

have the potential to interfere with the immune response (reviewed in refs. 135 and 305). CMV has evolved strategies for immune evasion that involve multiple gene products that can interfere with the host immune response via multiple mechanisms, and at different times in the viral replication cycle (Table 2). For example, escape from CTL responses could be mediated by retention of major histocompatibility complex (MHC) class I heavy chain/b-2 microglobulin complexes in the endoplasmic reticulum (US3) (10), through destruction of MHC class I heavy chain molecules (US2 and US11) (148,306), by interference with antigen presentation (US6) (169), and by phosphorylation of a potentially important CTL target, the 72-kd immediate-early protein, preventing antigen processing (111). In addition to these mechanisms for interfering with MHC class I presentation, US2 can cause degradation of MHC class II proteins, preventing their presentation of antigen and the host CD4+ T-lymphocyte response to CMV (291). The extent to which some putative mechanisms of immune evasion are responsible for the persistence or virulence of human CMV infection is not yet clear. In some cases, the apparent mechanism of action of an immune evasion molecule is controversial. For example, the CMV-encoded MHC class I homolog (UL18) was nitially thought to block NK cell activity through binding with the killer inhibitory receptor as endogenous MHC class I would (150,238). However, Leong et al. found that UL18 was associated with enhanced NK cell killing of CMV-infected fibroblasts and did not appear to bind to the killer inhibitory receptor (171). A more convincing mechanism for escape from NK cell attack was offered by Tomasec and colleagues (290). They found that human CMV glycoprotein UL40 (gpUL40) contains a nine-amino-acid sequence homologous to the class I MHC sequence that up-regulates surface expression of HLA-E. HLA-E protects potential target cells from NK cell-mediated lysis by binding to inhibitory receptors on the surface of NK cells. The fact that the gpUL40 sequence was conserved in multiple isolates is consistent with a key role for NK cells in control of CMV, and with a significant role of gpUL40 in evading this control mechanism. In addition to the mechanisms listed in Table 2, CMV exhibits a number of other activities that could impede viral host defense. These include binding and sequestration of b-chemokines (US27, UL28, UL33) (39), competition with the TNF receptor superfamily through a homolog (UL144) (32), interference with apoptosis (322), down-regulation of MHC class II expression on the surface of macrophages (95), and protection of infected cells from complement-mediated lysis (267,276).

Host response	CMV gene	Evasion mechanism
NK cell killing	UL40	↑ Cell surface expression of HLA-E, which binds inhibitory receptors on NK cells
MHC I–antigen presentation/processing	US3	Retention of MHC I complexes in endoplasmic reticulum
	US11	Dislocation of MHC I heavy chains into cytosol
	US2	Export of MHC I heavy chains from endoplasmic reticulum via Sec61
	US6	Inhibition of TAP-mediated peptide translocation into the endoplasmic reticulum
	UL83	Inhibition of presentation of 72-kd IE antigen to CD8+ T cells
MHC II–presentation of antigen	US2	Degradation of MHC class II proteins, preventing presentation of antigens to CD4+ T cells

NK, natural killer; MHC, major histocompatibility complex; HLA, human leukocyte antigen; TAP, transporter associated with antigen processing; IE, immediate-early.

TABLE 2. *Human cytomegalovirus (CMV) genes associated with evasion of NK cell, CD8 CTL, and CD4 immune responses*

Release from the Host

After initial infection, CMV is shed in multiple body fluids, including saliva, urine, tears, semen, cervicovaginal fluid, and breast milk. In each of these sites, viral excretion is probably the result of infection of glandular epithelial cells, with release of progeny virus into excretions. Shedding of virus from multiple sites after primary infection implies dissemination of virus to multiple organs, although it must be noted that shedding from sites in the genitourinary tract and upper alimentary/respiratory tract could represent continued replication of virus at the original site of inoculation. During the first year after asymptomatic primary infection, CMV shedding is more common and more persistent in urine than in saliva or cervicovaginal secretions (319). However, in seropositive subjects with past infections, CMV excretion is most commonly found in the female and male genital tracts (84,157,239). One could hypothesize (based on the model of latency described later) that reactivation of CMV in these sites is the result of stimulation of latently infected monocytes to differentiate to permissive tissue macrophages by inflammation from intercurrent infections due to other pathogens.

Virulence

Although a number of host factors or clinical variables (see later section, Clinical Features) related to virulence of CMV infection have been identified, the contributions of specific viral genes and gene products in determining virulence of CMV infection are poorly understood. Evidence that CMV strains differ in ability to cause disease was suggested by challenge experiments with Towne vaccine strain and a low-passage isolate, Toledo. Healthy adults injected with 10 or 100 plaque-forming units (pfu) of Toledo developed a systemic, mononucleosis-like illness and shed virus. In contrast, vaccine recipients had only local reactions, with neither systemic illness nor virus shedding, and they were protected from disease when challenged with Toledo (221,223). To gain insight into the genetic basis for the virulence of Toledo (or attenuation of Towne), Cha et al. compared nucleotide sequences from a heterogeneous region near the U_L and *b*-repeat boundaries of Towne, Toledo, AD169, and five clinical isolates (58). Toledo and the clinical isolates had 13 to 15 kbp of DNA, approximately 22 open reading frames, not present in the highly laboratory-adapted Towne and AD169 viruses. Some of these open reading frames appear to encode glycoproteins. The function and biologic role of these genes remains to be defined. Experiments with severe combined immunodeficiency (SCID)-hu mice confirmed the ability of the Toledo strain to grow better in human tissue than Towne or AD169 CMV and demonstrated significant variability among wild human isolates in growth in this model (55).

A role for the upper tegument protein of CMV, pp71 (UL82), as a determinant of infectivity was suggested by experiments in which pp71 expression was shown to enhance infectivity of viral DNA, increase late gene expression, and increase

cell-to-cell spread of virus (25). Differences in ability to replicate could be an important marker of CMV virulence, as lytic infection of host cells is a likely pathogenic mechanism. Furthermore, observations in immunocompromised patients have linked viral load in various body fluids to severity of CMV disease.

The envelope glycoprotein gB has been proposed as a determinant of virulence based on reported associations between gB genotype and disease in immunocompromised patients. Human CMV was subdivided into four genotypes based on sequence analysis of a variable region within the gB gene by Chou and Dennison (68); a fifth genotype was later identified by others (254). Some studies of gB genotype distribution among immunocompromised patients have linked specific genotypes to clinical outcome, such as protection from severe or fatal CMV disease among bone marrow transplant patients (gB1), development of fatal bone marrow suppression (gB3 and gB4), acute rejection episodes in liver transplant patients (gB1), and retinitis in AIDS patients (gB2) (105,243,293,295). However, the biologic mechanism through which gB genotypes affect virulence is a matter of conjecture at this time. In addition, variations in genotype have been related to geographic origin and route of infection; different genotypes have been recovered simultaneously from the same immunocompromised patient and the reproducibility of the clinical associations has not been consistent between studies (44,234,324).

The different mechanisms through which CMV evades host defenses offer a number of possible virulence determinants. For example, in the mouse model, deletion of the murine CMV gene for the MHC class I homolog results in virus with diminished ability to infect *in vivo*, and this attenuation is linked to NK cell activity (93). However, the interplay between the evasion strategies and the host immune response is complex, and virulence of human CMV infection has not been linked to alterations in these strategies to date.

Persistence

Human CMV persists within its host indefinitely. There is growing evidence that cells in bone marrow and peripheral blood are a key reservoir for CMV through latent infection. A small percentage of peripheral blood monocytes from subjects with past (presumably latent) infection harbor CMV DNA, but viral gene expression is limited to early genes (75,141,289). However, tissue macrophages (a differentiated form of circulating monocytes) express early and late CMV antigens (256). These observations led investigators to propose a model for human CMV persistence and reactivation in which bone marrow precursors of monocytic peripheral blood cells are a key site of latency; peripheral blood monocytes provide a means to disseminate virus, and differentiation of latently infected monocytes into macrophages leads to reactivation and productive infection. Kondo et al. showed that granulocyte–macrophage progenitors from human fetal liver and bone marrow could be latently infected *in vitro*; these cells had a CD14+, CD15+, CD33+ phenotype and expressed only IE1 transcripts (158). Söderberg-Nauclér et al. reported reactivation of CMV *in vitro* by allogeneic stimulation of peripheral blood mononuclear cells from seven out of seven healthy, seropositive donors (263). They demonstrated recovery of CMV from macrophages expressing dendritic cell markers CD1a and CD83, as well as monocyte/macrophage markers CD14 and CD64. They estimated the frequency of CMV latently infected peripheral blood mononuclear cells at 0.01% to 0.12%. Hahn et al. reported that between 0.001% and 0.01% of CD33+/CD14+ or CD33+/CD15+ bone marrow mononuclear cells from seropositive human donors express transcripts associated with latency, whereas these latency-associated transcripts could not be found in T cells, B cells, or CD33– mature granulocytes and macrophages (121). The experimental evidence supports a model of CMV persistence in which myelomonocytic stem cells resident in bone marrow maintain latent infection, and latently infected CD14+ monocytes circulate in peripheral blood. Differentiation of latently infected monocytes into tissue macrophages as a result of allogeneic stimulation (transplantation or transfusion), or triggering of proinflammatory cytokines as occurs with intercurrent infections, leads to productive CMV infection.

Using traditional virus isolation techniques, infectious virus can be recovered from various body sites for many months after primary infection. It is likely that application of more sensitive techniques for detection of CMV in body fluids will reveal that the duration of viral shedding with primary infection is longer and the frequency of episodes of shedding (reactivation of latent virus) years after primary infection is greater than current knowledge suggests. The possibility remains that some tissues maintain productive CMV infection over many years.

EPIDEMIOLOGY OF HUMAN CMV INFECTION

Distribution, Age, and Demographics

Seroepidemiologic studies show that CMV is universally distributed among human populations from developed, industrial societies to isolated aboriginal groups (13,209). Although prevalence of CMV infection increases with age in every group that has been studied, the overall prevalence of infection and the age at initial acquisition of virus vary greatly according to living circumstances. In general, prevalence is greater and CMV is acquired earlier in life in developing countries and in the lower socioeconomic strata of developed countries. Although in the United States and Europe, CMV infection rates are higher in nonwhites than in whites, racial differences appear to reflect differences associated with socioeconomic status and living circumstances. Seasonal variation in incidence of CMV infection has not been recognized, and epidemics have not been described, aside from reports of very high infection rates in institutional populations such as day care centers.

Transmission

Although CMV is predictably transmitted in settings where susceptibles have frequent contact with body fluids from persons excreting virus, CMV is not highly contagious and transmission appears to require direct contact with infectious material. Following initial acquisition of CMV, infectious virus is present in urine, saliva, tears, semen, and cervical secretions for months to years. Not surprisingly, high rates of CMV infection occur in settings where close contact with body fluids is expected, such as between sex partners, among children in day care centers, and between preschool-aged children and their care givers.

Transmission of CMV through sexual contact is an important means of spread. The prevalence of CMV infection is higher among populations with other markers of sexual activity, such as greater number of partners and sexually transmitted diseases (59,218,264). High rates of incident CMV infection have been reported in clinics for sexually transmitted diseases and among sexually active adolescents (59,197). Restriction enzyme analysis of DNA from CMV strains from sex partners has demonstrated identical restriction fragment patterns, confirming transmission of virus (123). Spread of CMV also occurs frequently in child care centers. Cohort studies and restriction enzyme analysis of CMV strains indicate that children in day care centers frequently transmit virus to each other (3,208). Those who are infected, either from a maternal source or in the day care center, shed virus in saliva and urine for years, providing the opportunity for continued spread to classmates or day care workers. Transmission in this setting is undoubtedly enhanced by frequent mouthing of hands and toys by preschoolers and by the almost unavoidable contact with body fluids that occurs in the care of children this age. Surveillance cultures in day care centers detected CMV on toys, surfaces, and the hands of workers (140). Day care workers have markedly increased rates of CMV infection, ranging from 7% to 20% per year, compared with an expected rate in U.S. adults of around 2% per year (4,193,213). Parents of young children who attend day care centers are also at increased risk for CMV infection, as are parents of premature babies who acquired CMV nosocomially while in the hospital nursery (210,316). Among the former group, risk of CMV infection is clearly related to shedding of virus by the child; a seroconversion rate of 45% per year was noted in parents of toddlers who shed CMV, compared to 0% among parents whose child did not shed CMV (210). Restriction enzyme analysis of viral DNA has provided laboratory confirmation of transmission of CMV from child to parent and from child to day care worker (3,211). Table 3 lists rates of CMV seroconversion for various groups, including sexually transmitted disease clinic patients, child care workers, and parents.

Group	Rate*	Ref.
Blood donors	1.57	28
Hospital employees		
Richmond, VA	2	4
Birmingham, AL	2.2	24
Pregnant women		
Middle income	2.5	283
Low income	6.8	
Women in STD clinic	37	60
Parents of CMV-shedding child		
0–12 months	47	316
≤18 months	32	210
19 months–6 years	13	210
Day care workers		
Iowa	7.9	193
Richmond, VA	11	4
Toronto	12.5	97
Birmingham, AL	20	213

*Rate is percent per year who seroconverted from antibody negative to antibody positive.
STD, sexually transmitted diseases.

TABLE 3. *Incidence of CMV infection in various groups*

Vertical Transmission

Cytomegalovirus is unique among the human herpesviruses in that transmission from mother to fetus or newborn not only occurs but is common and plays an important role in maintaining CMV infection in the population. Human CMV is spread from mother to baby by three routes: transplacental, intrapartum, and human milk (Table 4). Transplacental infections occur in women who were infected long before conception (recurrent infection) as well as in those who have primary CMV infection during pregnancy. The role of recurrent maternal infection as a source of fetal CMV infection was initially suggested by the occurrence of congenital infection in consecutive offspring to the same mother (277,314). In addition, a high rate of congenital CMV infection was reported in an African population with near-universal acquisition of CMV prior to sexual maturity (249). The observation that congenital CMV infection rates are higher in populations with high rates of maternal seropositivity has been offered as evidence that in many populations most congenital CMV infection is caused by reactivation of endogenous, latent virus (284). Confirmation of the role of recurrent maternal infections was provided by a cohort study in a low income population by Stagno and colleagues (279); the rate of congenital infection in offspring of women with CMV infection more than a year prior to conception (documented by virus shedding or serum antibody) was 2.2%. Congenital CMV infection in offspring of women who were immune prior to conception has usually been considered the result of reactivation of latent virus, but these infections could also be caused by reinfection or by persistent infection due to primary infections within the past few years. Although CNS damage in congenital CMV infection is usually the result of primary gestational infection, it has also been reported after recurrent maternal infection (49,99,282,283).

Route	Maternal situation	Rate of CMV in infant
Transplacental	Seropositive before conception	0.2%–2.2%
	Primary gestational infection	20%–40%
Intrapartum	Seropositive	5%
	Virus in genital tract at term	50%
Breast milk	Seropositive mother	25%
	Virolactia	65%–70%

TABLE 4. *Vertical transmission of human CMV infection*

The rate of primary maternal infection during pregnancy varies from 0.7% to 4.1%, with higher rates noted in young, unmarried women of low socioeconomic status (215). The rate of transplacental transmission of CMV to the fetus with primary maternal infection during pregnancy is around 20% to 40% (215). There is no clear evidence of a gestational age effect on the rate of transmission.

Intrapartum transmission of CMV is related to local shedding of virus. Approximately 10% of women shed CMV from the vagina or cervix; near the time of delivery, rates of 2% to 28% have been reported (281). Genital tract shedding is more common among younger women and distinctly uncommon after age 30. If virus is present in the maternal genital tract at the time of delivery, the rate of transmission to the newborn is around 50% (239). Newborns who acquire CMV during birth are virus negative during the first 3 weeks of life and usually begin to shed virus at around 6 weeks of age.

The most common route for mother-to-infant transmission of CMV is human milk. Transmission of CMV to nursing infants is related to duration of nursing prior to weaning to formula and the presence of virus in milk. Dworsky et al. followed a cohort of infants nursed by CMV seropositive mothers (86). They found that no infants of seropositive mothers nursed less than 1 month were infected, compared with CMV infection in 39% of those nursed for more than 1 month. With repeated sampling, CMV was recovered from the milk of 30% of seropositive women. Overall, 25% of infants nursed by seropositive mothers acquired CMV by 1 year of age. When CMV could be detected in mother's milk by virus isolation, 69% of infants were infected, compared with 10% of infants nursed by seropositive mothers whose milk was negative for CMV. A Swedish study of serial milk specimens from seropositive women reported isolation of CMV from 70% of samples collected from 9 days to 3 months postpartum; all of the samples collected prior to or after this interval were negative (9). More recent studies using PCR to detect CMV DNA in milk reported similar rates of transmission of CMV from seropositive mothers and a strong relationship between the presence of viral DNA in milk and transmission of CMV to the infant (22,296).

Although intrapartum and breast milk transmission of CMV are not associated with the morbidity seen in congenital CMV infection (except in very small premature newborn infants), they play an important role in the population epidemiology of CMV infection. Young infants who acquire CMV from a maternal source usually shed CMV for years and are an important source of virus that can be transmitted to other children and to adults. The proportion of infants who acquire CMV during the first year of life is directly related to the prevalence of maternal infection and the proportion of mothers who nurse their infants. In countries where almost all mothers are seropositive and breast-feeding is nearly universal, more than 50% of infants acquire CMV before 1 year of age. In the United States, it has been estimated that around 10% of infants acquire CMV from a maternal source (209).

Molecular Epidemiology

Molecular tools have improved knowledge of the epidemiology of CMV infection, mainly by providing laboratory evidence for suspected sources of infection and routes of transmission. A number of approaches have been used (Table 5). All are based on the general premise that epidemiologically linked isolates of human CMV share extensive nucleotide sequence homology, and furthermore that isolates that are not epidemiologically related have sequence diversity that is readily detectable. Early investigations compared CMV isolates based on restriction enzyme analysis of genomic DNA using multiple restriction enzymes and radioisotope or ethidium bromide labeling for identification of restriction fragments separated in agarose gels (139,268). This approach is slow and expensive because it requires laboratory propagation of CMV isolates to acquire sufficient viral DNA. In addition, serial passage *in vitro* could select genetic variants. Techniques that are more rapid and require much smaller amounts of DNA were developed by focusing on the variable junctional region of the CMV genome and by using PCR to amplify selected segments of the genome (65,270,318). More recently, envelope glycoprotein genes from clinical isolates have been sequenced and compared. Chou and Dennison found that clinical strains and laboratory strains Towne and AD169 could be grouped into one of four gB genotypes (68). The distribution of gB genotypes has been studied in immunocompromised patients, but the epidemiologic and clinical significance of gB genotype remains unclear. Although gH sequence is more highly conserved, peptide variation in the first 37 amino acids of gH segregated clinical isolates into two groups, with laboratory strains Towne and AD169 falling into different groups (66).

RFLP, restriction fragment length polymorphism; PCR, polymerase chain reaction.

TABLE 5. *Approaches to molecular epidemiology of CMV infection*

Molecular investigations of CMV isolates have been tremendously valuable in increasing our understanding of the epidemiology of CMV infection. They have provided laboratory evidence for the following: vertical transmission of reactivated endogenous virus (139), transmission of CMV from child to child and child to parent (2), spread of virus from children to day care workers (4), spread of virus from child to mother to fetus (194,211), nosocomial spread of CMV in a hospital nursery (269), acquisition of donor strains of CMV by transplant patients (64), and reinfection by new strains in

immunocompromised patients, children, and sexually active women (27,60,84,168). In some cases, molecular tools have failed to confirm homology between CMV isolates thought to be epidemiologically linked, thus providing powerful evidence against the spread of CMV from a suspected source in the hospital (5,317).

CLINICAL FEATURES

CMV Mononucleosis

It has been estimated that CMV is responsible for 20% to 50% of heterophile-negative mononucleosis and that it accounts for approximately 8% of all cases of mononucleosis (156). As a rule, acquired CMV infection in the normal host is clinically silent. Studies of CMV infection in pregnant women show that less than 5% of acquired infections are symptomatic, and an even smaller percentage are associated with a mononucleosis syndrome (215). Symptomatic infection is also uncommon in infants who acquire CMV during birth or from mother's milk and in preschool-aged children who acquire CMV in day care centers. Even among nonimmunocompromised patients with transfusion-acquired CMV, most infections are without clinical manifestations (70).

Mononucleosis due to CMV is very similar in clinical manifestations to the more common Epstein-Barr virus (EBV)-induced disease (149,197,204). Clinical manifestations encountered in patients with CMV mononucleosis are listed in Table 6. Malaise, headache, and fatigue are commonly present and may persist for weeks. Fever is present in 98% of cases of CMV mononucleosis. The mean duration of fever is 2 weeks, and temperatures as high as 39° to 40°C are common. Lymphadenopathy, pharyngitis, and splenomegaly are each seen in around 30% of patients and thus are more constant findings in the EBV-induced disease. Rash is also present in around 30% of CMV patients. Over 90% of patients have mild elevation of hepatic transaminases. Slight elevation of serum bilirubin and jaundice have been reported but are uncommon. Lymphocytosis with atypical lymphocytes in peripheral blood is common. A variety of other clinical abnormalities have been associated with acquired CMV infection in the normal host, including Guillain-Barré syndrome, peripheral neuropathy, meningoencephalitis, Rasmussen encephalitis, myocarditis, hemolytic anemia, thrombocytopenia, retinitis, gastrointestinal ulceration, hepatitis, and pneumonitis (138,197). These complications are sufficiently unusual that even when their occurrence is temporally related to CMV infection, other possible etiologies should be carefully sought and the immune competence of the patient should be assessed.

Feature	Frequency (%)
Fever >10 days	94–95
>18 days	41–53
Cervical adenopathy	6–56
Sore throat	56
Exudative pharyngitis	0
Splenomegaly	33–53
Hepatomegaly	0–53
Rash	0–44
Elevated serum ALT or AST	78–100
Lymphocytosis (>5000/μL)	78–95
Atypical lymphocytes (>1000/μL)	71–95

Note: Table was compiled from three published reports covering a total of 45 adult patients (149,156,204). These patients typically had malaise, fatigue, and myalgia, as well as the features listed.
ALT, alanine transaminase; AST, aspartate transaminase.

TABLE 6. *Clinical findings in CMV mononucleosis*

Congenital CMV Infection

When congenital CMV infection is clinically evident (customarily termed symptomatic), it is typically manifest by signs and symptoms that indicate *in utero* involvement of multiple organ systems (45). The chief clinical findings are summarized in Table 7. These abnormalities are nonspecific and are very similar to those produced by other viral and nonviral causes of congenital infection. Laboratory evaluation of newborns with symptomatic congenital CMV infection confirms the multisystem nature of the disease. Hematologic abnormalities are common; approximately 75% of patients have thrombocytopenia and 50% have evidence of hemolytic anemia. Modest elevations of hepatic transaminases are present in over 80%, and a similar proportion have elevated conjugated bilirubin. Cerebrospinal fluid is usually normal except for elevation of protein to above 120 mg/dL in around 50%. Approximately two thirds of newborns with symptomatic congenital CMV infection have evidence of CNS involvement such as microcephaly, elevation of cerebrospinal fluid protein, or neurologic abnormalities such as poor feeding, lethargy, or generalized hypotonia (45). Cranial computed tomography (CT) scans are abnormal in 75% of symptomatic newborns; periventricular calcification, a hallmark of congenital CMV infection, is the most common abnormality (Fig. 3) (48). Other abnormalities include cortical atrophy, lissencephaly, and ventriculomegaly. Although the abnormalities caused by involvement of the reticuloendothelial system (jaundice, hepatitis, hepatosplenomegaly, petechiae, thrombocytopenia) usually clear spontaneously within a few weeks of birth, newborn disease can be severe, leading to prolonged hospitalization for supportive care and to neonatal death in around 10% of symptomatic newborns (45). However, only around 5% to 10% of newborns with congenital CMV infection are symptomatic as newborns.

TABLE 7. *Clinical findings in 106 newborns with symptomatic congenital CMV infection*

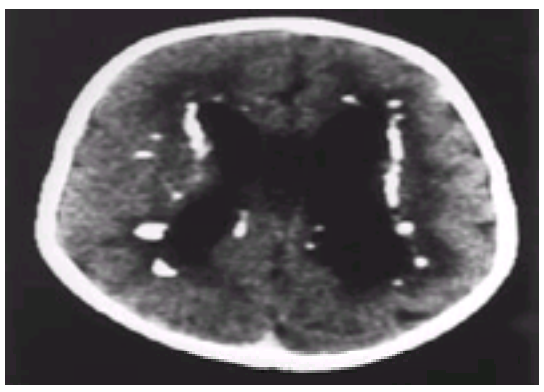

FIG. 3. Computed tomographic scan of the brain of an infant with symptomatic congenital CMV infection, demonstrating periventricular calcification.

Congenital CMV infection is an important medical and public health problem because it causes damage to the CNS and organs of perception. The majority (50% to 90%) of symptomatic newborns will have some combination of deficits, including mental retardation, cerebral palsy, sensorineural hearing loss, and impaired vision (26,205,232). Newborn clinical abnormalities associated with increased risk of CNS sequelae in symptomatic congenital CMV infection include chorioretinitis (Fig. 4), microcephaly, an abnormal neurologic examination, and an abnormal cranial CT scan (48,73). CNS sequelae also occur among the over 90% of newborns with congenital CMV infection who are asymptomatic at birth, but much less frequently than in the symptomatic group. Approximately 7% to 25% of infants with asymptomatic congenital CMV infection will have CNS sequelae, mainly sensorineural hearing loss (100,143,160,246,308). Type of maternal infection (primary or recurrent) is also an important determinant of outcome. Primary maternal infection is more likely to result in symptomatic congenital infection and significant CNS sequelae in infected infants (99,283). However, symptomatic congenital infection and CNS damage have been reported after recurrent maternal infection. In a low income population where most mothers of babies with congenital CMV infection were young, single African-American women, symptomatic congenital CMV infection was as common in babies born to mothers who were immune prior to conception as in those born to mothers with primary infection (49). Considering both the frequency and outcome of congenital CMV infection, it has been estimated to be the leading cause of sensorineural deafness and the leading infectious cause of brain damage in children (100).

CMV Infection in Infants and Children

Although CMV is frequently spread from mother to infant during birth or through milk, clinical evidence of infection is rare in the healthy, full-term neonate infected intrapartum or postnatally from a maternal source. Associations between CMV infection in young infants and hepatomegaly, mild elevations of hepatic transaminases, and pneumonitis have been reported (63,161,280). Others have found little or no evidence of clinical abnormalities associated with perinatal CMV infection in term infants (117,278). However, among very low birth weight premature infants, acquired CMV infection is a significant cause of morbidity. Risk of disease is particularly great for newborns with birth weight less than 1,500 g who

are born to CMV-seronegative mothers and are infected via receipt of red blood cell transfusions from seropositive donors (316). Even infections acquired from mother's milk can cause disease in small premature newborns. A recent report described CMV excretion in mother's milk and transmission of virus to 59% of preterm infants fed CMV-positive (by culture or PCR) milk (296). Abnormalities associated with the onset of CMV excretion included thrombocytopenia, neutropenia, apnea, and sepsis syndrome. As in adults, mononucleosis-like illness can accompany acquired CMV infection in children. A comparison of adults and children with CMV mononucleosis showed that children were less likely to be febrile (43% versus 94%) but were more likely to have hepatomegaly (100% versus 53%) and splenomegaly (86% versus 53%) (204).

CMV Infection in the Immunocompromised Host

Cytomegalovirus is one of the most common and difficult of the opportunistic pathogens that complicate the care of immunocompromised patients. Infection is common because it can occur (a) by reactivation of latent virus, (b) by reinfection in patients who have had past infection, and (c) by primary infection. Procedures that are part of the patient's care, such as transfusions or organ transplant, can transmit CMV at a time when the patient is maximally immunosuppressed. CMV infection in the immunocompromised patient is difficult because diagnosis requires not only detection of virus but also determining whether CMV is causing disease: CMV shedding and viremia are common in patients with impaired cellular immunity even when disease due to CMV is not present. In addition, preventive and therapeutic options are few and not completely effective. The severity of CMV infection roughly parallels the degree of immunosuppression. The most severe infections are seen in recipients of allogeneic bone marrow transplants and in patients with acquired immunodeficiency disease (AIDS) with very low CD4 counts; CMV disease is also seen in solid organ transplant patients, in patients receiving immunosuppressive chemotherapy for cancer or collagen vascular disease, and in congenital immunodeficiencies. Infection is often clinically silent even in the immunocompromised, and when disease occurs, its severity ranges from a brief, self-limited febrile illness to multisystem disease that can be life-threatening or debilitating.

Observations of CMV infections in immunocompromised patients have resulted in improved understanding of the pathogenesis of human CMV infection. For example, evidence of reinfection with new strains of virus was convincingly demonstrated in immunocompromised patients. The importance of antibody was supported by observations and clinical trials in transplant patients (261). The key role of CTLs in limiting CMV infection and preventing disease was confirmed *in vivo* by adoptive transfer of autologous CMV-specific CD8 cells in bone marrow transplant patients (300). The only evidence for clinical efficacy of a CMV vaccine came from studies of Towne vaccine in renal transplant patients (222). The development of antivirals for CMV infection resulted primarily from the need to manage infections in immunocompromised patients, and studies that led to definition of a molecular basis for antiviral resistance were performed in these patients as well.

Solid Organ Transplantation

The potential for CMV infection must be considered for every patient undergoing solid organ transplantation. Risk factors for disease and the manifestations of disease can vary with different organs, and a wide variety of diagnostic tools and management strategies are employed by transplant centers. Recent reviews provide detailed coverage of this subject (128,176,228). The onset of CMV infection, as indicated by detection of virus in blood or shedding of CMV is around 4 to 8 weeks after solid organ transplant. However, the time of onset is variable; it may be shorter with profound immunosuppression or delayed if antiviral prophylaxis is used during the immediate posttransplant period. The sources of these CMV infections include reactivation of the recipient's latent virus or virus from cells in the transplanted organ or blood products. Primary infection acquired from the transplanted organ is generally more severe than reactivation or reinfection, although this varies with the specific organ and with the degree of immunosuppression. Table 8 compares the rates of CMV infection and disease according to donor and recipient serology in kidney and liver transplant patients.

Pretransplant serostatus of donor/recipient	Type of infection	Kidney		Liver	
		Infection (%)	Disease (%)	Infection (%)	Disease (%)
−/+	Reactivation or reinfection	51	19	66	23
+/+	Primary	67	50	77	61
−/+	Reactivation	59	12	45	18
+/−	Primary, not from graft	0	0	10	10

TABLE 8. *Rates of CMV infection and disease in kidney and liver transplant patients, according to type of infection*

The most common manifestations of CMV disease are fever, leukopenia, malaise, arthralgias, and macular rash. Studies performed prior to the widespread use of prophylactic or preemptive antiviral treatment showed that the majority of patients with primary infection after transplant, experience a febrile illness related to the onset of CMV excretion, and most of these resolve spontaneously, although some patients develop life-threatening disease such as pneumonitis, gastrointestinal ulceration, severe hepatic dysfunction, opportunistic fungal infection, or impaired graft function. Primary CMV infection in solid organ transplant patients has been consistently linked with dysfunction of the transplanted organ—renal impairment in kidney recipients, hepatitis after liver transplantation, coronary stenosis or rejection in heart transplant patients, and pneumonitis after lung or heart-lung transplant. Febrile illnesses and even the more severe forms of disease can also be seen in patients who were seropositive prior to transplantation, but reactivation infections are

generally less likely to be symptomatic or to be associated with life-threatening abnormalities.

Cytomegalovirus can be isolated from urine, saliva, or white blood cells (WBC) from patients with primary infection after transplant. The majority of patients with reactivation infection in the posttransplant period shed CMV in urine or saliva, and a smaller percentage have viremia detectable by virus isolation. Although viruria is not strongly predictive of disease, viremia is associated with increased risk of clinically significant CMV disease. Quantitation of viremia using PCR, DNA hybridization, or detection of CMV pp65 antigen in WBC has been used to establish threshold levels above which risk of CMV disease is high and antiviral treatment justified (127,129).

Bone Marrow Transplantation

Among bone marrow transplant patients, as among solid organ transplant patients, the main sources of CMV infection are reactivation of endogenous virus in seropositive patients and transplanted cells or blood products in seronegative and seropositive patients. Pneumonitis is the most common clinically significant CMV disease in bone marrow transplant patients. For allogeneic transplants, it has been reported that 0% to 15% of seronegative recipients of marrow from a positive donor and 6% to 36% of seropositive patients have CMV pneumonia (41). In contrast, CMV pneumonia has been reported in 2.1% to 8.5% of autologous marrow transplant patients (41). In a review of CMV infection and disease in allogeneic marrow recipients in a Swedish hospital, there were 384 transplants in which donor, recipient, or both were seropositive for CMV over a 20-year period, and 33 (8.6%) developed CMV disease (176). Among patients with CMV disease, 21 (63.6%) had pneumonitis, three (9.1%) had pneumonia plus gastrointestinal disease, six (18.2%) had gastrointestinal disease alone, and there was one case each of hepatitis, encephalitis, and retinitis. Ljungman noted that rates of CMV disease by day 100 after transplant and death due to CMV infection decreased respectively from 13% and 13%, to 2.2% and 0%, comparing 1975–1985 with 1992–1994 (176). Similar results have been reported from a major U.S. transplant center, where the incidence of CMV disease in allogeneic marrow transplant patients during the first 100 days after transplant fell from 38% to 5% over an approximately 10-year interval (41). Reasons for the decline in CMV disease include prevention of transfusion-acquired CMV infection in seronegative patients, decreased frequency of graft-versus-host disease, improved methods for rapid diagnosis and prediction of patients at risk, the availability of effective antiviral agents, and improved knowledge of how to use antiviral agents to prevent CMV disease.

In addition to the pretransplant serostatus of recipient and donor, allogeneic reactivity is a significant risk factor for CMV disease. Excretion of CMV is common after autologous or identical twin marrow transplant, but CMV disease is not. Among allogeneic marrow recipients, degree of donor–recipient mismatch has been identified as a risk factor for CMV disease. However, graft-versus-host disease and the treatment it necessitates are more common when there is significant donor–recipient histoincompatability. Ljungman performed multivariate analysis of risk factors for CMV disease, including the following variables in the model: prophylactic antiviral treatment, preemptive antiviral treatment, high-dose immune globulin, intravenous (IGIV), HLA match, acute graft-versus-host disease, and total-body irradiation (176). Only graft-versus-host disease emerged as a statistically significant risk factor for CMV disease and death due to CMV. Although the approach to diagnosis, prevention, and treatment of CMV infection varies considerably among marrow transplant centers, there is general consensus that successful management of CMV infection requires pretransplant donor and recipient screening, preventing blood product transmission of CMV, virologic and clinical screening for CMV infection and disease after transplant, and appropriate use of antivirals. Because peripheral shedding of CMV is not very predictive of disease in marrow transplant patients, laboratories have focused on detection of CMV in blood and bronchoalveolar lavage fluid, and on relating the quantity of virus in blood to the risk of disease. Antiviral therapy can be administered prophylactically to all patients at risk for CMV infection, preemptively to those in whom weekly posttransplant virologic surveillance indicates impending disease, or as treatment when disease develops. Prophylactic or preemptive antiviral therapy are currently favored, but specific regimens vary from center to center (130,228).

CMV Infection and HIV/AIDS

Cytomegalovirus infection is important in patients with HIV infection because it is arguably the leading opportunistic infection among adults with advanced AIDS, and some investigators have found that CMV infection is associated with clinical progression of HIV infection. Almost all adults and approximately 50% of children with HIV infection have serologic evidence of CMV infection. Among children born to HIV-infected women, the rate of congenital CMV infection is not increased, although the rate of acquisition of CMV during birth and infancy is increased in HIV-infected infants compared to the uninfected (159,195). Prior to the use of combination regimens of highly active antiretroviral agents, it was estimated that around 40% of adults and 9% of children with AIDS would develop disease due to CMV. Among adults with advanced HIV-1 infection, approximately 10% to 30% per year develop CMV disease (102,253). Risk of CMV disease is linked closely with immune impairment as reflected by low CD4 T-cell counts. A cohort study of over 1,000 adults with CD4 counts below 250/mm^3 who were on zidovudine found that 109 developed CMV disease (106). Among patients with under 100 CD4 cells/mm^3 at enrollment, 21.4% developed CMV disease within 2 years, compared with 10.3% for patients with above 100 CD4 cells/mm^3. The distribution of clinical manifestations among the 109 patients with CMV disease was retinitis, 85.3%; esophagitis, 9.2%; colitis, 7.3%; and both retinitis and esophagitis, 2.7%. Less common clinical presentations of CMV disease in AIDS patients include encephalitis, peripheral neuropathy, polyradiculoneuritis, pneumonitis, gastritis, and hepatitis (62). Retinitis due to CMV infection in HIV-1-infected children is less common than in adults, although this difference is at least in part the result of the lower prevalence of CMV infection in the children (78). Among 40 infants with HIV-1/CMV co-infection who were followed to 18 months of age, only three developed characteristic CMV diseases (one each: disseminated disease, colitis, pneumonitis) (159).

Cytomegalovirus has been suspected of being a cofactor in the development of AIDS because clinical studies link CMV and progression of HIV-1 infection, and laboratory studies provide a biologic framework for CMV enhancement of HIV-1 infection. Proposed mechanisms through which CMV could enhance HIV-1 replication or reactivation from latently infected cells include transactivation of the promoter in the HIV-1 long terminal repeat (30), induction of Fc receptor expression (184), and immune activation with production of proinflammatory cytokines (201). Although some clinical studies in adults have linked markers of active CMV infection (such as viremia or quantitative plasma CMV load

determined by PCR) with progression of HIV infection, others have not found CMV to be a risk factor for progression of HIV-1 disease (253,274,301). Among children with HIV-1 infection, CMV infection has been associated with progression to AIDS, encephalopathy, and death (103,159). The frequency of development of progressive CNS disease (loss of developmental milestones, impaired brain growth, and symmetric motor deficits) in infants co-infected with HIV-1 and CMV, compared with those with only HIV-1 infection, was particularly striking in a recent cohort study (159). Whether co-infection with CMV promotes progression of HIV-1 infection, or the occurrence of CMV infection and disease are simply markers for immune dysfunction remains a point of controversy. It is, however, quite clear that treatment with combinations of highly active antiretroviral agents that reduce HIV-1 viral load is associated with a reduction in CMV viremia and disease (79,109,202).

CMV and Atherosclerosis

Epidemiologic data and pathologic studies from the 1980s suggested a link between CMV infection and atherosclerosis (1,133,185). These associations between CMV and vascular disease have been given biologic plausibility by data from cohort studies and animal experiments, and from the identification of CMV gene products with the potential for facilitating development of atherosclerotic lesions. Zhou et al. measured serum IgG antibody to CMV in patients undergoing atherectomy for symptomatic coronary disease, and they performed coronary angiography 6 months later to assess restenosis (320). They found that seropositive patients had more coronary artery narrowing 6 months after the procedure, and that CMV seropositivity and the amount of CMV IgG antibody were each independently associated with restenosis in a multivariate model, achieving odds ratios of 12.9 and 8.1, respectively. Two studies in cardiac transplant patients reported that CMV infection was significantly associated with the development of posttransplant coronary artery restenosis (118,183). Grattan et al. reported that the CMV-infected cardiac transplant patients had higher rates of graft rejection, more severe coronary artery atherosclerosis, and higher death rates (118). McDonald et al. examined seven putative risk factors in a multivariate model and found that only CMV infection was significantly associated with risk of posttransplant coronary artery disease (183). Experimental CMV infection in rats and mice has been shown to increase the accumulation of lipids in the vascular wall (266). In the rat model, CMV infection was shown to enhance smooth muscle proliferation and neointimal formation even when virus could not be detected in the vessel wall, suggesting a general proinflammatory effect (170,173). *In vitro* studies of the cell biology of CMV infection have suggested several mechanisms through which CMV could influence the development of atherosclerotic vascular abnormalities (Table 9). These mechanisms provide a pathogenic connection between CMV infection and vascular inflammation. Considering all of the available evidence, one could postulate a role for CMV in the pathogenesis of atherosclerosis that involves reactivation of latent CMV followed by virus-induced enhancement of vascular inflammation and damage. Circulating monocytes will be drawn to developing atherosclerotic lesions because of the inflammatory process. In seropositive patients, latent CMV will be reactivated in these monocytes by inflammatory cytokines and by contact with vascular endothelial cells, smooth muscle cells, and oxidized low-density lipoproteins (120). Reactivation of CMV would then promote further vascular changes through the mechanisms listed in Table 9, leading to smooth cell proliferation, uptake of low-density lipoproteins by smooth cells, neointimal formation, and narrowing of the vessel lumen. Although the role of CMV in atherosclerosis remains uncertain, it is clear that CMV is neither a necessary nor a sufficient factor for the development of atherosclerosis. Substantial numbers of patients who have never had CMV infection have coronary artery disease, and atherosclerotic vascular disease is uncommon in many populations in which there is near-universal acquisition of CMV at an early age. However, atherosclerosis is a multifactorial disease process of which inflammation is a key component. There is growing evidence that CMV can contribute to vascular damage, which might eventually make it possible to change the course of vascular disease by antiviral treatment.

Type of study	Results	Ref.
In vitro		
Human SMC	CMV infection of SMC ↑ p53; IE86 binds to and inhibits p53	311
Promonocytic cell line	Endothelial cells, SMC and exposure to LDL ↑ reactivation of CMV	120
SMC	IE84 antagonizes p53-mediated apoptosis	288
Rat SMC	HCMV infection → ↑ SMC proliferation; ↑ SMC migration toward PDGF; ↑ PDGF β receptor expression	321
SMC	CMV US28 promotes migration in presence of CC chemokines	287
In vivo		
Rat, with and without hypercholesterolemia	CMV infection increases lipid accumulation in proximal aorta	266
Rat, aortic allografts	CMV infection → ↑ SMC proliferation; ↑ intimal arteriosclerotic changes	170
Rat, aortic allografts	CMV infection → ↑ neointimal proliferation in MCH mismatched grafts	173
Rats, carotid injury	CMV infection ↑ neointimal response	321
Cardiac transplant patients	CMV infection associated with ↑ graft atherosclerosis, ↑ graft rejection, and ↓ patient survival	118
Cardiac transplant patients	CMV infection in 83% of patients with posttransplant CAD; vs. 35% in patients free of CAD	183
Patients with postangioplasty restenosis	CMV in lesions associated with ↑ p53	311
Postatherectomy patients	CMV infection associated with restenosis in 43% vs. 8% in patients free of CMV	320

TABLE 9. *Experimental and clinical evidence that CMV infection plays a role in development of atherosclerosis and coronary artery restenosis*

DIAGNOSIS

Differential Diagnosis

The most common signs of congenital CMV infection in the newborn, jaundice, petechiae hepatosplenomegaly, intrauterine growth retardation, and microcephaly, are nonspecific. Congenital CMV infection cannot be reliably distinguished on clinical grounds from congenital infection caused by other agents such as *Toxoplasma gondii*, syphilis, and rubella virus, and patients with noninfectious diseases such as erythroblastosis fetalis, osteopetrosis, and metabolic diseases can have jaundice, petechiae, and organomegaly that suggest congenital infection. Specific laboratory tests for isolation or detection of CMV resolve the diagnosis in newborns quickly and reliably. In immunocompetent children and adults with mononucleosis-like illnesses, CMV infections must be distinguished from acute infections caused by EBV, *Toxoplasma gondii*, human immunodeficiency virus, and hepatitis viruses (A, B, and C).

In transplant patients, the signs of CMV infection are also nonspecific. A variety of viral (notably EBV and human herpesvirus-6, in addition to CMV) and nonviral infections, as well as rejection episodes or graft-versus-host disease, can cause fever, leukopenia, malaise, hepatitis, pneumonitis, enteritis, or impaired graft function. The role of CMV infection is sorted out by knowledge of the CMV serostatus of donor and recipient and by specific laboratory tests for CMV infection. Disease caused by CMV in AIDS patients typically presents as retinitis, enteritis, or esophagitis. Hepatitis, encephalitis, pneumonitis, peripheral neuropathy, or polyradiculopathy are less frequently encountered. Although retinitis caused by CMV infection can be identified with reasonable accuracy by ophthalmologic examination, there are myriad other possible viral, bacterial, and fungal causes for the other clinical syndromes in AIDS patients. Sorting out the role of CMV infection may require tissue diagnosis, exhaustive search for other pathogens, and assessment of response to antiviral therapy aimed at CMV.

Laboratory Diagnosis

Serology

Serologic tests for antibody to CMV are useful for determining whether a patient had CMV infection in the past, a determination of great clinical importance for organ and blood donors, and in the pretransplant evaluation of prospective transplant recipients. In addition, serologic tests for seroconversion and for IgM antibody to CMV are commonly used to establish whether or not infection in the normal host occurred recently. The laboratory diagnosis of recent primary infection is useful in patients with mononucleosis and in pregnant women who, based on clinical signs or exposure, might have primary CMV infection. A variety of different laboratory methods have been used successfully to measure antibody to CMV (214).

Traditionally, serologic evidence of recent primary CMV infection depended on the demonstration of conversion from IgG antibody negative to positive or demonstration of IgM antibody. Tests for IgM antibody to CMV often lack specificity for primary infection because of false-positive tests or because patients with past infection may have IgM antibody to CMV. The reliability of the serologic diagnosis of primary CMV infection in pregnant women is reportedly improved by testing for low-avidity antibodies in women who were positive for IgM antibody when screened (167). Antibody tests are not useful in the diagnosis of CMV disease in the immunocompromised host. Although detection of IgM antibody to CMV has been used to diagnose congenital CMV infection, viral isolation techniques are more accurate and are preferred.

Studies of the kinetics and isotype specificity of the antibody response to CMV reveal patterns that can be exploited for diagnostic purposes. Peak levels of neutralizing antibody are achieved later than antibody to virion after primary infection in renal transplant patients and in normal adolescents (206,319). Schoppel et al. reported that appearance of antibody to gB and gH was delayed by 50 to 100 days compared with antibody to other structural and nonstructural proteins, pp28 (UL 99), pp71 (UL82), pp65 (UL83), p52 (UL44), and pp150 (UL32), after primary infection in normal hosts and solid organ transplant recipients (250). Others have reported delayed appearance but indefinite persistence of antibody to pp150 in contrast to antibody to pp65 and to p52, which appeared early after infection and then frequently declined to undetectable levels with passage of time (119,163,199). Schoppel reported that among healthy adults with past CMV infection, the percent with antibody to pp150, gB, and gH was respectively 98%, 97%, and 82%, compared with only 33% with antibody to pp65 (250). Some differences in isotype specificity of responses to CMV proteins have also been noted. Preferential binding of IgM antibody to p52 (UL44), pp65 (UL83), p38, and pUL57 have been reported (164,298). In the future, use of specified combinations of CMV proteins in serologic assays in place of infected cell lysates or virions may improve ability to establish timing of infection and allow preparation of consistent, standardized lots of antigen.

Virus Detection

The time-honored method for detection of CMV is inoculation of human embryonic lung or foreskin fibroblast monolayers with clinical material and identification of the slowly developing, focal CPE that is characteristic of CMV. However, this approach is slow, sometimes taking more than 2 weeks for recognition of CPE, and it is expensive because of the cost of maintaining tissue and holding cultures for 4 to 6 weeks. In addition, viral isolation is less sensitive than more modern methods. Rapid CMV isolation in tissue culture based on enhancement of infection of the monolayer by low-speed centrifugation and detection of immediate-early antigens by monoclonal antibodies allows detection of virus within 24 to 48 hours, but it is no more sensitive than traditional virus isolation (46,112,231).

Widely used nonculture assays for detection of CMV are detection of pp65 antigen in WBC and PCR detection of CMV DNA. These methods are clearly more sensitive than viral isolation for detection of CMV in blood, and both have been extensively evaluated in immunocompromised patients. A number of other nonculture methods for detection of CMV have been studied, including detection of antigens by enzyme immunoassay, DNA and RNA hybridization techniques, RNA amplification, and cyto-hybridization techniques. These are discussed in recent reviews and will not be discussed further here (129,166,214). Both pp65 antigenemia and CMV DNA PCR provide results that are semiquantitative, and quantity of pp65 antigenemia or CMV DNAemia has correlated with risk and severity of CMV disease in immunocompromised patients (23,40,88,101,102,108,312). Detection of pp65 antigenemia has the advantage that it yields results rapidly and is commercially available, allowing standardization between centers; a major disadvantage to detection of pp65 antigenemia is that samples must be tested within a few hours of collection. PCR has the advantage that it can be used to detect CMV DNA in samples other than WBC, such as whole blood, plasma, cerebrospinal fluid, or bronchoalveolar lavage fluid (23,69,271,311). The major disadvantage to PCR is that its great sensitivity can detect low levels of CMV that are not predictive of disease (80,154,323).

PREVENTION OF CMV INFECTION AND DISEASE

Community-Acquired Infection

Although prevention of maternal CMV infections that lead to congenital infection is an important public health goal in the

United States, an effective means of achieving this goal is not currently available. In the United States and Europe, 25% to 85% of women are seronegative to CMV during their reproductive years (281). CMV infection is very common in the community; it is almost always clinically inapparent, and it results in shedding of virus for months to years. These features of CMV infection make it difficult to plan strategies for prevention based on limiting exposure to the virus. For most community-acquired CMV infections, the timing of infection and the source of virus are not known. Although exposure to young children and sexual activity have been linked with increased risk of CMV infection, it is unlikely that avoidance of either of these activities will be a practical means of preventing CMV infection for women of childbearing age. Use of good hand washing and careful hygiene have been recommended as a means to prevent CMV infection in day care workers and parents of young children (16, 200). A more rigorous approach, involving formal instruction in hygiene and prevention of contact with body fluids and use of gloves, has been evaluated in a controlled trial in parents of young children who were shedding CMV (6). A statistically significant advantage (reduced rate of maternal infection or time to onset of infection) for the intervention group was not demonstrated, although the study was limited by small sample size. Prevention of disease due to congenital CMV infection in the United States and in other countries where primary infection is common during the childbearing years will probably require wide use of a vaccine.

Hospital-Acquired/Nosocomial Infection

Hospital Workers

Hospital workers are potentially at risk for acquisition of CMV infection through contact with body fluids from patients who are shedding CMV, such as immunocompromised patients, infants, and children. Studies of hospitalized patients show that from approximately 1% to 30% of hospitalized patients shed CMV in urine or saliva (212). However, in the era of universal precautions, hospital workers do not appear to have an increased risk of CMV infection. The incidence of CMV infection in dialysis and newborn nursery personnel was found to be similar to that of blood donors or the general population (28, 85a). A study in a children's hospital that included employees with and without patient contact found no statistically significant difference in incidence of CMV infection among workers with patient contact (24). The lack of evidence of increased risk of CMV infection for hospital workers suggests that infection control procedures such as hand washing and avoiding contact with body fluids that are a routine part of care of every patient are effective in preventing transmission of CMV.

Blood Transfusion

Transmission of CMV to immunocompromised patients and premature newborns through blood products should be avoided. Screening blood donors so that blood products from CMV seronegative donors can be provided for seronegative recipients is an effective means of preventing transmission, although this screening and selection process adds significantly to the cost of preparing blood products and may limit the availability of donors in populations where almost all donors are seropositive (189, 247). WBCs are the main source of CMV in peripheral blood, and procedures that remove them from blood products have been shown to reduce the risk of CMV transmission. Filtration of whole blood using cotton-wool filters has been shown to be very effective in removing WBCs and platelets and in preventing transmission of CMV infection (110, 247).

Organ Transplantation

The most common source of CMV infection in organ transplant patients is reactivation of the transplant recipient's latent virus, and there is no means to prevent these infections. Although selection of seronegative donors for seronegative recipients will prevent primary CMV infection in solid organ transplant patients, this approach is not practical because of the restrictions that it places on availability of donors. Prophylactic and preemptive antiviral regimens have been used to prevent disease from primary and reactivated CMV infection, as described later in the section on Antiviral Treatment. It is common practice to provide only irradiated, CMV seronegative, or filtered blood products for transplant patients.

Other Routes of Nosocomial Infection

Cross-infection with CMV in a hospital nursery has been documented by restriction enzyme analysis of viral isolates (269). The presumed mechanism of spread is through hands of hospital workers. These events appear to be rare based on restriction enzyme study of DNA from CMV isolates collected from patients in a newborn nursery (5). Human milk is another potential vehicle for nosocomial transmission of CMV, where banked human milk is provided to hospitalized newborns without consideration of donor and recipient serostatus. Milk from seropositive donors should not be given to seronegative newborns, especially those who are premature or hospitalized.

Excretion of CMV in semen is common (72, 165). Virus is shed in higher concentration and for a longer period in semen compared with other body fluids. Shedding of CMV in semen is more common in younger men and is particularly common and persistent among homosexual men (72, 191). Testing of cryopreserved semen from sperm banks by culture and PCR detected CMV in samples from 2.0% of donors (3.9% of seropositive donors) (180). Thus, there is the potential that CMV could be transmitted during artificial insemination, causing maternal and even fetal infection. Although there are no reports in the medical literature of congenital CMV infection attributed to donor insemination, it is reasonable to take steps to avoid this complication. The American Fertility Society has recommended serologic screening of semen donors for antibody to CMV (15). Whether semen from seropositive donors should be screened for virus is a matter for further consideration. Seronegative patients receiving donor insemination should be limited to semen from seronegative donors. Whether it is reasonable to take similar precautions in donor oocyte programs is uncertain. A study of oocytes from 71 women undergoing infertility evaluations (62% seropositive) reported no detection of CMV by PCR in any donated oocytes, although 25% of semen samples from 60 partners were positive (310).

Passive Immunization

Cytomegalovirus immune globulin is used in organ transplant patients as prophylaxis against CMV disease. A regimen

using a high-titer CMV immune globulin prior to kidney transplant and weekly for 3 weeks after transplant was shown to decrease the severity of CMV disease significantly in seronegative recipients of kidneys from seropositive donors (261). Not surprisingly, passive immunization did not prevent infection. CMV immune globulins have been evaluated in transplant patients receiving other solid organs and in bone marrow transplant patients (52,74,187,262,309). In addition, there are numerous studies of CMV immune globulin or immune serum globulin in combination with various antiviral agents. Results have been mixed and there continues to be difference of opinion concerning the role of immune globulins in prevention of CMV disease in transplant patients (41,155,176).

CMV Vaccines

Although attempts to develop a vaccine for prevention of maternal and congenital CMV have been made for over 25 years, no vaccine is currently licensed or near licensure. However, improved understanding of the role of specific viral proteins in eliciting protective immune responses and recent recognition of the potential benefit to society and cost-effectiveness of CMV vaccines will probably stimulate development of new vaccines (286). Investigational vaccines employing different formats have been evaluated in clinical trials; these include attenuated live virus, a recombinant protein in a fowl pox vector, and recombinant protein given with a new adjuvant. The Towne strain of CMV, originally isolated from a child with congenital CMV infection, was passaged more than 125 times *in vitro* to achieve attenuation (220). Subsequent study showed that the Towne strain was attenuated in that it did not produce a febrile illness in challenge studies, whereas a low-passage Toledo strain did (223). In addition, Towne strain of CMV could not be recovered from vaccine recipients even after immunosuppression (222). Immunization with the Towne CMV vaccine induced both antibody responses and lymphocyte proliferative responses to CMV (285). An efficacy trial in renal transplant patients showed that pretransplant immunization of seronegative patients with Towne vaccine protected them from severe disease although it did not prevent infection (222). The Towne CMV vaccine was also evaluated in a placebo-controlled trial in seronegative parents of preschool age, CMV-infected children (8). There was no evidence of vaccine efficacy in this group of normal hosts; the CMV infection rate was nearly identical in vaccine and placebo groups. Although the Towne vaccine is immunogenic, the infection that it produces is quite different from that induced by wild-type viruses, which results in prolonged viral shedding and induces stronger immune responses; it does not appear to confer the protection from reinfection that comes from naturally acquired infection. Genomic comparisons of the Towne CMV strain and Toledo, a low-passage strain that retains the ability to cause disease and can be isolated from body fluids when injected into volunteers, revealed differences in their DNA sequences (58). In an attempt to produce a live virus vaccine that would be less attenuated and more immunogenic, chimeric viruses that include portions of Towne genome and portions of the Toledo genome that appeared to have been lost from Towne have been produced as potential vaccine candidates; these are in phase I clinical trials (151).

A subunit vaccine composed of a modified gB molecule expressed in Chinese hamster ovary cell culture combined with a novel oil-in-water adjuvant has been developed (265). Initial clinical trials with this subunit vaccine established safety, immunogenicity, and optimal antigen dose (104,216). Immunization of healthy adults with three doses of vaccine on a 0-, 1-, and 6-month schedule resulted in serum antibody to gB, neutralizing antibody, and lymphocyte proliferative responses to gB similar to those from naturally acquired infection. This subunit vaccine is currently being evaluated in an expanded phase II placebo-controlled clinical trial that will test its ability to prevent infection in women of childbearing age.

Canary pox has been used a vector for CMV gB (224). This format has potential advantages in that it undergoes a single round of replication in vaccinees, thereby allowing optimal, intracellular presentation of antigens for stimulation of CTL responses and avoiding concerns over persistence and reactivation. Preclinical trials with the canary pox vector in mice and guinea pigs showed that it could be used to stimulate antibody and CTLs (114). It has also been used in phase I clinical trials to prime vaccinees for boost immunization with Towne vaccine (7). Multiple other approaches to producing a CMV vaccine have been investigated, including viral vectors for CMV proteins and DNA vaccines (225).

ANTIVIRAL TREATMENT

Although antiviral agents currently available for CMV are far from ideal, their use has decreased the burden of CMV disease in transplant patients and improved survival and quality of life of AIDS patients with retinitis and other severe diseases due to CMV. The three antiviral agents currently approved by the U.S. Food and Drug Administration for treatment of CMV disease in immunocompromised patients are listed, along with key pharmacologic properties, in Table 10; their pharmacology is reviewed in Chapter 15. Each of the available antivirals for treatment of CMV disease has the potential for significant toxicity. Because CMV infections in the normal host resolve spontaneously, antiviral treatment is not indicated. A role for antiviral treatment of the extremely rare patient with a presumably normal immune system and severe CMV infection has been suggested and is probably justified if the disease is life-threatening or likely to lead to disability (87).

Agent (refs.)	Route	Plasma half-life (hr)	Usual dose and frequency for treatment: Induction	Usual dose and frequency for treatment: Maintenance	Major toxicity
Ganciclovir (18,20,41,271)	Intravenous (i.v.) Oral (prophylaxis only)	i.v. 3.5 ± 0.8 p.o. 4.8 ± 0.9	5 mg/kg, q12 hr	5 mg/kg/d or 6 mg/kg/d, 5 days per week	Hematologic
Foscarnet (20,142,200)	i.v.	4.0 ± 2.0	90 mg/kg, q12 hr	90–120 mg/kg, q24 hr	Renal
Cidofovir (20,152,182)	i.v.	2.6[a]	5 mg/kg per week,[b] for 2 weeks	5 mg/kg, alternate weeks[b]	Renal, neutropenia

Note: Recommended dosages vary considerably depending on renal function, other organ dysfunction, concomitant medications, and indication for treatment. Acyclovir and valacyclovir, although not appropriate for treatment of CMV disease, have been used prophylactically to prevent disease in organ transplant patients.

[a] Intracellular half-life is much longer, allowing weekly administration.

[b] Dosage must be individualized based on patient's renal function, and probenecid is given prior to dose to minimize renal excretion of drug.

TABLE 10. *Antiviral agents used for treatment and prevention of CMV infections in immunocompromised patients*

Treatment of CMV Disease in AIDS Patients

Nearly all adult AIDS patients have antibody to CMV. With progression of AIDS and decline in the immune system, virologic evidence (viral shedding, viremia) of CMV infection are common. Prior to the use of highly active antiretroviral therapy (HAART), based on combinations of agents, CMV disease occurred in around 40% of adults with advanced AIDS, and a number of clinical trials evaluated antiviral therapy for prevention and treatment of CMV disease (62). The risk of CMV disease is closely associated with severity of immune system damage; the majority of patients with CMV disease have CD4 counts of less than 100. Not surprisingly, the ability of HAART to prevent (or delay) the onset of profound immune impairment in AIDS patients has resulted in a dramatic reduction in the frequency of CMV disease (83).

The association between immune impairment and CMV disease suggests a role for antiviral prophylaxis in AIDS patients at high risk for CMV disease. Two randomized, placebo-controlled clinical trials of oral ganciclovir for prevention of CMV retinitis were performed and yielded disparate results. One found a statistically significant reduction in occurrence of retinitis or disseminated disease in patients receiving ganciclovir (273); the other did not (54). The benefit of prophylaxis must be weighed against the disadvantages of possible drug-induced neutropenia and anemia, increased risk for development of antiviral resistance, and high cost. Currently, oral ganciclovir is the only agent approved for prevention of CMV in AIDS patients. The U.S. Public Health Service/Infectious Diseases Society of America Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus recommend consideration of oral ganciclovir for prophylaxis in adults and adolescents who are CMV seropositive and have CD4+ T-lymphocyte counts of less than 50/µL (19). However, prophylaxis with oral ganciclovir is not completely effective in preventing retinitis, and it is not clear that it will result in improved survival or preservation of sight compared with clinical screening and treatment at the onset of disease (182). No other regimens are currently approved or recommended for consideration as prophylaxis.

Clinical trials have provided evidence of the ability of intravenous treatment with ganciclovir, foscarnet, or cidofovir to bring acute retinitis into remission and to slow the progression of retinitis (61,162,203,272). In untreated patients, retinitis usually progresses within 2 to 3 weeks; antiviral treatment lengthens this interval to approximately 2 to 3 months. In addition, a trial comparing ganciclovir to foscarnet found a survival advantage for the latter (17). Usual intravenous dosages for ganciclovir, foscarnet, and cidofovir for induction and maintenance therapy are listed in Table 10. Local treatment for retinitis with intravitreal injection of an antiviral or use of an implant, which allows slow release of drug, are also options for treatment of retinitis (182). Successful treatment of gastrointestinal, neurologic, and respiratory disease caused by CMV in AIDS patients has been reported, although the evidence for a beneficial effect of anti-CMV therapy with disease in these organ systems is less clear (62). Antiviral therapy for esophagitis, enterocolitis, encephalitis, peripheral neuropathy, polyradiculoneuropathy, and pneumonitis has usually been accomplished with intravenous ganciclovir or foscarnet regimens similar to those used for retinitis (38,62,81). Combination therapy with foscarnet and ganciclovir has been studied in patients with advanced AIDS and severe CMV disease. In a three-arm study in retinitis patients, active disease recurred at around 4 months in those assigned to combination therapy with both drugs, compared with 2 months or less for those on monotherapy with either ganciclovir or foscarnet (18,82). Patients with CNS or neurologic disease often respond poorly to monotherapy, and combination therapy has been recommended for them (21). Combination therapy should be considered for patients who show poor clinical response to monotherapy or develop new manifestations of CMV disease while on monotherapy.

Maintenance therapy for CMV retinitis is an essential part of treatment in patients with advanced AIDS, and it is often employed for other CMV disease syndromes, especially CNS or neurologic disease. Whether the immune restoration that accompanies HAART is sufficient to allow discontinuation of maintenance therapy for CMV disease in retinitis patients has not yet been determined. In addition to the intravenous route, oral and local approaches to maintenance anti-CMV chemotherapy are available (85). Oral ganciclovir, 1 to 2 g three times per day, has advantages over the intravenous maintenance regimen; it is more convenient for patients and avoids the potential risks of intravenous lines. However, oral maintenance is not as effective as intravenous in preventing disease in a contralateral eye that is initially disease free, and there is concern that it may not be as effective in preventing extension of scars near the fovea or optic nerve (62). Local treatment of CMV retinitis has been accomplished using intraocular injections and implantable devices. Intraocular regimens with weekly intravitreal injections or with intraocular implants are similar in efficacy to intravenous maintenance therapy (145). Although intraocular maintenance avoids the inconvenience and risk of intravenous treatment, it appears to be less effective in preventing disease in the contralateral eye, and it increases risk of ocular complications such as infection, retinal detachment, and hemorrhage.

Treatment and Prevention of CMV Disease in Transplant Patients

In transplant patients, the considerable body of knowledge of the sources of CMV infection, timing of onset of infection and disease, expected frequency and severity of CMV disease, and risk factors for severe disease, provides a foundation for selecting an approach to prevention. In seropositive recipients of allogeneic bone marrow, studies have shown that prophylactic treatment with ganciclovir will reduce the incidence of CMV disease during the first 100 days after transplant, although overall mortality and graft survival are not improved (41). Compared with early regimens employing intravenous or oral acyclovir, ganciclovir is more effective in reducing the rate of CMV infection and disease (41). Ganciclovir regimens typically involve an induction phase of around 1 week before the transplant, with treatment doses (5 mg/kg twice a day), followed by a maintenance dose (half the treatment dose), given once a day for 5 or 7 days per week up to 120 days after transplant. Disadvantages of prophylactic ganciclovir treatment include neutropenia in 30% or more of patients, selection of antiviral resistance mutations, and the occurrence of late-onset CMV disease in around 5% of patients after prophylaxis is discontinued (41). Foscarnet has been studied for prophylaxis in marrow transplant patients as a means to avoid ganciclovir's marrow suppression; active CMV infection occurred in 15%, compared with 3% to 20% with ganciclovir regimens (142,228). Regular prolonged administration of antiviral agents is clearly able to reduce the amount of CMV disease in marrow transplant patients at risk (either donor or recipient is seropositive). However, use of prophylactic antiviral treatment means that all patients are subject to the notable disadvantages of this approach (marrow suppression or renal toxicity, development of antiviral resistance, and risk of late-onset disease) to prevent the CMV

disease that occurs in about one third of allogeneic marrow recipients.

An alternative approach to preventing CMV disease involves sentinel laboratory screening, using a positive result on a test for CMV as the indication for initiation of antiviral therapy. The ability to detect CMV prior to the onset of disease is clearly critical to this approach, as is a detection method for which a positive result is reasonably predictive of disease. Early studies of preemptive antiviral therapy used culture of multiple body fluids (116) or detection of CMV in bronchoalveolar lavage fluid at day 35 after transplant (248). More recently, in an effort to increase the sensitivity of early detection of CMV, investigators have focused on viremia, using detection of pp65 antigenemia in WBCs and PCR detection of CMV in blood. Because of the extreme sensitivity of the latter, methods to provide an estimate of quantity of input DNA have been studied (130). Comparison of prophylactic ganciclovir with preemptive therapy based on pp65 antigenemia found that CMV disease rates at day 100 after transplant were higher in the latter group (42). Einsele et al. studied PCR screening of blood for CMV as a basis for initiation of preemptive treatment with ganciclovir, and negative PCR results as the basis for withholding or stopping antiviral treatment; they reported a significant reduction in CMV disease, reduced antiviral use, and improved survival when PCR was used for screening (88). Foscarnet appears to be similar to ganciclovir in effectiveness in preemptive therapy (177).

Among autologous marrow and stem-cell recipients, the rate of CMV disease is lower than among allogeneic marrow recipients, and prophylaxis with antivirals for CMV is generally considered unnecessary. Preemptive antiviral treatment has been investigated in autologous marrow and peripheral blood stem-cell recipients (43,127). This approach is complicated by the fact that approximately 30% of these patients do not have detectable viremia prior to the onset of disease (41). Improved, more sensitive and specific approaches for identifying autologous and peripheral blood stem-cell marrow recipients at risk for CMV disease are needed. Frequent PCR screening of blood is promising for this purpose (127).

Immune globulin preparations (including CMV hyperimmune globulin) have also been evaluated in prophylactic regimens for CMV in marrow transplant patients. Whether their prophylactic use is able to prevent CMV disease is a controversial point (41). Their use for prevention of CMV disease in bone marrow transplant patients does not appear to be justified at this time, although immune globulin is of benefit in treatment of interstitial pneumonitis associated with graft-versus-host disease and CMV (41).

In summary, the frequency and severity of CMV disease in bone marrow transplant patients is influenced by multiple factors. There is no universally accepted approach to prevention and treatment with antivirals at the present time. Continued improvement in the therapeutic index and ease of administration of antiviral treatment for CMV and refinement of methods for early detection of infection are needed and will lead to improved control of CMV disease in these patients.

Among solid organ transplant patients, the issues with regard to antiviral prevention and treatment of CMV disease are similar to those encountered in marrow transplantation. In the era prior to availability of antivirals, mortality due to CMV was low among solid organ transplant patients, in contrast with the situation in bone marrow transplantation. However, morbidity associated with CMV disease in solid organ transplant patients results in prolonged hospital stay, substantially increases the cost of care, increases the risk of opportunistic fungal infection, and is associated with impaired graft function. Strategies to control this morbidity have included antiviral prophylaxis, preemptive treatment based on laboratory evidence of active infection, and use of immune globulin preparations. A recent meta-analysis aimed at developing practice guidelines for renal transplant patients using evidence-based medicine, recommended use of prophylactic antiviral therapy when donor or recipient is seropositive if antilymphocyte treatment is included in the immunosuppressive regimen, and for seronegative recipients of grafts from seropositive donors (146). Among renal transplant patients, prophylaxis with high-dose oral acyclovir has been shown to reduce the incidence of CMV disease in seronegative recipients of a kidney from a seropositive donor (29), and prophylaxis with high-dose oral valacyclovir has been shown reduce the rate of CMV disease in seropositive recipients as well as seronegative patients with seropositive donors (178). Oral ganciclovir was found to be superior to oral acyclovir in preventing CMV disease in a comparative trial in renal transplant patients (96). Morbidity due to CMV is generally greater among heart, lung, heart-lung, and liver transplant patients than among renal transplant patients. In these patients, regimens based on intravenous ganciclovir, oral ganciclovir, and oral acyclovir have been evaluated and considered effective (128). The preemptive approach to prevention of CMV disease was also found to be effective in liver transplant patients (255). The availability of laboratory techniques for early detection and quantitation of CMV in blood will potentially allow greater use of preemptive rather than prophylactic antiviral therapy, thus decreasing the numbers of patients exposed to antiviral toxicity and decreasing the risk of development of resistance. Prophylactic treatment with CMV immune globulin has been shown to reduce the incidence of severe CMV disease in seronegative renal transplant patients with seropositive donors (261). A similar study in liver transplant patients found that prophylaxis with CMV immune globulin reduced the rate of CMV disease, but curiously, not in seronegative patients with seropositive donors (262). The approach to prevention of CMV disease among solid organ transplant patients will differ among programs based on assessment of the risks and consequences of CMV disease in patients and the costs, benefits, and risks of the various approaches.

Antiviral Treatment of Congenital CMV Infection

At present, there are no antiviral agents approved for use in treating congenital CMV infection. A number of case reports, a small series comparing two different administration regimens (198), and a phase II clinical trial (304) describe the use of ganciclovir in newborns with symptomatic congenital CMV infection. In sum, these reports indicate that ganciclovir is relatively safe in newborns, based on acute toxicity. Although the authors were encouraged by clinical improvement in study patients, there is currently no evidence that ganciclovir treatment of the newborn with symptomatic congenital CMV infection decreases mortality or will improve the long-term outcome. Caution is recommended in concluding, on the basis of uncontrolled studies, that treatment improves newborn clinical abnormalities (thrombocytopenia, jaundice, abnormal liver function), given the fact that these abnormalities resolve spontaneously in surviving patients (45). Acute toxicity of ganciclovir required withholding or reducing the dose of medication in 19% of patients in the phase II clinical trial because of neutropenia (304). Compared with experience with ganciclovir in adult immunocompromised patients, the drug appears to have less impact on CMV shedding in newborns with congenital infection. Although the proportion of patients with viruria decreased steadily over the 6-week period of treatment, a number of patients were viruric for more

than 4 weeks (304). Viruria resumed within 1 week of cessation of ganciclovir in all patients. A randomized, placebo-controlled phase III clinical trial of ganciclovir in newborns with severe symptomatic congenital CMV infection was recently completed. Participants all had evidence of CNS disease prior to enrollment; they were randomized to receive 12/mg/kg/day of glanciclovir or no treatment for six weeks. Although results of this clinical trial have not been published as of this writing, treatment was associated with significant reduction in risk of worsening of hearing loss at 6 months of age and at one year or older (Personal communication, D.W. Kimberlin, UAB School of Medicine). Over half of treated patients experienced neutropenia which cleared when drug was discontinued or dosage was reduced. The study did not demonstrate a beneficial effect of treatment on newborn disease, and it was not designed to assess the effect of treatment on other sequelae such as mental retardation or cerebral palsy. Ganciclovir treatment of newborns with symptomatic congenital CMV infection and evidence of CNS disease may improve outcome by preserving hearing, but this benefit must be considered in relation to possible risk of late complications of therapy such as reproductive toxicity or carcinogenicity. Unfortunately there is insufficient data on the risk of these potential late complications of ganciclovir therapy in new borns to allow an informed risk:benefit analysis. However, evidence that antiviral treatment of newborns with symptomatic congenital CMV infection improved outcome is a very encouraging finding that should spur further development and evaluation of antiviral drugs for this indication.

Antiviral Drug Resistance

Chronic administration of antiviral drugs in immunocompromised patients is associated with the appearance of mutations in CMV genes for the UL97 phosphotransferase and UL54 DNA polymerase. Specific mutations have been associated with phenotypic resistance to antiviral drugs both *in vitro* and *in vivo* (see Chapter 15 for a discussion of the mechanisms and genetics of antiviral drug resistance). Clinically, development of antiviral drug resistance is associated with treatment failure, although it is important to recognize that breakthrough disease or treatment failure are common in severely immunocompromised patients with CMV disease, independent of the appearance of mutations associated with resistance. Genetic mutations associated with resistance are uncommon in patients prior to antiviral treatment, but they are quite common after 3 or more months of antiviral therapy (37,144). Patients are often infected with multiple strains of CMV that may differ with regard to antiviral susceptibility, and resistant strains can persist for months after antivirals have been discontinued (67,91). Recognizing and managing antiviral drug resistance in the clinical setting is a complex problem because *in vitro* susceptibility testing is not widely available and the relationship between *in vitro* susceptibility or genotypic changes and clinical effectiveness of ganciclovir, foscarnet, or cidofovir for CMV infection is not well defined. The problem is further compounded by the fact that the isolate selected for study may not contain the same strain or mix of CMV strains present at the site of disease. In addition, cross-resistance to cidofovir occurs in patients with high-level ganciclovir resistance, and patients with multiply resistant viruses have been reported (67,124,258). Clinically significant antiviral drug resistance should be considered a possibility for patients who are responding poorly to treatment and have a history of exposure to antivirals. If phenotypic or genotypic testing of viral isolates is available, it can be used to guide selection of an alternative regimen. However, choices are limited at this time. Changing to a drug to which the patient's virus is susceptible, optimizing the dose of antiviral based on serum levels within the limits of toxicity, and use of combination therapy may prove beneficial.

FUTURE DIRECTIONS

Control of CMV disease, whether the result of congenital infection or immune impairment, is proving to be a difficult goal. Current antiviral therapy has limited efficacy and significant toxicity, and an effective vaccine is more a dream than reality. Improved understanding of two broad areas in the biology of CMV infection is needed. We need to know more about the role of specific CMV genes in determining the virulence, persistence, and establishment of latency in humans. This knowledge might help explain the wide range in severity of CMV disease among patients. More important, it could form the basis for rational design of attenuated live vaccines that lack the ability to cause disease or establish latent infection. In addition, a more complete view of the complex interaction between host defense mechanisms and the virus is needed. This view should encompass knowledge of how CMV immune evasion mechanisms interact with host defense mechanisms. This knowledge could be exploited to lead to new strategies for control of CMV in hosts with immune impairments and for design of attenuated vaccine strains that are more readily controlled by the host immune system.

CHAPTER 78 Varicella-Zoster Virus and Its Replication

Jeffrey I. Cohen and Stephen E. Straus

CLASSIFICATION

Based on its morphology, varicella-zoster virus (VZV) is classified as a member of the family *Herpesviridae* (210). It is further classified together with the herpes simplex viruses (HSV), the prototypical herpesviruses, in the subfamily *Alphaherpesvirinae* by virtue of their common abilities to replicate and spread efficiently, and to destroy their host cells in the process. Although HSV replicates in tissues or cells of numerous animal species, VZV has a narrow host range extending almost exclusively to selected cell types of human and simian origin. In common with other alphaherpesviruses, VZV establishes a life-long latent infection of sensory nerve ganglia, from which it can later reactivate on one or more occasions.

VZV, pseudorabiesvirus (suid herpesvirus 1), and equine herpesvirus 1 (equid herpesvirus 1) are subgrouped together as members of the genus *Varicellovirus*, as is the closely related simian varicella virus (cercopithecine herpesvirus 9). This simian virus exhibits marked genome organizational and sequence homology to VZV and is emerging as a useful model for the study of VZV biology and disease pathogenesis (93,145,257). All of the alphaherpesviruses of this genus share an ability to disseminate widely through their natural hosts to produce infection of the skin, mucous membranes, viscera, and nervous system. They also share a genomic arrangement in which two isomeric forms predominate by virtue of inversion of the shorter unique DNA segment and its flanking repeat elements.

To complete its classification, VZV is the formal species name for the only *Varicellovirus* known to infect humans. Archaic names for this virus, such as herpes varicellae, herpes zoster virus, varicella virus, or zoster virus, reflect earlier uncertainties as to whether the causative agents of varicella and zoster were one and the same organism (20,252,255).

VIRUS STRUCTURE

Morphology

A full investigation of the VZV virion and its structural elements has not been conducted. One formidable obstacle to any such undertaking is the inability to emulate in cell culture that which VZV achieves in the course of natural infection—namely, the efficient assembly and release of infectious progeny.

The VZV particle was first identified by light microscopy of vesicle fluids recovered from patients with varicella or zoster (8). Van Rooyen and Illingworth (251) described the VZV “elementary bodies” as being both less numerous and smaller (only 125 to 175 nm in diameter) than those seen in smallpox lesion fluids. Despite this observation, there remained confusion for a number of years as to whether VZV particles were inherently different from those of smallpox; questions regarding the relationship between the viruses of varicella and zoster persisted even longer. Ruska (212) discerned that the VZV elementary bodies are distinct, spherical, pleomorphic particles. More refined electron microscopic studies showed the viruses of varicella and zoster to be indistinguishable in appearance (75,243).

Before the electron microscopic studies, clinical observations had already suggested that the agents that cause varicella and zoster were identical. In 1888, von Bokay (252) observed varicella arising in children exposed to family members with zoster. In 1925, Kundratitz (134) induced varicella in susceptible children by inoculating them with zoster vesicle fluids.

Serologic studies were also fully concordant with identity, if not merely a close antigenic relationship, between the viruses of varicella and zoster. Netter and Urbain (187) and Brain (20) used vesicle fluids as the source of viral antigens in complement-fixation assays. Convalescent sera from patients with varicella and zoster responded comparably.

With the development by Weller (255) of procedures to propagate VZV in cultured cells, further analyses were undertaken with the more plentiful and reliable source of virus. The cytopathic effects of each virus were

indistinguishable, as were the complement-fixing and neutralizing antibody responses (256). Molecular proof that the viruses of varicella and zoster were identical, however, awaited electrophoretic analyses of their proteins and genomes and the ultimate demonstration that a single electropherotype of virus was responsible for both the primary varicella episode and the subsequent reactivation zoster in the same person (238). The VZV particle, like that of all herpesviruses, is now appreciated as one comprising four major elements: the core, the nucleocapsid, the tegument, and the envelope (Fig. 1).

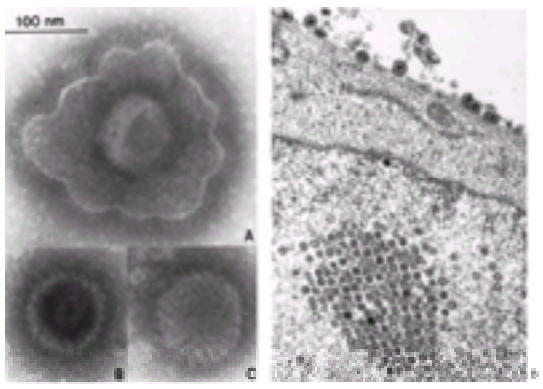

FIG. 1. Electron microscopic appearance of the VZV particle and infected cells. **A:** Enveloped particle. **B:** Purified nucleocapsid. **C:** Negatively stained nucleocapsid preparation. **D:** Infected Mewo (melanoma) cell. (A, B, and C from ref. 236, with permission, and courtesy of W. Ruyechan.)

The Core

One copy of the viral linear, double-stranded DNA genome is incorporated into each virion. Existing data regarding VZV structure and morphology are consistent with the models developed for HSV. Initial suggestions that the genome is wound tightly as a toroid around a dense protein rod have been questioned by recent findings. Particles fixed for electron microscopy with nondehydrating agents show a loose fibrillar cage of strands surrounding a dense cylindrical core of DNA fibers (202). Zhou et al. (266) examined herpes simplex virus by electron cryomicroscopy and found that the viral DNA was organized in regularly spaced layers within the nucleocapsid.

The Nucleocapsid

The VZV nucleocapsid is indistinguishable in appearance from that of other herpesviruses. Electron microscopic studies verify an assemblage of 162 capsomeres with a 5:3:2 axial symmetry in which pentameric proteins form the vertices of an 80- to 120-nm icosahedron, and hexameric elements comprise its facets (6). Whereas HSV nucleocapsids have electron-dense cores, VZV nucleocapsids obtained from virus grown in cell culture often lack dense cores, perhaps reflecting the low infectivity of VZV released from cultured cells (96,103). The specific viral gene products that assume these structural roles have not been verified but should include the products of VZV open reading frames (ORFs) 20, 23, 33, 33.5, 40, and 41, the analogs of HSV-1 capsid proteins VP19C (UL38), VP26 (UL35), VP24 (UL26), VP22 (UL26.5), VP5 (UL19), and VP23 (UL18), respectively.

The Tegument

The prototypical tegument component of the herpesviruses is the VP16 protein of HSV-1 and -2, and it was no surprise when the VZV homolog of VP16, the ORF10 gene product, was found in its tegument. Kinchington et al. showed that the VZV tegument also includes immediate-early (IE) proteins encoded by ORFs 4, 62, and 63 (124,126), and Stevenson et al. (228) showed that ORF47 is very likely a tegument protein.

The Envelope

The nucleocapsid assembles within patches of host cellular membranes that have been modified to display virally encoded glycoproteins. Modifications of the particle occur while it is transported along various membranous networks extending from the nuclear envelope to the cell surface, where infectious virions accumulate and bud outward to infect neighboring cells. Opportunities exist for the evolving particle to capture membranous elements of the nucleus, Golgi, rough endoplasmic reticulum, cytoplasmic vesicles, and the cell surface so that the “true” or singular source of the viral envelope is not known (3,41,72). The enveloped particle is pleomorphic to spherical, and 180 to 200 nm in diameter.

Physical and Chemical Properties

The VZV particle is fragile. Its lipid envelope renders VZV susceptible to disinfection by brief treatments with organic solvents (216). The particle is also subject to degradation by multiple other physical and chemical treatments, including detergents, proteases, heating to 60°C, prolonged storage at temperatures of –10°C or above, extremes of pH (<6.2 or >7.8), or ultrasonic disruption (23,91). Ironically, this latter physical procedure is traditionally used to release infectious cell-free virus from cells (23).

For analytic studies, VZV particles have been concentrated from stocks of cell-free virus using a variety of precipitation and centrifugation techniques (60,140). Enveloped particles band at a density of 1.274 g/cm^3 in cesium chloride; VZV DNA exhibits a buoyant density in cesium chloride of 1.705 g/cm^3 (140).

GENOMIC STRUCTURE AND ORGANIZATION

The complete nucleotide sequence of the VZV genome (strain Dumas) was determined in 1986 by Davison and Scott (50). The genome is a linear double-stranded DNA molecule, about 125,000 bp in length (Fig. 2). It consists of a unique long region (UL, about 105,000 bp) flanked by inverted repeat regions [terminal repeat long (TRL) and internal repeat long (IRL), each 88.5 bp], and a unique short region (US, 5,232 bp) flanked by internal repeat regions [terminal repeat short (TRS) and inverted repeat short (IRS), each 7,319.5 bp]. The inverted repeat structure of the VZV genome has been verified using electron microscopy of the VZV DNA molecule (66,90,237). The genome has a G+C content of 46%. The G+C content of the UL and US regions is 43% to 44%, whereas the G+C content of the TRS and IRS regions is 59% and of the TRL and IRL regions is 68%.

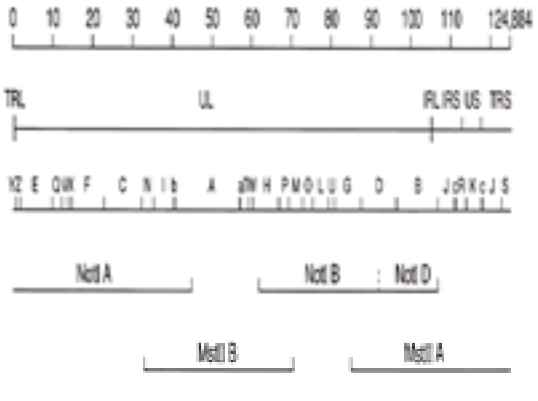

FIG. 2. Structure of the VZV genome. The prototype VZV genome (50) consists of 124,884 bp of double-stranded DNA (*line 2*) arranged into unique long (*UL*) and unique short (*US*) regions bounded by terminal repeats (*TR*) and internal repeats (*IR*) (*second line*). A *Bam*HI restriction map (*line 3*) is shown. *Not*I and *Mst*II restriction fragments are used to produce recombinant VZV by transfection (*lines 4 and 5*).

Although the HSV-1 genome is similarly organized, the length of the US region of VZV is about 40% the size of the HSV-1 US, whereas the length of the VZV TRL/IRL region is about 1% of the size of the corresponding region in HSV-1. In addition, the HSV-1 genome, unlike that of VZV, exists as four isomers in equal proportions.

The VZV genome is usually present as a linear molecule in virions; however, a circular, supercoiled form has been detected in rare virions (129,234). The VZV genome exists predominantly in two different isomeric forms (61,66,234). The US region is directed in either orientation in 50% of genomes; however, the UL is directed in one orientation in 95% of genomes and in the opposite orientation in only 5% of genomes (47,129). Thus, VZV, like HSV, can exist in four isomeric forms; however, in VZV two isomeric forms predominate. The ends of the VZV genome have a single unpaired nucleotide at each 3' terminus; these residues, C at the left end and G at the right end, may base-pair to form a circular molecule (47). In latently infected cells, the termini are adjacent, suggesting a circular molecule (27).

The genome consists of five regions with direct sequence repeats, termed R1 to R5 (50). R1 to R4 are GC-rich, like the GC-rich repeats present in HSV-1. The R1, R2, and R3 regions are located in the UL segment of the genome and each is in the coding sequence of a gene. The R1 region, located within ORF11, consists of four separate repeated elements (132). The R2 region, present within the glycoprotein C (gC) gene, consists of 42 bp repeats, the number of which differs among different strains of VZV (130). The largest repeat region, R3, is about 1,000 bp in length and is located in ORF22 (50). The R4 region is located in both IRS/TRS regions between ORF62 and ORF63 (and ORF70 and ORF71) and consists of multiple 27-bp elements (22). The R5 region is located between ORF60 and ORF61, consists of 88-bp and 24-bp repeats, and is AT-rich (109). The Dumas strain of VZV has only one copy of the R5 repeats, whereas other strains of VZV have multiple R5 repeats. The R1 to R5 repeats differ in length and have been used to distinguish different strains of VZV by restriction endonuclease analysis (109,235). The variability in the number of repeats implies that the genomes of the different strains of VZV have different overall lengths.

Sequencing of different isolates of VZV shows many minor nucleotide changes. For example, comparison of the nucleotide sequence of 34 kb of VZV strain Dumas with the Oka vaccine strain showed more than 80 nucleotide differences, resulting in 24 predicted amino acid differences (9). Moreover, comparison of the sequence of the Oka vaccine strain with its wild-type parental strain showed 15 nucleotide differences in ORF62 alone (92). The predicted amino-acid sequences of five proteins were identical in the vaccine and parental virus; however, ORF62 showed eight amino acid differences. The vaccine and parental Oka viruses could be distinguished by restriction fragment-length polymorphisms at some of these sites. Sequencing of glycoprotein genes from 10 VSV strains showed multiple sequence polymorphisms on gH amd gE (74a).

The genome contains at least 70 unique genes, three of which are present in two copies in the IRS and TRS regions (Table 1). Although some of the genes have putative polyadenylation signals shortly after the end of their ORFs, many are arranged in unidirectional families of up to four genes with a single putative polyadenylation signal at the 3' end of the family. Eleven VZV genes are thought to have overlapping reading frames. Two ORFs (ORF42, ORF45) are thought to be spliced segments of the same gene (50); one ORF (S/L) is spliced in the 31 noncoding region (119a).

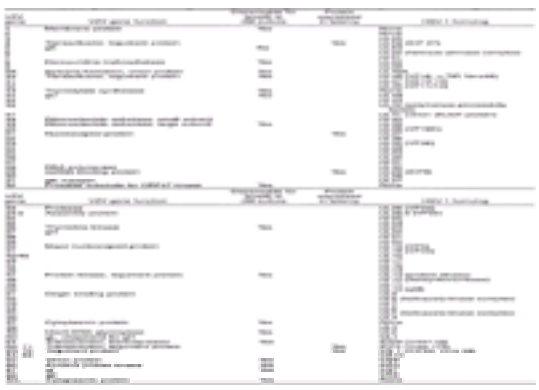

TABLE 1. *VZV genes with their functions and HSV-1 homologs*

Large portions of the VZV genome are colinear with the HSV-1 genome (51). Comparison of the predicted amino acid sequences of VZV and HSV-1 proteins indicates that the organization of homologous genes is similar in both genomes. Within the UL region of VZV, 56 of the 62 genes have HSV homologs, and 55 are located in a similar region of the genome. One gene in the UL region, ORF61, has its HSV-1 homolog, ICP0, located in the IRL/TRL region of HSV-1.

In the US region of VZV, all four of the VZV genes have homologs in the US region of HSV-1, although the positions of the genes are rearranged relative to those of HSV-1 (49). The three genes in the IRS/TRS regions of VZV (ORF62, ORF63, ORF64) each have HSV-1 homologs; ORF62 has its HSV-1 homolog ICP4 located in the IRS/TRS repeat region of HSV-1, whereas ORF63 and ORF64 have their HSV-1 homologs located in the US region of HSV-1.

Six genes in VZV (ORF1, ORF2, ORF13, ORF32, ORF57, and ORF S/L) do not have homologs in HSV-1. Five of these genes (ORF1, ORF13, ORF32, ORF57, and ORF S/L) are dispensable for growth of VZV in cell culture (33,36,42,119a,205). Four of them (ORF1, ORF2, ORF32, and ORF57) have homologs in equine herpesvirus types 1 and 4, which also are members of the alphaherpesvirus subfamily. A fifth gene, ORF13, has no homolog in the alphaherpesvirus subfamily, but it does have homologs in gammaherpesviruses (human herpesvirus 8, herpesvirus saimiri, and herpesvirus aeteles).

Comparison of the VZV genome with that of the seven other human herpesviruses indicates that VZV has at least 40 conserved genes shared with them, all of which are located in the UL region of VZV (46). These core genes are located in several blocks that have been rearranged during evolution of the viruses. Many of the genes are colinear between viruses within a given block. These conserved genes include an IE gene (ORF4), viral enzymes, and structural proteins (major nucleocapsid protein, glycoproteins gB, gH, gL).

There are only three regions of the VZV genome that apparently do not contain ORFs. These are located at the 3' end of UL between ORFs 60 and 61, and between ORFs 62 and 63 (and in its corresponding repeat ORFs 70 and 71). This last region contains an origin for VZV DNA replication, whereas other regions may contain sites important for cleaving and packaging viral DNA.

STAGES OF REPLICATION

Overall Pattern of Replication

Like other herpesviruses, VZV is thought to attach to cells by fusion of the viral envelope with the cytoplasmic membrane (Fig. 3). VZV proteins encoded by ORF4, ORF10, and ORF62 (124,126), located in the viral tegument, may be released and transported with the nucleocapsid to the nucleus, where they may serve to initiate transcription of viral genes. Other tegument proteins, including ORF47 and ORF63, may also be important early in infection. VZV IE messenger RNAs (mRNAs) are transcribed, transported to the cytoplasm, and translated, and the proteins are transported back to the nucleus. VZV early mRNAs may then be transcribed in the nucleus, translated in the cytoplasm, and transported back to the nucleus, where they facilitate viral DNA replication. VZV late mRNAs are then transcribed, they are translated in the cytoplasm, and capsid proteins are transported back to the nucleus for assembly of capsids. Newly replicated VZV DNA is then packaged into capsids and transported out of the nucleus. The capsids are enveloped and carried to the cytoplasmic membrane, where the virions are released.

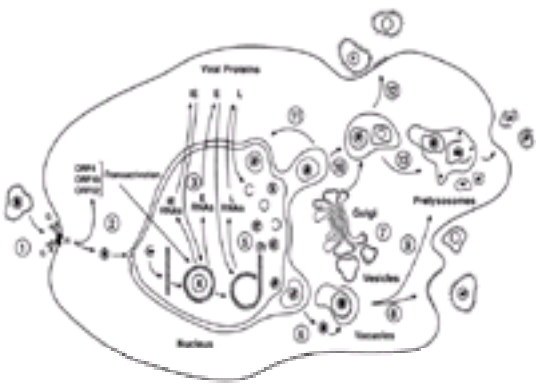

FIG. 3. Replication of VZV. The schema shown accommodates observations from multiple sources and relies as well on analogies drawn from studies of HSV replication. (*1*) Infectious virions attach to cell surface glycosaminoglycans (*G*) and engage specific, but still unidentified, receptors (*R*), and nucleocapsids penetrate into the cell. (*2*) The nucleocapsid enters the nucleus where, with the aid of regulatory tegument proteins encoded by ORFs 4, 10, and 62, (*3*) a cascade of

viral immediate-early (*IE*), early (*E*), and late (*L*) transcripts and proteins are synthesized. (*4*) Viral DNA replication follows a rolling-circle model. (*5*) Nucleocapsids are assembled and package newly synthesized DNA. Controversy exists regarding the mode of nucleocapsid egress from the nucleus, the site of envelopment, and the pathway leading to release of particles from the infected cell. (*6*) In one view by Gershon et al. (88), nucleocapsids are transiently enveloped as they bud through the inner nuclear lamellae. These nucleocapsids lose their envelopes when they fuse with the rough endoplasmic reticulum, resulting in the release of naked nucleocapsids in the cytoplasm. (*7*) Virion glycoproteins are synthesized in the rough endoplasmic reticulum, mature in the Golgi, and line the inner surfaces of cytoplasmic vesicles. Viral tegument proteins are synthesized by free ribosomes and line the outer surfaces of the cytoplasmic vesicles. (*8*) Nascent particles are drawn into these vesicles and intact, enveloped virions coalesce within them. These vacuoles may fuse with the cell membrane to release infectious progeny. (*9*) Many of the vacuoles, however, fuse with pre-lysosomes in which the particle is partially degraded before release, leading to an abundance of defective progeny VZV. (*10*) Another model by Harson and Grose (103) proposes that nucleocapsids retain their envelopes as they egress the nucleus. Their envelopes are glycosylated by fusion with Golgi-derived vesicles. Late in infection some particles reenter the nucleus (*11*), although most are transported to the cell surface (*12*) for release or (*13*) to pre-lysosomes. Pathways that avoid the pre-lysosomes (*8* and *12*) must exist in humans for efficient spread of infection

Studies using VZV-infected cells to inoculate uninfected cells indicate that viral proteins are expressed 4 to 6 hours after infection, and virus spreads to neighboring cells as early as 8 to 16 hours after infection (11,204).

Attachment, Entry, and Uncoating

Specific cell surface receptors have been identified for some alphaherpesviruses but not VZV. For all alphaherpesviruses, including VZV, the initial attachment to the cell surface appears to entail nonspecific electrostatic interactions between viral envelope glycoproteins and cellular surface glycosaminoglycans like heparan sulfate, but unlike chondroitin sulfate (267). In HSV, glycoproteins gB and gC participate in electrostatic attachment to cells. Work to date verifies that gB binds to heparin sulfate (115), but it is uncertain that gC does so (R. Williams and S. Straus, unpublished observations). Zhu et al. (267) reported that VZV glycoproteins bearing mannose-6-phosphate residues bind to another low-affinity receptor, facilitating entry.

Following low-affinity interactions with the cell surface, HSV gD binds to one of a family of cell surface receptor molecules known as the herpesvirus entry mediators. VZV, however, possesses no obvious gD homolog, and the virus may not utilize any of the known herpesvirus entry mediators.

Following the interaction of gD with its receptor, HSV gB, gH, and gL are required for fusion of the viral envelope with the cell membrane. VZV possesses homologs of all three of these glycoproteins, but all of their roles in fusion of the viral envelope and subsequent penetration of the nucleocapsid into the cell are unproven. Rodriquez et al. (209) have shown, however, that VZV gH facilitates fusion of the VZV envelope with the cell membrane. Monoclonal antibody to gH inhibits syncytia formation and cell-to-cell spread of VZV in culture.

Because antibodies directed against VZV gB, gE, gH, and gI all neutralize infectivity (79,153,261), these four proteins must participate in one or more aspects of attachment and penetration of the particle. Once penetration has occurred, the nucleocapsid is transported to the nuclear surface, through which it penetrates and releases its genomic contents. It is not known whether cellular cytoskeletal elements facilitate centripetal movement to the nucleus or in what form the viral core arrives there. Because various preformed tegument proteins (ORFs 4, 10, and 62 products) transactivate IE gene expression, they must accompany the viral core into the nucleoplasm.

Viral Transcripts and Their Products

All evidence suggests that the process of VZV transcription is a coordinated one that follows a temporal program, as does HSV transcription. Nonetheless, the inability to obtain high-titered, cell-free VZV has made it difficult to achieve synchronous infection of cells in culture required to define the temporal classes of individual VZV genes. Infection of cells with relatively high-titered VZV in the presence of cycloheximide followed by treatment with actinomycin-D has identified ORF4 (53), ORF62 (81,218), and ORF63 (52) as IE proteins. Although each of the HSV-1 IE genes contains an upstream TAATGARAT sequence element, only VZV ORF62 encodes an upstream TAATGARAT-like element (131,173) that the other VZV IE genes lack.

Transcription Map

The most extensive transcription mapping of VZV used double-stranded DNA and single-stranded RNA probes to map the polarity of transcripts in VZV-infected cells (207). There were 78 abundant transcripts of 6.8 kb or less, and the orientation of 77 of the transcripts was determined. Thirty-five of these RNAs were transcribed from left to right, and 42 were transcribed from right to left. Many of the transcripts were located in regions corresponding to the ORFs predicted by Davison and Scott (50) (Fig. 4), but most transcripts could not be assigned with certainty to a given gene.

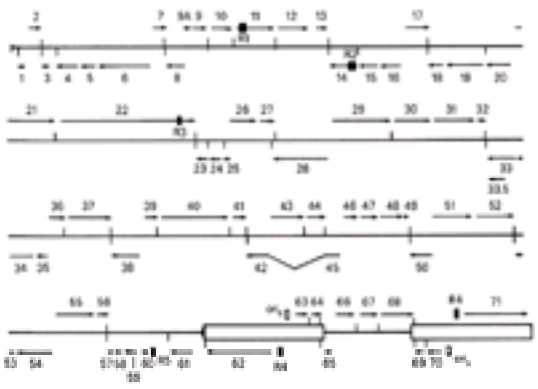

FIG. 4. VZV ORFs. The genome contains 69 unique ORFs, including ORF9A and ORF33.5 (an in-frame truncation of ORF33), but not counting ORFs 69 through 71, which are duplications of ORFs 62 through 64. The genome consists of unique regions (*horizontal lines*), terminal and internal repeats flanking the unique short region (*open boxes*), and terminal and internal long repeats flanking the unique long region (*short vertical lines*). ORF transcripts are numbered and shown by *arrows*, and potential polyadenylation sites are indicated by *light vertical lines.* Repeats (R1 to R5) are indicated (*filled rectangles*). The origins of DNA replication (oris) are shown. ORF S/L, which begins at the right end of the circularized genome and extends across the terminal repeat into the unique long region at the left end of the genome, is not shown. (Adapted from ref. 50, with permission.)

Transcripts for 12 viral genes (ORFs 4, 14, 21, 28, 29, 36, 37, 61, 62, 63, 67, and 68) have been formally mapped, and several features of VZV transcription can be gleaned from these studies. First, a single VZV ORF can be encoded from multiple colinear and coterminal transcripts. For example, three transcripts (1.65, 2.9, and 3.6 kb) map to gI (ORF67); the most abundant transcript (1.65 kb) is thought to be the primary transcript used for expression of the gene (117,138). Second, VZV uses TATA elements whose sequences may differ substantially from the standard consensus sequence. Although some transcripts are generated from standard TATA sequences [ORF61 (229)], other transcripts arise from TTTTAA [ORF62 (156)], ATAAAA [ORF67 (138)], or ATTTAAATT [ORF14 (137)] sequences located 25 to 33 bases upstream from the transcription start site. Third, VZV polyadenylation signals may deviate from the typical AATAAA or ATTAAA elements. Although some transcripts have a typical polyadenylation signal [ORF67 (138)], other transcripts use AGTAAA [ORF36 (50)], ATAAA, ATAATT, or ACGTAAAA [ORF14 (137)]. Fourth, VZV, like HSV-1, contains GU-rich sequences GTCTGTGT and TGGTGGTA [ORF14 (137)], downstream of polyadenylation sites that may be important for termination of transcription. Fifth, VZV genes that are homologous to HSV-1 genes may manifest different patterns of transcription. VZV ORF14 (137) and VZV ORF61 (229) are thought to be expressed from unspliced transcripts, whereas their HSV-1 homologs gC and ICP0, respectively, are encoded by spliced transcripts. The VZV ORF14 transcripts are derived from coterminal 5' ends, whereas the HSV-1 gC transcripts have coterminal 3' ends (137). Sixth, different strains of VZV may vary in the level of transcription of a given gene. VZV strain Scott expresses about 20-fold more gC mRNA than the amount of gC mRNA expressed from a particular strain of VZV Oka (137).

Another feature of VZV transcription was revealed in studies of the VZV polymerase (ORF28) and major DNA-binding protein (ORF29) genes. These two genes are transcribed in opposing directions from overlapping promoters. The ORF28 and ORF29 promoters are responsive to VZV transactivators, and the activity of one promoter cannot be separated from the other (161). VZV ORF62 protein interacts with the transcription factor USF to activate the bi-directional VZV ORF28 and ORF29 promoter (159) and the ORF4 promoter (163). In VZV-infected cells, ORF28 is transcribed as a 4.1-kb RNA, and ORF29 may arise from either of two RNAs of 4.1 and 4.2 kb. In contrast, in human trigeminal ganglia, ORF29 is expressed only from the 4.2 kb transcript, whereas ORF28 is apparently not expressed (158).

Regulators of Transcription

ORF62

VZV ORF62 encodes a 175-kd phosphoprotein (76,81) that is incorporated into the viral tegument (126). The protein is primarily localized to the nucleus of infected cells. Although ORF62 contains a nuclear localization signal (14), coexpression of ORF66 with ORF62 results in cytoplasmic accumulation of ORF62 (125). ORF62 is the homolog of HSV-1 ICP4 and has been shown to complement HSV-1 ICP4 mutants (76). An HSV-1 mutant in which both copies of ICP4 have been replaced by VZV ORF62, can replicate efficiently, further confirming that ORF62 is the functional homolog of ICP4 (57). Replacement of the DNA binding domain of ICP4 with that of VZV ORF62 resulted in an HSV mutant that cannot appropriately regulate expression of ICP4 (247). VZV ORF62 increases the infectivity of transfected VZV DNA (182).

VZV ORF62 and HSV-1 ICP4 share extensive homology in conserved regions 2 and 4 (155), including a conserved DNA binding domain that recognizes similar sites in their corresponding promoters (260). HSV ICP4 and ORF62 proteins can bind to the same consensus sequence in the ICP4 DNA binding site (15). A single amino acid change in the DNA binding domain of ORF62 results in loss of its transactivating function (244). While the DNA binding domain of ORF62 can dimerize and form a heterodimer with the corresponding domain of ICP4 (245), the DNA binding domain of ORF62 is less sequence-specific and does not induce DNA bending upon binding its own promoter, when compared with HSV-1 ICP4 (246).

VZV ORF62 transactivates VZV putative IE (ORF4, ORF61), early (ORF36), and late gene promoters in transient expression assays (111,196). VZV ORF62 activates its own promoter in lymphocytes but represses its own promoter in simian cells (58,76,198). The differential activation of a broad spectrum of promoters by ORF62 reflects its capacity to interact with cellular transcription factors and depends on the sequence of the TATA motif in the targeted promoter (194).

Some activities of VZV ORF62 are different from those of HSV-1 ICP4 in transient expression assays. For example, HSV-1 ICP4 represses the expression of some HSV-1 IE genes, such as ICP0 and ICP4. Furthermore, although ICP4 activates the HSV-1 thymidine kinase (TK) promoter in transient expression assays, it does not activate the VZV ORF36 promoter (112). VZV ORF62 contains a transcriptional activation domain at its amino terminus that is not conserved with HSV-1 ICP4 (30,197).

Only 45 bases upstream of the ORF62 cap site, or 15 bases upstream of the TATA box, are necessary to mediate activation of the ORF62 promoter by ORF62 in lymphocytes. In contrast, 124 bases upstream of the ORF62 cap site are necessary to mediate activation by HSV-1 ICP4; therefore, activation of the ORF62 promoter by ORF62 and HSV-1 ICP4 appears to occur through different mechanisms (198). HSV-1 infection stimulates expression of ORF62 (76). The upstream region of ORF62 contains three TAATGARAT-like elements. These elements contribute to the transactivation of the ORF62 promoter by the VZV ORF10 protein (173). The ORF62 promoter also contains a cyclic AMP-responsive element and a GA-rich element that are important for transactivation of the promoter. The ORF10 protein forms a complex with two of the TAATGARAT-like elements in the ORF62 promoter that lack an overlapping octamer-binding motif, but not with the TAATGARAT-like element with the octamer motif. Two cellular proteins, Oct1 and host cell factor (HCF) form a complex with the ORF10 protein and at least one of the TAATGARAT-like elements on the ORF62 promoter. Oct2 also binds to the TAATGARAT-like elements on the ORF62 promoter and inhibits ORF10-mediated transactivation. Two additional cellular proteins, the NF-Y CCAAT box-binding protein (175) and a member of the ATF/AP-1 family, have also been shown to bind to the ORF62 promoter (156).

ORF61

ORF61 encodes a 62- to 65-kd phosphoprotein that localizes to the nucleus of infected cells (229,230). Unlike the other VZV IE genes, ORF61 is not present in the viral tegument (124). VZV ORF61 protein is homologous to HSV ICP0 and can functionally complement an HSV-1 ICP0 deletion mutant (179). The amino terminus of ORF61 can substitute for the corresponding region of ICP0 in transient expression assays (174).

VZV ORF61 protein transactivates putative VZV IE, early, and late promoters in transient expression assays (181). When transfected into lymphocytes, it cannot transactivate diverse VZV promoters (196). VZV ORF61 can either repress or enhance the activation of other VZV genes by ORF4 and ORF62, depending on the transfection conditions and cell lines used (181,185,196). The amino terminus of ORF61 contains a RING-finger domain that binds zinc (74) and is required for the transactivating activity of the full-length protein (174). Transient expression of VZV ORF61 enhances the infectivity of VZV and HSV-1 DNAs (181). Carboxyl-terminal truncation mutants of ORF61 that retain the RING-finger domain act as dominant-negative transrepressors and reduce the infectivity of viral DNA.

HSV-1 ICP0, the homolog of ORF61, shows different patterns of activities in transient expression assays. Whereas ICP0 activates the HSV-1 TK promoter in transient expression assays, ICP0 does not activate the VZV ORF36 promoter (112). Unlike ORF61, ICP0 does not show repressing activity in transient expression assays.

Deletion mutants of VZV ORF61 can replicate, but they are impaired for syncytia formation and growth in cell culture (32). Cells infected with these mutants show reduced expression of gE but normal levels of ORF62 protein.

ORF4

VZV ORF4 encodes a 52-kd protein that is predominantly localized to the cytoplasm; however, when coexpressed with ORF62, ORF4 protein is primarily located in the nucleus (54). ORF4 protein is associated with viral particles, most likely in the tegument (124). ORF4 has amino acid sequence homology to HSV-1 ICP27; however, infection of cultured cells with VZV does not effectively complement infection with an HSV-1 ICP27 mutant (77), and a cell line expressing ORF4 does not complement infection with HSV-1 ICP27 mutants (178). The region of greatest homology of ORF4 with ICP27, the carboxyl portion, contains a putative zinc-finger domain; however, mutagenesis of this domain indicates that several cysteine residues are not required for functional activity of ORF4 (195). The amino terminus of ORF4 protein is required for transactivation and can functionally replace the corresponding domain of ICP27 (176).

In transient expression assays, ORF4 protein transactivates expression of some, but not all, VZV putative IE promoters, early promoters, and late promoters. For example, ORF4 does not transactivate expression of the ORF63 IE or ORF28 putative early gene promoter. In transient expression assays, VZV ORF4 synergizes with VZV ORF62 to transactivate expression of putative IE, early, and late promoters. ORF4 activation of target genes occurs at the level of transcription (195) and probably also at a posttranscriptional level (53). Gene activation by ORF4 requires its dimerization, and several portions of the protein are required for its transactivation function (13). ORF4 protein has been shown to directly interact with TATA-binding protein, transcription factor IIB, and the nuclear factor (NF)-kB p50 and p65 subunits *in vitro* (56). ORF4 protein also binds to an underphosphorylated form of ORF62 (226). Unlike HSV ICP27, ORF4 has not been shown to have transrepressing activity (55,111,178,196). The ORF4 promoter was recently mapped, and a region between 59 and 69 bases upstream of the transcription start site was shown to be critical for its activity (163).

ORF63

ORF63 encodes a protein of 45 kd; additional smaller proteins of 38 and 28 kd have also been reported in infected cells (52,124,189). ORF63 is phosphorylated predominantly in the third quarter of the protein (231). ORF63 protein is located primarily in the nucleus of infected cells, although early in infection the protein is present in both the cytoplasm and the nucleus. The protein is present in virions, most likely in the tegument. ORF63 is the homolog of HSV-1 ICP22. Although ORF63 has been reported to repress the ORF62 promoter, another study suggested that ORF63 has little transregulatory activity (114,133).

Replication of Viral DNA

Replication Proteins

VZV encodes homologs (see Table 1) of each of the HSV-1 genes that are essential for origin (ori)-dependent replication of viral DNA; however, studies of VZV have not yet been performed to determine the minimum repertoire of genes needed to do so.

DNA Polymerase

The large subunit of the VZV DNA polymerase is encoded by ORF28 (50,73). The VZV DNA polymerase has been partially purified from VZV-infected cells and requires magnesium for maximal activity. Unlike the cellular polymerase, the VZV enzyme is sensitive to phosphonoacetic acid, and its activity is enhanced in the presence of ammonium sulfate (151,164). Comparison of the VZV and HSV-1 DNA polymerases indicates that the VZV enzyme has a different elution profile during phosphocellulose chromatography, is less sensitive to inhibition by phosphonoacetic acid, is less active in the presence of ammonium sulfate, and is more thermolabile (150). The large subunit of the VZV DNA polymerase gene has been inserted into baculovirus, and the recombinant 130-kd protein has enzymatic properties and inhibition profiles similar to those of the native protein from VZV-infected cells (73). The small subunit of the VZV polymerase is thought to be encoded by ORF16.

DNA Binding Proteins

VZV ORF29 encodes the 130-kd single-stranded DNA binding protein that localizes to the nucleus of VZV-infected cells (50,127). About 50% of the solubilized ORF29 protein extracted from VZV-infected cells binds to single-stranded DNA, and the protein can be eluted with 0.5M sodium chloride. Both the VZV ORF29 and the homologous HSV-1 ICP8 proteins bind single-stranded DNA, although the VZV protein binds with lower efficiency (127) and cannot substitute for its HSV homolog with other HSV proteins in a DNA replication assay (254). The ORF29 protein binds to the VZV gI promoter *in vitro* (19). Whereas the ORF29 protein does not affect transcription when expressed alone in transient expression assays, the ORF29 protein increases or decreases transactivation of a reporter gene by the ORF62 protein, depending on the cell line used (19). ORF29 protein is secreted from VZV-infected cells *in vitro* and the extracellular protein can be endocytosed by neurons (7).

VZV ORF51 encodes the ori binding protein (233). The carboxyl portion of ORF51 binds to three DNA sequence motifs in the VZV origin of replication *in vitro* with similar affinities (24). As in its HSV-1 homolog UL9, a CGC triplet in the VZV origin is required for binding of ORF51 protein. VZV ORF51 can substitute for UL9 with other HSV-1 proteins in an origin-dependent HSV DNA replication assay (254). ORF51 can partially complement the growth of an HSV-1 UL9-null mutant *in vitro* (25). Five additional DNA binding proteins have been identified, ranging from 175 to 21 kd (208).

Replication of the Genome

VZV DNA replication is thought to occur in four stages, based on evidence from replication of the HSV genome (47). First, the linear DNA molecule in the virion circularizes shortly after it enters the cell. VZV has an unpaired nucleotide at both 3' ends of the genome (C at the left end, G at the right end). These ends could ligate together to form a circle; the presence of a fused UL-US joint, demonstrated by cloning of VZV genomic DNA, supports this concept. Second, the circular DNA molecule begins to replicate, and isomerization may occur by homologous recombination between the inverted repeats. Third, more extensive replication of the circular molecule generates head-to-tail concatemers, probably by a rolling-circle mechanism (see Fig. 3). Fourth, the concatemers of VZV DNA are cleaved by sequence-specific nucleases to generate linear DNA for packaging into virions. The finding of concatemeric VZV DNA molecules supports the view that VZV, like HSV-1, replicates by a rolling-circle mechanism (232).

Both the VZV and the HSV-1 genomes have an AT-rich sequence near the left end of the genome and an AT-rich sequence surrounded by a GC-rich sequence at the right end of the genome. The HSV-1 sequences have been implicated in cleavage and packaging, and thus the VZV sequences may have a similar role (48). Because VZV exists predominantly as two of four isomers, cleavage presumably occurs at one UL-US joint 95% of the time, but occasionally (5%) at the other UL-US joint to yield the minor two isomers (129).

The VZV genome contains an origin of replication in the IRS/TRS regions—termed ori $_S$—located between ORFs 62 and 63 [and between ORFs 70 and 71 (50,232)]. It does not contain a replication origin within the UL region, ori $_L$, as HSV-1 and HSV-2 do. Transfection of cells with a plasmid containing ori $_S$, followed by infection of the cells with VZV, results in replication of the plasmid containing ori $_S$. The ori$_S$ contains a 45-bp, almost-perfect palindrome with the sequence $(TA)_{17}$ at its center. Mutation of the palindrome results in loss of replicative activity. HSV-1 has the sequence $(AT)_5$ and $(AT)_6$ in its ori$_L$ and ori$_S$, respectively. Adjacent to the VZV ori$_S$ palindrome is the sequence CGTTCGCACTT, which is present in both the ori$_S$ and the ori$_L$ of HSV-1 (232). Further upstream from the ori$_S$ palindrome is the sequence CATTCGCACTT. Transfection experiments using the VZV replication assay indicate that the 45-bp palindrome and the sequence CGTTCGCACTT are essential for replication activity, whereas the sequence CATTCGCACTT contributes additional activity but is not essential. A second CGTTCGCACTT sequence further upstream from the other two sequences does not contribute to replication activity (233).

The VZV ori-binding protein (encoded by ORF51) recognizes three sites adjacent to the palindrome at the sequences CGTTCGCACTT (located at two sites) and CATTCGCACTT (24). The former sequence conforms to, whereas the latter sequence contains a single base mismatch of, the consensus sequence YGYTCGCACT used by the HSV-1 ori-binding protein.

As indicated, VZV does not have an analog of the HSV-1 ori $_L$ sequence. Transfection with a plasmid containing the VZV region corresponding to HSV ori $_L$, between ORFs 28 and 29, followed by infection with VZV, does not result in replication of the plasmid. Furthermore, the ORF28-to-ORF29 region does not contain a palindrome similar to that seen in HSV-1 ori $_L$. VZV is not able support the replication of a plasmid containing HSV-1 ori $_S$; however, HSV-1 is able to partially support the replication of a plasmid containing VZV ori $_S$ (232).

Other Viral Enzymes

Thymidine Kinase

VZV ORF36 encodes the viral TK gene (215). The VZV enzyme is a 70-kd homodimer composed of two identical 35-kd subunits. The viral enzyme has optimal activity at a higher pH and it has a broader substrate specificity than its cellular homolog (26,98). The VZV enzyme has greater deoxycytidine kinase than TK activity, unlike its HSV-1 counterpart (59,84,190); therefore, it has been referred to as a deoxypyrimidine kinase. In addition, the VZV enzyme is more thermostable and more susceptible to inhibition by deoxythymidine triphosphate than its HSV-1 homolog (190). The enzyme is active when expressed in *Escherichia coli* (215) or when translated *in vitro* (143). The VZV TK phosphorylates and thereby activates acyclovir and the similar guanosine analog, penciclovir. Most acyclovir- (and penciclovir-) resistant strains of VZV have point mutations in the TK gene near the adenosine triphosphate (ATP) or thymidine binding site, or that result in a truncated protein (172,214). Mutagenesis of the VZV deoxypyrimidine kinase gene followed by phenotypic selection in *E. coli* has been used to define the ATP and substrate binding sites for the enzyme (239). Replacement of the HSV TK with its VZV homolog resulted in an HSV mutant with *in vitro* sensitivities to nucleoside analogs that resembled VZV rather than HSV (17). The VZV TK gene is dispensable for replication of the virus *in vitro*.

Ribonucleotide Reductase

VZV ORF18 and 19 are homologous to the small and large subunits of HSV-1 ribonucleotide reductase, respectively (50). The ribonucleotide reductase enzyme has been partially purified from VZV-infected cells and has similar enzymatic activities to its HSV-1 homolog. Both the VZV and HSV-1 enzymes differ from the cellular enzyme in that they are not inhibited by increased intracellular levels of deoxyribonucleotides; however, the activity of the VZV enzyme, unlike that of its HSV-1 counterpart, is inhibited by ATP and magnesium (225). Chemical inhibition of the VZV ribonucleotide reductase potentiates the antiviral activity of acyclovir, presumably by decreasing the intracellular pool of deoxyribonucleoside triphosphates and increasing the level of acyclovir triphosphate (224). Antibody to a synthetic peptide corresponding to the small subunit of the HSV-1 ribonucleotide reductase immunoprecipitates the small subunit of the VZV enzyme (63). VZV ORF19 is not essential for growth of the virus in cell culture. Deletion of VZV ORF19 from the viral genome abolishes viral ribonucleotide reductase activity, impairs the growth of the virus *in vitro*, and potentiates its inhibition by acyclovir (105).

Protein Kinases

VZV ORF47 encodes a 54-kd serine-threonine protein kinase, a capsid/tegument component, whose putative catalytic domain is homologous to that of the HSV-1 enzyme encoded by UL13 (221,228). The activity of VZV ORF47 protein kinase is enhanced by manganese, and the enzyme phosphorylates both acidic and basic proteins. Like its UL13 HSV-1 homolog, ORF47 protein uses both ATP and guanosine triphosphate (GTP) as phosphate donors and phosphorylates exogenous casein (188). This protein phosphorylates both itself and ORF62 protein in protein kinase assays *in vitro* (189); however, ORF47 is not required for phosphorylation of ORF62 in VZV-infected cells *in vitro* (106). VZV ORF47 protein is responsible for posttranslational modification of VZV ORF32 protein associated with its phosphorylation (205). Although ORF47 is dispensable for VZV replication in cell lines (106), it is important for infection of, and spread from, primary lymphocytes *in vitro* (223). In addition, ORF47 is required for growth of VZV in human fetal lymphocytes and skin in the severe combined immunodeficiency (SCID)-hu mouse (168).

VZV ORF66 encodes a 48-kd phosphoprotein located in the cytoplasm of infected cells (228). ORF66 is thought to encode a serine–threonine protein kinase whose putative catalytic domain is homologous to the corresponding region of the HSV-1 US3 protein kinase (154). Cells infected with VZV unable to express both ORF47 and ORF66 lack a 48-kd phosphoprotein that is present in cells infected with VZV unable to express either of the VZV proteins alone (108). ORF66 is dispensable for replication *in vitro* and in human fetal skin in the SCID-hu mouse; however, VZV unable to express ORF66 is impaired for growth in human fetal lymphocytes in the mouse (168).

Miscellaneous Viral Enzymes

VZV ORF8 encodes a dUTPase, which hydrolyzes dUTP to dUMP and pyrophosphate (211). VZV unable to express this enzyme is unimpaired for growth *in vitro*.

VZV ORF13 encodes the viral thymidylate synthetase, which is dispensable for replication of virus *in vitro* (33). *E. coli* expressing the VZV enzyme or virus-infected cells contain a protein that binds to 5-fluoro-2-deoxyuridylate, a ligand specific for the enzyme (242).

VZV ORF59 encodes the VZV uracil DNA glycosylase that removes uracil residues from DNA (206). VZV unable to express this enzyme, as well as virus expressing an inhibitory protein that inhibits both the viral and cellular enzyme, are unimpaired for replication in cell culture.

VZV-infected cells express a DNase activity (26) thought to be encoded by ORF48, the homolog of HSV-1 UL12.

Late Gene Products

ORF10

VZV ORF10 encodes a 50-kd protein that is incorporated into the viral tegument (126). ORF10 protein is expressed diffusely in the cytoplasm after transfection into cells; however, ORF10 protein is localized to the trans-Golgi network after cotransfection of ORF10 and gI or after the virus infection (252a). The VZV protein is the homolog of the HSV-1 a-transinducing factor VP16. ORF10 complements an HSV VP16 mutant that lacks the transactivating function of VP16, and it enhances the infectivity of transfected VZV virion DNA (180).

VZV ORF10 transactivates the VZV ORF62 but not the putative IE ORF61 and ORF4 promoters. ORF10 forms a complex with TAATGARAT-like sequences and Oct1 and HCF to transactivate the IE ORF62 promoter (173). VP16 is more active than ORF10 in transactivating a VZV IE gene promoter in transient expression assays (180). Whereas the transactivating domain of VP16 is located at its carboxyl terminus, the activation domain of ORF10, which has a similar sequence, is located near the amino terminus of the protein (177). Surprisingly, although VP16 is essential for replication of HSV, ORF10 is dispensable for replication of VZV in cell culture (35).

ORF9A and ORF65

VZV ORF9A encodes a 7-kd virion protein located in the membranes of infected cells (211; Sato and Cohen, unpublished data). Although the protein is not required for replication in cell culture, VZV unable to express the protein is impaired for syncytia formation *in vitro*.

VZV ORF65 encodes a 16-kd virion protein that localizes to the Golgi apparatus of virus-infected cells (32a).

Nucleocapsid Proteins

ORF33 (Protease)

VZV ORF33 encodes the precursor of the viral serine protease. Expression of ORF33 in baculovirus results in a protein that is autocatalytically cleaved at two sites (86,157). The mature 31-kd protease is the amino-terminal cleavage product. The VZV protease has been expressed in a functional form in bacteria and the crystal structure has been determined (203). The active form of the VZV protease is predicted to be a dimer. The structure has an overall protein fold similar to that of the cytomegalovirus protease. A serine and two histidines comprise the catalytic site of the VZV protease; mutation of one of these histidines in the protease precursor protein prevents self-cleavage.

ORF33.5 (Assembly Protein)

The 40-kd precursor of the viral assembly protein is encoded by VZV ORF33.5, which is located in the 3' half of the ORF33 gene. The mature 37-kd assembly protein is obtained after cleavage of its precursor by the viral protease (157,201). The assembly protein is presumed to act as a scaffolding protein for assembly of the nucleocapsid, and it can function as a scaffolding protein for HSV capsid shell proteins. When expressed *in vitro*, the ORF33.5 protein forms long, hollow rods, predominantly in the nucleus of cells (201).

Three nucleocapsid forms have been detected in VZV-infected cells (102). Immature B capsids lack viral DNA and contain 32- and 36-kd proteins, presumed to be the mature viral protease and assembly proteins. Mature C capsids contain viral DNA but lack the 32- and 36-kd proteins. Intermediate B/C capsids are thought to contain viral DNA and the 32- and 36-kd proteins. These proteins are probably identical to the 32- and 36-kd proteins that bind DNA and are present in the nuclear matrix of VZV-infected cells (82).

Other Nucleocapsid Proteins

VZV ORF40 encodes the 155-kd major nucleocapsid protein, which is present in the nucleus of VZV-infected cells. Monoclonal antibody to the VZV major nucleocapsid protein cross-reacts with the corresponding protein (UL19) from HSV-1; conversely, monoclonal antibody to the HSV-1 UL19 protein cross-reacts with VZV ORF40 protein (249).

VZV ORF21 encodes a 115-kd protein located in the nucleocapsid (144). The protein localizes to both the nucleus and the cytoplasm of infected cells.

VZV Glycoproteins

VZV Glycoprotein B

Glycoprotein B (gB, gpII), encoded by VZV ORF31, has a higher degree of amino acid identity (49%) with its HSV-1 homolog than the other VZV glycoproteins (which range from 24% to 27% (139)]. Polyclonal or certain monoclonal antibodies raised against HSV gB detect both HSV and VZV gB (69). Glycoprotein B is the second most abundant VZV glycoprotein. It is cleaved in the cell into two polypeptides that are held together by disulfide bonds. Thus, gB appears as a 140-kd protein under nonreducing conditions; under reducing conditions, two proteins of 60- and 70-kd are detected. Two regions in the cytoplasmic domain of gB are essential for its transport from the endoplasmic reticulum to the Golgi (107a). Glycoprotein B contains both N- and O-linked sugars and is sialated, sulfated, and palmitylated (67,94,118,169). Recombinant gB binds to cellular heparan sulfate proteoglycans, and the recombinant protein delays VZV adsorption of virus to cells (115). Like its HSV homolog, gB may also be important for entry of VZV into the cell (250).

VZV Glycoprotein C

Glycoprotein C (gC, gpV), encoded by ORF14, contains N-linked sugars. Different strains of VZV contain different numbers of the R2 repeat unit, which is located in the coding sequence of gC; therefore, the size of gC varies from 80- to 170-kd, depending on the strain of virus. The amount of gC expressed in infected cells also varies depending on the strain of VZV and on the level of transcription of gC RNA (128,130,137). Glycoprotein C is dispensable for growth in cell culture (34), but gC-negative mutants are impaired for replication in fetal human skin in the SCID mouse (167).

VZV Glycoprotein E

VZV glycoprotein E (gE, gpI), the product of VZV ORF68, is an 85- to 100-kd protein that contains both N- and O-linked sugars and is heavily sialated (68,70,94,171). Glycoprotein E is the most abundant VZV glycoprotein on the surface of virus-infected cells (171). It is modified by myristylation, palmitylation, and sulfation (67,100,186). Its monomeric form is phosphorylated at serine and threonine residues by casein kinase II, whereas the dimeric form is phosphorylated by a tyrosine kinase (191,264). Glycoprotein E forms a heterodimer with VZV gI that requires the amino terminus of gI for its interaction (123,263). Glycoprotein E binds the Fc receptor of human immunoglobulin (139). A portion of gE is homologous to the cadherins (165a). Expression of gE in epithelial cells induces formation of tight junctions and enhances establishment of trans-epithelial resistance, resulting in increased cell-cell contact. A naturally occurring isolate of VZV that lacks a B cell epitope of gE has enhanced cell-to-cell spread both *in vitro* and in human fetal skin implants in the SCID mouse (213a).

After synthesis and maturation in the Golgi apparatus, gE is transported to the cell membrane either directly or by the trans-Golgi network (TGN). This transport requires a tyrosine motif (AYRV) and an acidic amino acid–rich patch located in the cytoplasmic tail (268,269). At the cell membrane, gE can undergo endocytosis to the TGN and subsequently be recycled through endosomes back to the cell membrane (5,193). A tyrosine localization motif (YAGL) in the cytoplasmic tail of gE is required for its endocytosis (193). Although gI is also endocytosed from the cell surface and has a methionine-leucine internalization motif in its cytoplasmic tail, the gE–gI complex undergoes endocytosis more efficiently than either protein alone (4,192).

VZV Glycoprotein H

Glycoprotein H (gH, gpIII), the product of VZV ORF37, is a 118-kd glycoprotein that contains N-linked but not O-linked sugars, and it is sialated and sulfated (67,94,119,170) and secreted into the medium of cells in culture (219). Glycoprotein H is the third most abundant VZV glycoprotein. It acts as a fusogen that facilitates cell-to-cell spread of virus because monoclonal antibody to gH blocks the entry, cell-to-cell spread, and egress of VZV from infected cells (113,209). Glycoprotein H requires gL for processing in the Golgi and transport to the cell surface (65,80,152). Coexpression of gH with either gE or gI allows an immature form of gH to be transported to the cell surface but it is not fusogenic (64).

VZV Glycoprotein I

Glycoprotein I (gI, gpIV), encoded by VZV ORF67, is a 58- to 62-kd glycoprotein that contains N- and O-linked sugars (94,171,262). Glycoprotein I is phosphorylated on its cytoplasmic tail by a cyclin-dependent kinase (265). It is a component of the gE–gI Fc receptor (139). It is not required for replication of VZV in human cells, but it is required for replication in Vero cells (31,149). VZV gI mutants are impaired for efficient cell-to-cell spread of virus, adsorption to cells, and syncytia formation *in vitro*. A threonine in the endodomain of gI targets the glycoprotein to the TGN when expressed alone in cells. When gI is expressed with gE, however, gI is more rapidly localized to the TGN (4,253). The carboxyl terminal domain of gI is required for envelopment of the virus in the TGN (252a). VZV gI is required for normal maturation of gE and appropriate distribution of gE on the cell surface.

VZV Glycoprotein L

Glycoprotein L (gL, gpVI), encoded by ORF60, is a 20-kd glycoprotein that forms a complex with gH. Glycoprotein L is thought to have an N-linked oligosaccharide (65). Unlike gH, which requires gL for its maturation, gL is fully processed in the absence of gH. Expressed alone or with gH, gL accumulates in the cytoplasm, but not on the surface, of transfected cells (64). It acts as a chaperone that associates with the immature but not the mature form of gH (65). Glycoprotein L contains an endoplasmic reticulum–targeting sequence and is recycled between the endoplasmic reticulum and the Golgi (64). Coexpression of gH and gL leads to syncytia formation; expression of either protein alone does not (65).

VZV Glycoprotein K

Glycoprotein K (gK), encoded by ORF5, is a 40-kd glycoprotein containing N-linked sugars (166). It is required for replication of VZV; HSV gK cannot complement a VZV gK-minus virus. Overexpression of VZV gK in a cell line inhibits syncytia formation by ild-type virus.

Assembly and Release

Few studies of human tissues illuminate the assembly and release of VZV *in vivo*, but infectious progeny are liberated efficiently, accounting for the infectiousness of virus-laden aerosols and vesicle fluids. Weller first noted that VZV is highly cell-associated in culture (255). In electron microscopic studies, Cook and Stevens (40) showed that most cytoplasmic particles develop dense cores and fragmented membranes, supporting a degradative insult. The implication of this is that the replication of VZV in cultured cells is different from that in cells in the human body, and that any model of how VZV replicates *in vitro* or *in vivo* must account for these properties of virus growth. Figure 3 is a schematic effort to depict various aspects of the competing notions about VZV assembly, maturation, degradation, and release

(40,85,87,88,103,116).

Two similar models of VZV replication *in vitro* have been proffered. One model stipulates that nucleocapsids are enveloped as they exit and traverse the nuclear membrane and then become incorporated into large cytoplasmic vesicles (103,116). Virus-specific glycoproteins are released from the TGN borne in microvesicles. These fuse with large cytoplasmic vesicles so that their glycoprotein content is available to decorate the envelopes of the newly arriving particles. The vesicles migrate to the cell surface, where progeny are released by reverse endocytosis. In this model, it is presumed that only a tiny proportion of particles are formed properly (see Fig. 3, pathway 12), but the probability that they do so is greater in cell lines derived from melanocytes than in human diploid lung cells.

Gershon et al. (87,88) propose a slightly different scenario for VZV maturation and release. In their view, nucleocapsids first acquire and then lose their envelopes as they traverse the nuclear membrane. “Naked” nucleocapsids in the cytosol are enveloped by cisternae of the TGN. The cisternae are decorated with VZV-encoded glycoproteins with their cytoplasmic tails in the cytosol. Tegument proteins adhere to the cytosolic face of the TGN. The naked nucleocapsids attach to the tegument and invaginate into the cisternae. In cultured cells, these vesicles are usually diverted to pre-lysosomes, where they are subjected to degradative enzymes (see Fig. 3, pathway 9). The particles enter pre-lysosomes because some of their envelope proteins are glycosylated with mannose-6-phosphate residues (85). Mannose-6-phosphate side chains render the evolving particles susceptible to binding and uptake by lysosomes bearing mannose-6-phosphate receptors. This latter feature of the model requires that an alternative secretory pathway must be operative in some cell types *in vivo* to allow virus egress without lysosomal degradation (see Fig. 3, pathway 8).

Fate of the Host Cell: Apoptosis, Effects on Host Proteins

Productive infection of cells with VZV results in lysis of the cell. The nuclei become enlarged, the nucleoli are fragmented and contain dense granular aggregates, and the chromatin is marginated (41). Basophilic granules, followed by eosinophilic inclusions, form in the nucleus of infected cells.

Light microscopy of infected cells initially shows increased refractility followed by formation of syncytia. In melanoma cells, virions cluster on the surface of the infected cells in elongated patterns termed viral highways (Fig. 5) (103). The syncytia gradually enlarge and the cells detach from the monolayer. At least five VZV proteins, ORF9A (211), ORF61 (32), gI (149), and gH–gL (64) have been shown to contribute to syncytia formation. Syncytia formation is less prominent *in vivo*.

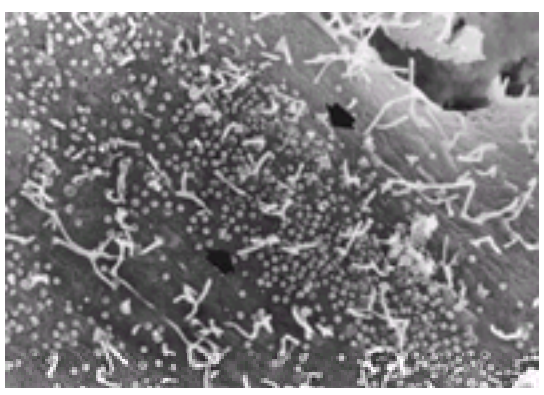

FIG. 5. Scanning electron micrograph of VZV viral highways. In infected cell monolayers, VZV emerges in distinctive linear patterns that have been termed viral highways. The highways consist of thousands of viral particles, as demarcated between the *solid arrowheads* (×10,000). (Micrograph provided by J. Padilla and C. Grose.)

Unlike HSV, VZV does not rapidly shut off host protein synthesis (11). Host protein synthesis gradually diminishes over a period of 48 hours after infection. Although VZV ORF17 encodes the homolog of the HSV virion host shutoff (vhs) protein, the VZV protein has not been shown to shut off host protein synthesis. The predicted sequence of the VZV vhs protein shows greater homology to the equine herpesvirus 1 vhs than to the HSV-1 vhs protein. Unlike the HSV vhs, the equine herpesvirus vhs does not induce degradation of cellular mRNA, and no virion-associated inhibition of protein synthesis is seen with the equine herpesvirus (78).

VZV induces apoptosis in Vero cells, with DNA fragmentation and chromosomal condensation (213). In more permissive cells, such as human fibroblasts and melanoma cells, however, VZV infection does not induce apoptosis (Turner and Cohen, unpublished data).

Like other alphaherpesviruses, VZV down-regulates expression of major histocompatibility complex (MHC) class I molecules on the surface of infected cells (1,28). The total amount and level of nascent synthesis of class I molecules, however, is unchanged in VZV-infected cells. VZV also inhibits interferon-gamma induction of MHC class II molecules on the surface of infected cells (2). VZV inhibits the expression of Stat 1-alpha and JAK2 proteins, and it inhibits the transcription of interferon regulatory factor I and the MHC class II transactivator that mediate interferon-gamma signal transduction. VZV also down-regulates expression of glial fibrillary acidic protein on human astrocytes *in vitro* (122).

Latency

The nature of VZV latency has not been clarified as well as that of HSV (see Chapter 73). Latency is established during varicella, a primary viremic infection. Its persistence in sensory nerve ganglia was predicted by the seminal studies of Head and Campbell in 1900 (104), who mapped all cutaneous dermatomes according to the distribution of lesions in 392

cases of zoster. VZV may access neural tissues either hematogenously or by centripetal neural transport from mucocutaneous lesions. Histopathologic and *in situ* hybridization studies of human ganglia recovered after fatal chickenpox showed widespread infection, favoring the hematogenous mechanism of spread (43,184). That the distribution of zoster lesions closely mimics that of primary varicella, and that the Oka vaccine virus tends to cause zoster outbreaks at sites of initial inoculation, both argue that VZV can access the ganglia by anterograde neural transport (99,227).

Using the polymerase chain reaction (PCR), latent VZV DNA is readily detected in most human trigeminal ganglia and many dorsal root ganglia (147,148). VZV DNA also has been found in human geniculate ganglia and olfactory bulbs (83,136). The cellular localization of the persistent virus, the quantity of latent virus, and the pattern of latent gene expression, however, are less well established.

Initial reports by Mahalingam et al. (147) suggested that only 6 to 31 copies of the VZV genome can be detected in DNA equivalent to 100,000 human ganglion cells. In more recent studies using quantitative real-time PCR techniques, Pevenstein et al. (200) reported, on average, 258 genome copies per 100,000 ganglion cells—a level about 1/10th that for latent HSV-1 in human trigeminal ganglia. Similar studies by Cohrs et al. detected 577 to 55,543 VZV genomes, but fewer HSV-1 genomes, per 100,000 ganglionic cells in older persons (38a).

Using *in situ* hybridization, Hyman et al. (110) and Gilden et al. (89) showed that latent VZV resides in neurons. Croen et al. (43) and Meier et al. (158), however, showed that VZV persists in nonneuronal cells (Fig. 6A). Several more recent studies established that VZV can persist in both neuronal and nonneuronal cells of sensory ganglia. Lungu et al. (141) used an enzyme-amplified *in situ* hybridization method to detect VZV DNA in 5% to 30% of neurons and nearly as great a percentage of nonneuronal cells. Using different *in situ* hybridization and PCR-*in situ* techniques, Kennedy et al. (120) showed VZV DNA in 2% of human dorsal root neurons and some 0.1% of nonneuronal cells. LaGuardia et al. (135), using PCR to analyze dissociated human neurons and nonneuronal cells, found that VZV was present almost exclusively in neurons at a frequency of two to five copies per neuron.

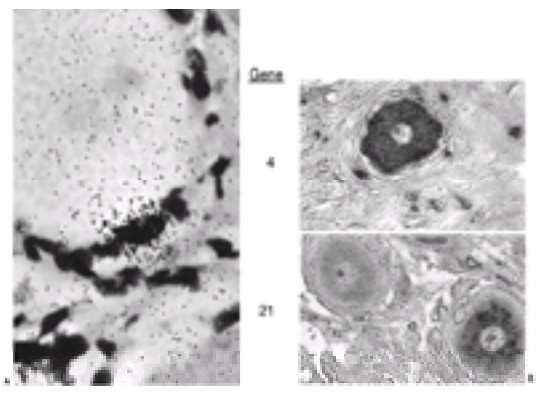

FIG. 6. A: *In situ* hybridization of an adult human trigeminal ganglion demonstrating expression of VZV gene 29 transcripts. Concentrations of silver grains indicates the specific accumulation of VZV RNA, primarily over a satellite cell (×498). (Reproduced from ref. 158, with permission.) **B:** Immunohistochemical detection of VZV proteins encoded by genes 4 and 21 in latently infected human dorsal root ganglia. The proteins were detected using purified rabbit antibodies raised to specific GST-fusion proteins and then an alkaline phosphatase-conjugated goat anti-rabbit secondary antibody. The *upper panel* displays reactivity with antisera to VZV gene 4 protein over the cytoplasm of one neuron and several nonneuronal cells. The *lower panel* shows reactivity over the cytoplasm of one of two neurons. (Modified from ref. 220, with permission.)

Unlike HSV latency, in which only one gene is efficiently transcribed, VZV latency is characterized by the transcription of multiple genes. Meier et al. detected polyadenylated RNAs homologous to ORF29 and ORF62 but not to ORF28 or ORF61 (158). Through a series of studies of cDNAs prepared from human ganglia, Cohrs et al. identified sequences encoded by ORFs 21, 29, 62, and 63 but not by ORFs 28, 40, or 51 (37,38 and 39). Using *in situ* RT-PCR, Kennedy et al. (119b,121) showed that ORFs 4, 21, 29, 62 and 63 RNA are expressed in human ganglia. The VZV genome possesses no obvious homolog of the HSV latency associated transcript (LAT)-encoding sequences, and nothing analogous to the LATs has been detected in VZV latency.

Studies in VZV-infected animals suggest another major difference between VZV and HSV latency in addition to the expression of multiple VZV transcripts. Although animal models have, in general, not been very helpful adjuncts to clarifying VZV pathogenesis because the virus does not replicate efficiently and cause disease in them, they have shed light on the mechanisms of VZV latency. Debrus et al. (52) reported the detection by immunohistochemical methods of VZV ORF63 protein in dorsal root ganglionic neurons of rats that had previously been inoculated in their footpads with virus-infected cells. Similar methods were then applied to human ganglia by Mahalingam et al. (146) and Kennedy et al. (119b), who demonstrated ORF63 protein in neurons. Lungu et al. (142) reported that proteins encoded by ORFs 4, 21, 29, 62, and 63 are expressed in human neurons (see Fig. 6B).

Persistence in both neuronal and nonneuronal cells suggests a unique mode of latency and reactivation of VZV that could explain diverse features of zoster that distinguish themselves from recurrent HSV infection (43,160).

YIELD OF CELL-FREE AND CELL-ASSOCIATED VIRUS

VZV is highly cell-associated when grown in cell culture. Despite its growth and passage in numerous cell types, no primary cells or cell lines in culture that support VZV replication yield substantial amounts of cell-free virus (255).

Because of this limitation, virus is usually propagated by treating VZV-infected cells with trypsin and passaging them onto uninfected cells.

Cell-free virus is usually prepared by sonicating VZV-infected cells. Titers of 10^3 to 10^5 plaque-forming units per milliliter have been obtained by mechanically dislodging VZV-infected thyroid, human melanoma, or human embryo lung fibroblast cells (97,101). Electron microscopic examination of cell-free VZV prepared in this manner often shows virus particles attached to fragments of cell membranes. Precipitation of cell-free virus with polyethylene glycol allows an up-to-50-fold concentration of the virus with preservation of infectivity. Concentration by other methods, including ultracentrifugation and dialysis against hydrophilic compounds, typically leads to a marked decrease in virus titer. VZV has been further purified with retention of infectivity by centrifugation in 10% to 50% linear potassium tartrate or potassium tartrate and glycerol viscosity–density gradients; however, centrifugation in cesium chloride or metrizamide gradients is associated with loss of infectivity (95,97).

Analysis of VZV excreted from human embryonic lung cells in culture shows 1 to 2×10^9 viral particles per milliliter of medium, and 30% to 80% of the particles are enveloped; however, no infectivity could be detected. A similar analysis of particles from sonicated cells showed 1 to 2×10^9 particles per milliliter, and 30% to 50% of the particles had envelopes. The particle-to-infectivity ratio was 10^6:1. In contrast, HSV-2 obtained from sonicated cells had a particle-to-infectivity ratio of 60:1 (219). Cell culture–derived VZV often has an incomplete coat and may lack a central core, unlike cell culture–derived HSV-1, which is enveloped and has a dense, central core (40). Unlike VZV grown in cell culture, vesicle fluid contains substantial amounts of infectious cell-free virus, which is less labile than virus obtained from cultured cells (23,241).

INHIBITORS OF REPLICATION

Effective agents are available to treat VZV infections (29). The clinical application of these agents is reviewed more fully in Chapter 15 and Chapter 79. The first proven treatment, human leukocyte interferon, benefited immunocompromised patients with varicella (10) or zoster (162). Greater antiviral activity is exhibited by nucleoside and pyrophosphate analogs. The first effective analog was vidarabine (258). Vidarabine is a modestly active, but selective, competitive inhibitor of the VZV-encoded DNA polymerase.

Acyclovir proved more versatile, effective, and safe than vidarabine for treatment of varicella and zoster in the immunocompromised (12,217,259) and in the normal host (62,183). Acyclovir is an analog of deoxyguanosine, bearing an acyclic side chain in the 9 position in place of deoxyribose. VZV replication is inhibited *in vitro* at concentrations of 1 to 5 µg/mL, whereas cellular growth and metabolism are not impaired until concentrations exceeding 50 µg/mL are achieved (18,45). Acyclovir is selectively monophosphorylated by the VZV-encoded TK and further modified to acyclovir di- and triphosphates by cellular kinases (165). Acyclovir triphosphate not only accumulates preferentially in VZV-infected cells, but it serves as a selective substrate and inhibitor of the VZV DNA polymerase. Incorporation of acyclovir terminates chain growth by virtue of its lack of a 3'-OH group to which the subsequent nucleotide would link (71).

Molecular proof of the pivotal role of the VZV TK in the action of acyclovir and penciclovir (another guanosine analog) was derived both from the cloning and stable expression of the gene in TK-deficient cells, and from the subsequent demonstration by sequencing of the VZV gene in acyclovir-resistant viral mutants (214,240). Missense mutations in the ATP-binding site and the nucleoside-binding site, and mutations clustered between these two sites, confer acyclovir resistance. Nonsense mutations leading to expression of grossly truncated VZV TK protein also result in drug-resistant viruses. Acyclovir resistance also can be conferred by mutations in the VZV DNA polymerase, but these are rare and less well characterized. VZV strains that are resistant to both acyclovir and penciclovir, because of mutations in the TK gene, retain sensitivity to the pyrophosphate analog, foscarnet. Foscarnet is effective for acyclovir-resistant VZV infection (21). Cidofovir is a novel acyclic nucleoside phosphonate that retains activity against acyclovir-resistant strains of HSV and VZV. It may be useful as a topical or systemic alternative to foscarnet (222).

Two nucleoside analog prodrugs have been approved in the United States for treatment of zoster (16,248). Valaciclovir is a six-valine ester derivative of acyclovir that is deesterified by hepatic enzymes to yield acyclovir (199). Famciclovir is a diacetyl derivative of penciclovir that is enzymatically converted to penciclovir by intestinal and hepatic enzymes (44). The advantage of these prodrugs is that they are better absorbed from the gastrointestinal tract than their parent compounds acyclovir and penciclovir, allowing higher serum levels of drug. Penciclovir has an added pharmacologic advantage in achieving and sustaining higher intracellular triphosphate concentrations, yet, on balance, this advantage is offset by the poorer ability of penciclovir triphosphate to inhibit VZV DNA polymerase compared with acyclovir triphosphate (44).

PERSPECTIVE

The study of VZV has long lagged behind that of the other human alphaherpesviruses HSV-1 and HSV-2. This was a result of the low titers of cell-free VZV that could be obtained *in vitro* and, until recently, the lack of a genetic system to produce viral mutants. Two groups have now independently generated sets of cosmids that have been used to produce VZV mutants. The ability to manipulate the VZV genome and the availability of an effective VZV vaccine may allow VZV to be used as a vaccine vector for expression of additional antigens. For example, VZV expressing HSV-2 gD partially protects animals from genital herpes (107).

Although the VZV and HSV genomes have a large number of genes in common, many of their genes have strikingly different properties. For example, whereas HSV VP16 is essential for virus replication, the homologous VZV ORF10 is dispensable for growth *in vitro*. Continued elaboration of the function of VZV genes will undoubtedly show further differences in homologs shared between these viruses.

VZV also has a large number of biologic properties that are different from those of HSV. Unlike HSV, VZV disseminates throughout the body during primary infection. Some of the genes that contribute to this aspect of pathogenesis have only

recently been defined. The ORF47 protein kinase is important for virus replication in lymphocytes, which may be important for its dissemination, whereas gC is needed for VZV penetration into the dermis.

It is striking that VZV usually reactivates only once, if at all, whereas HSV usually reactivates multiple times. While HSV expresses only one family of LATs, VZV expresses several genes, including their protein products, during latent infection. The mechanism for VZV latency, and especially the role of the large number of latency-associated gene products, remains a conundrum. The ability of these latently infected cells, which express a number of viral proteins, to escape destruction by the immune system, raises a number of questions for future research.

CHAPTER 79 Varicella-Zoster Virus

Ann M. Arvin

Varicella-zoster virus (VZV) is a human alphaherpesvirus that causes varicella, commonly called *chickenpox,* during primary infection of the host. Varicella is a febrile illness characterized by a generalized, pruritic vesicular rash and is most prevalent in childhood. Primary VZV infection is highly contagious, producing annual epidemics among susceptible individuals during winter and spring in temperate climates. VZV is unique among the alphaherpesviruses in its tropism for T lymphocytes, which allows dissemination of the virus to skin. The virus establishes latency in cells of the dorsal root ganglia during primary infection. Its reactivation from latency produces herpes zoster, which is commonly referred to as *shingles,* and is usually observed in elderly or immunocompromised patients. Herpes zoster is a vesicular rash restricted to a dermatomal distribution. Acute VZV reactivation produces severe acute pain, which may progress to the chronic syndrome called *postherpetic neuralgia* (PHN). The symptoms of varicella and herpes zoster are known throughout the world because VZV infection is ubiquitous in the human population. Ordinary names for varicella in other languages are *varicelle* (French), *varicela* or, in older usage, *viruela* (Spanish), and *windpocken* (German); the terms for herpes zoster are *zone, zona,* and *gurtel rose.* Speculations about the origin of the colloquial English term, *chickenpox,* include an association between the appearance of varicella lesions and that of the chickpea, which is called chiche in French and a corrupted form of the Old English word for itching, which is *gican* (131). The term *zoster* derives from the Greek word for girdle, while shingles originates from the equivalent Latin term, *cingere,* reflecting the partial encircling of the abdomen when the rash involves the lower thoracic or lumbosacral dermatomes.

HISTORY

Varicella and herpes zoster were described in the earliest medical literature, although the similarities between the exanthems of smallpox and varicella delayed the definitive recognition of varicella as a separate clinical entity. Heberden distinguished these two diseases in 1867, but since smallpox has been eradicated, its differentiation from varicella is of historical interest only. Galen referred to clusters of vesicular skin lesions as herpes but did not distinguish lesions now associated with herpes simplex from herpes zoster. The dermatomal eruption of herpes zoster and the associated neuralgia were recognized later as differentiating characteristics.

Von Bokay suggested the infectious etiology and the probable pathogenic relationship between the causative agents of varicella and herpes zoster in 1892, based on the occurrence of varicella in children after household contact with herpes zoster (46). Varicella was then observed in susceptible children after the inoculation of vesicular fluid recovered from herpes zoster lesions; episodes of secondary transmission resulted in typical varicella (323). The cutaneous lesions of varicella and herpes zoster were similar in early histopathologic studies (78,211). “Elementary bodies” in vesicular fluid differed from those in smallpox vesicles but suggested that the causative agent was a virus (7), and virions from varicella and herpes zoster were shown to be identical by electron microscopy (5). That herpes zoster was caused by reactivation of latent virus acquired during varicella was considered by Garland in 1943 and further elucidated by Hope-Simpson (128,177,178).

In 1944, Goodpasture and Anderson observed multinucleated cells and cells containing intranuclear inclusions when human skin cells, maintained by grafting to chick embryo chorioallantoic membranes, were inoculated with vesicular fluid from a herpes zoster lesion (147). The first isolation of VZV in tissue culture was reported by Weller and Stoddard in

1953 (366). Focal cytopathic effects (CPE) and virion morphology were indistinguishable in cells inoculated with vesicular fluid recovered from cutaneous lesions of patients with varicella or herpes zoster (62,367,368,369 and 370). Comparable antigenic profiles were documented using immune sera (211). VZV was first classified as a DNA virus because its replication in tissue culture was inhibited by iododeoxyuridine (281). Restriction endonuclease analysis of VZV DNA from viruses isolated from an immunocompromised patient during varicella and herpes zoster confirmed that herpes zoster resulted from the reactivation of the same VZV strain (325).

Much progress has been made recently toward understanding the molecular biology of VZV. Recent milestones include the sequencing of the complete VZV genome and the production of infectious virus from cosmids (71,87,235). Generating mutants from VZV cosmids has overcome the difficulty of plaque purifying VZV that had hampered the functional analysis of VZV genes. Critically important medical advances have been made in parallel, including the demonstration that VZV infections, whether primary or recurrent, can be treated with antiviral agents selected for their capacity to inhibit VZV replication *in vitro* (374). VZV is also the first human herpesvirus for which a vaccine has been developed (134,330,335). Live attenuated varicella vaccine protects susceptible individuals against primary VZV infection and is recommended for universal immunization in the United States (6).

INFECTIOUS AGENT

The virion structure of VZV and its replication are described in Chapter 78. Knowledge about the unique characteristics of VZV as an infectious agent, particularly those that distinguish VZV from other alphaherpesviruses, is beginning to emerge. Nevertheless, information about how specific viral gene products mediate VZV infectivity in cell culture or, most importantly, within differentiated cells that compose intact host tissues, remains limited.

Propagation and Assay in Cell Culture

VZV can be isolated from cutaneous lesions or other infected tissues using primary, diploid, or transformed human cells (137,152,367). Human cell lines are the most sensitive for initial recovery of the virus, but VZV can be propagated in nonhuman cells, including primary rhesus or African Green monkey kidney cells, Vero cells, and guinea pig embryo fibroblasts (137). CPEs usually appear within 2 to 7 days after inoculation of vesicle fluid, which contains cell-free VZV, but may require up 14 days (137). VZV replication is highly cell associated, with no virus release into supernatant; efficient propagation of the virus requires the use of intact infected cells or an infected cell inoculum disrupted by trypsin, sonication, or freeze-thawing. The infectious virus yield from VZV-infected monolayers is low (131). Infected cells are dispersed with trypsin at 50% to 90% CPE, transferred to a fresh monolayer at ratios of 1 infected cell to 2 to 10 uninfected cells, and incubated for 24 to 72 hours. Centrifugation, as well as blind passage, can enhance initial replication when viral titers are low (362).

Even keratinocytes, which release cell-free virus into cutaneous vesicle fluid *in vivo,* do not allow viral egress *in vitro* (392). Sonication and gradient purification permits the recovery of low quantities of cell-free VZV from various cell types, but the best ratios of plaque-forming units (PFUs) to uninfected cells that can be achieved range from 1:5 to 1:10 (131).

Plaque assays of VZV infectivity can be performed using human fetal diploid cells, melanoma cells, Vero cells, or primary African green monkey kidney cells (137). Trypsinized infected cells or sonicated preparations of infected cells are inoculated in serial dilutions, adsorbed for 30 to 60 minutes, incubated for 5 to 7 days, and stained with neutral red or crystal violet to enhance plaque visibility. VZV plaque assays may be performed without an overlay because the virus is so cell associated, but detachment of infected cells can lead to secondary foci. Early detection of infected cell foci can be accomplished with immunohistochemical stains (355,382). By using a standard inoculum of infected cells, VZV plaque titration methods can be adapted to assess neutralizing antibody titers or the activity of antiviral drugs (307).

Biologic Characteristics in Cell Culture

VZV infectivity requires the preservation of an intact virion envelope (96) and is also relatively temperature dependent; optimal growth of VZV in melanoma cells occurs at 32°C (169). Complete viral inactivation is observed after short intervals of exposure to temperatures of 56° to 60°C, or storage at temperatures above –70°C. Rapid freezing with 5% to 15% glycerol helps to maintain the viability of VZV-infected cell preparations (150). Lyophilization preserves the infectivity of cell-free virions as well as VZV-infected cells (37).

VZV-infected cells are visible by immunohistochemical staining methods within 4 to 10 hours after inoculation (62,387). When CPE appears, it is characterized by syncytial formation; the presence of syncytia is a hallmark of VZV infection in cell culture and contrasts with the CPE caused by most herpes simplex virus (HSV) isolates. CPE appears about 24 hours after infection of melanoma cells; syncytial formation involving about 75% of the monolayer is observed by 48 hours, and at 60 hours, the fused cells detach from the surface. VZV induces large foci of rounded, refractile cells in uman diploid cells (Fig. 1). Multinucleated giant cells appear with enlarged nuclei, abnormal nucleoli, and marginated chromatin (see Fig. 1C). VZV virions are usually enclosed in membrane-lined vacuoles within the cytoplasm (123,152). By electron microscopy, the virions appear to deteriorate as the particles move through cytoplasm into extracellular spaces, explaining the failure to detect infectious virus in supernatants (81,82,284). At late times, exposure to protein-precipitating fixatives reveals eosinophilic intranuclear inclusion bodies that do not appear to contain viral DNA. By scanning electron microscopy, both complete and light particles, lacking a nucleocapsid, are visible, and VZV CPE is associated with the formation of “viral highways”; viral particles are visible on the surface of cells, clustered along the syncytia (284).

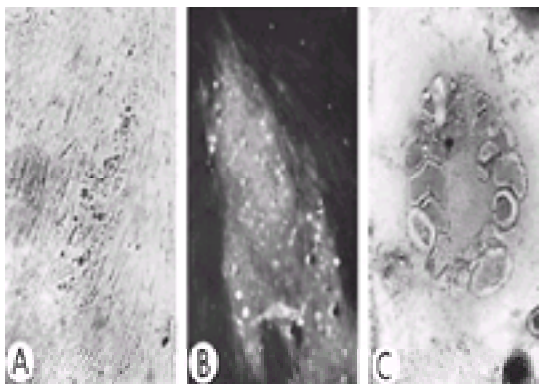

FIG. 1. Varicella-zoster virus (VZV) infection of human fibroblasts *in vitro.* **A:** An early focus of VZV infection in a monolayer of human embryonic fibroblasts. (H&E, ×240) **B:** Immunofluorescence in a focus of VZV-infected human embryonic lung fibroblasts after reaction with human convalescent zoster serum and fluorescein isothyocyanate–conjugated goat antihuman immunoglobulin G. (H&E, ×2,100) **C:** An isolated multinucleated giant T lymphocyte containing intranuclear inclusion bodies from a monolayer of VZV-infected human fibroblasts. The cells were fixed in Bouinís solution (H&E, ¥2,600). (From ref. 127, with permission.)

VZV exhibits a high degree of genetic stability during *in vitro* propagation, at the level of assessment possible by restriction digest analysis of viral DNA using several enzymes (92). Although VZV isolates have variable restriction enzyme profiles, altered patterns of CPE have not been associated with spontaneously occurring genetic variations. The only exception is a newly identified VZV strain with a mutation in glycoprotein E (gE), which exhibits accelerated cell-to-cell spread and increased numbers of cell surface virions (298).

Several genes have been shown to be dispensable for VZV replication in tissue culture, without changing VZV CPE, including thymidine kinase (TK), dUTPase, thymidylate synthetase, uracil DNA glycosylase, open reading frames 47 and 66 (ORF47 and ORF66), serine-threonine protein kinases, ORF10 virion-associated transactivator, the gene products of ORF32, ORF57, and ORF61 (72) and gC (see Chapter 78). However, when gI (ORF67) is deleted, or its expression is blocked, VZV mutants exhibit a small plaque phenotype with distortion of polykaryocyte formation in melanoma cells, and no growth is detected in Vero cells (76,235). Syncytial formation is also reduced if the products of both ORF8 and ORF9A are not expressed (287).

VZV infection of cells in culture is lytic, rather than transforming (375). Early experiments suggested that VZV could transform primary hamster embryo cells; these nonpermissive cells, which were infected with a clinical isolate of VZV and passaged blindly, exhibited abnormal morphology, showed transient expression of VZV proteins, and induced fibrosarcomas in inbred hamsters, but no VZV DNA was detected in the transformed cells (133,388).

Replication in Specialized Cell Types in Culture

VZV replication has been studied *in vitro* using differentiated primary human cells or cell lines selected to reflect the tropisms of the virus *in vivo.* When VZV interactions with peripheral blood mononuclear cells (PBMCs) were examined by *in situ* hybridization, only 0.01% of T lymphocytes showed nuclear hybridization (207). Infectious VZV was recovered from cultures of activated T lymphocytes (207), and VZV infects cord blood T lymphocytes *in vitro* (318a). The major immediate early protein IE62 has the potential to transactivate all classes of VZV genes *in vitro* in a human T-cell line (264), and abortive replication occurs in a CD4+ T-cell hybridoma line (II23 cells) (392). The nonpermissiveness of most PBMCs, including resting T lymphocytes, for VZV replication *in vitro* parallels the low frequency of VZV-infected mononuclear cells that can be detected during acute varicella (207,234); this limited replication, despite virion uptake and functional activity of the IE62 protein, benefits the host, but its mechanisms have not been explained. VZV also replicates in EBV-transformed human B lymphocytes *in vitro* (207); VZV gE and IE62 protein are expressed on the surface of these cells. Infection of keratinocytes was demonstrated, but infectious virus yields were low (310).

VZV infects cells cultured from nervous system tissue, including both neuronal and nonneuronal cells (Schwann cells and astrocytes) (30,143,240,318,376). When cells derived from fetal dorsal root ganglia were infected with VZV, the supporting nonneuronal cells were more susceptible to CPE than were the neurons (376). VZV replication was more rapid in astrocytes than in Schwann cells and neurons, although CPE was seen in all cell types. In astrocytes and fibroblasts, a VZV IE protein was detected before a putative early protein, whereas in Schwann cells and neurons, a putative early protein was detected before an IE protein (28). Infection of cultures containing both human fetal neurons and satellite cells in the presence of bromovinylarauracil (BVaraU) followed by withdrawal of the antiviral resulted in recovery of infectious VZV, but persistence did not occur when neurons or satellite cells were cultured separately (318). Infection of human fetal neurons with a wild-type isolate of VZV resulted in sevenfold greater virus replication compared with the vaccine Oka strain. VZV inoculation of a human neuroblastoma cell line (IMR-32) also yields infectious virus (53).

Effects on Cell Functions

In addition to the effects on cellular morphology that are evident as syncytial formation and typical CPE, VZV alters other characteristics of mammalian cells in culture. VZV elicits down-regulation of the constitutive expression of class I major histocompatibility (MHC) molecules on the surface of infected cells (1,73). Because class I MHC molecules present peptides to CD8+ T lymphocytes, interference with their transport to the cell surface makes the infected cells less visible to this component of the antiviral immune response. This effect is observed on VZV-infected T lymphocytes, which may facilitate the transport of VZV to cutaneous sites of replication during the incubation period, without evoking adaptive immune responses (1). Class I MHC molecules are also decreased on fibroblasts infected with VZV, which may delay

clearance of the virus at cutaneous sites (1,73). In contrast to HSV and cytomegalovirus (CMV), class I MHC molecules transit the endoplasmic reticulum (ER) but are retained in the Golgi compartment of VZV-infected cells (1).

VZV infection also interferes with the up-regulation of class II MHC expression that is usually triggered by interferon-g (IFN-g); IFN-g–induced up-regulation of class II MHC expression is blocked at the level of host cell gene transcription through the Jak-Stat pathway (2). Because viral peptides complexed with class II MHC molecules elicit antigen-specific CD4+ T lymphocytes and support their clonal expansion, this effect may restrict the initial CD4 T-lymphocyte response to VZV. Examination of skin biopsy specimens taken early in the course of varicella or herpes zoster lesion formation demonstrate no class II MHC expression on VZV-infected cells *in vivo,* suggesting transient protection of VZV-infected cells from immune surveillance by CD4 T lymphocytes. In contrast, VZV does not down-regulate class II MHC expression on cells that are exposed to IFN-g before infection. Therefore, VZV-specific CD4+ T lymphocytes that produce IFN-g at the site of VZV replication can limit virus spread to adjacent uninfected cells because local release of IFN-g should make these secondarily infected cells subject to immune clearance.

Other examples of effects of VZV on cell function include interference with apoptosis mediated by Fas ligand (166) (see Chapter 78) and the capacity of VZV gE to act as a Ca^{2+}-independent adhesion molecule, triggering rapid confluence of polarized epithelial cells *in vitro* (244).

Description of Major Antigenic Proteins

As described in Chapter 78, the VZV genome consists of at least 69 unique ORFs (87). No systematic analysis has been made, but sera from human subjects who have had recent varicella or herpes zoster contain immunoglobulin G (IgG) antibodies to many of these gene products, and many have been shown to elicit antibody production in animals (94,395). The antigenicity of viral proteins was first defined by antibody reactivity, but major antigens can now be characterized in terms of their recognition by VZV-specific memory T lymphocytes as well. The broad spectrum of reactivity observed by serologic methods is also documented by T-lymphocyte recognition (23). Whether antibody or T-cell responses are used as the measure, no single protein or class of VZV proteins has emerged as the major antigen or antigens of the virus. The comparison of epidemiologically distinct VZV strains using polyclonal or monoclonal antibody reagents indicates that there is little antigenic diversity among VZV isolates. Japanese isolates have been shown to lack an epitope within the ORF10 gene product when compared with VZV strains from the United States and Europe, as assessed by reactivity to an antiserum generated to an ORF10 synthetic peptide (204). The ORF10 mutation and the gE ectodomain mutant identified in the United States (298) are the only examples of VZV antigenic variants that have been reported.

Initial analyses of the antigenic determinants of VZV focused on the glycoproteins. VZV produces several mature glycoproteins—gB, gC, gE, gH, gI, gL, and gK; other ORFs for putative glycoproteins (e.g., gM) are also present in the genome (86,101,117,148,151,199,203,243,244,253,342) (see Chapter 78). The VZV glycoproteins are important antigens because they mediate the binding of complement and Fc-receptor formation and are presumed to be involved in virus entry and cell fusion (148). The gE protein (Gp I [ORF68]), which is the glycoprotein produced most abundantly in VZV-infected cells, binds the Fc fragment of IgG; it induces antibodies that have neutralizing activity in the presence of complement, as does gI (gp IV [ORF67]), which is noncovalently linked to gE in infected cells (101,224,389). Dominant antibody-binding epitopes of gE have been localized to residues 86 to 105, 116 to 135, and 56 to 75 using human sera (120). Human monoclonal antibodies that bind to gE have been generated (116,326). The gB protein (Gp II [(ORF31]) elicits antibodies that have complement-independent neutralizing activity against VZV and probably has a role in virus entry, by analogy with HSV (148). The gH (Gp III [ORF 37]) and gC proteins (gpV [ORF14]) also induce antibodies with complement-independent neutralizing function (117,199,200 and 201). A monoclonal antibody to gH (gp III) prevented syncytial formation, suggesting that anti-gH (gp III) antibodies can modulate viral pathogenesis even after infection of the target cell (284). Although gC is antigenic, in contrast to the other glycoproteins, gC (gp V) is not always produced by VZV after passage in cell culture (201,246). VZV gK illustrates the discordance between viral protein antigenicity and the role of the protein in replication; gK is not a major antigenic protein, as defined by immunologic criteria, but it is an essential protein for VZV replication (244). All of the major glycoproteins are equivalent and prominent antigens as defined by T-lymphocyte recognition (22). VZV proteins other than the glycoproteins are also important antigens. For example, an increase in antibodies to the viral thymidine kinase follows VZV reactivation; and the IE62 and IE63 proteins are equivalent to the major viral glycoproteins in inducing T-cell responses (14,20,202,294).

Early studies of the antigenic relationships between VZV and HSV demonstrated heterologous antibody responses, especially in individuals who were already immune to HSV when primary VZV infection was acquired (307,380). Comparisons of the DNA sequences and predicted proteins of VZV and HSV, as well as direct experiments using purified VZV glycoproteins and monoclonal antibodies, have accounted for these antigenic relationships, with cross-reactivity due to homology between gB (gp II) and HSV-1 gB being particularly prominent (148). ORFs with homologies to VZV are also present in the pseudorabies virus and simian varicella genomes, but the extent to which the corresponding viral proteins share antigenic determinants is not known (276).

Infection in Experimental Animals

The host range of VZV is highly restricted compared with that of other herpesviruses (250a). VZV infects some nonhuman primates, but the animals have remained asymptomatic, except for varicella in an infant gorilla and transient lesions after experimental inoculation of two chimpanzees (74,251). VZV DNA was detected in PBMC of the chimpanzees after inoculation with VZV, and an erythematous, papular rash appeared in the dermatome near the site of inoculation. Experiments inoculating primates with VZV have also been done in African green monkeys, *Erythrocebus patas,* and pygmy marmosets (248). Infectious virus was not recovered from these animals, but VZV IgG antibodies were elicited; the administration of VZV antiserum before challenge blocked seroconversions in African green monkeys, suggesting that viral replication was required to induce the host response. Protection experiments cannot be done with VZV in primates, except possibly in chimpanzees, because of the absence of symptoms and the failure to recover infectious virus. Simian varicella viruses are antigenically related to human VZV, but the disease caused by these viruses in primates is usually severe (112,115). African green monkeys infected with simian varicella virus expressing green

fluorescent protein developed necrotizing pneumonia (233). Simian varicella infection has been used to evaluate antiviral activity of nucleoside analogues (317). Inoculation of patas monkeys with VZV protects against challenge with delta herpesvirus (112). Human leukocyte interferon prophylaxis modified the interval to onset of disease in an outbreak of varicella-like disease in patas monkeys (19). Simian varicella viruses establish persistent infection of dorsal root ganglia in primates, but symptomatic recurrent disease has not been observed (317). Subclinical reactivation probably occurs because outbreaks of simian varicella have been described in primate colonies housing colony-borne and wild-borne animals (19).

Mice, including suckling mice, are resistant to any signs of disease after infectious VZV challenge, but viral DNA can be detected in ganglia (58). The guinea pig model reproduces some critical events in VZV pathogenesis (231,248,300a). Viremia was demonstrated in strain 2, Hartley, and euthymic hairless guinea pigs after subcutaneous inoculation of VZV-infected cells (231,300a) and nasopharyngeal shedding with animal-to-animal transmission was documented. Strain 2 guinea pigs kept at low temperatures developed a mild exanthem, and euthymic hairless guinea pigs, which are immunologically intact but lack essential genes for hair growth, also have a transient cutaneous eruption that is blocked by passive antibody prophylaxis or antiviral drugs. Limitations of the model include difficulties with achieving adequate inocula of infectious virus and variations in the percentage of animals that develop cutaneous lesions. Administering immunosuppressive drugs to Hartley guinea pigs did not enhance VZV pathogenicity (231). Guinea pigs and rabbits have been used to investigate the pathogenesis of VZV-induced ocular keratitis, and pneumonitis has been described after intrabronchial inoculation of guinea pigs (263,350). VZV reaches the dorsal root ganglia, as shown by *in situ* hybridization (336); VZV was detected in trigeminal ganglia tissue from 63% of infected guinea pigs by polymerase chain reaction (PCR), and thoracic dorsal root ganglia tissue was positive in 75% of the animals (231). Intravitreal inoculation of guinea pigs with a VZV recombinant that expressed *lacZ* caused chronic uveitis, with viral persistence in the ciliary body, iris, and retinal pigmented epithelial cells in some animals (75).

Guinea pigs can be used to evaluate the host response to VZV (232,238,299). Guinea pigs inoculated with VZV develop neutralizing antibodies, antibodies to glycoproteins, delayed-type hypersensitivity (DTH), and helper and cytotoxic T lymphocytes (21,170,232,238). Priming of the T-lymphocyte response was observed in animals immunized with gE, gI, gC, or IE62 protein and exposed to VZV. In protection experiments, the IE62 protein was highly effective, whereas the major DNA-binding protein (ORF29), a nonstructural DNA replication protein, was not (291).

Transfer of virus to dorsal root ganglia cells has been documented after subcutaneous inoculation of adult rats and intraperitoneal inoculation of suckling mice and in mice after ocular infection (10,203,293,384). In adult rats, ganglia harvested after 1 to 9 months showed VZV persistence by immunoperoxidase and *in situ* hybridization; blind passage of cells cultured from ganglia of some animals yielded infectious virus. VZV DNA and antigen were detected in rat neurons and satellite cells 2 weeks after subcutaneous inoculation (10). VZV was also detectable in dorsal root ganglia and other tissue sites for 33 days after ocular inoculation in a mouse model (384).

The SCID-hu Mouse Model

The SCID-hu mouse model of VZV infection differs from other animal systems that assess VZV infectivity across species barriers or evaluate viruses related to VZV in their natural hosts. SCID-hu mice carry differentiated human tissues, which contain the expected cellular subtypes (248). The immunodeficient state allows maintenance of allografts of human thymus-liver, containing CD4+, CD8+, and dual positive T cells, or intact human skin with no murine cells in the allografts. In contrast to HSV, VZV does not escape into murine cells. The SCID-hu model allows the analysis of VZV tropism for these critical cell types (245,246 and 247). Because the mice are immunodeficient, no immune-mediated effects on viral pathogenesis are observed; conversely, the host response to VZV cannot be evaluated in this model. VZV infectivity for T lymphocytes was demonstrated by infectious focus assay and by flow cytometry analysis using VZV-specific antibodies and dual staining with reagents that bind T-lymphocyte markers, such as CD3, CD4, and CD8. Maximum virus titers were observed from 7 and 14 days after inoculation of thymus-liver implants with low passage VZV strains, and cell-free virus is released by VZV-infected T lymphocytes. Infection of skin implants resulted in epidermal lesions that progressed to large vesicles; cell destruction penetrates the basement membrane, extending into the dermis. The histopathologic changes were typical of those observed in varicella lesions; many intact virions were observed by electron microscopy and release of infectious virus was documented (Fig. 2).

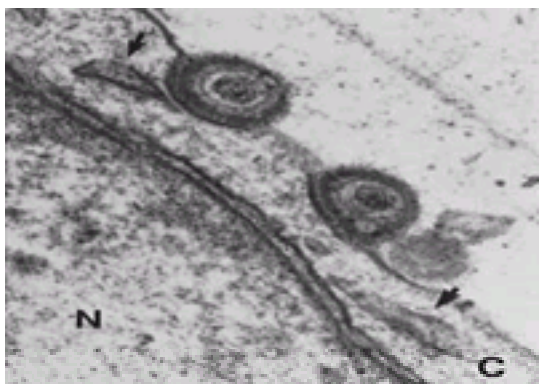

FIG. 2. Varicella-zoster virus (VZV) release from skin cells. Transmission electron micrograph of skin cells 21 days after inoculation with VZV-S. **Left:** Enveloped virons containing dense cores have dispersed from the cell (*arrows*). Vacuoles from which particles egressed are visible adjacent to the cell membrane. Nucleocapsids are not visible in the nucleus (*N*) by this staining method (×24,000). **Right:** Higher magnification view of virions with intact lipid bilayer on cell surface. Remnants of cytoplasmic vacuoles which carried virions to plasma membrane are indicated by *arrows* (×108,000), N, nucleus; C, cytoplasm. (From ref. 246, with permission.)

PATHOGENESIS AND PATHOLOGY

Varicella

Entry into the Host

Primary VZV infection is presumed to be initiated by inoculation of the mucous membranes of the respiratory tract, with infectious virus transferred in respiratory droplets or by contact with infectious vesicular fluid from an infected individual (149). However, documentation of the inoculation stage of VZV pathogenesis by isolation of infectious virus from respiratory sites has not been accomplished.

Site of Primary Replication and Viral Spread

The pathogenesis of primary VZV infection appears to fit the Fenner model for exanthematous illnesses in studies of mousepox, as suggested by Grose (149). Although several of the stages of pathogenesis have not been proved, infectious VZV probably moves to regional lymph nodes after inoculation of mucous membranes, and may undergo a phase of replication at this site (Fig. 3). This event is thought to be followed by a primary viremia during which the virus is transported to the liver and other cells of the reticuloendothelial system. These stages occur during an incubation period of 10 to 21 days. The occurrence of a secondary viremia in the last 4 or 5 days of the incubation period or during the first 24 hours of acute varicella has been documented by isolation of the virus from PBMCs, by *in situ* hybridization, and by PCR (25,206,234,260,344) (Fig. 4). This secondary viremic phase allows the dissemination of the virus to cutaneous epithelial cells. Cell-associated viremia continues after the initial skin lesions develop, as shown by the recovery of VZV from 11% to 24% of PBMC samples taken within 24 hours after the appearance of the varicella exanthem and its detection by *in situ* hybridization or PCR in 67% to 74% of otherwise healthy individuals who were tested immediately after the appearance of the rash (206,302). The frequency of circulating PBMCs that carry the virus is quite low in the immunocompetent host; VZV was detected by *in situ* hybridization in only 0.01% to 0.001% of PBMC during acute varicella (206). Infected, circulating PBMCs are usually cleared within 24 to 72 hours after the appearance of the rash in the immunocompetent host. The phenotype of the PBMC subpopulations that are infected with VZV during the secondary viremic phase has not been determined precisely in children with varicella because of the low frequency of positive cells; B cells and monocytes from acutely infected individuals bind antibodies to VZV proteins, but whether these cells have surface VZV antigens only or are infected is not certain (234). That differentiated human CD4+ as well as CD8+ T lymphocytes are permissive for VZV *in vivo* was demonstrated in the SCID-hu model (245).

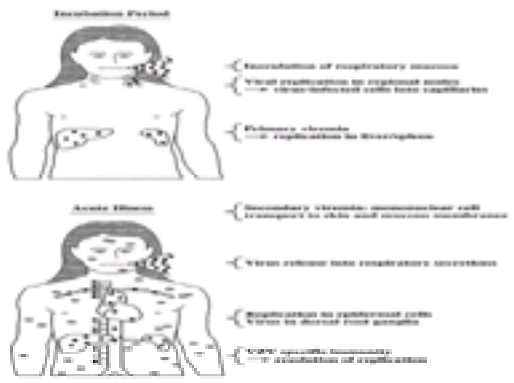

FIG. 3. The pathogenesis of primary infection with varicella-zoster virus (VZV). Primary infection with VZV is initiated by inoculation of the respiratory mucosa. During the incubation period, which lasts from 10 to 21 days, the virus probably spreads to regional lymph nodes and then causes a primary viremia with associated viral replication in the liver and spleen. A secondary cell-associated viremic phase begins at 24 to 96 hours and results in the transport of the virus to skin and respiratory mucosal sites. Replication in epidermal cells causes the characteristic rash of varicella, often referred to as *chickenpox.* The induction of VZV-specific immunity is required to terminate viral replication. The virus gains access to cells of the trigeminal and dorsal root ganglia during primary infection and established latency.

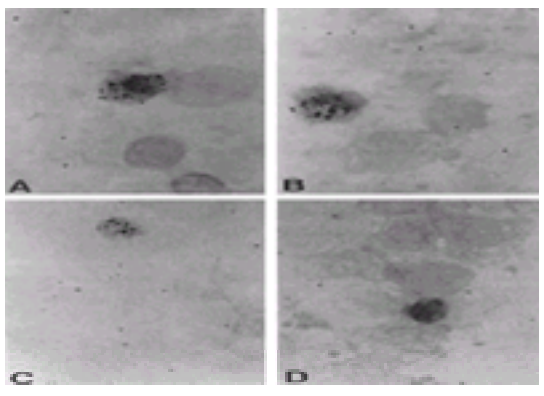

FIG. 4. Detection of varicella-zoser virus (VZV) in peripheral blood mononuclear cells (PBMC) during primary VZV infection by *in situ* hybridization. PMBC obtained from subjects 24 hours after the onset of acute varicella (**A** and **B**) and from a guinea pig 5 days after inoculation with VZV, 9 $\times 10^5$ PFU, showed VZV DNA within the cells after hybridization with a VZV DNA probe (From ref. 207, with permission.)

During the late incubation period, VZV must also be transported back to respiratory mucosal sites because it can be transmitted to susceptible contacts who are exposed within 24 to 48 hours before the appearance of cutaneous lesions. Nevertheless, infectious virus has rarely been recovered from nasopharyngeal secretions during the preeruptive phase and was found in only 4.2% of children with acute varicella; viral DNA has been detected by PCR in oropharyngeal specimens obtained before and after the appearance of the cutaneous rash (302).

Cellular and Tissue Tropism

The essential cellular tropisms of VZV during primary infection include T lymphocytes, skin cells, and cells of the dorsal root ganglia. Although T-lymphocyte tropism is a necessary component of primary VZV infection, the site where T lymphocytes become infected and the molecular mechanisms by which virus entry occurs have not been defined. After the virus has been transported to skin during primary VZV infection, the cells of the epidermis become the major target cells for further replication (Fig. 5; see Fig. 2). The virus may gain access to cutaneous epithelial cells by migration of intact, infected T lymphocytes out of the capillaries into cutaneous tissue, followed by release of virions (245). Alternatively, infectious virus may move from T lymphocytes into endothelial cells forming the capillary walls, followed by replication and spread to adjacent epithelial cells. Viral inclusions and viral proteins have been observed in capillary endothelial cells and in adjacent fibroblasts as well as in epithelial cells from VZV lesion biopsies (9,255). The lymphatics of the superficial dermis are also involved in cutaneous infection, showing dilated lining cells with intranuclear inclusions (220). The pathogenesis of the characteristic varicella lesion was described by Tyzzer in 1906 (340), who noted that the first changes consisted of vasculitis involving the endothelium of small blood vessels and that enlarged, multinucleated epithelial cells with intranuclear eosinophilic inclusions were typical of the second, maculopapular stage of the lesions. These intranuclear inclusions are identical to those that appear in tissue culture cells during VZV replication, indicating direct viral infection of the affected cell type. Progressive “ballooning” degeneration of epithelial cells associated with formation of multinucleated cells, coalescence of fluid-filled vacuoles between cells, and increased numbers of infected cells at the base of the lesion are noted as the maculopapular lesions evolve into vesicles; destruction of the germinal layer of the epithelium is observed in larger lesions (131,220) (Fig. 6).

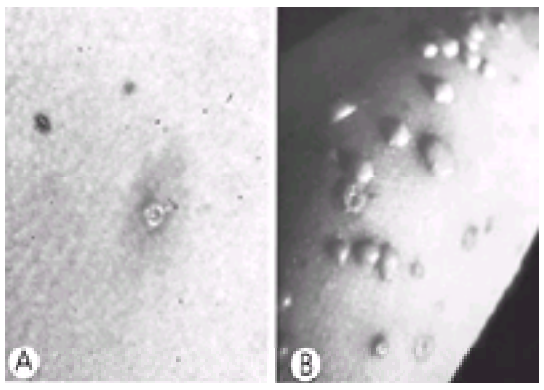

FIG. 5. Varicella skin lesions. **A:** Umbilicated, somewhat elliptical early lesion. **B:** Multiple stages or “crops” of lesions appearing simultaneously. (From ref. 127, with permission.)

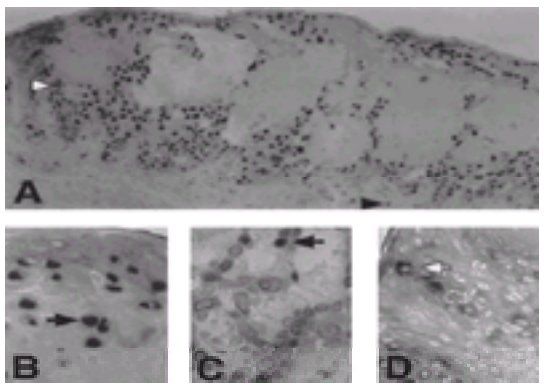

FIG. 6. Punch biopsy specimen of a varicella-zoster virus (VZV) skin lesion analysed for VZV proteins by immunohistochemistry. **A:** ORF29p in the nuclei of VZV-infected cells underlying an intact vesicle. The *open arrow* indicates an infected epithelial cell; the *closed arrow* indicates an inflammatory cell. **B:** Higher magnification of **A**, showing the nuclear localization of ORF29p. **C:** IE63p, which is located predominantly in the nucleus (*closed arrow*). **D:** gC in the cytoplasm of epithelial cells (*open arrow*). (Courtesy of Paula Annunziato.)

Events in the initial stages of primary VZV infection occur with little or no sensitization of the host immune system, as measured by antibody or T-cell responses to VZV antigens. Infiltration of the involved skin sites by inflammatory cells is minimal in the early vesicular phase. Later, cutaneous lesions progress to ulceration and are characterized by necrosis into the dermis. Using electron microscopy, virions can be seen in the capillary endothelial cells of varicella lesions, in the keratinocytes of the epidermis, and as cell-free virus in vesicular fluid. Extensive aggregates of virus particles, including complete and hollow capsids, are visible in the nuclei of some keratinocytes (220). Virions are also detected in lysosomal compartments of macrophages within late-stage lesions. In skin biopsy specimens analyzed by immunohistochemical or *in situ* hybridization methods, early lesions showed IE63 in keratinocytes; later, gE, gB, and IE63 were detected in keratinocytes, sebocytes, Langerhans cells, dermal dendrocytes, monocyte-macrophages, and

endothelial cells. Viral proteins were also expressed in dermal nerves and in perineural type I dendrocytes (9,257).

VZV exhibits tropism for other tissues when cell-associated viremia and viral replication are not controlled adequately by the host response to primary infection; under these circumstances, VZV produces disseminated infection that may involve the lungs, liver, central nervous system, and other organs (250). Lung cells are the most important secondary target of VZV from a clinical perspective because pneumonia is the most common complication of varicella and has a high mortality rate. The pathologic changes of varicella pneumonia are associated with active infection of the epithelial cells of the pulmonary alveoli (13). Infection induces mononuclear cell infiltration of the alveolar septa and edema of alveolar septal cells, along with the accumulation of exudate, formation of hyaline membranes, and desquamation of alveolar cells in the alveolar spaces. Desquamated septal cells in the alveoli and bronchiolar epithelial cells contain eosinophilic intranuclear inclusions, and dense patterns of virions are visible in these cells by electron microscopy. Alveolar cell desquamation and interstitial inflammation interfere with oxygen transfer from the alveoli to the pulmonary capillaries, resulting in severe hypoxemia and respiratory failure. Focal necrosis involving capillaries, alveolar cells, and arterioles is characteristic of fatal varicella pneumonia. Transient replication in the liver is probably a usual component of the pathogenesis of primary VZV infection (149). This process differs from the extensive viral replication in the liver associated with progressive varicella, which causes widespread lysis of hepatocytes and clinical signs of fulminant hepatic failure (107).

The pathogenesis of central nervous system involvement, manifest as meningoencephalitis or cerebellar ataxia, during primary VZV infection is not well defined. The pathologic mechanism of cerebellar ataxia is particularly intriguing because it is associated so uniquely with varicella. Varicella encephalitis is observed in compromised patients who have persistent cell-associated viremia, suggesting a role for direct viral invasion in its pathogenesis. VZV was isolated from the brain tissue of a leukemic child with fatal varicella (332). The detection of herpesvirus particles in cerebrospinal fluid (CSF) by electron microscopy and of viral DNA by PCR support the possibility that varicella encephalitis involves active viral replication in the central nervous system in some cases. That VZV has the potential for invading and replicating in brain tissue is also evident in patients with a form of multifocal leukoencephalitis; VZV has been isolated, detected by electron microscopy, or demonstrated by staining cells for the expression of late viral proteins in these lesions (61). The histopathology of brain tissue from rare cases of fatal varicella encephalitis demonstrates demyelination, axonal damage, perivascular infiltration with mononuclear cells, microglial proliferation, and neuronal degeneration; however, histologic abnormalities are often minimal (332). Vasculitis involving large and small vessels in the central nervous system is an important pathogenic event in these disorders (8,205).

Some neurologic syndromes of varicella have been attributed to an immune-mediated process. The usual complete resolution of neurologic disorders associated with varicella contrasts with the necrotizing encephalitis caused by HSV and is consistent with a vasculitic or immune-mediated pathogenesis. These mechanisms of pathogenesis could account for the common failure to detect VZV in neural tissue and for the predominance of perivenous demyelination, mononuclear cell infiltration, and microglial proliferation, as opposed to the focal necrosis with neuronal destruction that would be expected with direct viral invasion and cell-to-cell spread of infectious virus. Histopathologic correlates of cerebellar ataxia have not been described because this complication is not fatal. It may be an immune-mediated disorder, but ataxia and encephalitis have been described during the preeruptive phase of varicella (225,345).

Thrombocytopenia, a marked decline in the number of platelets in the circulation, can be a pathologic event during primary VZV infection, causing coagulopathy and bleeding disorders. Interference with platelet production by direct viral infection is suggested by the detection of herpesvirus particles within bone marrow megakaryocytes by electron microscopy. Megakaryocytes have toxic changes, including vacuolization and degeneration of the nuclei in cases of hemorrhagic varicella. Platelet survival may be reduced as a result of endothelial cell damage caused by vasculitis or transient hypersplenism, or as part of the syndrome of intravascular coagulopathy. Thrombocytopenia is also a postinfectious complication of varicella, associated with increased production but shortened platelet survival and detection of antiplatelet antibodies (383a).

Adrenal infection, characterized by focal necrosis, is not uncommon in fatal, disseminated varicella. Renal pathology may occur, with hypercellularity of the glomeruli, epithelial proliferation, focal necrosis, and an interstitial inflammatory infiltrate; whether these changes are due to immune-mediated mechanisms or to direct viral invasion is not known. The virus can also cause arthritis, uveitis, myocarditis, pancreatitis, and orchitis, but these inflammatory processes are unusual in the pathogenesis of primary VZV infection.

Placental infection with chronic villitis has been described after maternal varicella in pregnancy (283). VZV can be transmitted to the fetus, probably secondary to maternal viremia, and in rare instances, it causes the congenital varicella syndrome. Varicella embryopathy exemplifies the consequences of VZV infection of cells of the developing nervous system. The unusual characteristic limb hypoplasia of congenital varicella syndrome is attributed to denervation due to infection of spinal ganglia cells, whereas damage to sensory neurons accounts for the unusual cicatricial skin scars, cutaneous defects, and hypopigmented skin areas. Esophageal dysfunction and hydroureter result from damage to the developing autonomic nervous system. Severe microcephaly with cortical atrophy and calcification follows intrauterine encephalitis and necrosis of brain parenchyma.

Release from the Host

An important difference between VZV and the other human herpesviruses is that infectious VZV is released from the infected host in respiratory secretions, allowing its airborne transmission. Isolation of infectious virus from respiratory mucosal sites has rarely been accomplished, despite intensive efforts, but viral DNA can be detected by PCR in specimens obtained from these sites in the late stage of the incubation period and during the first few days of rash (24,302). These observations confirm the epidemiologic evidence that VZV is transmissible for 24 to 48 hours before the exanthem begins (56). VZV DNA has also been detected on the hands of cases and household contacts as well as on environmental surfaces (28). Because many VZV virions are released into vesicular fluid, direct contact with cutaneous lesions provides another mechanism for VZV transmission and probably accounts for the high rate of secondary spread

among close contacts.

Virulence

Naturally circulating strains of VZV do not exhibit intrinsic differences in virulence, as judged by the similar patterns of clinical illness that occur during the annual epidemics of primary VZV infection. VZV isolates that have different geographic or temporal origins vary in their restriction enzyme profiles, but associations with virulence have not been identified. No systematic analyses have been undertaken, but animal experiments done with different VZV strains do not suggest variations in pathogenic potential. Knowledge about the effects of genetic mutations on VZV virulence is limited. In addition to the spontaneously occurring gE mutant, gC (gp V)-negative viruses can be plaque purified after serial passage of VZV in cell culture (201,203,246), and TK-negative variants can be recovered from wild-type virus by selective pressure with antiviral agents (333). These mutations do not affect replication *in vitro,* but VZV gC-negative mutants have limitations in infectivity for human skin cells in the SCID-hu mouse model (246); VZV TK-negative viruses have been isolated from patients given prolonged acyclovir therapy, but no altered pathogenicity has been described (374).

Based on analysis of VZV tropisms in the SCID-hu model, the ORF47 gene product is a virulence determinant for T lymphocytes and skin cells, the ORF66 kinase contributes to infectivity for T lymphocytes, and gC is required for effective replication in skin (245,246 and 247). Eliminating the expression of ORF66, a second serine-threonine protein kinase unique to the alphaherpesviruses caused a partial reduction of VZV infectivity for T lymphocytes but did not impair replication in skin (247). These experiments provided the first evidence that specific VZV gene products have essential roles for viral pathogenesis in differentiated human cells within intact tissues. Despite the fact that the viral proteins are dispensable for VZV replication in cell culture, certain gene products are necessary for efficient T-cell replication (ORF66), and others are required in both skin and T cells (ORF47).

Persistence

Current information about the cellular sites of VZV latency is reviewed in Chapter 78. Briefly, although pathologic documentation is incomplete, latent infection of cells in the dorsal root ganglia appears to follow primary VZV infection invariably (121,143,183,325). How the virus reaches the site of latency is not known. By analogy with HSV, VZV may travel from mucocutaneous sites of replication along the neuronal cell axon to the dorsal root ganglia. Alternatively, as indicated by *in situ* hybridization testing of tissue from a child with fatal varicella, the virus may be carried to sensory ganglia by infected PBMCs before any cutaneous lesions appear.

The characteristics of VZV persistence have been considered to differ significantly from the other human herpesviruses, in which frequent episodes of asymptomatic reactivation are demonstrated by recovery of infectious virus from mucocutaneous sites, or the virus persists in circulating peripheral blood cells. It is true that reactivation of VZV has been difficult to document virologically in the absence of cutaneous lesions. However, periodic episodes of subclinical VZV reactivation probably occur, unless mechanisms for restricting the replication of the latent virus are extraordinarily efficient compared with those governing other herpesviruses. In support of this hypothesis, subclinical VZV viremia was demonstrated by PCR in 19% of bone marrow transplant recipients who had no clinical symptoms of herpes zoster, and elderly adults have episodes of transient, asymptomatic VZV viremia (90,308,377).

Recurrent Infection: Herpes Zoster

The pathologic consequence of VZV reactivation is a vesicular rash that usually involves the dermatomal distribution of a single sensory nerve. The pattern of unilateral dermatomal involvement is so consistent that early mapping of the sensory dermatomes was based in part on observations of the cutaneous areas involved during episodes of herpes zoster (190). The histopathology and cellular expression of viral proteins in recurrent cutaneous lesions generally resemble varicella lesions (9,255,361) (see Fig. 6). By immunohistochemistry, VZV proteins were detected in the erythematous stage only in ballooning cells of the lower epidermis or follicular epithelium; biopsies of vesicular lesions showed viral proteins in cells within the intraepidermal vesicles and in histiocytes of the dermis; and in the late pustular stage, viral antigens were detected primarily in necrotic keratinocytes (249). In addition, viral proteins and inclusion bodies have been described within the small nerves in the dermis beneath the vesicles, which is consistent with transmission of the virus to the epidermis along cutaneous nerve pathways instead of by infected PBMCs, as occurs during primary VZV infection (9,220).

As described in Chapter 78, the pathologic changes of acute VZV reactivation in dorsal root ganglia have been documented in a few patients who died of other causes during an episode of herpes zoster. VZV has been identified in both neuronal and nonneuronal cells of dorsal root ganglia by the histopathologic detection of inclusion-containing cells, immunofluorescence staining to demonstrate cells expressing viral proteins, viral culture, and *in situ* hybridization (36,106,143). The pathologic changes include inflammatory necrosis of dorsal root ganglia, motor and sensory root degeneration, neuritis and segmental myelitis, and localized leptomeningitis. In contrast to HSV, recovery of infectious VZV from explant cultures of human ganglia has been accomplished only when the patient had acute infection at death (270,314).

Cell-to-cell spread of VZV within ganglia, or reactivation in many cells, allows access of the virus to sensory neural axons for transport to skin. The appearance of clusters of lesions in scattered areas of the involved dermatome suggests infectious virus transport along multiple axons. Subsequent cell-to-cell spread probably occurs between skin cells in the involved dermatome. Inflammation and necrosis sometimes extend into the anterior horn cells, producing deficits of motor function. VZV has been isolated from the spinal cord of a patient with transverse myelitis, and herpes particles were observed in the glial cells of the spinal cord by electron microscopy; extensive necrosis of the affected segments of spinal cord was observed with destruction of gray and white matter, mononuclear cell infiltration, and replacement of neural tissue with fibrin (194). VZV-infected cells have been detected in subependymal microvessels in fatal cases of VZV reactivation (305). VZV reactivation in the absence of cutaneous rash was documented using histochemical stains to

demonstrate VZV-infected cells in the meninges and nerve roots of an immunosuppressed patient who had acute radiculoneuropathy (95). Three pathologic patterns of VZV encephalitis have been described, including cases associated with infarction of large or medium vessels; those characterized by deep white matter, ovoid mixed necrotic, and demyelinative lesions due to small vessel vasculopathy; or cases with ependymal and periventricular necrosis associated with vasculopathy of subependymal vessels and secondary infection of ependymal and other glial cells in the periventricular region. Many cases have features of two or three of these patterns (205).

The pathogenesis of VZV reactivation in the immunocompromised host differs in that the dermatomal rash is usually more extensive, and cutaneous replication is often accompanied by cell-associated viremia (109,341). Unusual, chronic, verrucous lesions have been described in patients with acquired immunodeficiency syndrome (AIDS) who had recurrent VZV infection (Fig. 7); these lesions were characterized histologically by epidermal hyperplasia and massive hyperkeratosis with multinucleated giant cells, necrotic acantholytic keratinocytes, and the detection of VZV by viral culture and PCR (3,219,256). In compromised patients, VZV can disseminate hematogenously to cause the same pathologic consequences that occur in patients with progressive varicella, including infection of lung, liver, central nervous system, and other organs. In some cases, VZV reactivation in immunocompromised patients produces visceral dissemination without clinical signs of localized dermatomal disease; these cases suggest that the virus can be taken up by T lymphocytes trafficking through ganglia, so that cell-associated viremia occurs without initial axonal transport of the virus to skin and cutaneous replication (229). VZV has been found by PCR in CSF from patients who have human immunodeficiency virus (HIV) infection, with or without signs of VZV encephalitis or meningoencephalomyelitis (68). Multiple cutaneous isolates or cutaneous and blood isolates from individual patients with herpes zoster and viremia have indistinguishable restriction endonuclease patterns when viral DNA is analyzed, indicating that no alteration of the virus is required for progressive or invasive disease.

FIG. 7. Recurrent varicella-zoster virus (VZV) infection in a patient with human immunodeficiency virus–related acquired immunodeficiency syndrome (AIDS). This photograph illustrates the unusual hyperkeratotic cutaneous lesions observed in patients with AIDS who have VZV activation and who fail to establish latency after varicella. A chronic course with continued or intermittent formation of new lesions is common. (Courtesy of S. Straus.)

Reinfection

Reinfection with VZV appears to be a very rare event. Second episodes of varicella are described, but confirming reinfection with VZV is difficult because vesicular rashes in childhood have other etiologies and laboratory documentation is usually lacking. One adult known to have antibodies to VZV before exposure developed varicella 15 days later; clinical varicella has also been described in three children with leukemia despite serologic evidence of past infection with VZV (136). In a cohort of adults who developed varicella despite a past history, none had VZV antibodies in sera that had been obtained before the acute illness (349). Most immunocompromised patients who have had primary VZV infection and develop clinical signs of varicella probably have generalized, atypical reactivation without dermatomal involvement, rather than reinfection. Differentiating generalized reactivation of endogenous latent virus and reinfection requires comparing restriction endonuclease patterns of the DNAs of the VZV isolates from the first and second episodes, which is seldom possible. Immunologic evidence of reinfection is indirect; whether the increases in antibody and cellular immunity to VZV that occur when immune subjects have close contact with the virus mean that the virus reaches any of the sites of replication that are characteristic of primary VZV infection is not known. Antigen presentation with enhancement of adaptive immunity may occur without any viral replication, as is observed when immune individuals are given inactivated varicella vaccine (320).

The Host Response

Primary Infection: Varicella

Although primary VZV infection almost always causes disease, the host response terminates its progression within a few days. VZV has evolved to infect cells of the host immune system directly, exhibiting tropism for T lymphocytes. Although the virus has mechanisms for transient immune evasion of CD4 and CD8 T-lymphocyte responses, replication is controlled when virus-specific immunity is induced (22). Unless the host is compromised, this pattern of virus–host interaction favors the virus first because cutaneous viral replication allows VZV transmission, and then the host, because the acquisition of memory immunity protects against illness upon subsequent exposures and preserves latency, or at least blocks disease owing to VZV reactivation.

Innate Immunity

Natural killer (NK) cells from nonimmune individuals have the capacity to lyse VZV-infected fibroblasts, which can be

enhanced by incubating the effector cells with interleukin-2 (IL-2); this cytotoxic activity is eliminated when PBMCs are incubated with anti-CD16 antibodies in the presence of complement (47,185,186). IFN-a is detected in serum at the onset of varicella (16,18,348) and may limit early viral replication, as suggested by its clinical efficacy in modifying the severity of varicella in immunocompromised children and the association of more severe varicella in adults with reduced serum IFN-a. Granulysin is a novel cytolytic protein made by NK cells as well as by antigen-specific CD8+ T lymphocytes. Granulysin enhances the death of VZV-infected cells *in vitro* and inactivates intracellular virus (166), reversing viral inhibition of apoptosis. IFN-g, NK cell cytotoxicity, and granulysin represent innate mechanisms for controlling spread of the virus before adaptive immunity is elicited.

Adaptive Immunity

Primary VZV infection is associated with the production of IgG, IgM, and IgA antibodies directed against many viral proteins (13,15,45,94,137,214,327). Antibodies are not present in serum during most of the incubation period but may be measured in low concentrations at the time of onset of the varicella exanthem and become detectable within 3 days in most individuals. Antibodies to VZV proteins have neutralizing activity, either directly or in the presence of complement, and function in antibody-mediated cellular cytotoxicity (118,185,307). Neutralizing activity by antibodies to VZV gE is mediated through three distinct domains as mapped using monoclonal antibodies (385). That virus-specific antibodies can interfere with the initial phases of VZV replication *in vivo* is evident from studies showing that the attack rate for varicella is reduced by VZV immune globulin prophylaxis (390). Even if infection occurs, the severity of the cutaneous disease and the risk for varicella pneumonia are modified by passive antibody administration, indicating that passive antibodies present at the beginning of the incubation period can restrict the pathogenic potential of the virus. The modulation of viral replication *in vitro* by monoclonal antibody to gH (gp III) suggests that anti-gH (gp III) antibodies may mediate this effect (284). Whether antibodies limit replication at initial sites, such as mucous membranes or lymphoid tissue, or block or diminish primary viremia is not known. Transplacentally acquired IgG antibodies to VZV also protect infants from primary VZV infection, or modify the severity of varicella. In contrast, passive antibodies administered after the appearance of the varicella rash have no effect on disease progression. The role of the active humoral immune response in limiting the progression of primary VZV infection also appears to be limited. Children with agammaglobulinemia had uncomplicated varicella, whereas those with primary immunodeficiency diseases affecting cell-mediated immunity often died (13). Among healthy children, the early detection of high IgG or IgM antibody titers against VZV does not predict milder infection, and immunocompromised children may develop progressive varicella despite adequate production of VZV antibodies (16). Whether failure to produce antibodies to particular viral proteins is important in the host response is not known, although some immunocompromised children with progressive varicella lack VZV IgG antibodies to some major viral proteins (360).

The critical role of virus-specific cell-mediated immunity has been shown in studies correlating the induction of virus-specific T-cell recognition with the outcome of primary VZV infection (reviewed in 22 and 23) (Table 1). Intact cellular immunity appears to be important for terminating cell-associated viremia as well as limiting virus replication at localized cutaneous sites. Healthy children who have T lymphocytes that recognize VZV antigens within 24 to 72 hours have milder primary VZV infection, with fewer cutaneous lesions (16). An absolute lymphopenia of less than 500 mm^3 at the onset of illness and a failure to acquire VZV-specific T-cell proliferation correlates with persistent viremia and dissemination in high-risk children (16,210). T-lymphocyte proliferation to VZV antigen is accompanied by the production of cytokines of the helper T-cell subtype 1 (T_H1) type, including IL-2 and IFN-g (38,190,394). IFN-g, which potentiates the clonal expansion of virus-specific T cells, is detected in serum during acute varicella (16). By comparison with children, adult subjects were less likely to have detectable IFN-g at the onset of primary VZV infection, but there was no correlation between relative serum tumor necrosis factor-a (TNF-a, IL-2, or IFN-g concentrations and disease severity in adults with varicella (348).

Host	Clinical/VZV T-cell proliferation Correlations		
Healthy susceptible	Varicella	Early acquisition	Mild infection
Immunodeficient susceptible	Varicella	Delayed or no acquisition	High risk for dissemination
Healthy immune	Varicella exposure	Enhanced response	No disease
Healthy immune	Age >60 y	Low or absent response	High risk for herpes zoster
Immunodeficient immune	Low or absent response	High risk for herpes zoster and dissemination	

From Arvin AM, Cell-mediated immunity to varicella-zoster virus. J Infect Dis 1992;165(Suppl 1):S62–S67.

TABLE 1. *Correlations between cell-mediated immunity and varicella-zoster virus disease*

T lymphocytes from healthy immune subjects recognize gB, gC, gE, gH, gI, and the immediate early gene products of ORF62 and ORF63 (22,23,169,294). T-cell responses to gE, gH, and the IE62 protein are elicited during primary VZV infection, although the kinetics of acquisition of T-cell immunity to each of these VZV proteins varies; VZV infection also induces T lymphocytes that recognize gB and gC (169). Cell-mediated immunity to IE62 and IE63 proteins, gE, gB, gH, and gC persists for years after primary VZV infection in the immunocompetent host (14,23) (Table 2). When responses to synthetic peptides corresponding to residues of the IE62 protein and gE were evaluated, immune donors had circulating T lymphocytes that recognized an average of 7 of 10 IE62 peptides and 6 of 10 gE peptides (39). Dendritic cells acted as potent antigen-presenting cells to induce recognition of VZV peptides by naive donor T lymphocytes, and positive response to a peptide was predictive of T-cell sensitization against the same epitopes after *in vivo* exposure to VZV (191). T-cell clones that recognize amphipathic regions of gB and gI, some of which exhibit B-cell helper function, are also present in CD4+ T-cell populations from immune individuals (169). The memory helper T-cell response is associated

with the persistence of IgG antibodies that bind to all of the glycoproteins and to many other VZV polypeptides (57,94,151,360).

Assay	T-cell subset	Viral proteins

TABLE 2. *Varicella-zoster virus proteins and peptides recognized by T lymphocytes from immune individuals*

T lymphocytes that exhibit class I and class II MHC-restricted lysis of target cells expressing VZV antigens can also be demonstrated from immune individuals (92,175,179). VZV-specific CD4+ T cells, which are class II MHC restricted, have cytotoxic function against autologous lymphoblastoid cells expressing VZV proteins (92). CD8+-mediated cytotoxic T-lymphocyte (CTL) activity has also been demonstrated using VZV-infected fibroblasts as targets, which express only MHC class I antigen, and by testing highly purified subpopulations of CD8+ T lymphocytes as effectors against lymphoblastoid cells expressing VZV proteins (20,175). CTLs that recognize the IE62 protein or gE are present in both the CD4+ and CD8+ memory T-cell populations, at equivalent precursor frequencies (22). VZV gC or gI is also recognized by CTL from immune donors, as are the structural-regulatory proteins encoded by ORF4 and ORF10 (22,179,312). The ORF33 gene product, a virion assembly protein, is immunogenic in animals but has not been evaluated for recognition by human T lymphocytes (127).

Memory immunity to VZV is required to preserve latency. VZV memory T lymphocytes are maintained at precursor frequencies of about 1 per 20,000 to 40,000 PBMCs in immune adults (168,221). Memory CD4+ and CD8+ CTLs specific for particular VZV proteins are present at frequencies of about 1:150,000 PBMCs. By intracellular cytokine assay, the mean percentage of VZV-specific CD4 T lymphocytes was 0.12% by IFN-g synthesis and 0.34% using TNF-a as the marker (29). Immune subjects also have persistent DTH responses to VZV skin test antigens (195). Cellular immunity is likely to be enhanced periodically in immune individuals because of exogenous reexposures. Enhanced VZV T-cell proliferation responses, as well as increases in IgG antibodies, occur in immune adults after household contact (17). Immune children who are reexposed to varicella also have a significant enhancement of DTH to VZV. Although symptomatic reinfection with VZV is rare, these immunologic changes indicate that reexposure to the virus may result in subclinical reinfection, or at least in a sufficient uptake of viral antigens by antigen-presenting cells to boost immunity. VZV DNA was detected by PCR in nasopharyngeal secretions from immune household contacts of children with varicella (28,80). The potential for endogenous reexposure to increase the frequency of VZV specific T lymphocytes is also suggested by the enhanced responses of elderly immune adults given varicella vaccine (171,259). The gene products of ORF4, ORF21, ORF29, ORF62, and ORF63 may be expressed in neuronal or satellite cells during latency, but peptides can only be detected in MHC complexes, and class I MHC requires IFN-g exposure to be up-regulated on neurons; because satellite cells express class I MHC, and class II can be induced, these cells could function for antigen presentation. Whether co-stimulatory molecules necessary for signaling CD4 and CD8 T-lymphocyte expansion are expressed by neurons or satellite cells harboring VZV is not known. However, if conditions for antigen presentation occur, VZV immunity could be maintained by repeated antigenic stimulation due to subclinical VZV reactivations, producing endogenous reexposure to viral antigens. This possibility is supported by the recovery of cell-mediated immunity to VZV in bone marrow transplant recipients who have not had any clinical signs of herpes zoster but in whom subclinical reactivations can be detected by PCR (377).

Recurrent Infection: Herpes Zoster

The high incidence of herpes zoster in elderly and immunocompromised patients suggests that host factors have a significant effect on whether VZV reactivation occurs, or at least on whether reactivation produces symptomatic disease. That cellular immunity is essential for maintaining the balance between the host and the virus is indicated by correlations between diminished *in vitro* T-lymphocyte proliferation to VZV antigens in elderly patients and in patients receiving immunosuppressive therapy, and their susceptibility to herpes zoster (13). Among these high-risk populations, low or absent cellular immune responses to VZV represent a necessary but not a sufficient condition for the occurrence of symptomatic recurrent VZV. Patients who have the most severe and prolonged suppression of VZV-specific cellular immunity are at highest risk for herpes zoster, viremia, and dissemination. The age-related increase in the risk for herpes zoster among elderly subjects is attributed to immunosenescence and has been correlated with a decrease in DTH responses to VZV skin test antigen as well as a decrease in the frequencies of circulating T lymphocytes that recognize VZV antigen (29,195).

When reactivation occurs, T-lymphocyte responses increase immediately (168). The resolution of the rash is accompanied by local production of IFN-a in lesions (324). Unless further immunosuppression intervenes, enhanced immunity persists for a prolonged period and may explain why second episodes of herpes zoster are rare. Herpes zoster in young children after intrauterine or early postnatal varicella and the short interval between primary and recurrent VZV infections in children with HIV infection probably represent inadequate cell-mediated immunity (31,89). Among children with HIV infection, 70% of those with fewer than 15% CD4 T lymphocytes, when they acquired varicella, developed

zoster (89).

The susceptibility of elderly and immunocompromised individuals to VZV reactivation is not associated with decreasing titers of VZV IgG antibodies (360). No effect on viral replication at local cutaneous sites was demonstrated when high-titer VZV immune globulin was given to immunocompromised individuals with herpes zoster (324), but low VZV IgG titers may enhance their susceptibility to viremia (360).

EPIDEMIOLOGY

Incidence and Prevalence

Varicella

VZV is a ubiquitous human pathogen with a worldwide geographic distribution. The annual incidence of varicella has been 4 million cases a year in the United States, equivalent to the annual birth rate, but this incidence is expected to fall with the introduction of the varicella vaccine (161). Without immunization, early childhood is the peak age for primary VZV infection. In the 1970s to 1980s, the highest annual incidence occurred in U.S. children who were 5 to 9 years old (89 to 90 cases per 1,000), followed by those aged 1 to 4 years (79 to 82 per 1,000); in the early 1990s, the incidence was highest in preschool-aged children, suggesting a change in the epidemic pattern, perhaps related to day care center exposures (371). By 20 to 29 years of age, only about 5% of individuals remain susceptible in the United States and other geographic areas with temperate climates (88,108); the susceptibility rates are higher among African Americans in each age cohort up to 40 years. Although the percentage of adults who give a clinical history of varicella is as low as 50%, the discrepancy reflects failure to identify or recall mild cases of varicella or incorrect diagnoses (226). In tropical regions, only about half of individuals who are younger than 24 years old have had varicella (129,236,259). In these regions, rural populations have lower seroprevalence than adults living in cities (236). Only 42% of rural adults had been infected with VZV; higher susceptibility rates were also observed in early studies in rural Massachusetts, suggesting that living conditions rather than climate may account in part for the lower incidence of varicella in some areas. The varicella attack rate is very high when susceptible adults from tropical areas move to temperate zones.

Restriction digest patterns demonstrate the identity of epidemiologically related VZV isolates and variability in unrelated isolates (49). For example, profiles obtained using a few restriction enzymes differentiate many VZV isolates recovered in the United States from children with varicella from the Oka strain, a Japanese clinical isolate used to produce the live attenuated varicella vaccine (3,213). However, these differences are not known to reflect clinically significant strain differences that could account for variations in prevalence (331). Further analysis of VZV isolates from diverse geographic locations may lead to new understanding of these patterns of high and low prevalence. Although incidence and prevalence rates must be multifactorial, differences in incidence may also have some as yet undefined relationship to host susceptibility to primary VZV infection.

Herpes Zoster

Because herpes zoster is caused by the reactivation of latent virus, susceptibility requires previous primary VZV infection. Given the high incidence of varicella, most adults are at risk for VZV reactivation. Early studies documented the incidence of herpes zoster as 3.4 cases per 1,000 people per year in the United Kingdom (177). Herpes zoster was very rare in children younger than 10 years old, occurring at a rate of 0.74 per 1,000 persons per year. Although herpes zoster is rare in childhood (155), varicella during the first year of life, or VZV infection acquired by intrauterine transmission, is associated with an increased risk; the incidence of herpes zoster was 2.8 times higher compared with that in children who had varicella after the first year (31). Hope-Simpson observed that the incidence rose to 7.8 cases per 1,000 people older than 60 years of age, compared with 2.5 per 1,000 people 20 to 50 years of age (177). The incidence continues to rise after age 60 years, such that the lifetime risk is as high as 50% among those who survive to 85 years (304). The disease burden of herpes zoster in the United States is about 600,000 cases per year (1.7 per 1,000 population) and will increase predictably as the population ages (304). Incidence rates are equivalent between men and women. Herpes zoster is significantly less common in black Americans than in whites (303). A comparison of white Hutterite and non-Hutterite populations in Manitoba revealed a lower rate of herpes zoster among the Hutterites as well as a lower incidence of varicella before age 10 years and lower seroprevalence at all ages, suggesting that later age at acquisition of primary VZV infection may correlate with a reduced risk (288). Analysis of stressful life events did not reveal a definite relationship to risk of herpes zoster (304). Second episodes of herpes zoster are rare among healthy individuals; the frequency was 4% in the Hope-Simpson study and 1.7% to 5.2% in U.S. studies (125,279).

Herpes zoster is particularly frequent among patients with leukemia, Hodgkin's and non-Hodgkin's lymphoma, and oat cell carcinoma of the lung. Patients with Hodgkin's disease often undergo splenectomy, but splenectomy alone does not appear to predispose patients without underlying malignancy to VZV reactivation. The incidence of herpes zoster after bone marrow transplantation is very high, with attack rates of 25% to 50% reported during the first year. Among renal transplant recipients, 15% had had herpes zoster at a mean of 5 years after transplantation. Patients with systemic lupus erythematosus are also more likely to develop herpes zoster, with an estimated incidence of 22 cases per 1,000 person years (237). Clinical experience suggests that steroid therapy enhances the risk in patients with collagen vascular diseases, but prospective studies have not been reported. The incidence of herpes zoster is estimated to be 15 to 25 times higher in individuals with HIV infection than the general population, and 3 to 7 times higher in those with HIV than among healthy elderly adults (59,140,176). HIV infection increases the risk for herpes zoster regardless of age. Among HIV-infected children, 27% had herpes zoster within a mean of 1.9 years after varicella (138).

Although cancer is correlated with a higher risk for herpes zoster, herpes zoster in healthy individuals is not associated with an increased risk for malignancy (280). Herpes zoster associated with risk factors for HIV infection suggests this underlying diagnosis, but herpes zoster is not a marker for enhanced risk for HIV progression.

Epidemic Patterns

Episodes of herpes zoster provide a continuous source for transmission of VZV to susceptible individuals, who then develop varicella. VZV causes annual epidemics of varicella in temperate regions, particularly during the late winter and spring. Epidemic years characterized by a high incidence of varicella are followed by years in which fewer cases occur (67,371). Varicella epidemics probably begin from sporadic cases in children caused by exposures to recurrent VZV in adults. Amplification to involve large numbers of susceptible children results from the relative efficiency of VZV transmission by the respiratory route. The annual pattern of varicella epidemics may be related to the return of children to school, which heightens close contact among newly infected and susceptible children. A clinical experience reported from the Shetland Islands illustrated the origin of a varicella outbreak in an isolated population from a single adult case of herpes zoster. The attack rate for previously uninfected household contacts exposed to varicella is about 90%, whereas the transmission rate from more casual exposures, such as those associated with school classrooms or hospitals, is estimated at 12% to 33%. In a day care center outbreak, the cumulative attack rate was 88% over a 15-week period, indicating a much lower secondary attack rate from index cases than occurs in households (99a). The attack rate for primary VZV infection in children is not affected by sex or by ethnic or socioeconomic factors. Varicella epidemics may have been less well sustained in rural communities when the demographics of the United States was characterized by a more scattered distribution of the population. Why varicella epidemics are less extensive in tropical areas is difficult to explain because the overcrowded living conditions that are common in many of these regions of lower prevalence should enhance the spread of the virus. These effects may be countered by more dispersed population in rural conditions.

New cases of herpes zoster are diagnosed with the same frequency throughout the year, exhibiting no seasonal pattern (177,279). The epidemiology of herpes zoster reflects the fact that this infection originates from the reactivation of endogenous, latent virus rather than exogenous acquisition. Some clinical case reports have suggested that exposures to varicella resulted in herpes zoster, but the epidemiologic data do not support a mechanism of transmission in which reinfection results in localized disease, and there is no known mechanism by which reactivation of endogenous VZV would be triggered by a new exposure. The probable effect of these exposures is to enhance VZV immunity and, potentially, to reduce the risk for recurrent VZV disease (17).

Morbidity and Mortality

The high prevalence of symptomatic primary and recurrent VZV infections in the general population means that almost all individuals experience some morbidity due to VZV in the course of their lives (64,65,271). Morbidity in otherwise healthy individuals is usually limited to the symptoms caused by the acute illness and the inability to pursue usual activities for a period of 1 to 2 weeks. The risk for life-threatening morbidity or mortality during primary or recurrent VZV infection depends on host factors rather than virulence characteristics of the virus.

Varicella

In 1935, Bullowa and Wishik (60) observed that varicella is “the disease of childhood which is taken least seriously by the laity and by the medical profession.” Nevertheless, varicella complications result in annual hospitalization rates of 11,000 per year in the United States (2.2 to 4.3 per 1,000 cases). Serious complications are least common among children 1 to 9 years old and are 6 to 15 times higher among adults. Case fatality rates are 10 and 24 times higher in infants (6.7 per 100,000 cases) and adults (17.1 per 100,000 cases), respectively, than in children 1 to 4 years of age (0.7 per 100,000) (311). Secondary bacterial infections, usually caused by *Staphylococcus aureus* or *Streptococcus pyogenes,* constitute the most common cause of varicella-related morbidity and mortality in children (114,173,174,213). Mortality from sepsis or necrotizing fasciitis remains significant despite antibiotic therapy (114). One third of invasive group A streptococcal disease in children is associated with varicella (154). Most of the increased morbidity and mortality in adults is due to varicella pneumonia (67,156,157,258,271).

Neurologic complications are the second most common indication for hospitalization of immunocompetent children with varicella (114,157). Primary VZV infection accounted for 13% of encephalitis cases of known etiology from 1972 to 1977 (271). Central nervous system morbidity is higher among patients younger than 5 years and older than 20 years of age (272). The mortality rate due to neurologic complications of varicella among otherwise healthy children and adults is difficult to estimate because compromised patients are included in some reports, and VZV encephalitis is not easily distinguished from Reye's syndrome. Reye's syndrome was estimated to affect healthy children with varicella in 2.5 per 10,000 cases before the association with salicylates was reported (182). Estimates of mortality due to central nervous system complications have ranged from 5% to 18%; when encephalitis was distinguished from cerebellar ataxia, mortality rates were 35% and 0%, respectively (192). No precise data are available concerning the risk for long-term sequelae; most patients recover fully, but some have recurrent seizures and neurologic deficits (271). Although arterial ischemic strokes are rare in children, one case-control study showed a significant association with VZV infection (309).

Data concerning varicella morbidity and mortality among children with lymphoproliferative malignancy or solid tumors, accumulated before effective antiviral drugs were available, showed that 32% to 50% of patients developed visceral dissemination; varicella pneumonia occurred in 20% of cases; and the mortality rate was 7% to 17% (111). Children with acute lymphoblastoid leukemia or lymphoma were at highest risk, and disease severity was enhanced if chemotherapy had been given during the incubation period—especially within 5 days before the appearance of the rash—and if the patient had an absolute lymphopenia of less than 500 cells.

Varicella during pregnancy may be fatal, or serious for the mother and fetus or infant. Most women of childbearing age who were born in geographic regions where epidemics occur annually have had varicella. In the United States, the incidence of maternal varicella was 0.7 per 1,000 women; a recent prospective study in Germany showed an incidence of 2 per 1,000 pregnancies (103). Although some retrospective reports indicate maternal mortality rates as high as 41%, Siegel and colleagues (316) found one maternal death due to varicella pneumonia among 150 pregnancies (0.7%) complicated by varicella; surveillance of 1,373 cases showed a predicted maternal mortality rate of 1 per 2,000 cases

(103). Varicella pneumonia is the cause of most maternal deaths and may be more common when varicella occurs during the third trimester. The outcome of pregnancy may be affected adversely by spontaneous abortion, fetal demise, and premature delivery, although the frequency of these complications is low (32).

The congenital varicella syndrome (CVS) is a rare consequence of maternal varicella during pregnancy (103,275). The highest risk for varicella embryopathy follows primary VZV infection during the first 20 weeks of gestation and is estimated to be 1% to 2% (32,103). Among 1,373 pregnancies, CVS occurred in 0.4% when maternal varicella occurred from 0 to 12 weeks' gestation, compared with 2% for infection from 13 to 20 weeks' gestation (103). Maternal varicella later in pregnancy was associated with cutaneous scarring, limb deformities, or unilateral ocular defects (241,296). VZV-specific immunity in asymptomatic infants and herpes zoster in infancy, without prior varicella, indicate that the virus is transmitted to the fetus during the second and third trimester of maternal varicella with about the same frequency as in the first trimester (262); in a large prospective study, no infants had CVS or other morbidity at birth if the mother had varicella between 25 and 36 weeks' gestation, but the incidence of herpes zoster in early childhood, a marker for intrauterine infection, was 1.7% (103). When maternal varicella occurs at the end of gestation, infants are at risk for neonatal varicella, with an attack rate of about 20% (272). Without passive antibody prophylaxis, the mortality rate was about 30% in infants whose mothers developed varicella from 4 days before to 2 days after delivery, whereas none of the infants whose mothers had varicella from 21 to 5 days before delivery had serious disease.

Herpes Zoster

Herpes zoster is not commonly fatal, even in compromised patients. Postherpetic neuralgia (PHN) is the most common and potentially disabling morbidity due to herpes zoster. PHN lasting from 4 weeks to more than 10 years occurs in about 10% of all patients with herpes zoster (279,280). The frequency of PHN is higher in older patients, increasing from 3% to 4% in those 30 to 49 years of age, to 21%, 29%, and 34% in patients 60 to 69, 70 to 79, and more than 80 years of age, respectively (177). Children are not at risk for PHN (172). Among older patients, symptoms persisted for more than 1 year in 22%. The average age of patients with PHN was 67 years, compared with 46 years among those without PHN (279). The prevalence of pain at 30 days after the onset of rash was 15-fold higher among those older than 50 years of age. In an analysis of 2,367 subjects who participated in controlled trials of antiviral drugs, age over 50 years, prodromal symptoms, and the severity of acute pain at diagnosis showed the highest correlation with risk for PHN. The risk for prolonged pain was higher when two or more of these factors were identified (375). The risk for PHN is not predictable from the severity of the cutaneous eruption. Immunocompromised patients appear to be at higher risk for PHN.

The incidence of zoster-associated encephalitis ranges from 0.2% to 0.5%. Risk factors include older age and cranial nerve involvement. The mortality rate of cerebral angiitis following herpes zoster is much higher, with a case-fatality rate as high as 20%. Immunosuppressive therapy for malignancy increases the morbidity and mortality associated with herpes zoster, due primarily to a higher risk for VZV pneumonia, although the overall risk for fatal VZV infection after reactivation of the virus in immunocompromised patients remains less than 1%. VZV reactivation as atypical, nonlocalized zoster in immunocompromised patients has a much worse prognosis than localized herpes zoster; the risk for visceral dissemination was 45% in bone marrow transplant recipients, and mortality was 28% without antiviral treatment (229). HIV infection predisposes patients to a higher risk for progressive or chronic cutaneous lesions, meningoencephalitis, and retinitis (4,59,70,79).

Motor deficits occur in an estimated 1% of cases of herpes zoster and are prominent when the facial nerve is involved (279). Significant residual loss of function has been described in 10% to 15% of patients. Transverse myelitis is an extremely rare complication of herpes zoster, but the mortality rate for this complication was 22 of 41 cases.

Herpes zoster is not unusual in pregnancy, but it does not cause significant maternal or fetal morbidity. Enders and colleagues identified no intrauterine infections in 366 pregnancies complicated by maternal herpes zoster (103). The only case of congenital varicella syndrome after maternal herpes zoster was associated with disseminated infection, indicating viremia. No cases of neonatal varicella have been associated with maternal herpes zoster at term.

CLINICAL FEATURES

Varicella

Varicella follows an incubation period that ranges from 10 to 21 days, with symptoms most often beginning between 14 and 16 days (386). Prodromal symptoms of fever, malaise, headache, and abdominal pain precede the appearance of the rash by 24 to 48 hours in about 50% of patients. Fever, irritability, listlessness, and anorexia are prominent during the 24 to 72 hours after the first cutaneous lesions are noted; respiratory symptoms and vomiting are unusual. The temperature elevation is usually less than 101.5°F but may be as high as 106°F. The varicella exanthem begins on the scalp, face, or trunk (see Fig. 5). The cutaneous lesions consist of erythematous macules that evolve rapidly (within several hours) to form a clear, fluid-filled vesicle surrounded by an irregular erythema margin, the classic “dew drop on a rose petal.” Lesions in the maculopapular or vesicular stages are usually intensely pruritic. After 24 to 48 hours, the vesicular fluid becomes cloudy in appearance, and the lesions umbilicate as crusting begins. As the first cutaneous lesions are progressing through these stages, new crops of lesions form on the trunk and then the extremities. Lesions that develop late in the course of the illness are more widely distributed and may resolve without progressing to form vesicles. Lesions of the mucous membranes of the oropharynx, conjunctivae, and vagina are common. In the final phase, the crusted lesions are sloughed as new epithelial cells are generated at the lesion site.

The duration of varicella in otherwise healthy children, judged by the number of days of new lesion formation, ranges from 1 to 7 days. In a large clinical study, more than half of the children developed new lesions for 3 to 6 days, whereas only 1 of 521 children had new lesions for 7 days (286). The total number of varicella lesions ranged from 12 to 1,968, with most children having fewer than 300 lesions. Although the illness may be so mild that it escapes diagnosis, subclinical varicella is documented rarely when susceptible children are examined carefully during the period of risk. Preexisting skin damage such as eczema or sunburn acquired during the incubation period exacerbates the severity of

the exanthem (48). Children who develop varicella after household exposure are more likely to have more extensive varicella (97,286). Hypopigmentation of the skin often persists for several weeks, but extensive scarring is unusual. However, a single, shallow scar on the forehead is a common consequence of varicella because the initial lesions, which often occur along the hairline or eyebrow, involve deeper layers of the skin.

Abnormal laboratory values are to be expected during primary VZV infection, including a decrease in the total white blood cell count, reflecting lower polymorphonuclear leukocyte and lymphocyte counts during the first 72 hours of rash, which is then followed by a relative and absolute lymphocytosis (60). Lymphoblasts and prolymphocytes may be present in the peripheral blood during the acute and convalescent phases of varicella. Slight elevations of liver function tests are also common (107).

Complications

S. aureus and *S. pyogenes* (group A b-hemolytic streptococcus) cause secondary bacterial infection of skin lesions (60,114,189,379). “Impetigo” may be difficult to differentiate from bullous varicella caused by VZV (13). Cellulitis, bacterial lymphadenitis, or subcutaneous abscesses usually appear by 3 to 6 days but may appear up to 2 weeks after exposure (85,154,266,378). In a case-control analysis of group A streptococcal complications, cases were more likely to be secondary household cases, to have fever after day 2, and to have asthma (266). Varicella gangrenosa or necrotizing fasciitis is usually due to *S. pyogenes* (54,393). In its classic presentation, a single varicella lesion, usually on the trunk or an extremity, manifests an unusual appearance early in the course of the varicella eruption. The surrounding skin becomes erythematous, warm, and painful. The erythematous area enlarges rapidly over a few hours, often turning a dusky, dark-red color, and extensive edema develops in the soft tissue around the lesion. Bacteremia, usually caused by *S. aureus* or *S. pyogenes,* may lead to acute bacterial sepsis, with high temperature, hypotension, and disseminated intravascular coagulopathy. Alternatively, the hematogenous spread of the bacterial pathogen may not be detected until signs of a focal infection appear. Staphylococcal or streptococcal pneumonia, arthritis, and osteomyelitis following varicella exemplify this process.

Varicella pneumonia is a serious concern in healthy adults and particularly in the third trimester of pregnancy (258,278). In one early series, varicella pneumonia was diagnosed in 9% of adults (364), but more recent studies indicate that it is somewhat less common (278,346,347). Cough and dyspnea begin about 3 days (1 to 6 days) after the onset of the rash and may be associated with cyanosis, pleuritic chest pain, or hemoptysis (364). Although rales and rhonchi may be detected, the abnormal physical findings are often restricted to fever and tachypnea. Hypoxemia is often much more severe than is suggested by the physical examination or by the chest radiograph. The chest radiograph may be normal but more often demonstrates diffuse bilateral infiltrates with small nodular densities, especially in the perihilar area. Varicella pneumonia is often transient, resolving completely within 24 to 72 hours, although calcified nodules may persist for weeks or months. In severe cases, interstitial pneumonitis progresses rapidly to cause respiratory failure.

Varicella hepatitis can occur subclinically, although some children with the highest elevations of SGOT (range 200 to 800 IU/L) have severe vomiting (107), which must be differentiated from Reye's syndrome. Aspirin is contraindicated in children with varicella because it predisposes to this syndrome of fatty degeneration of the liver and encephalopathy. Varicella encephalitis or cerebellar ataxia have been described during the incubation period, but neurologic symptoms usually occur within 2 to 8 days (13,100,192,205,267,345). Ataxia may be accompanied by nystagmus and slurred speech; meningoencephalitis presents with vomiting, seizures, diminished level of consciousness, nuchal rigidity, and extensor plantar reflexes. Patients with encephalitis usually have the sudden onset of seizures and altered sensorium, whereas those with cerebellar disease show a gradual progression of irritability, nystagmus, and gait and speech disturbances. Some patients have fever, headache, and meningismus only, without altered consciousness or seizures. The CSF usually shows a mild lymphocytic pleocytosis (less than 100 cells/mL) and a slight to moderate protein level (less than 200 mg) with normal glucose. Cell counts and CSF protein are higher with encephalitis than with cerebellar disease, but CSF is often normal. Encephalitic symptoms usually resolve rapidly (within 24 to 72 hours); sequelae are rare. Ataxia may persist for days to weeks, but resolution is almost always complete. A few cases of transverse myelitis have been associated with varicella; paraplegia and sensory loss occurred 5 to 16 days after onset of lesions (144,192). Optic neuritis may occur alone or with transverse myelitis; a few cases of Guillain-Barré syndrome have been reported.

Acute thrombocytopenia causes petechiae and purpuric skin lesions, hemorrhage into the varicella vesicles, epistaxis, hematuria, and gastrointestinal bleeding. Hemorrhagic complications are usually transient, but platelet counts may remain low for days to weeks. Postinfectious thrombocytopenia occurs from 1 to 2 weeks or longer after varicella and causes bleeding complications for an average of 5 weeks. Purpura fulminans, due to arterial thrombosis and hemorrhagic gangrene, is a rare but life-threatening complication. The symptoms of varicella nephritis are hematuria and diffuse edema with or without hypertension and appear within about 3 weeks (13). Laboratory abnormalities include proteinuria, microscopic hematuria, elevated blood urea nitrogen and creatinine, and decreased creatinine clearance. A few cases of nephrotic syndrome and hemolytic-uremic syndrome have been reported in children with varicella. Varicella arthritis is rare; it resolves spontaneously within 3 to 5 days with no residual joint disease. Other rare complications of varicella include myocarditis, pericarditis, pancreatitis, and orchitis. Varicella vesicles are common on eyelids and conjunctivae, but eye disease is unusual (102); if present, unilateral anterior uveitis or corneal lesions usually resolve spontaneously.

Varicella in High-Risk Populations

Immunocompromised children are susceptible to prolonged new lesion formation and visceral dissemination manifesting as varicella pneumonia, hepatitis, encephalitis, and disseminated intravascular coagulopathy (13,33). Varicella vesicles in these patients are usually larger and more numerous, and more than half of the immunocompromised children have new lesion formation for at least 7 days, with an average time to lesion crusting of 14 days (374). They may develop diffuse interstitial nodular pneumonitis within 3 to 7 days after the onset of skin lesions, with rapid progression to respiratory failure. All of the deaths from varicella in children with leukemia occurred within 3 days after the diagnosis of varicella pneumonia (111). Varicella hepatitis is accompanied by jaundice and elevated serum transaminase levels. Thrombocytopenia and disseminated intravascular coagulopathy are common; hemorrhage into lesions is a sign of severe varicella, as is severe abdominal or back pain. Encephalitis occurs but is rarely the immediate cause of death; the

syndrome of inappropriate antidiuretic hormone secretion may accompany disseminated varicella with or without clinical encephalitis. Myocarditis and severe hypertension, possibly related to nephritis, are less frequent complications. Disseminated VZV infection in children with cancer has also produced pancreatitis, necrotizing splenitis, esophagitis, and enterocolitis. Neutropenia due to chemotherapy and radiation enhances susceptibility to secondary bacterial infections.

Children who acquire varicella after organ transplantation are also at risk for progressive VZV infection (122). Thrombocytopenia and hepatitis, rather than pneumonitis, were the major clinical complications in renal transplant recipients. Among 2,320 pediatric patients who received renal transplants between 1987 and 1993, 44 children required hospitalization for varicella during the first year; varicella was not fatal and was not associated with transplant rejection. Children on long-term, low-dose steroid therapy for asthma are not usually at risk for serious varicella (321). However, fatal varicella has been described in patients receiving higher doses of prednisone during the incubation period. Severe cutaneous lesions occur in children receiving steroid therapy for other diseases, such as rheumatoid arthritis, nephrotic syndrome, and ulcerative colitis, but visceral dissemination is unusual.

Untreated varicella is severe or fatal in children with severe combined immunodeficiency or T-cell deficiencies, including adenosine deaminase or nucleoside phosphorylase deficiency and cartilage hair hypoplasia. Varicella can also be severe in children with Wiskott-Aldrich syndrome or ataxia telangiectasia. Fatal varicella in a previously healthy child does not suggest that siblings are at risk for severe VZV in the absence of an identifiable inherited immunodeficiency disorder. Unusual clinical findings of varicella, including lesions that develop a unique hyperkeratotic appearance, and chronic new lesion formation for weeks or months have been described in children with HIV infection (89,138,194,200,219,328).

Maternal varicella may result in premature labor or, rarely, the congenital varicella syndrome (32,103,254,262,273,274,300). Affected infants have unusual cutaneous defects, with cicatricial skin scars, atrophy of an extremity, microcephaly, seizures, mental retardation, intrauterine growth retardation, and other sequelae, including chorioretinitis, microophthalmia, and cataracts. Dysfunction of the autonomic nervous system produces neurogenic bladder, hydroureter, hydronephrosis, and severe gastroesophageal reflux with recurrent aspiration pneumonia. Limb anomalies and other sequelae of intrauterine varicella may be apparent by ultrasonographic evaluation of the fetus (165). Varicella is common in infants born to women with acute varicella beginning just before or after delivery; transmission of the virus may occur prenatally, but signs of disseminated intrauterine infection are not evident. Some infants with neonatal varicella are born with the typical varicella exanthem in various stages, including vesicles, crusted lesions, or hypopigmented skin areas; other infants develop symptoms during the first few weeks of life. Infants whose lesions are present at birth or within the first 5 days of life are not at risk for severe varicella, probably because the interval between maternal infection and delivery permits transplacental transfer of maternal IgG antibodies to VZV along with the virus. Those who are born within 4 days after or 2 days before the onset of maternal varicella may develop progressive varicella. Most infants are protected from exposure to nonmaternal contacts by passively acquired VZV antibodies.

Herpes Zoster

The classic clinical manifestation of recurrent VZV infection is a cluster of vesicular lesions surrounded by erythema, localized unilaterally in the dermatomal distribution of one or more adjacent sensory nerves (Fig. 8). The initial cutaneous lesions usually appear in groups at one or several sites anteriorly and posteriorly along the affected dermatome; discrete vesicles resembling varicella lesions often merge to form larger, fluid-filled lesions as the exanthem evolves. The cutaneous lesions are often preceded by and almost always accompanied by the pain and hyperesthesias of acute neuritis and by pruritus. About half of the cases involve the thoracic dermatomes, particularly T5 to T12; the eruption is in the distribution of one of the cranial nerves in 14% to 20% of patients (177,279). Cranial nerve V was involved in 14% of the cases described in the classic study by Hope-Simpson (177). Lumbosacral dermatome disease was observed in 16% of these patients, predominantly in the L1 to L2 distribution. The localized dermatomal infection is occasionally accompanied by disseminated cutaneous lesions in the normal host. The cutaneous eruption usually subsides rapidly, with new lesion formation in the primary dermatome ceasing within 3 to 7 days. However, the cutaneous rash may progress to confluent involvement of the whole dermatome. Crusting followed by complete healing of the cutaneous process is expected within 2 weeks but may require as long as 4 to 6 weeks. When herpes zoster occurs in children, the cutaneous eruption is mild, and symptoms of acute neuritis are unusual. Patients who have neuropathic pain but no cutaneous eruption may have the syndrome of *zoster sine herpete* (141,144,145). Idiopathic facial palsy without obvious cutaneous herpes zoster has also been attributed to VZV reactivation (110).

FIG. 8. Herpes zoster in the distribution of the ventral division of the right eighth and ninth thoracic nerves. **B:** Herpes zoster involving the ophthalmic division of the trigeminal nerve with associated conjunctivitis and involvement of the side of the nose. (Courtesy of A. A. Gershon.)

Many patients with uncomplicated herpes zoster have CSF pleocytosis, consisting predominantly of mononuclear cells, as well as elevated protein. VZV can be isolated from CSF and is detected by PCR (146,160,277). Abnormal CSF does not predict chronic sequelae, but spinal cord abnormalities seen by magnetic resonance imaging were associated with prolonged pain (160).

Complications

The most common complication of herpes zoster is PHN, a severe, debilitating, chronic pain (356). Hypersensitivity of the skin to touch or temperature changes persists for several months among 5% to 10% of patients (279,375). When meningoencephalitis occurs, it produces an altered state of consciousness, headache, photophobia, or meningismus at an average of 9 days after rash, with the range up to 6 weeks (205). The electroencephalogram may be abnormal, with diffuse slowing or epileptiform activity. The mean duration of encephalitic symptoms is 16 days, or longer among patients with associated paresis. Neurologic sequelae are unusual. VZV was isolated from brain tissue of a patient who had subacute encephalitis and AIDS, but progressive panencephalitis is rare (142,205). Syndromes attributed to encephalitis, particularly hemiplegia, in patients with herpes zoster may often represent vasculopathy involving the large or small arteries of the central nervous system (6,205). Cerebral angiitis, or granulomatous arteritis, is associated with contralateral herpes zoster involving the trigeminal nerve in elderly patients. Cerebral angiography demonstrates segmental constriction of the ipsilateral cerebral arteries, and computed tomographic brain scans usually show cerebral artery infarcts.

VZV reactivation in the trigeminal ganglion can produce ophthalmic disease, including conjunctivitis, dendritic keratitis, anterior uveitis, iridocyclitis with secondary glaucoma, and panophthalmitis (197,381). Blindness following herpes zoster ophthalmicus is very uncommon. Loss of vision associated with herpes zoster is predominantly caused by retrobulbar neuritis and optic atrophy. Some episodes of retinitis in patients with AIDS are due to VZV rather than human CMV (130,174,222). Herpes zoster of the seventh cranial nerve produces facial palsy on the same side as the cutaneous lesions. Facial palsy may accompany VZV reactivation, affecting other cranial nerves, including the third, fourth, and sixth cranial nerves. Herpes zoster oticus and facial palsy, referred to as the Ramsey-Hunt syndrome, is associated with VZV reactivation in the geniculate ganglion of the seventh cranial nerve and the eighth nerve (110). Herpes zoster of the second branch of the fifth cranial nerve produces oral lesions, primarily on the palate, that can be difficult to diagnose clinically. Lesions on the tongue indicate seventh nerve involvement and are associated with loss of taste.

Neurogenic bladder dysfunction or ileus with intestinal obstruction can accompany lumbosacral herpes zoster (358). Transverse myelitis, with ascending paralysis and sensory deficits, occurs (173), but Guillain-Barré syndrome is rare. Chronic paralysis of an extremity can follow herpes zoster.

Herpes Zoster in High-Risk Populations

Herpes zoster in compromised patients is characterized by a more severe local dermatomal infection (33,163,290,338). Before antiviral therapy was available, the duration of cutaneous disease in these patients was about a week longer than the disease in healthy patients (374). Occasionally, immunocompromised patients, particularly patients with AIDS, develop a chronic reactivation of VZV, which can persist for months (4,124). Cutaneous dissemination occurs in 10% to 40% of immunocompromised patients with herpes zoster. Cutaneous lesions outside of the primary dermatome indicate that the patient has VZV viremia and provide an important marker for potential visceral dissemination (109). Hematogenous spread can produce pneumonia, hepatitis, encephalitis, and disseminated intravascular coagulopathy. Atypical nonlocalized herpes zoster is a syndrome seen in immunocompromised patients, especially bone marrow transplant recipients (229); these patients have widely scattered vesicular lesions that cannot be distinguished from varicella. Neurologic complications are more common in immunocompromised patients (205).

Patients with HIV infection have unusual complications, including chronic cutaneous disease, retinitis, and central nervous system infections that occur without any associated cutaneous disease or are progressive after resolution of the herpes zoster rash (4,59,70,79,153,174,217).

DIAGNOSIS

Differential Diagnosis

Historically, the most important differential diagnosis for varicella was smallpox, or generalized vaccinia after smallpox immunization. Now, varicella must be differentiated from vesicular rashes associated with infections caused by other common pathogens, such as enterovirus or *S. aureus,* or with rashes due to scabies, drug reactions, contact dermatitis or rarely, rickettsial pox, or disseminated HSV infection.

The clinical diagnosis of herpes zoster is most difficult when acute pain and paresthesias precede the cutaneous eruption; the pain is severe enough to mimic myocardial infarction, cholecystitis, appendicitis, and other conditions. Localized contact dermatitis is the most common alternative cause of the cutaneous signs. A localized vesicular rash involving the lumbosacral dermatomes must be distinguished from HSV; a history of recurrent symptoms at the same site suggests HSV-2 disease. Generalized atypical VZV reactivation, such as is seen in severely immunodeficient patients, can be differentiated from primary VZV infection only if the patient has VZV IgG antibodies before symptoms appear.

Laboratory Diagnosis

Laboratory diagnosis is not necessary for the clinical management of most VZV infections in the immunocompetent host. Rapid diagnostic techniques are often useful to document suspected cases of varicella or herpes zoster in high-risk

patients so that informed decisions can be made about antiviral treatment.

Virologic Methods

Virologic methods for diagnosis include the detection of viral proteins using immunologic reagents, viral isolation in tissue culture, and detection of viral DNA by *in situ* hybridization or PCR (84,119,137). Rapid diagnosis of cutaneous VZV infection is accomplished by obtaining epithelial cells from the base of a lesion in the vesicular stage and staining with immunohistochemical methods, including an HSV control (55). Enzyme immunoassay methods can be used to test solubilized preparations of cells and vesicle fluid from cutaneous VZV lesions. Immunohistochemical stains are also valuable to demonstrate VZV-infected cells in lung, liver, and other tissues when disseminated VZV infection is suspected. Cytologic methods can be used to detect multinucleated giant cells, but false-negative results are common, and VZV and HSV infections are not differentiated. VZV virions cannot be distinguished morphologically from other herpesviruses by electron microscopy.

A definitive diagnosis requires the recovery of infectious virus using cell culture methods (51,137). Because the pathogenesis of cutaneous VZV infection involves the release of virus into the vesicle, viral isolation is enhanced by obtaining vesicular fluid and infected cells from the base. VZV is most often recovered from early, clear vesicles. Immunologic assays for viral proteins may be positive when cultures are negative. Infectious VZV is usually recoverable from varicella lesions for 3 days, and for 7 days or longer from herpes zoster lesions. Specimens should be kept on dry ice or frozen at –70°C; storing the specimen at –20°C for 24 hours or longer usually inactivates VZV (137). Viral cultures usually do not influence clinical decisions but rather confirm diagnoses made using rapid viral antigen detection methods. The shell vial culture method may improve the sensitivity of VZV isolation and permit earlier identification of positive specimens, within 1 to 3 days (51,52,306). Even with improved methods, a significant percentage of viral cultures remain negative despite VZV detection by direct immunofluorescence stain of lesion material (69). The similar plaque morphology produced by VZV, HSV, and human CMV requires identification with virus-specific antisera.

Other clinical specimens from which infectious VZV may be recovered include peripheral blood mononuclear cells, joint fluid, CSF from patients with herpes zoster, and bronchial washings from patients with varicella pneumonia. The lungs are the most common autopsy tissue from which VZV has been isolated, but the virus has been recovered from many sites, including heart, liver, pancreas, gastrointestinal tract, brain, and eyes.

VZV can be detected in clinical specimens from patients with primary or recurrent VZV infection using radiolabeled or biotinylated nucleic acid probes that hybridize to VZV DNA or RNA in Southern blot or *in situ* hybridization procedures or by PCR (84,277,302). VZV PCR methods have been shown to detect the virus in PBMC during acute varicella and in some cases of herpes zoster. CSF from patients with central nervous system syndromes related to VZV and from patients with uncomplicated herpes zoster may be positive by PCR. PCR methods are usually more sensitive than viral culture, but positive results do not indicate whether infectious virus is present. Because of risk for contamination, PCR assays may lack specificity; therefore, relying on PCR for diagnosis of VZV as an etiology in clinical circumstances in which cutaneous signs of disease are absent is problematic. VZV detection in CSF by PCR has not been evaluated in enough cases to allow its use for prognostic purposes. Assessing fetal risk after maternal varicella during pregnancy by PCR is complicated by the fact that infection often occurs without damaging the fetus. The relatedness of VZV isolates from clinical specimens can be established by restriction endonuclease digestion of viral DNA, but this information is rarely needed for clinical purposes. The virologic diagnosis of intrauterine VZV infection is difficult because methods, including PCR, lack sensitivity, and detection of VZV does not mean that the fetus has been damaged.

Serologic Methods

The characteristics of the humoral immune response to VZV limit serologic approaches to the diagnosis of acute varicella or herpes zoster. Serologic diagnosis by VZV IgG titers is retrospective, and methods to detect VZV IgM antibodies lack sensitivity and specificity; false-positive results are common. Because VZV reactivation also induces IgM antibodies to VZV in many patients, their presence in serum does not differentiate primary from recurrent infection (15). Similar problems are encountered with assays for VZV IgA antibodies. Fetal VZV infection does not elicit an IgM response consistently, and VZV IgG antibodies in fetal blood reflect transplacentally transferred maternal antibodies. Local antibody production in CSF has been documented in some patients with VZV-related encephalitis (137).

Assays for VZV IgG antibodies are most useful for determining the immune status of individuals whose clinical history of varicella is unknown or equivocal (208). Defining VZV immune status is important to assess the risk for primary VZV infection in exposed individuals, the risk for reactivation in patients who are receiving immunosuppressive therapy, and the need for varicella immunization. The most sensitive methods detect binding of antibodies in sera to membranes of unfixed VZV-infected cells, referred to as the *fluorescent-antibody membrane antigen assay* (FAMA) or to purified VZV protein preparations by enzyme immunoassay (137); neutralization and radioimmunoassay are sensitive. Most commercial enzyme immunoassay methods have high specificity, generating few false-positive results, but 10% to 15% of immune individuals may be identified as susceptible. Using cell-mediated immunity to VZV as the marker of past infection, VZV enzyme immunoassay had a sensitivity of 87%, specificity of 91%, positive predictive value of 87%; latex agglutination had a sensitivity, specificity, and positive predictive value of 96%, 91%, and 97%, respectively, compared with enzyme immunoassay (363). Latex agglutination methods provide a useful alternative to FAMA (322).

TREATMENT

The severe complications of varicella and herpes zoster in patients with malignant diseases created an urgent need for antiviral agents. Initial studies of antiviral therapy were done using vidarabine (adenine arabinoside) or human leukocyte IFN-a; both agents reduced the duration of viral replication and the risk for disseminated illness (18,239,319,373). These agents were replaced by the nucleoside analog, acyclovir (9,2-hydroxyethoxymethylguanine), because of its higher specific activity against VZV, better clinical efficacy, and few adverse effects (43). Famciclovir and valaciclovir are nucleoside analogs that have improved oral absorption and are licensed for treatment of herpes zoster (99,126,339).

Dihydroxypropoxymethylguanine (ganciclovir) has *in vitro* activity against VZV equivalent to acyclovir, but efficacy studies have not been done because of its toxicity. Sorivudine [1-b-D-arabinofuranosyl-E-(2-bromovinyl)uracil] is an oral drug with high *in vitro* activity against VZV and is effective *in vivo* in patients with HIV infection complicated by herpes zoster (126); however, toxicity from interactions with other drugs, particularly 5-fluorouracil, has blocked its licensure in the United States. Netivudine [1-(beta-D-arabinofuranosyl)-5-(1-propynyl)uracil] is another new agent that inhibits VZV *in vitro* (113).

Acyclovir, famciclovir, and valaciclovir are metabolized to the triphosphate form within infected cells by the viral TK; the phosphorylated compound functions as a competitive inhibitor and chain terminator of viral DNA polymerase. The antiviral activity of acyclovir is significantly lower against VZV than HSV-1 and HSV-2, which are usually inhibited by 0.125 µg/mL and 0.215 µg/mL of acyclovir, respectively, in contrast to 0.82-4.64 µg/mL for VZV, with variations from as low as 0.3 to as high as 10.8 µg/mL. Ensuring that plasma concentrations are several-fold above the inhibitory concentrations for most VZV isolates requires the intravenous administration of the drug at doses of 10 mg/kg or 500 mg/m^2; these doses achieve plasma drug concentrations of 15 to 25 µg/mL (373). Only about 20% of acyclovir administered orally is absorbed; even high doses yield peak plasma concentrations of only about 1.0 to 1.5 µg/mL.

Prolonged exposure of VZV isolates to acyclovir *in vitro* permits the emergence of TK-negative mutants (188,223,295); selection of these variants *in vivo* is rare, but it has been observed in severely immunocompromised patients, especially AIDS patients, who are treated with acyclovir for repeated or chronic episodes of VZV infection. Foscarnet, which acts directly on the viral DNA polymerase, is an alternative to the nucleoside analog drugs for the treatment of resistant VZV infection; recombinant interferon may also be useful (239,295,343). Resistance to foscarnet can also emerge, probably owing to a mutation in the viral DNA polymerase (343). The VZV polymerase, ribonucleotide reductase, and other genes are targets for new antiviral drug development.

Varicella

Acyclovir therapy diminishes the clinical severity of varicella in immunocompromised children by ensuring that cell-associated viremia is terminated efficiently despite the impaired host response. Early antiviral therapy prevents progressive varicella and visceral dissemination (309). The dosage of intravenous acyclovir for varicella in high-risk patients is 500 mg/m^2 every 8 hours, with administration continuing for 7 days, or in milder cases until no new lesions have appeared for 48 hours. When intravenous acyclovir was given to children with malignancy in a placebo-controlled trial, the incidence of varicella pneumonia was decreased from 45% to none (342). At one pediatric cancer center, none of 16 children given acyclovir developed pneumonitis, compared with 6 of 21 (29%) treated with vidarabine (111). None of 37 children with varicella who received vidarabine or acyclovir had fatal infection, compared with a case-fatality rate of 7% before antiviral drugs were available.

The optimal use of acyclovir requires beginning treatment within the first 24 to 72 hours after the onset of the rash. Waiting to initiate treatment until prolonged new lesion formation has been documented is not an option because visceral dissemination occurs during the same time period. Most high-risk children do not have clinical signs of VZV dissemination immediately, but the interval during which therapy to prevent viral spread can be initiated is only a few days. In addition to preventing life-threatening dissemination, early acyclovir therapy minimizes cutaneous disease, which may reduce the risk for secondary bacterial infections. Immunocompromised patients who have pneumonia, hepatitis, thrombocytopenia, or encephalitis should receive immediate treatment with intravenous acyclovir (374). In addition to antiviral treatment, these patients require supportive therapy with assisted ventilation and other intensive care measures.

Oral acyclovir can be used to diminish varicella symptoms in healthy children, adolescents, and adults when administered within 24 hours after the appearance of the initial cutaneous lesions (6,34,35,88). In children 2 to 12 years of age, acyclovir given at 20 mg/kg four times a day for 5 days reduced fever, pruritus, days of new lesion formation, and total lesions. Acyclovir recipients also had fewer lesions that progressed from the maculopapular to the vesicular stage. These effects suggest that the plasma and tissue drug concentrations were sufficient to decrease viremia, resulting in diminished transport of the virus to epithelial cells, and to inhibit replication when the virus reached skin sites. Although the clinical benefit was modest because varicella is usually less severe in the youngest children, immediate acyclovir therapy converted all cases to an illness in which fever and lesion formation continued for 3 days or less and total lesions were fewer than 300 (365). Children 5 to 12 years of age and secondary household cases may be judged more likely to benefit because the duration of symptoms was longer and the rash was more extensive in untreated children in these groups. No effect on the risk for secondary bacterial infection or other serious sequelae of varicella was documented given the size of the study cohorts.

The benefit of oral acyclovir for varicella in adolescents aged 13 to 18 years and in adults has more clinical relevance because of the age-related increase in severity of varicella (35,346). Adolescents given acyclovir were significantly less likely to have residual hypopigmented skin lesions at 4 weeks, suggesting that drug therapy minimized the spread of the virus to cells deeper in the dermis. Although the study groups were not large enough to document it, the evidence of diminished viremia and cutaneous viral replication supports the assumption that oral acyclovir therapy reduces the risk for varicella pneumonia. In adults, as in young children, acyclovir must be given within 24 hours after the first lesions appear to have demonstrable clinical efficacy. Adults with varicella pneumonia require immediate treatment with intravenous acyclovir (159). Acyclovir did not have any detrimental effect on the host response to VZV when measured by assays for humoral as well as cell-mediated immunity (88,98,104,289). This finding supports the concept that limited viral replication provides sufficient antigenic stimulation to induce persistent immunity to VZV and is consistent with evidence that protective immunity is elicited even when varicella is mild.

Herpes Zoster

Acyclovir is effective for the treatment of recurrent VZV infection in healthy and immunocompromised patients (Table 3). Among healthy individuals, the period of continued new lesions in the involved dermatome was shortened, as was the

time to complete healing (374,382,383). Acyclovir treatment is important for ophthalmic zoster because of the risk for acute uveitis and chronic keratitis. Acute neuropathic pain was reduced, but effects on PHN have been less predictable (181). The definitive effect of antiviral therapy on acute pain suggests that different mechanisms may contribute to these two components of zoster-related pain (375). There is no evidence that longer courses of treatment alleviate PHN (373).

No. subjects		Interval to treatment	Viral replication	Measures of drug effect		Postherpetic neuralgia	Reference
Acyclovir[a]	Placebo			resolution of cutaneous disease	Acute pain[b]		
93	94	≤72 hr	2.3 d vs. 3.1 d ($p < .0001$)	7.1 d vs. 9.6 d[c] ($p < .0001$)	7.8 d vs. 9.5 d (NS) 4-6 mos (NS)	1-3 mos (.01)	199
43	43	≤72 hr	ND	21.5 d vs. 27.5 d[d] ($p < .027$)	1-4 wk (NS)	2 mos (.01)	282a
102	105	≤48 hr	ND	7.8 d vs. 10.0 d[e] (.032)	Decrease at day 6 (.0268)		281

[a]The dose of acyclovir was 800 mg five times per day in all studies.
[b]Pain was evaluated using scoring systems as described for each study.
[c]50% healing in the affected dermatome.
[d]Full healing in the affected dermatome.
[e]100% crusting in the affected dermatome.
ND, not done.

TABLE 3. *Efficacy of early oral acyclovir therapy for herpes zoster in immunocompetent adults*

The therapeutic benefit of oral famciclovir against cutaneous disease was comparable to acyclovir, and resolution of PHN was accelerated (98,339). Valaciclovir, the l-valyl ester of acyclovir, is metabolized to acyclovir *in vivo* but is absorbed threefold to fivefold more efficiently than acyclovir. Valaciclovir treatment was associated with faster resolution of herpes zoster–associated pain compared with acyclovir and with a decrease in the proportion of patients with pain persisting for 6 months (42,383). Thus, both famciclovir and valaciclovir, in addition to the simplified three-times-daily dosage regimen, have better therapeutic effects against zoster-associated pain. Whether the addition of steroid therapy as an antiinflammatory drug to initial antiviral treatment reduces chronic pain has been difficult to document (374).

Acyclovir is given intravenously to immunocompromised patients who are at high risk for disseminated disease, at a dose of 500 mg/m^2, or 10 mg/kg given every 8 hours. Acyclovir is given for 7 days or for 2 days after the cessation of new lesion formation, whichever provides the longer treatment course. This dosage regimen resulted in improvement of the cutaneous symptoms within 24 hours, cessation of new skin lesions after 24 hours, and prevention of visceral dissemination. Among bone marrow transplant recipients (198,229), acyclovir compensation for the deficient immunity produces earlier cessation of new lesions, more rapid healing, and prevention of dissemination when compared with vidarabine (313). Acyclovir initiated within 72 hours after the onset of VZV reactivation reduces new lesion formation to about 3 days, cessation of acute pain within 4 days, crusting by 7 days, and complete healing by 2 to 3 weeks. Some benefit is observed even when therapy is delayed for more than 3 days because the pathologic process is more extensive (373). Among HIV-infected patients, sorivudine was more effective than acyclovir for rapid cutaneous healing, but no differences were seen effects on pain (126).

Although acyclovir therapy usually eliminates the risk for visceral dissemination, relapse of herpes zoster occurs in some immunocompromised patients. In one series, 5 of 40 bone marrow transplant recipients had recurrent herpes zoster (12%); 3 of the 5 patients developed new lesions within 4 days after treatment was stopped (228). Nevertheless, most patients respond to treatment with a second course of acyclovir. Zoster recurrences and new episodes were experienced by 11% of HIV-infected patients given sorivudine, compared with 26% of those who received acyclovir (126). Oral acyclovir is reserved for patients considered at lower risk for dissemination (228). Foscarnet is an option for rare cases of VZV resistant to acyclovir (50).

The treatment of PHN is often difficult. Mild pain is managed with nonopioid analgesics or nonsteroidal antiinflammatory drugs. These agents can be given in combination with adjuvant analgesics, including tricyclic antidepressants or anticonvulsants. Opioids are used when these combination drug regimens fail. Short-term pain relief may result with lidocaine or other topical analgesics. In the most severe cases, anesthetic interventions such as nerve block are used, but their efficacy may be limited.

PREVENTION AND CONTROL

In most circumstances, preventing the transmission of VZV to susceptible individuals is difficult because infected individuals are contagious for 24 to 48 hours before the onset of varicella. As a consequence, restrictions on attendance failed to alter the course of varicella epidemics in schools (56). Infection-control practices, including caring for infected patients in isolation rooms with filtered air systems, are essential in hospitals that treat patients for whom varicella might be life-threatening. VZV transmission by air-flow systems has been documented, and VZV has been detected in air samples by PCR (218,301). Susceptible health care workers who have had a close exposure to varicella are not permitted to care for high-risk patients during the incubation period or acute illness (6,158).

Passive Antibody Prophylaxis

Varicella zoster immune globulin (VZIG) is a passive antibody preparation containing VZV IgG antibodies made from high-titer immune human serum. VZIG is distributed by the American Red Cross Blood Services; the dosage is 1 vial per 10 kg given intramuscularly. VZIG is indicated for susceptible individuals who have had a close exposure to an individual with varicella or herpes zoster and who are at risk for serious varicella (6,63). Its efficacy depends on administration within 96 hours and preferably within 48 hours after exposure. VZIG prophylaxis is recommended for compromised children, pregnant women, and newborn infants exposed to maternal varicella (282). Adults should be tested for VZV IgG

antibodies because many with no history of varicella are immune.

Giving VZIG prophylaxis does not eliminate the possibility that primary VZV infection will occur (242,390). VZIG administration can prolong the incubation period to 28 days. The incidence of varicella despite VZIG prophylaxis is significantly higher after household exposures and is related to the VZV IgG titer of the preparation. Passive antibody prophylaxis lowered the risk for varicella pneumonia, but 11% of children developed pneumonia (111). Some immunocompromised patients, particularly bone marrow transplant recipients, are given high-dose intravenous immune globulin (100 to 400 mg/kg) for other indications; if these preparations have been given within 3 weeks before the exposure, it is not necessary to administer VZIG. Because passive antibody titers decline over 2 to 4 weeks, a second dose of VZIG should be given if a new exposure occurs after 2 weeks. Although the risk for VZV transmission from an individual with herpes zoster is low, close contact between a susceptible, high-risk patient and a patient with recurrent VZV lesions also justifies the administration of VZIG.

Passive antibody prophylaxis dose not reduce the risk for VZV reactivation in high-risk populations, and passive antibody administration after the onset of illness does not alter the severity of varicella or herpes zoster (324).

Antiviral Prophylaxis

Although acyclovir has been given as prophylaxis during the incubation period, but the benefit, compared with treatment if and when acute illness occurs, is not well defined (180,329). Acyclovir prophylaxis has been evaluated for the prevention of recurrent VZV infection in bone marrow transplant recipients; in one series, the incidence of herpes zoster was 15% in the placebo group and none in the acyclovir recipients. However, VZV reactivation occurred when acyclovir was discontinued, and prophylaxis did not result in an overall reduction in episodes by 1 year. Acyclovir prophylaxis is not a universal practice because the prompt initiation of acyclovir for the treatment of recurrent VZV infections is very effective (265). Avoiding prolonged, low-dose administration of acyclovir may help to minimize the emergence of TK-negative VZV strains that are resistant to the drug.

Varicella Vaccine

The live attenuated varicella vaccine is the first human herpesvirus vaccine licensed for clinical use in several countries (66,134,209,335). Its development and initial clinical evaluation was first reported by Takahashi in 1974 (330). The vaccine virus was derived from a clinical isolate of VZV, the Oka strain, and is propagated in guinea pig embryo fibroblasts and WI38 cells. In contrast to experiments in which susceptible children were inoculated with infectious VZV from vesicular fluid (46), tissue culture propagation appears to attenuate the virus so that vaccine containing as much as 9,000 PFU per dose of infectious virus induces immunity to VZV but does not produce clinical symptoms (12).

The molecular mechanisms of attenuation of the Oka strain have not been identified. The attenuation of the Oka vaccine strain is not related to known restriction enzyme profile differences because it resembles other Japanese isolates that cause varicella. The comparative analysis of the vaccine virus in the SCID-hu mouse model demonstrated that vaccine Oka has a diminished capacity to replicate in human skin but remains infectious for T lymphocytes (246). The pathogenicity of vaccine Oka was compared with that of its parent, another low-passage clinical isolate, and VZV-Ellen, a standard laboratory strain. All of these VZV strains replicated well in tissue culture, but only the low-passage clinical isolates, including parent Oka, were fully virulent in skin, whereas prolonged growth of VZV in tissue culture cells was associated with reduced infectivity. Analysis of a variant of vaccine Oka showed that infectivity of the vaccine strain was further diminished in the absence of gC expression, but the vaccine strain itself was not diminished for gC expression *in vivo.* The clinical attenuation of V-Oka in healthy children can be explained by its impaired virulence for human skin. The fact that the vaccine Oka strain retained infectivity for T lymphocytes explains its capacity to cause scattered lesions in some vaccinees and to cause varicella-like symptoms in some immunocompromised children. Sequence analyses of vaccine Oka strain, its parent, and other clinical isolates have identified some differences in vaccine Oka, but their relationship to attenuation has not been established.

Clinical Experience

The live attenuated varicella vaccine (Oka-Merck strain) was administered to more than 7,000 children and more than 1,600 healthy, susceptible adults during clinical trials in the United States. It is now licensed and recommended as a routine childhood vaccination and for immunization of susceptible older children and adults (282). From a societal perspective, an analysis based on medical and other costs associated with the annual epidemics of varicella indicates that universal immunization programs are cost-effective (83,187,226). In prelicensure trials, the vaccine-induced protection against household exposure with an efficacy rate of more than 95% in an initial placebo-controlled study; subsequently, vaccine efficacy has been judged in open trials based on the predicated attack rate of 90% following household contact (212,359,372). Seroconversion rates are more than 95%, with complete protection against disease in 85% to 95% of exposures. Mild breakthrough infections have been observed in some children, but the disease is modified to fewer than 50 cutaneous lesions without associated fever (134,227,354). In the experience with 2,163 vaccinees evaluated at one center, 114 children developed varicella a median of 44 months after immunization; the median number of skin lesions was 18; the incidence of transmission to other vaccinated children in the household from these cases was 12% (354). Achieving seroconversion rates of more than 95% in susceptible adults has required the administration of two doses of the vaccine, separated by at least 4 weeks, which is consistent with the evidence of a diminished host response to natural varicella among adults (12,135,252). Adults are also more likely to have adverse effects, particularly transient local reactions and rash, and to have waning VZV antibody titers. However, immunizing susceptible adults has important clinical value because of their susceptibility to serious varicella, and protection or modified illness is documented despite lower antibody titers. Health care workers and others with frequent exposures to children benefit from immunization (357).

Varicella vaccine is immunogenic when administered concurrently with measles, mumps, and rubella vaccines (105). A reformulation of live attenuated varicella vaccine allows its storage at +4°C to +8°C without loss of infectious virus titer.

The safety and immunogenicity of this preparation has been established in healthy children aged 9 to 24 months (335).

The vaccine Oka strain of VZV can be transmitted from individuals when the vaccine virus causes rash, but transmission is unusual because most healthy children do not have vaccine-related rash. In one experience, a healthy adult developed a rash 12 days after vaccination; 16 days later, two children who were household contacts had lesions due to vaccine virus, as shown by restriction endonuclease analysis (132,215). The vaccine virus was also transmitted from a healthy child to a pregnant contact; there was no laboratory evidence of transplacental transmission, which is consistent with the low risk for wild-type VZV spread across the placenta (296).

The Oka-Merck varicella vaccine has been given to children with acute leukemia in remission, reducing the attack rate after household exposure to 13% (135,139). Seroconversion in these patients is associated with a high degree of protection, but most children required two doses of vaccine. Varicella vaccine must be given to these children with careful attention to the status of their underlying disease and immunosuppressive therapy regimens because it contains infectious virus (11,184). Vaccine-related rashes occurred at about 1 month after immunization in about 50% of children with leukemia in remission. Rashes occurred at the site of inoculation but also as widely scattered vesicles, indicating that the vaccine virus has not lost the capacity to cause cell-associated viremia. The vaccine virus was transmitted from about 15% of leukemic children to their healthy, susceptible siblings, but the contacts had mild clinical illness or asymptomatic seroconversion; this clinical experience provides further evidence that the vaccine virus is attenuated (134). Vaccine virus was not transmitted unless the immunocompromised child had rash, indicating that there was no significant replication of the vaccine at respiratory sites (337). Immunizing susceptible, healthy household contacts may reduce the risk for household exposure (297). No transmission of vaccine virus was observed in this clinical setting despite the heightened susceptibility of immunocompromised children to varicella, indicating that the vaccine virus does not replicate effectively in respiratory mucosa, in contrast to wild-type VZV (91,196). VZV was detected by PCR in oropharyngeal secretions from 7% of children given varicella vaccine in Japan, but infectious virus was not recovered (261).

VZV reactivation has been described in a few healthy vaccine recipients (269). When the incidence of herpes zoster was assessed in children with leukemia who had vaccine-induced immunity versus past natural infection, the vaccine virus was found to reactivate less often than wild-type VZV (164). Whether this observation indicates that the vaccine virus is less likely to establish latency or has less potential for reactivation is not known. If symptomatic reactivation occurs, the vaccine virus is susceptible to inhibition by acyclovir. In one instructive case, an otherwise healthy adult vaccine recipient had household exposure to varicella but did not develop symptoms of primary VZV infection; a subsequent episode of herpes zoster was shown to be caused by wild-type VZV, indicating that superinfection with the wild-type virus had occurred despite vaccine-induced immunity (162). Assuming that introduction of the varicella vaccine will eliminate or modify the annual varicella epidemics, exposures should be reduced significantly, and opportunities for superinfection with wild-type VZV will be minimal.

In addition to vaccination to induce primary VZV immunity, the live attenuated varicella vaccine and a heat-inactivated preparation are being evaluated for capacity to enhance immunity in seropositive individuals. Studies are in progress to determine whether the vaccine might be used to prevent or reduce the risk for VZV reactivation associated with age (221,320). The safety of the varicella vaccine also suggests that VZV may be useful as a live virus vector, and the expression of Epstein-Barr virus gp350 and hepatitis B surface antigen by recombinant VZV strains has been demonstrated *in vitro* (230,315).

Vaccine-Induced Immunity

Clinical studies of the Oka-Merck live attenuated varicella vaccine demonstrated seroconversion in more than 90% of children. The varicella vaccine also elicits VZV-specific cellular immunity (38,93,252,351), which is likely to be essential to its long-term protective efficacy. T-lymphocyte responses to VZV are detected in 98% to 100% of healthy children given the varicella vaccine by 2 to 6 weeks after immunization, as would be expected among healthy children who were convalescent from natural varicella (38). Some more immunogenic vaccine preparations had higher relative antigen content, suggesting a role for antigen as well as infectious virus in inducing the optimal host response (38,353). Vaccination elicited neutralizing antibodies and antibodies to gB and gE in titers that were equivalent to those detected after natural infection (167). In addition to requiring two doses of vaccine to achieve high levels of seroconversion, cellular immunity to VZV was significantly lower in adults given two doses compared with children who received one dose of vaccine, and lower T-lymphocyte proliferation correlated with lower IFN-g responses (190,252).

The kinetics of the induction of VZV-specific T-lymphocyte proliferation and cytotoxicity indicate rapid acquisition of these effector cells after immunization (38,92,93,208,312,352). This early T-lymphocyte response may account for the efficacy of vaccine given immediately after exposure (26). VZV-specific T lymphocytes were detected within 10 to 14 days in most individuals, whereas IgG antibodies to VZV were detected in only 40% of children tested at 2 weeks. Immunization elicits T lymphocytes that proliferate and produce lymphokines in response to stimulation with the IE62 protein and the viral glycoproteins, generating responses that are comparable to those of subjects who have naturally acquired immunity to VZV (38). Immunization with the varicella vaccine also induces memory cytotoxic T lymphocytes that can lyse cells expressing VZV proteins, with responder cell frequencies that are comparable to those elicited by natural VZV infection (221,312). When the persistence of cytotoxic T-cell responses to IE62 protein, gE, gI, and gC was examined in vaccinees about 4 years after immunization, the mean CTL frequencies were comparable in vaccinees and in adults with natural immunity (312). By intracellular cytokine assay, VZV-specific CD4+ T-cell frequencies in young adults with vaccine-induced immunity were comparable to frequencies in those with natural immunity, representing about 0.1% of peripheral blood T cells (29). The induction of VZV-specific T cells and IgG antibodies was associated with transient increases in IL-10 and IL-12 production (190).

Persistence of immunity has been documented using assays for IgG antibodies and T-cell proliferation in 94% to 100% of vaccine recipients; sustained protective efficacy of 95% was shown among vaccine recipients from the original placebo-controlled trial who were followed for 7 years (246). At a mean of 5 years after vaccination, 93% of children and 94% of adults had VZV IgG antibodies to VZV, with titers significantly higher at 5 years than at 1 year after immunization

(391). Cell-mediated immunity to VZV was detected in 87% of children and 94% of adults and was also significantly higher at 5 years. Initial differences between cell-mediated responses in children and adults diminished over time; by 5 years, cytokine responses to VZV, including IL-2, IFN-g, and IL-10, were equivalent between children and adults. In a 6- to 10-year study, 2% to 3% of children developed varicella (193). The frequency of breakthrough varicella and severity of symptoms did not change with time after vaccination; those with low or undetectable FAMA titers 6 weeks after immunization were four times more likely to have varicella. A two-dose regimen has been associated with higher immune responses in children evaluated after 1 year, but whether protective efficacy is more complete has not been determined (252,355). Evaluation of Japanese vaccine showed persistence of humoral and cellular immunity for as long as 20 years (27).

Cell-mediated immunity is elicited less reliably in leukemic children given the varicella vaccine, which is consistent with the finding that immunocompromised children often have diminished T-lymphocyte proliferation to VZV antigens after natural varicella (139). VZV-specific T-lymphocyte responses were higher in leukemic children who had been vaccinated but who did not experience recurrent VZV compared with children who developed herpes zoster (216).

The availability of the varicella vaccine has made it possible to assess the effects of exogenous reexposure to VZV antigens upon virus-specific, cell-mediated immune responses and to consider its immunogenicity among older individuals with waning responses to VZV. VZV-specific responder cell frequencies increased from 1 per 68,000 to 1 per 40,000 healthy adults older than 55 years of age who received varicella vaccine, which was equivalent to the numbers of VZV responder cells in naturally immune individuals aged 35 to 40 years; the higher responder cell frequencies persisted for at least 2 years after immunization (221). Increased production of IFN-g by T lymphocytes incubated with VZV antigen was also documented, and administration of the vaccine to elderly individuals was associated with the recovery of skin test reactivity to VZV antigen in most vaccinees. Vaccination might help to reduce the risk for herpes zoster associated with waning immunity in the elderly (40,221,320). When the immunogenicity of vaccine with concentrations of infectious virus of 3,200, 8,500, and 41,650 PFU/dose was evaluated in healthy older adults, vaccination enhanced humoral and cellular immunity regardless of the infectious virus content (41). Live attenuated vaccine may be most effective for boosting immunity because it was more likely to increase class I MHC-restricted CTL function than inactivated VZV vaccine (171).

PERSPECTIVES

New knowledge about VZV pathogenesis and immunity have been accompanied by significant advances in antiviral drug therapies and vaccine prevention of VZV disease. Further progress depends on a better understanding of VZV replication, the genes that determine VZV tropisms for lymphocytes, skin and cells of the dorsal root ganglia, and mechanisms of immune evasion. These efforts can be expected to bring further improvements in the clinical efficacy of antiviral agents against VZV and in the design of varicella vaccines.

CHAPTER 80 Human Herpesviruses 6A, 6B, and 7 and Their Replication

Philip E. Pellett and Geraldina Dominguez

Human herpesvirus 6 variants A and B (HHV-6A and HHV-6B) and human herpesvirus 7 (HHV-7) are relatively recently discovered herpesviruses. They share many properties with other herpesviruses, including virion structure, some features of genomic and genetic architecture, high prevalence in their natural host, and the ability to establish latent infections in the host. The outline of the lytic replication cycle shown in Figure 1 is similar in its general features to that for other herpesviruses, but as described later, it differs in its details and in essence describes viruses that share a number of properties that make them molecularly and biologically distinct from their relatives elsewhere in the herpesvirus family.

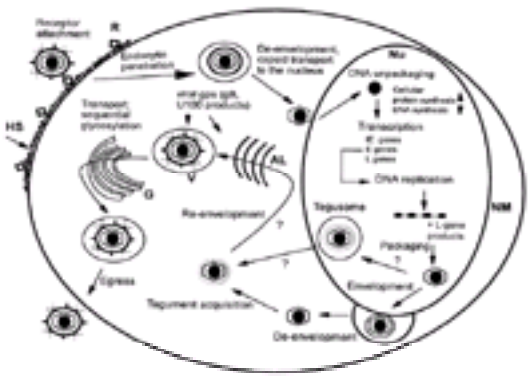

FIG. 1. Stages of replication. The replication scheme is based on published data (23,50,108,139,147). A single receptor is shown, although it is likely that the virus employs multiple receptors to enable entry into a wide range of cell types. AL, annulate lamellae; G, Golgi complex; HS, heparan sulfate; Nu, nucleus; NM, nuclear membrane; R, receptor (CD46 for HHV-6A and HHV-6B, CD4 for HHV-7); V, vacuole.

CLASSIFICATION

HHV-6A, HHV-6B, and HHV-7 compose the *Roseolovirus* genus of the betaherpesvirus subfamily. Members of this genus are characterized by growth in T lymphocytes (although they can also infect other cell types), high prevalence, and association with febrile rash illness. As betaherpesviruses, the roseoloviruses share several properties with the more extensively studied human cytomegalovirus (HCMV), including having genetically colinear genomes, encoding several genes found only in members of this subfamily, and having generally protracted replication cycles.

The HHV-6 variants are closely related, yet molecularly and biologically distinct viruses that differ with respect to their cell tropisms, interactions with cells and signaling pathways of the immune system, DNA sequences, and epidemiology (2,9,113; reviewed in 1,18,21,37, and 67). *In vivo* recombinants have not been detected that would indicate a genetic gradient between the variants. These viruses satisfy the requirements for recognition as separate herpesvirus species (18,21,37), although they have not been formally designated as such; thus, the variant designations.

VIRION STRUCTURE

Members of the *Roseolovirus* genus share the standard features of herpesvirus virion structure: an icosahedral capsid 90 to 110 nm in diameter that contains the 145- to 170-kb double-stranded DNA genome, a tegument that surrounds the capsid, and a lipid bilayer envelope that is studded with viral specified integral membrane proteins and glycoproteins; enveloped extracellular virions are 160 to 200 nm in diameter (12,13,75,147) (Fig. 2). Under some conditions of fixation, by thin-section electron microscopy, HHV-6 teguments are smooth and fill the space between the capsid and envelope, whereas the HHV-7 tegument has an electron lucent space between the tegument and envelope (13,75). Immunoelectron microscopy with a monoclonal antibody (MAb) against a tegument protein encoded by the HHV-7 gene *U14* showed

reactivity primarily at the outer periphery of the tegument (126), indicating that although the tegument can appear to be amorphous by electron microscopy, it is an ordered structure.

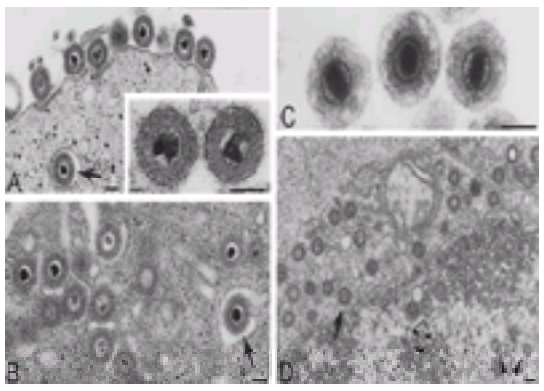

FIG. 2. Ultrastructural characteristics of HHV-6B(Z29) and HHV-7(SB) grown in human umbilical cord blood lymphocytes. **A:** HHV-6B virus particles accumulated along the plasma membrane and within a vesicle (*arrow*) of an infected cell. **Inset:** Detail of HHV-6B virions. **B:** Tegument-coated nucleocapsids of HHV-6 within the cytoplasm and apparently budding into the cisternae of the Golgi apparatus (*arrow*). **C:** Extracellular HHV-7 virions. **D:** HHV-7 nucleocapsids within the nucleus (*arrowheads*), accumulated within the perinuclear space (*open arrow*), and surrounded by tegument within the cytoplasm (*arrow*). Bars, 100 nm. (Courtesy of C. S. Goldsmith, C. Lopez, P.E.P., and J. B. Black, Centers for Disease Control and Prevention.)

GENOME STRUCTURE AND ORGANIZATION

Genomic Architecture

Genomic architecture is similar among the roseoloviruses: genomes are composed of a central unique segment (U) bracketed by a pair of direct repeat structures, DR_L and DR_R (77,86) (Fig. 3; Table 1). The overall genetic arrangement of HHV-7 is more compact than that of HHV-6. HHV-6 DR consists of 25 to 29 base pairs (bp) of unique sequence, a conserved *pac1* (cleavage and packaging) element, an array of heterogeneous repeats (L-TRS) based on the sequence TA(A/G)(C/G)(C/T)C that span about 300 bp in laboratory-passaged strains and up to 3 kb in low passage viruses, about 7 kb of unique sequence that encodes a handful of genes, an array of sequences similar to those present at the telomeres of mammalian chromosomes [R-TRS, (TAACCC)n], a conserved *pac2* element, and 16 to 18 bp of unique sequence (32,37,56,74,77,132). HHV-7 DRs follow this basic pattern but differ in some details, including R-TRS being more heterogeneous than for HHV-6 (36,109,118). Despite the differences, HHV-7 cleavage and packaging signals are recognized and processed during HHV-6 infections, and vice versa (109). Intriguingly, the HHV-6 telomeric repeat element (TAACCC) is also sparsely dispersed throughout the U segment in a palindromically symmetric manner that is centered at the origin of lytic replication (*ori*Lyt), with TAACCC to the left of the origin and GGGTTA to the right (37,57). Other repeat arrays (R0 to R3) are located in the U segment of each of the viruses (37,57,67,88,96) (see Table 1 and Fig. 3). Compared with other herpesviruses, roseoloviruses have low G+C content (see Table 1).

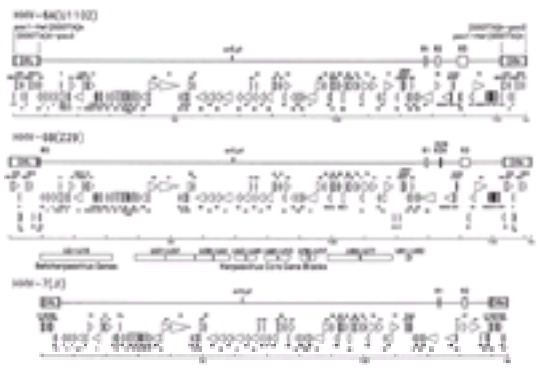

FIG. 3. HHV-6A, HHV-6B, and HHV-7 genomic and genetic architecture. The diagrams are based on annotations of published genomic sequences (37,57,88,96). The positions and arrangements of the major internal repeat elements, the origin of replication (*ori*Lyt), and the structure of the DR termini are shown for each virus. Open reading frame (ORF) sizes, orientation, and location are indicated. HHV-6A genes *DR4, DR5, DR8, U1, U61, U78, U88, U92,* and *U93* do not have counterparts in the other viruses; ORFs found in HHV-6B and not in HHV-6A are designated B1 through B9, and those present in HHV-7 and not in HHV-6A or HHV-6B as H1 through H8. The orientation and order of the seven conserved herpesvirus core gene blocks are indicated, as is the block (*U2* to *U19*) found only in the betaherpesviruses. Genes unique and common to the roseoloviruses are indicated by horizontal lines between the forward and reverse strand genes.

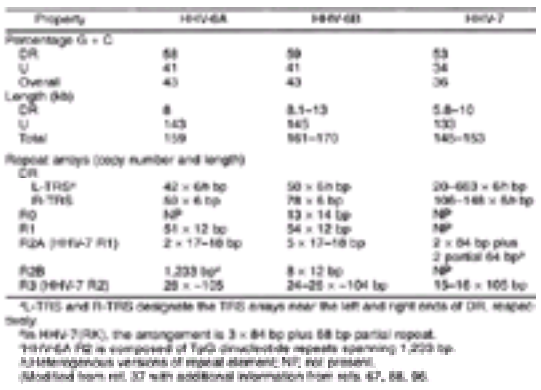

Property	HHV-6A	HHV-6B	HHV-7
Percentage G + C			
DR	58	59	53
U	41	41	34
Overall	43	43	36
Length (kb)			
DR	8	8.1–13	5.8–10
U	143	145	133
Total	159	161–170	145–153
Repeat arrays (copy number and length)			
DR			
L-TRS[a]	42 × 6/7 bp	50 × 6/7 bp	20–663 × 6/7 bp
R-TRS	50 × 6 bp	78 × 6 bp	106–148 × 6/7 bp
R0	NP	13 × 14 bp	NP
R1	51 × 12 bp	54 × 12 bp	NP
R2A (HHV-7 R1)	2 × 17–18 bp	5 × 17–18 bp	2 × 84 bp plus 2 partial 64 bp[b]
R2B	1,233 bp[c]	8 × 12 bp	NP
R3 (HHV-7 R2)	28 × ~125	24–28 × ~104 bp	15–16 × 105 bp

[a] L-TRS and R-TRS designate the TRS arrays near the left and right ends of DR, respectively.
[b] As HHV-7 (RK), the arrangement is 3 × 84 bp plus 68 bp partial repeat.
[c] HHV-6A R2 is composed of TpG dinucleotide repeats spanning 1,233 bp.
NP, heterogenous versions of repeat element; NP, not present.
(Modified from ref. 37 with additional information from refs. 67, 88, 96).

TABLE 1. *Properties of roseolovirus genomes*

The function of the mammalian telomere-like sequences is not known. They appear to have no role in either nuclear retention of viral DNA, efficiency of DNA replication, or packaging-associated DNA cleavage (19,32). A possible function is mediation of the site-specific integrations of HHV-6 genomes that have been observed in the vicinity of host chromosome telomeres (31,32,138).

Genetic Structure and Genetic Relationships

Protein-encoding open reading frames (ORFs) are encoded on both strands, with little overlap among adjacent ORFs (see Fig. 3). In addition to most of the repeat arrays, there are two genomic regions of no obvious protein coding capacity: the region between *U41* and *U42* that harbors the origin of lytic DNA replication (*ori*Lyt), and the region between *U77* and *U79.*

Many of the genes encoded in the central portion of roseolovirus genomes are conserved among the alpha-, beta-, and gammaherpesviruses (37,57,67,88,96) (herpesvirus core genes; Table 2; see Fig. 3 and Chapter 71). A group of genes conserved among the betaherpesviruses is located to the left of the core genes. Clusters of genes unique to the roseoloviruses are located to the left and right of the core genes.

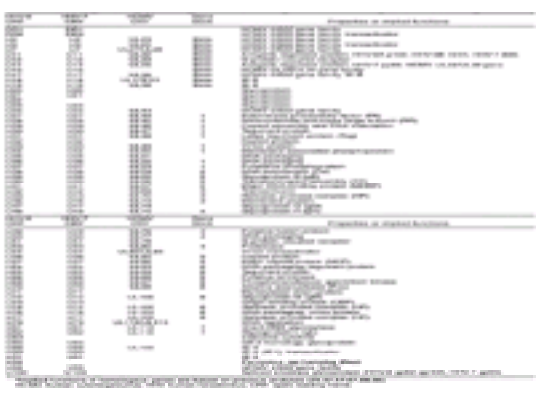

TABLE 2. *HHV-6 and HHV-7 genes of known or implied functions and their HCMV homologs*[a]

In comparisons with *Cytomegalovirinae* and *Muromegalovirinae,* the roseoloviruses are genetically colinear over the conserved domains, although the cytomegaloviruses encode many genes that have no counterparts in roseoloviruses. Among the roseoloviruses, HHV-7 is about equally related to the HHV-6 variants, with amino acid sequence identities ranging from 22% to 75%, most being in the vicinity of 50% (37,67,96). HHV-6A and HHV-6B are closely related viruses, with overall nucleotide sequence identity of 90%; the portions of the genomes that span *U32* to *U77* are highly conserved (95% identity) (37,67). The segment spanning U86 to U100 is 72% identical, with only one gene in this region having amino acid sequence identity over 90% (*U94,* 97.4% identity).

Roseolovirus DNA sequences vary less from strain to strain within a species than do many other herpesviruses, such as herpes simplex virus (HSV) or HCMV. Across segments spanning several kilobases, HHV-6A strains differed by less than 0.5%, although there were short segments of greater variability (54,55,130); HHV-6B strains HST and Z29 differ by less than 1% across their entire genomes (G.D. and P.E. Pellett, unpublished analysis); other than repeat copy number differences, HHV-7 strains JI and RK differ by only 179 bp (0.1%) over their genomes (88). Conservation can be even higher at the amino acid sequence level, with U94 amino acid sequences being identical among 13 HHV-6B isolates from Africa, Japan, and the United States (105), and nearly as high conservation in HHV-7 glycoprotein B (gB) (48). The biologic forces that restrict sequence variation this tightly are not understood but must in some way be linked to the low G+C content of these viruses, which precludes easy variation at third-position “wobble” codons.

There is evidence for subgrouping within the HHV-6B variant at some genomic loci (27,54) and among HHV-7 isolates (48), but there is no indication that this is anything other than intraspecies allelic variation.

Roseoloviruses differ somewhat from each other in their genetic complement. According to a recent analysis, nine HHV-6A ORFs do not have HHV-6B counterparts, and nine HHV-6B ORFs have no HHV-6A counterpart (37). Interpretation of these differences is difficult because somewhat different criteria have been employed to predict functional ORFs of the sequenced viruses. In addition, in the absence of clear similarity with genes from other

herpesviruses or in the sequence repositories, such predictions must be considered provisional pending experimental study. Megaw and colleagues (88) compiled a list of 16 HHV-6A ORFs considered unlikely to encode proteins, one of which was subsequently shown to encode a functional cytokine (151). It remains to be seen whether other of these or the other small unique ORFs are also functional. *DR3, U6, U22, U83,* and *U94* are encoded by both HHV-6A and HHV-6B but not HHV-7; interestingly, a *U94*–parvovirus *ns1–rep* homolog is encoded adjacent to a U95 homolog in rat cytomegalovirus, but in neither human nor murine cytomegalovirus (141). HHV-7 encodes a duplicated gene (*U55A* and *U55B*) that is present in a single copy in HHV-6A and HHV-6B. Among the betaherpesviruses, roseolovirus-specific genes include *U20, U21, U23, U24, U24A, U26,* and *U100.*

In addition to their overall genetic colinearity with the cytomegaloviruses, two aspects of similarity among the betaherpesviruses warrant specific mention. First, although the amino acid sequences have diverged to the point of no detected similarity, the general layout and splicing patterns of two cytomegalovirus immediate-early (IE) regions are conserved in the roseoloviruses. Thus the roseolovirus IE-B domain that spans *U17* to *U19* corresponds to the HCMV *UL36* to *U38* IE locus, and the IE-A domain spanning *U86* to *U90* corresponds to the HCMV major IE locus (85,96). Second, every betaherpesvirus encodes several members of a family of duplicated and diverged genes that are related to HCMV *US22* and are referred to as the *US22* gene family. *US22* homologs encode at least one of four conserved motifs (96). For HCMV, some are transcribed as IE genes and encode transactivating functions. In the roseoloviruses, *DR2, DR6/7, U2, U3, U5, U7* (*U5/7* in HHV-7), *U8, U17/16, U25,* and *U95* are all members of this gene family. Although their transcription has not been studied extensively, as discussed later, at least four of the HHV-6A US22 homologs encode transactivators (*DR6, U3, U16,* and *U25*).

STAGES OF REPLICATION

Entry

CD46 was recently identified as a cellular receptor for HHV-6 (111). CD46 is a member of the regulator of complement fixation family and is expressed on the surface of all nucleated human cells; it is a cellular receptor for measles virus. Evidence for the CD46 receptor activity included (a) down-modulation of CD46 expression in activated primary human CD4+ lymphocytes infected with HHV-6A or HHV-6B, (b) inhibition of HHV-6 infections and associated cell fusion by MAbs against CD46 and by soluble CD46, and (c) nonhuman cells being rendered susceptible to HHV-6–mediated membrane fusion and HHV-6 entry by expression of CD46. Nonetheless, expression of CD46 was not sufficient for HHV-6 fusion and infection in all human cell types, suggesting either that a specific co-receptor is needed or that some cells express an inhibitor of the CD46 receptor activity. In previous work, Lusso and colleagues, as well as others, also showed that HHV-7, but not HHV-6, uses CD4 as one of its receptors (84,144,146), although the virus can infect cells that do not express detectable CD4 (72). It is likely that other host molecules act as receptors; the need for multiple sequential receptors to enable cell-to-cell migration of the virus in tissues is a well-documented phenomenon in other herpesviruses (see Chapter 72).

The human immunodeficiency virus type 1 (HIV-1) co-receptors, CXCR4 and CCR5, have been studied to determine whether they serve similar functions for the roseoloviruses. Cells from individuals lacking CCR5 were able to support growth of all three viruses, and these individuals were seropositive for the viruses, indicating that this molecule is not essential for viral replication (143). Data for CXCR4 are conflicting. An MAb against CXCR4 did not inhibit infection by any of the viruses (120,143,149), nor did a specific CXCR4 antagonist that can inhibit HIV-1 infectivity (149). Nonetheless, the natural CXCR4 ligand, SDF-1a, inhibited HHV-7 infection at 2.5 µg/mL (120) but not at 1.0 µg/mL (149).

On the virus side, two HHV-7 glycoproteins have been identified as being able to bind the cell surface proteoglycans heparan and heparan sulfate: the virion glycoprotein, gB, and the spliced glycoprotein encoded by *U100* (102,119,123). It is likely that other virion proteins are involved in receptor interactions or entry, such as the gH–gL complex (4,45,78,128), which along with products of *U100* (102), are targets for complement-independent neutralization. Once attached, viral entry appears to be through an endocytic pathway rather than by fusion at the plasma membrane (29).

Transcription

Herpesvirus genes generally belong to one of two main categories: latent or lytic. As described for Epstein-Barr virus, latent gene expression can follow more than one program. There are three kinetic classes of lytic genes: IE, or genes that provide functions for regulation of gene expression; early (E), or genes that encode proteins needed for DNA replication; and late (L), or genes that encode virion proteins. IE gene transcription does not require *de novo* protein synthesis and begins at very early times after infection. Transcription of E genes is dependent on IE gene activity but not on viral DNA replication, and transcription of L genes is either partially or entirely dependent on viral DNA replication.

The kinetics of roseolovirus gene expression have not been extensively studied but appear to follow the general program of other herpesviruses. Studies of gene expression in these viruses have been complicated by the lack of methods for preparing high-titered cell-free virus stocks; the low-multiplicity infections used thus far have limited the sensitivity of detecting transcripts and proteins. For HHV-6A and HHV-6B, *U83* and *U89/90* encode experimentally proven IE genes (49,68,105,112). In both cases, multiple differently regulated transcripts are expressed. A protein encoded within *U89/90* has transcriptional activation activity, but its role in HHV-6 infections has not been defined. The IE transcript of *U83* is spliced and would express a truncated version of the chemokine encoded by *U83,* whereas the full-length transcript is expressed as a late gene (49,151; K. Yamanishi, personal communication). Genes *U16* through *U19* have been designated as IE locus B based on their HCMV homologs, but their transcriptional kinetics have not been studied experimentally. *U42* encodes a homolog of the HSV IE gene a*27* and HCMV *UL69,* which is regulated as an E gene; HHV-6B *U42* is not transcribed in the absence of *de novo* protein synthesis; thus, its regulation is similar to that of its HCMV counterpart (105).

Several genes encoding proteins involved in replication or structure of both HHV-6 and HHV-7 were identified as IE genes in studies that involved reverse transcription coupled with 35 cycles of polymerase chain reaction (PCR) (89,91); it

seems likely that the sensitivity of the assay led to detection of leaky E transcription under IE conditions and misassignment of the kinetic classes. In experiments that involved quantitative comparisons of transcript levels, some of these previously identified IE genes were not expressed in the absence of *de novo* protein synthesis (105). In studies of temporal kinetics, expression of the *U90* IE gene rose to more than 10 copies per cell within 8 hours, whereas a structural gene transcript (*U11*) took 16 hours to reach comparable levels; at 72 hours after infection, *U11* was expressed at several hundred copies per cell. Transcripts of the gene needed for initiation of DNA replication (*U73*) and the parvovirus *ns1–rep* homolog (*U94*) were expressed at much lower levels (less than 10 copies/cell).

Most transcripts expressed by these viruses are not likely to be spliced, although several are, some more than once. Among them are the major IE locus and *U100* (103,123). In addition, the use of some splice sites is kinetically regulated (89,91,112,151); others use noncanonical donor and acceptor sequences (49,151). On the basis of HHV-6A and HHV-7 genomic sequences, Megaw and colleagues provided detailed predictions of splicing patterns that will be useful in guiding and interpreting future experiments (88).

The cis-acting sites important for regulating the expression of roseolovirus genes have not been well-characterized. The locations of the 5' ends have been determined for a number of transcripts, which will enable study of their regulatory elements. The HHV-6 R3 repeat element (R2 in HHV-7) is a potential IE enhancer (134). R3 is present about 300 bp upstream of the *U89/90* IE ORF and is present in more than 25 copies per genome (see Table 1). The elements contain potential transcription factor–binding sites (NF-B and AP2 in HHV-6A, PEA3 and AP2 in HHV-6B, and PEA3 in HHV-7). The regulatory function of this region has not been studied experimentally. The two HHV-6A promoters that have been studied experimentally are from the genes encoding the DNA polymerase (*U38*) and its processivity factor (*U27*). Both promoters were active in infected, but not in uninfected, cells; thus, they have virally responsive promoter elements (3,131). The *U38* promoter is TATA-less, and its activity is dependent on a palindromic ATF/CREB-binding site (3). *U27* expression is dependent on a sequence that is located 52 to 73 bp upstream of the transcription initiation site and may be controlled by both positive and negative regulators.

Of the genes examined, the only transcript detected in primary peripheral blood mononuclear cells (PBMCs) that were PCR-positive for HHV-6 DNA was derived from *U94* (110), raising the possibility that this gene, or one whose transcript spans it, plays a role in establishment or maintenance of latency. If these results are confirmed and a role for *U94* in HHV-6 latency is identified, this would constitute a significant biologic difference from HHV-7 because HHV-7 does not encode a *U94* homolog. Hints to *U94* function may come from studies of rat cytomegalovirus, which encodes a *U94* homolog (141) and is amenable to genetic manipulation and then study in its natural host species. In a different study, none of three HHV-7 lytic cycle transcripts studied were detected in HHV-7 DNA-positive PBMCs (89), suggesting that the virus is truly latent in these cells.

Translation and Transport

Studies of roseolovirus translation have been limited by (a) the low multiplicities of infection described previously, (b) background due to stimulation of host cell protein synthesis by infections with these viruses, and (c) lack of extensive panels of MAbs to viral proteins. Nonetheless, progress has been made, and some interesting areas have been identified.

Infected cell proteins have been studied *en masse* by immunoprecipitation of radiolabeled HHV-6A proteins with high-titered human serum (10,11,122). Twenty to 25 polypeptides were identified, ranging in size from 26 to 280 kd, including at least 10 glycoprotein species. In one set of studies, a prominent species of 135 kd was detected by all sera tested (10,11). For HHV-7, human serum and serum from mice immunized with infected cells recognized 16 to 20 proteins, with sizes ranging from 26 to 210 kd, and including at least seven glycoproteins (44,94).

MAbs have been developed against proteins encoded by HHV-6A (10,20,107), HHV-6B (43,99,100,142), and HHV-7 (44,94). Some MAbs are cross-reactive with all three viruses, some cross-react only between HHV-6A and HHV-6B, and some are virus specific (94; summarized in 15,43, and 44).

HHV-6 *U94* is expressed as a low-copy-number spliced transcript that encodes several small AUG-initiated ORFs upstream of the *U94* ORF (105). None of the initiation codons, including that for *U94,* has the hallmarks of being efficiently translated. This suggests that in addition to tight control of its transcription, *U94* is translationally regulated to prevent high expression.

U51 encodes a G-protein–coupled receptor homolog that is expressed on the surfaces of transfected T-cell lines but in other cell lines accumulates intracellularly without being transported to the cell surface (90), suggesting the presence of a cell-specific transport or processing function.

Virally Encoded Transcription Regulators

As would be expected for herpesviruses, roseoloviruses encode genes that are predicted to regulate transcription. In addition, the broad stimulation of host cell protein synthesis on infection is evidence for viral modulation of cellular promoter activity (10,13,14). Thus far, HHV-6 genes have been studied only for their ability to regulate cellular promoters or promoters from other viruses. This provides evidence of the ability of the roseoloviruses to interact with and modulate cellular transcriptional machinery, which is likely to be important both during lytic growth and to maintain a persistent infection in the host. Little attention has been focused on the role of roseolovirus gene products in regulating expression from their native virus.

The regulators that have been studied are encoded by the HHV-6A IE-A and IE-B loci, *DR6, U3, U27,* and *U94.* Positive regulatory effects have been seen by transfection or infection in a variety of cell types on heterologous viral promoters, including the HIV-1 and HTLV-1 LTR (22,40,52,53,71,85,87,92,150), Epstein-Barr virus LMP-1 and EBNA-2 (30), HSV gD (22), human papillomaviruses 16 and 18 (26), and the adenovirus *E3* and *E4* genes (85). In addition, negative regulatory

effects have been observed on cellular promoters for p53, H-ras, and CXCR4 (6,70,143), along with mixed effects on the CD4 promoter (positive by HHV-6A and negative by HHV-7) (42,117). Up-regulation of the HIV-1 LTR is variously dependent on the presence of the NF-kB, AP-1, TAR, and SP1 sites, whereas its suppression by *U94* is independent of NF-kB and SP1 but dependent on the TAR element.

Functions of Other Virally Encoded Gene Products

Functional studies have been done on several genes in addition to those described in detail elsewhere in this chapter.

Structure and Morphogenesis

U11

U11 encodes p100 and 101K, the HHV-6A and HHV-6B homologs of HCMV pp150 (95,101). The protein is a tegument protein and is the dominant antigen recognized by HHV-6–specific IgG in immunoblots. The HHV-7 *U11*-encoded counterpart, 89K, is one of the major HHV-7 antigens (125; and E. Balada and P.E Pellett, unpublished data).

U14

HHV-7 *U14* encodes pp85, an 85-kd tegument-associated phosphoprotein that is its major antigen (46,125). As mentioned previously, an MAb against pp85 reacted with the outer surface of the tegument by immunoelectron microscopy, providing the first evidence that herpesvirus teguments are ordered structures (126).

gB

The glycoprotein gB is encoded by *U39.* It is a conserved herpesviruses glycoprotein that is found on virions of most herpesviruses, including roseoloviruses (28). It has roles in attachment and penetration and is a target for complement-independent neutralization (129). The primary HHV-6A gB translation product of about 112 kd is proteolytically cleaved to form disulfide-bond–linked subunits of 64 kd and 58 kd (39,47); for HHV-6B and HHV-7, the corresponding products were about 102, 59, and 50 kd, and 112, 63, and 51 kd, respectively (20,47,59). Similar to gBs of other herpesviruses, the extracellular domain of HHV-7 gB binds to cell surface heparan sulfate proteoglycans, suggesting a role in adsorption of the virion to cells (119).

gH and gL

As for other herpesviruses, the conserved virion glycoproteins gH and gL, encoded in roseolovirus by ORFs *U48* and *U82,* respectively, form heterodimers with each other (78,79,93), and together have roles in membrane fusion associated with both virus entry and cell-to-cell spread (45,104).

U53

The proteinase required for capsid maturation, DNA packaging, and virus assembly is encoded by *U53.* The HHV-6 proteinase, like that from other herpesviruses, is translated as a precursor molecule that is autolytically processed at two sites (the release and maturation sites) to produce the mature proteinase and assembly proteins. As in the other herpesviruses, the processing sites consist of an Ala-Ser sequence. In contrast to the other herpesviruses, roseoloviruses lack an internal autocatalytic cleavage site (Ala-Ala instead of Ala-Ser), which results in their proteinase being a single-chain enzyme (136,137).

Gene Regulation

U3

U3 is a member of the HCMV *US22* gene family. In HHV-6A, it is expressed as two unspliced transcripts of 2.0 and 3.5 kb. *U3* is expressed as early as 24 hours after infection and localizes to cytoplasmic granules associated with the endoplasmic reticulum. The U3 protein can transactivate the HIV-1 LTR (92).

U94

HHV-6A and HHV-6B *U94* encodes a homolog of the parvovirus *ns1* or *rep* gene (133), which is essential for parvovirus DNA replication (see Chapter 69). The Rep68 protein of adeno-associated virus type 2 (AAV-2) is a site-specific adenosine triphosphate–dependent endonuclease and helicase and is involved in site-specific integration of the viral genome into the host genome. HHV-6A *U94* can serve as a helper for AAV-2 replication, and *U94* can complement a point mutant of AAV-2 *rep* (135). In addition, *U94* suppressed H-*ras* and BPV-1 transformation (7) and transcription from the H-*ras* and HIV-1 LTR promoters (6). Cell lines expressing HHV-6B *U94* were refractory to infection by HHV-6A (110). As mentioned previously, *U94* is the only HHV-6 transcript detected during latency in PBMC (110), and HHV-7 does not encode a *U94* homolog, although rat cytomegalovirus does.

Replication of Genome

The three major problems these viruses need to solve to replicate their genomes lytically are ensuring adequate pools of nucleotides, initiation and chain elongation at a replication fork, and packaging and cleavage of nascent molecules.

Nucleotide Metabolism

As do the other herpesviruses, roseoloviruses encode several enzymes that have roles in nucleotide metabolism and provide the precursors needed for nucleic acid synthesis: ribonucleotide reductase, a phosphotransferase, alkaline exonuclease, and uracil-DNA glycosylase. In contrast to many ribonucleotide reductases, the one encoded by roseoloviruses consists of a single subunit that is homologous to the large subunit of two-subunit enzymes (97). Unlike some other herpesviruses, the roseoloviruses do not encode a thymidylate synthase or thymidine kinase.

Initiation and Elongation

Lytic DNA replication is initiated at an *ori*Lyt that is similar to alphaherpesvirus *ori*Lyts and markedly different from the *ori*Lyts of other betaherpesviruses and the gammaherpesviruses. As defined in transient replication assays, HHV-6 and HHV-7 *ori*Lyts map between the 5' end of *U41* and the 3' end of *U42* (33,109,140). *U41* encodes the major DNA-binding protein; *ori*Lyts for other herpesviruses also map in the region upstream of their homolog of this gene. The minimal *ori*Lyt segment is about 300 bp long, and a fully functional *ori*Lyt is about 800 bp long (33). The precise role of much of this sequence is not understood, but a critical element near the center of *ori*Lyt consists of two palindromically arranged sequences, OBP-1 and OBP-2, that are recognized by the origin-binding protein (OBP) encoded in roseoloviruses by *U73* (a homolog of HSV-1 *UL9*) (64). The core OBP sites flank an AT-rich sequence of about 30 bp (Fig. 4). Several positions within the OBP-binding sites are conserved among the viruses that encode OBP homologs, whereas others differ in a manner that provides viral specificity (65); mutations in these sequences can reduce or eliminate OBP binding and origin activity (34,64,65,140). Replication efficiency is also affected by the sequence and composition of the AT-rich spacer (38). By analogy with HSV, replication initiation is likely to initiate through a process that involves OBP molecules binding to the two OBP sites, dimerization through an amino-terminal domain (64) between OBP molecules bound to adjacent sites, bending- and helicase-induced strand separation in the AT-rich region between the OBP-binding sites, and then assembly of the replication fork complex on the OBP-anchored complex (17).

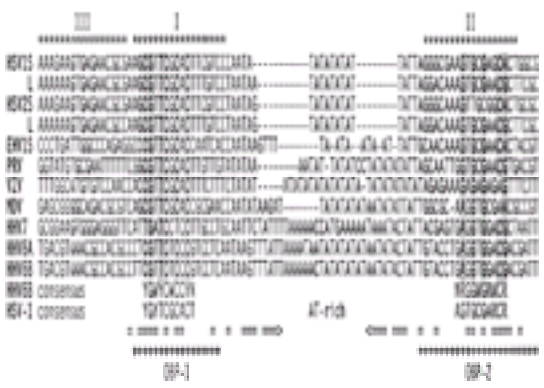

FIG. 4. OBP-binding regions of *ori*Lyts of alphaherpesviruses and roseoloviruses. HSV1 L, herpes simplex virus type 1 oriL; HSV1 S, herpes simplex virus type 1 oriS; HSV2 L, herpes simplex virus type 2 oriL; HSV2 S, herpes simplex virus type 2 oriS; EHV1 S, equine herpesvirus 1 oriS; PRV, pseudorabiesvirus; VZV, varicella-zoster virus; MDV, Marek's disease virus. Residues identical to the HHV-6 consensus are in *bold type. Horizontal arrows* indicate a structure with dyad symmetry in the HHV-6B sequence. I, II, III: Box I, II, III of HSV-1 oriS. (Modified from refs. 64 and 65; Courtesy of Naoki Inoue, Centers for Disease Control and Prevention.)

HHV-6A and HHV-6B are able to support replication of each other's *ori*Lyt (34,109), an indication of their close relationship. In contrast, plasmids containing the HHV-6 *ori*Lyt were replicated in HHV-7–infected cells, but not vice versa, suggesting that *ori*Lyt sequences and binding specificities differ between the viruses (140).

In some passage lineages of HHV-6B, an 856-bp segment that contains the OBP-binding sites and corresponds almost exactly to the minimal efficient origin region defined in transient replication assays was amplified to as many as 12 tandem copies per genome (124). In addition to the amplified segment conferring a growth advantage on cultured virus, a similar tandemly reiterated segment enabled more efficient replication of an origin-containing plasmid (34). The structure of the repeated element and its flanking region suggested that HHV-6B or a progenitor virus acquired *ori*Lyt by transposition from an unknown exogenous source.

In addition to OBP, roseoloviruses encode homologs of the six other virally encoded proteins needed for replication of plasmids containing an HSV *ori*Lyt. By analogy with HSV, these proteins are expected to operate at the replication fork; they include the major DNA-binding protein, the DNA polymerase and its processivity factor, and three gene products that compose the helicase–primase complex. In an *in vitro* DNA synthesis system that employed the single-stranded M13 genome as a template, the HHV-6A DNA polymerase alone synthesized molecules shorter than 100 nucleotides (76). Upon the addition of the 41-kd polymerase processivity factor homolog encoded by *U27* (p41), molecules greater than 7,200 nucleotides in length were synthesized, similar to the processivity increase produced by its homologs in other herpesviruses. The two proteins could be reciprocally immunoprecipitated from infected cells, an interaction mediated by domains from both the N- and C-terminal regions of the polymerase. The N-terminal portion of the processivity factor was required for the processivity-enhancing activity.

Genome Packaging and Cleavage

About 5% of genomes contained in nucleocapsids are circularized, creating a juxtaposition of DRR and DRL similar to that in concatemerized DNA (77); by analogy with HSV, it is possible that additional molecules are circularized when nucleocapsid DNA is released into the nucleus. Circularized molecules provide the template for rolling-circle replication, which leads to production of long concatemers of nascent DNA for packaging into capsids (109). In addition, the

juxtaposition of the DR elements results in assembly of a complete cleavage and packaging signal. The structure of an HHV-6 concatemeric or circular junction is as follows: DR_R-(TRS)n-*pac2*-$N_{16–18}$-junction-$N_{25–2ϱ}$-*pac1*-het(TRS)n-DR_L (32,37,56,109,118,132) There is some heterogeneity in the sequences of concatemeric junctions, with 1 to 8 bp of additional, possibly untemplated, DNA being inserted into some molecules (37,118). In the model of Frenkel and Roffman (50), concatemers are cleaved between properly juxtaposed *pac1* and *pac2* sequences after a headful threshold has been reached during packaging, leading to unit-length packaged genomes.

Identification of the *ori*Lyt and cleavage and packaging signals allowed development of HHV-6– and HHV-7–based amplicon systems (32,109) that feature T-cell replication, *ori*Lyt, and cleavage-packaging signals and can be used for expression of foreign genes. They have potential use as gene therapy vectors.

Assembly and Release

There appear to be two main pathways for herpesvirus virion maturation (see Chapter 71). One, used by HSV and other viruses, involves acquisition of the envelope during passage of the nascent virion from the nucleus through the inner nuclear membrane. Current evidence suggests that this envelope is retained throughout the subsequent maturation process; thus, this is the envelope worn by the virus when it leaves the cell. The other pathway, used by VZV and the roseoloviruses (among others), appears to involve a process of successive envelopment, de-envelopment, and re-envelopment as the virion moves from one membrane-bounded compartment to another. A model of roseolovirus virion maturation that is consistent with current information is illustrated in Figure 1. DNA replication and capsid assembly take place in the nucleus; nascent capsids that contain DNA appear about 3 days after infection (13,16). A feature that is likely to be a result of the envelopment-development process is the presence of abundant nonenveloped, tegumented nucleocapsids in the cytoplasm (12,13,98,108,139,147). In some studies, particles with neither tegument nor envelope were observed in the cytoplasm (13,139). In these studies, teguments appeared to be acquired cytoplasmically in pools of electron-dense material. The virion glycoproteins gB, gH–gL, and gp82–gp105 (encoded by *U100*) are absent from both the nuclear and plasma membranes but are concentrated in cytoplasmic structures known as annulate lamellae (23,28,139), which appear to be related to membranes of the endoplasmic reticulum and are possible sites for envelopment and glycoprotein maturation. Some authors have observed membrane-bound nuclear structures, in which capsids appear to have acquired their tegument. These structures, termed *tegusomes,* have been proposed as the site of tegument acquisition (50,98,108), but given the relatively low frequency with which they are observed, it seems unlikely that this is the major pathway. The absence of viral glycoproteins from plasma membranes precludes these membranes from being a site for envelopment or egress by budding directly from the cytoplasm. Thus, after passage through the Golgi, mature virions are released by exocytosis or cell lysis (28,139).

Fate of Host Cell

Roseolovirus infection has profound effects on host cells, including margination of chromatin (98), shutoff of host cell DNA synthesis (35), and a generalized stimulation of host cell protein synthesis (10,13,14). This leads to the development of the classic cytopathic effect of ballooning, refractile, multinucleated giant cells. For at least HHV-7, the multinucleated cells develop, not by fusion of cells into syncytia, but by polyploidization that is linked to dysregulation of cdc2 and cyclin B. This leads to an accumulation of cells in the G_2 to M phase of the cell cycle, with nuclei continuing to reproduce in the absence of cell division (114). Cytokines can be induced, including interferon-a, interleukin 1b (by HHV-6A but not HHV-6B), and tumor necrosis factor (41,63,73), as is the G-protein–coupled peptide receptor, EB1 (ligand unknown) (58). In addition, HHV-6A and HHV-6B can inhibit the proliferative responses of PBMCs to antigens and mitogens (61).

HHV-6A infection induces cell-surface expression of CD4, which then allows infection by HIV-1 of cells such as natural killer (NK) cells that were previously refractile to infection (80,81,83). HHV-6A, but neither HHV-6B nor HHV-7, down-regulates cell surface expression of CD3; HHV-7 sharply down-regulates CD4 (51,82,117).

Down-regulation of expression of the HIV-1 co-receptor, CXCR4, and a coupled reduction in Ca^{2+} flux in response to SDF-1a was observed in two studies (120,143); in contrast, no effect of HHV-7 infection on CXCR4 expression was seen in another study (149).

HHV-6A and HHV-6B modestly (twofold) induced several T-cell adhesion markers, including CD2, CD4, CD11a, CD44, CD49d, and HLA-DR, whereas HHV-7 had little effect on these or other tested markers. HHV-6B infection had little effect on CD4+ cytotoxic lymphocytes, but HHV-6A and HHV-7 decreased their activity; the inhibition by HHV-7 was overcome by lectin stimulation (51). Thus, the three viruses differ in their effects on T cells.

HHV-6A, HHV-6B, and HHV-7 were evaluated for their effects on *in vitro* colony formation of hemopoietic progenitor cells derived from human umbilical cord blood lymphocytes (69); HHV-6A suppressed erythroid colonies, HHV-6B suppressed erythroid and granulocyte-macrophage colonies, and HHV-7 had no effect on either lineage. In contrast, in bone marrow-derived cells, both HHV-6A and HHV-6B suppressed erythroid, granulocyte-macrophage, and multipotential precursors of the granulocyte, erythrocyte, monocyte, and megakaryocyte lineages, with HHV-6A being the more potent inhibitor (24).

Some parallels have emerged in studies of apoptosis induction during infections with HHV-6 and HHV-7. In fresh umbilical cord blood lymphocytes infected cells are apoptotic (13,62), whereas in cell lines, infected cells die by necrotic lysis and apoptosis is triggered in apparently uninfected or nonproductively infected cells (66,116). The latter observation suggested that the virus may be able to inhibit apoptosis in at least some cells and that its replication might be enhanced by suppression of apoptosis. This was borne out experimentally for HHV-7 in cells expressing high levels of the apoptosis suppressor, *bcl-2* (115). During *in vivo* primary HHV-6B infections, apoptosis was detected in 15% to 20% of circulating PBMCs (145). On the basis of other studies, it seems unlikely that such a high percentage of cells would be infected; thus, HHV-6B appears able to induce apoptosis in bystander cells. This is a possible cause of the transient lymphocytosis associated with primary HHV-6B infection and may contribute to controlling the viremic stage by reducing

the number of infected circulating lymphocytes.

The molecular mechanisms are just beginning to be understood for the many effects these viruses have on cells. *U83* encodes a cytokine that can induce transient calcium mobilization and serve as a chemoattractant for mononuclear cells (151), possibly to attract susceptible cells to sites of viral replication. At least one of the two homologs of cellular G-protein–coupled receptors encoded by HHV-6, *U12,* encodes a functional b-chemokine receptor, which has a selectivity that differs somewhat from its cellular homologs in its higher relative affinity for RANTES relative to macrophage inhibitory proteins 1a and 1b or monocyte chemoattractant protein 1 (68).

Growth Properties

Roseolovirus replication cycles are about 3 days in activated primary T lymphocytes grown in the presence of interleukin-2 (IL-2). Infectious yields are relatively low, with the concentration of virus in culture supernatants or in stocks prepared from infected cell lysates commonly ranging from 10^3 to 10^5 infectious units per milliliter; centrifugal concentration can be used to increase the infectious titer. Particle-to-infectious unit ratios of 10^3 and 10^4 were observed for HHV-6B in the culture supernatant and in sonicated infected cells, respectively (121).

In vivo, these viruses have been detected in a variety of cell types, but *in vitro,* they replicate most efficiently in activated primary lymphocytes, although both HHV-6A and HHV-6B can also replicate in primary fetal astrocytes and dendritic cells (8,60). Both HHV-6A and HHV-6B can produce infected foci in fibroblasts, but only HHV-6A produced infectious progeny (at low yield) (106). Laboratory strains have been adapted for growth in continuous T-cell lines that include HSB-2 and JJHAN for HHV-6A, Molt-3 for HHV-6B, and SupT1 for HHV-7 (reviewed in 15 and 18). Other than the use of CD46 and CD4 as the HHV-6 and HHV-7 receptors, respectively, the molecular restrictions on host cell range have not been identified.

INHIBITORS OF REPLICATION

Ganciclovir and phosphonoformate (foscarnet) and cidofovir are potent inhibitors of roseolovirus replication *in vitro;* acyclovir and other thymidine kinase–dependent drugs are only marginally effective (13,127,148; reviewed in 18). Ganciclovir is probably activated by the phosphotransferase encoded by gene *U69,* which can confer ganciclovir susceptibility on recombinant baculoviruses (5).

PERSPECTIVES

Studies of the roseoloviruses have been hampered by several factors, including the inability to prepare high-titered cell-free virus, the availability of relatively few MAbs, and lack of either a useful animal model system or a system for genetic manipulation of the viruses. Nonetheless, several interesting features of these viruses have been identified, including the presence near the viral genomic termini of arrays of sequences (TRS) that are similar to sequences found at mammalian telomeres, the presence of an OBP homolog and cognate-binding sequences that are similar to those previously found only in the alphaherpesviruses, a broad stimulation of host cell protein synthesis in infected cells that is unique with respect to effects on host cell metabolism described for other herpesviruses, and the presence in HHV-6A and HHV-6B genomes of a homolog of a parvovirus replication and regulatory protein. We anticipate that the implications of these observations will become apparent and that other novel aspects of the biology and molecular biology of these viruses will be identified in future studies.

CHAPTER 81 Human Herpesvirus 6 and Human Herpesvirus 7

Koichi Yamanishi

HISTORY

Human herpesvirus 6 (HHV-6) was first isolated from patients with lymphoproliferative disorders in 1986 and was initially named *human B-lymphotropic virus* (131). Several reports subsequently described the isolation of similar viruses that have been isolated mainly from patients with acquired immunodeficiency syndrome (AIDS), but later it was found mainly to infect and replicate in lymphocytes of T-cell lineage. HHV-6 isolates are classified into two groups as variants A (HHV-6A) and B (HHV-6B). The two variants are closely related but show consistent differences in biologic, immunologic, epidemiologic, and molecular properties. HHV-6B is the major causative agent of exanthem subitum (ES) (173), but no clear disease has yet been associated with HHV-6A.

Human herpesvirus 7 (HHV-7) was isolated in 1990 from a healthy individual whose cells were stimulated with antibody against CD3 and then incubated with interleukin-2 (IL-2) (62). This virus is one of the causative agents of ES (153). HHV-6 and HHV-7 are very ubiquitous, and more than 90% of adults have antibody to both viruses. These viruses have strong homology to each other and belong to the betaherpesvirus subfamily, as does human cytomegalovirus (HCMV).

INFECTIOUS AGENT

Propagation and Cell Tropism

HHV-6 infects a variety of human cells, such as T cells, B cells, natural killer (NK) cells, g/d T lymphocytes, and monocytes of peripheral blood (107,108 and 109). HHV-6 is, however, mostly T-cell tropic in the course of the *in vitro* infection of normal mononuclear cells, and especially HHV-6 infects the predominant CD4 mature T-lymphocyte of peripheral blood *in vitro* (107,151). Fresh isolates can be adapted to grow efficiently in continuous T-cell lines, such as HSB-2 and J JHAN cells for HHV-6A, Molt-3, and MT-4 T cells for HHV-6B. Although T cells are most widely used for propagation of HHV-6A and HHV-6B, cell lines of megakaryocytes and glioblastoma, neural, epithelial, and fibroblastic cells are also sensitive for HHV-6 infection, but their replication is generally poor (3,39,101,136). Both HHV-6A and HHV-6B can also infect highly purified primary fetal astrocytes *in vitro,* and infected cells showed cytopathic effects, forming giant syncytia (68). Recently, CD46 was proposed as a receptor of HHV-6 (132).

On the other hand, HHV-7 has a narrow cell tropism of CD4+ T cells, such as PHA-stimulated human cord and peripheral blood mononuclear cells (PBMCs), and in an immature continuous T-lymphoblastoid cell line SupT-1 (2,25,35). Both HHV-6 and HHV-7 induce a cytopathic effect in infected cells, which is characterized as a ballooning feature.

The *in vivo* cell tropism of HHV-6 is wider than *in vitro.* HHV-6 genomes or antigens are detectable in lymph nodes (96), PBMCs (1,74), tubular epitherial cells, endothelial cells and histiocytes in kidney (93), salivary glands (1,61,74,92), and central nervous system (CNS) tissues, where viral gene products have been localized to neurons and oligodendrocytes (36,103,104). HHV-6 was isolated from CD4+/CD8– and CD3+/CD4+ mature T lymphocytes but could not be isolated from CD4–/CD8+, CD4–/CD8–, and CD3– T cells in PBMCs of ES patients (151). Furthermore, it was reported that there was a relationship between high CD4+ cell numbers before HHV-6 infection and high HHV-6 infection rate (91). HHV-6 is also present in lesions of Langerhans cell histiocytosis in Langerhans cell histiocytosis (95).

HHV-7 infects CD4+ T lymphocytes *in vitro.* The glycoprotein CD4, a member of the immunoglobulin superfamily, is a critical component of the receptor for HHV-7 (112). A selective and progressive down-regulation of the surface membrane expression of CD4 was observed in human CD4+ T cells in the course of HHV-7 infection. Various murine monoclonal antibodies (MAbs) to CD4 and the recombinant soluble form of human CD4 caused a dose-dependent inhibition of HHV-7 infection in primary CD4+ T lymphocytes. Moreover, radiolabeled HHV-7 bound specifically to cervical carcinoma

cells (HeLa) expressing human CD4.

So far, two cell types were recognized as sites of HHV-7 infection *in vivo:* CD4+ T lymphocytes, believed to be the site of latent infection; and epithelial cells of salivary glands, the site of productive infection and viral shedding (23,62,164). Recent study showed that cells expressing the HHV-7 structural antigen were also detectable in lungs, skin, and mammary glands. Liver, kidney, and tonsils were also positive, although the number of HHV-7–positive cells was low. Large intestine, spleen, and brain were negative for infection (79).

Antigens

More than 20 proteins and 6 glycoproteins specific for HHV-6–infected cells were identified in total-cell extracts, and rabbit antibodies immunoprecipitated 33 HHV-6–specific polypeptides with approximate molecular weights ranging from 180 to 31 kd (21). Virion was found to have at least 29 polypeptides, and 6 polypeptides were identified in the envelope fraction (22,134,135). MAbs to HHV-6–infected cells reacted with single and multiple polypeptides specific for virus-infected cells and immunoprecipitated three distinct sets of glycoproteins, which were designated gp105k and gp82k; gp116k, gp64k, and gp54k; and gp102k (22). The sera and the MAbs reacted strongly with a 101-kd protein in the immunoblot, and human sera lacking HHV-6–specific antibodies and seropositive for one or more of the other human herpesviruses failed to react with this protein, indicating that it is a specific serologic marker for HHV-6 infection (171).

Hyperimmune rabbit and mouse sera raised to HHV-7–infected cells and an immune human serum identified 20 proteins, including 7 glycoproteins specific for HHV-7–infected cord blood mononuclear cells, ranging in apparent size from 136 to 30 kd (59). Human antibodies raised in response to HHV-7 infection are directed predominantly to one or more HHV-7–infected cell proteins with apparent molecular weight of about 85 (phosphoprotein 85 = pp85) to 89 kd. The pp85 is considered a major determinant of the human immune response to HHV-7, discriminating HHV-6 from HHV-7 infection, and human sera recognize additional epitopes of pp85 that are required for their full reactivity (60,142). It was also reported that the most commonly observed antigenic protein had an apparent molecular mass of 52 kd using hyperimmune human sera (117). Some MAbs reacted in immunofluorescence assays with HHV-6 antigens to the same degree as to HHV-7 protein (59,117).

Animal Model

Only PBMCs from chimpanzees were found permissive to productive infection by HHV-6 *in vitro,* indicating that the host range of HHV-6 may not be restricted to humans (111). A serologic survey of monkeys was conducted to determine the prevalence of antibody to HHV-6, and the antibody was found in species of monkeys, suggesting the existence of HHV-6 or an HHV-6–related virus in monkeys (71). Furthermore, when cynomolgus and African green monkeys were inoculated with HHV-6, an antibody response was observed, and HHV-6 DNA was detected in the lymph nodes and spleen of monkeys. The infection was asymptomatic, except in one monkey with rash. The results suggest that HHV-6 infects these species of monkey and that this system could be useful as an animal model of HHV-6 infection (170).

PATHOGENESIS AND PATHOLOGY

Transmission

Both HHV-6 and HHV-7 are ubiquitous viruses, and infection occurs during infancy. The mode of transmission of HHV-6 and HHV-7 to children is, however, not fully clear yet. In general, the route of viral infection during infancy is horizontal from people living closely with the infants, such as their parents and siblings, or doctors and nurses at the time of delivery or transplacental infection. Local spread and seasonal outbreak of ES are rare, although occasionally outbreaks of HHV-6 infection are observed in institutions for children (120). HHV-6 DNA has been detected in saliva or throat swab of children and healthy adults including their mothers by polymerase chain reaction (PCR) (65,74), suggesting the horizontal infection through saliva, although it is extremely difficult to isolate HHV-6 (K. Yamanishi, personal data). HHV-6 is also detectable in the cervix of pregnant women in the late stages of their pregnancies (121) and in the female genital tract by PCR (94), suggesting that infectious virus is also transmissible to newborn infants by perinatal spread through transvaginal delivery. No difference was found in the prevalence rates of HHV-6 infection between breast- and bottle-fed infants or between babies born by cesarean section and transvaginal delivery.

The next possible route of infection is intrauterine transmission. It was reported that viral DNA could be detectable in fetus or blood of new born babies (18,67,91). Furthermore, HHV-6 DNA was detected in 41% to 44% of the samples during months 3 to 8 of pregnancy, which is significantly higher than control (24% of age-matched controls) (47), and specific DNA could be detected in the specimens of 1% to 1.6% of cord blood of babies born to ostensibly healthy mothers (5,47). Thus, HHV-6 reactivation appears common during pregnancy, and transfer of HHV-6 to the fetus may occur. More interestingly, HHV-6 was found in chromosomes of peripheral blood as an integrated form (48,106), suggesting a possible transplacental route of transmission as an integrated form in chromosomes, if virus is reactivated in a baby.

Finally, other routes of transmission have been reported, such as during transplantations. HHV-6 latently infects early bone marrow progenitor cells, and HHV-6 may be transmitted longitudinally to cells that differentiate along the committed pathways. HHV-6B was also isolated from recipients about 2 weeks after liver transplantation, and a significant rise in HHV-6 antibody titers was observed in all recipients (177).

HHV-7 can frequently be isolated from saliva of the healthy adults (23,164). The possible transmission of HHV-7 from grandparents to parents and to children through close contact within a household was also reported by using molecular epidemiologic technique (152). It is also speculated that breast-feeding may be one of the transmission routes of HHV-7, although this is not the main route (63). Thus, a mode of transmission similar to that in HHV-6 can be speculated in HHV-7.

Immune Response During the Primary Infection

Serologic studies on the association between ES and HHV-6 infection have been reported mainly in Japan. When serum samples obtained from ES patients during the acute and convalescent phases were assayed for IgG and IgM antibodies, IgM antibodies were detected on day 5, and persisted for 3 weeks, but were not detectable in most sera 1 month after the onset of disease. As for IgG antibody, antibody was first detected at 7 days after the onset of illness, increasing until 3 weeks and lasted at least 2 months (88) (Fig. 1). The viremia observed during primary infection subsides with the appearance of neutralizing antibodies of the infected child (13). Interestingly, antibody titers to HHV-6 are boosted during infection with other viruses, such as HHV-7 (77,155).

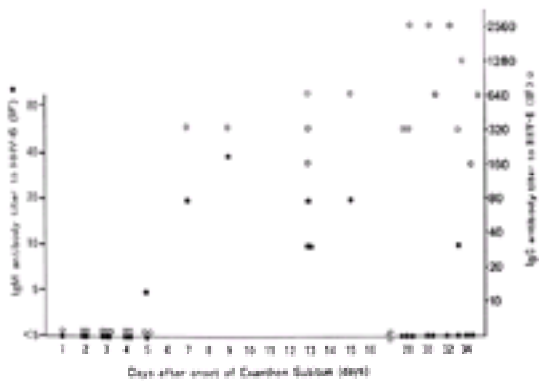

FIG. 1. Immunoglobulin M (IgM; *closed circle*) and IgG (*open circle*) antibody response in exanthem subitum patients. IgM and IgG antibody titers were tested by immunofluorescence antibody..

Clinical data indicate that a cellular immune function is important for control of the primary HHV-6 infection. The proliferative response of PBMCs from healthy adults to HHV-6 was examined, and a T-cell immune response against HHV-6 infection is generally present in healthy adult populations (162,168). *In vitro* study, T-cell clones with activity against HHV-6 have been described (169), and some T-cell clones responded not only to HHV-6 but also to HHV-7 and HCMV, indicating that the presence of epitopes common to HHV-6 and HHV-7 and to HHV-6, HHV-7, and HCMV, which are recognized by CD4+ T cells (174).

Only interferon-a (IFN-a) showed a significant increase in the plasma of patients during the acute febrile phase of ES compared with the convalescent period (150). NK cell activity was also significantly augmented in the acute phase, probably through IL-15 induction (58), especially in the exanthem period, rather than in the convalescent phase (150). These results suggest that the enhanced IFN-a response and NK cell activity in the acute early phase of the disease may play pivotal roles in the recovery from ES.

In *in vitro* studies, IFN-a activity was detected in PBMCs from healthy seropositive adults as early as 12 hours after exposure to HHV-6, plateaued at days 2 to 5, and gradually decreased thereafter. The response of cord blood mononuclear cells was lower than that of the cells from healthy adults (82). HHV-6 also induces IL-1b and tumor necrosis factor-a, but not IL-6 in PBMCs (56). These results indicate that HHV-6 can exert a strong immunomodulatory effect by stimulating the cells of myeloid lineage to produce these cytokines. IFN-g regulates the production of IL-10 and IL-12 at a transcriptional level mainly through inhibiting endogenous IL-10 production in HHV-6–infected monocyte-macrophage lineage (99).

Reports on the immune response during HHV-7 primary infection are few because HHV-7 primary infection appears to be mostly unapparent. Tanaka and colleagues (153) reported that HHV-7 was isolated from PBMCs of two infants with typical ES. During the convalescent period (16 days after onset of the disease) of the first patient, the titer of antibody to HHV-7 rose from less than 1:10 to 1:320 by an immunofluorescence antibody (IFA) test, whereas the titer of antibody to HHV-6 remained less than 1:10. In the second patient, who had two independent episodes of ES during 2 months, both HHV-6 and HHV-7 were sequentially isolated; seroconversion to HHV-7 during the second episode was observed at 4 days after the onset of the disease.

Host also responds to HHV-7 infection by up-regulating IL-15 production, which then results in an enhancement of NK cell activity; this, in turn, may play a major role in the control of the viral infection (17).

Immune Suppression

HHV-6 infects various kinds of immune cells as described previously and may immunomodulate *in vivo* and *in vitro.* In fact, infection of PBMCs or T-cell–enriched cultures by HHV-6A suppressed IL-2 synthesis after mitogen stimulation, and levels of IL-2 transcripts were diminished in experiments with enriched T-cell cultures or Jurkat cells (57).

Suppression of bone marrow function may be one of the most serious effects of HHV-6 infection in bone marrow transplant recipients. When normal bone marrow mononuclear cells were infected *in vitro* with HHV-6, the outgrowth of granulocyte-macrophage colony-forming units (GM-CFUs) was decreased by about 43%, that growth of granulocyte-erythrocyte-macrophage-megakaryocyte colony-forming units (GEMM-CFUs) was inhibited by an average of 71%, and that the erythroid burst-forming unit was decreased by approximately 73%. Further, outgrowth of the marrow stromal layer was reduced 74% (85). It was also reported that HHV-6B could inhibit GM-CFU and erythroid burst-forming unit from human bone marrow (51). Although HHV-6A suppressed the formation of erythrocyte burst-forming units colonies as efficiently as HHV-6B, the former did not exhibit significant suppressive effect on the formation of GM-CFU colonies.

HHV-6 either encodes or induces a soluble mediator or mediators that can interfere with the responses of bone marrow to growth factors and possibly block the normal differentiation of macrophages from marrow precursors (30). These studies implicate HHV-6 as a cause of bone marrow suppression in bone marrow transplant recipients.

Gobbi and associates (64) recently attempted to develop an *in vivo* model for immune suppression by HHV-6 using SCID-hu Thy/Liv mice. HHV-6A efficiently infected the human thymic tissue implanted in these mice, leading to the destruction of the graft. Viral DNA was detected in Thy/Liv implants by quantitative PCR as early as 4 days after inoculation and peaked at day 14. HHV-6 replication was associated with severe, progressive thymocyte depletion involving all major cellular subsets. However, intrathymic T progenitor cells appeared to be more severely depleted than the other subpopulations, and a preferred tropism of HHV-6 for intrathymic T progenitor cells was demonstrated by quantitative PCR on purified thymocyte subsets. These findings suggest that thymocyte depletion by HHV-6 may be due to infection and destruction of these immature T-cell precursors. Similar results were also obtained with a primary isolate belonging to HHV-6B. The severity of the lesions observed in this animal model underscores the possibility that HHV-6 may indeed be immunosuppressive in humans.

HHV-7 had no effect on hematopoietic colony formation (72) and few effects on immunosuppression by HHV-7 infection.

Persistence and Reactivation

In general, in virus infection, the persistent infection can tentatively be classified into latent infection and chronic infection. During latent infection, infectious progeny are not produced, and viral gene expression is limited to the genes required for maintenance of latency, but during chronic infection, the progeny is produced to be a source of transmission. The previously identified human herpesviruses all persistently infect their hosts after primary infection and reactivate late in life. Therefore, it is expected that HHV-6 and HHV-7 also persistently infect humans after primary acquisition.

Because HHV-6 is isolated from immunosuppressed patients, it is speculated that virus could be reactivated in immunosuppressive patients, such as those with AIDS, leukemia, lymphoma, organ transplants, chronic fatigue syndrome, or collagen vascular diseases. HHV-6 DNA or its antigen has also been detected in tissues of some lymphomas, kidneys, and salivary glands, as described previously. Viral antigens or genomes were shown to be located in glomerular cells of the kidney, histiocytes, and lymphocytes in rejected kidney (93) and lymph nodes of patients with necrotizing lymphadenopathy (147). These findings suggest that after the primary infection, this virus infects the body and can be reactivated in some conditions, such as the immunosuppressed state. HHV-6 is reactivated not only in immunosuppressive diseases as described previously but also in infections by Dengue virus (20) and measles virus (146).

The site of latent infection with HHV-6 is not completely clear. The amount of HHV-6 DNA that was detectable in PBMCs of healthy blood donors ranged among a variety of groups, possibly owing to the sensitivity of PCR. Although the virus was not isolated from PBMCs of ES patients during the convalescent phase or from healthy adults, HHV-6 DNA was detected in a fraction of them, mainly in monocytes (89). Because monocytes do not live long in a normal condition *in vivo,* it can be speculated that HHV-6 may be frequently reactivated in the monocyte-macrophages of the peripheral organs and infect other monocyte-macrophages. It was also reported that HHV-6 latently infects early bone marrow progenitors *in vivo* (105). These results suggest that HHV-6 may infect monocyte-macrophages and early bone marrow progenitors in a latent state, although it is still not clear whether these cells are the main site of its latent infection *in vivo.*

HHV-6 is also detectable by PCR from saliva, and HHV-6 antigen has been detected in salivary glands, as described previously. A high proportion of children with a history of HHV-6 infection retain HHV-6 DNA in cerebrospinal fluid (CSF) or viral antigens in CNS, suggesting that the CNS may also be a reservoir for persistent infection (33,36,37). HHV-6 DNA was detectable in biopsy samples of kidneys, lungs (45), cervix of pregnant women, and vaginal secretions of women.

In *in vitro* systems, HHV-6 infects latently in monocyte-macrophages (89); in novel cell lines, Philadelphia chromosome–positive myeloid cell lines from a patient with blast crisis of chronic myelogenous leukemia were infected latently with HHV-6 (175), indicating that these systems will be useful for studying the mechanisms of HHV-6 latency and reactivation.

It has been reported that HHV-7 infects latently, similar to HHV-6, after the primary infection in CD4+ cells (62), CD4+ T lymphocytes, epithelial cells of salivary glands, and other organs, such as lungs, skin, and mammary glands, liver, kidney, and tonsils, suggesting that a variety of tissues harbor cells at a late stage of infection (79).

HHV-7 is reactivated from latently infected PBMCs by T-cell activation, although HHV-6B could not be reactivated under similar conditions; however, the latent HHV-6B could be recovered after the cells were infected with HHV-7 (77,155). Therefore, HHV-7 can provide a transacting function, mediating HHV-6 reactivation from latency.

EPIDEMIOLOGY

A number of factors, including different methods and the cutoff value for enzyme-linked immunoabsorbent assay (ELISA), may account for differences in reported HHV-6 seroprevalence. Unfortunately, there have been few attempts to distinguish between HHV-6A and HHV-6B in serologic studies, and in addition, there is significant cross-reactivity between both HHV-6 and HHV-7, as described later.

When the study on the seroprevalence for HHV-6 infection was attempted in children under 2 years of age, children 0 to 5 months old had antibody, and their antibody titers gradually decreased with age in this period. Then, from 6 months after birth, the number of children having antibody gradually increased again, and almost all children older than 13 months of age had antibody (122). These results clearly suggest that almost all children are exposed to HHV-6 in the latter half of the first year of life. Because almost all pregnant women have antibody to HHV-6, immunoglobulin G (IgG) antibody is transferred from mother to child through the placenta, and the antibody is detectable in infants during the

early months after birth, it is believed that infants are protected against HHV-6 infection by antibody from their mother. A number of investigators have reported a decline in seropositivity with age among adults (28,54,98), but others have found no significant differences (27).

Serologic studies of HHV-6 infection have been undertaken throughout the world. The incidence of antibody to HHV-6 is high in almost all areas, but seroprevalence varied from about 39% to nearly 100% among ethnically diverse adult populations (97,128,166).

The infection by HHV-7 appears to occur later than that by HHV-6 (165). Antibody to HHV-7 was detected in 6 of 12 children (50.0%) at 0 to 5 months of age, in 4 of 12 (33.3%) at 6 to 11 months of age, in 12 of 16 (75.0%) at 12 to 23 months of age, and in 13 of 14 (92.9%) at 2 to 8 years of age (154). Another group reported that the positivity rate of antibody was 40% in the first 2 months of life, declined during the first 6 months, then gradually increased and was 45% at 1 to 4 years of age. It reached the highest level (60%) at 11 to 13 years of age and was maintained until the end of the third decade, then decreased thereafter (179).

CLINICAL FEATURES

Primary Infection

The first report of the HHV-6 infection and ES appeared in 1988 (173). ES was first described in 1910 by Zahorsky (182) and is a common disease of infants all over the world. Normally, an infant gets sudden fever, which lasts for a few days, and rash appears on the trunk and face and spreads to lower extremities during subsiding fever. A virus was thought to cause this disease because there was evidence: a long incubation time and leukopenia, lack of response to antimicrobial agents, and bacteria that have never been recovered from various body fluids of the patients. Furthermore, human transmission of the infection by experimental inoculation of blood of ES patients into other infants was reported by Kempe and associates (78) and by Hellstrom and Vahlquist (69). For a long time, efforts to isolate the causative agent of ES were unsuccessful. Isolating HHV-6 was finally successful at high frequency from ES patients during the acute phase of this disease. For isolation of HHV-6 from ES patients, PBMCs of ES patients were collected during the febrile period of the disease and were cultured in medium supplemented with IL-2 and phytohemagglutinin. About 10 days after cultivation, a cytopathic effect (CPE) could be observed, which showed balloon-like cells. When cells were fixed and stained with sera during the acute and convalescent phases of ES, positive staining was observed only using convalescent sera (Fig. 2). The typical herpesvirus particles could be found in the nucleus and cytoplasm by electron microscopy. This virus was serologically identified as HHV-6 using Z29 strain, which was already isolated by Lopez and associates (100), and antigen was reacted with paired of acute and convalescent phases sera from ES patients. The rate of virus isolation from PBMCs of ES patients was higher at the febrile phase than the exanthem phase of ES (13). Furthermore, it was reported that HHV-6 infection without clinical symptoms of rash or fever, or even without any clinical symptoms, could be seen in patients as the primary infection of HHV-6 (15,126,144). ES is caused by HHV-6B, and the magnitude of the virus replication in infants with ES is reflected in the severity of the disease (12). In most cases, ES is benign and is associated with other symptoms, including diarrhea, cough, lymph node swelling, and bulging fontanels. In adults, primary infections can cause mononucleosis-like disease and hemophagocytic syndrome (7,141). Symptomatic HHV-6A infection is rather rare, but reported manifestations appear to be similar to those of HHV-6B infection (70).

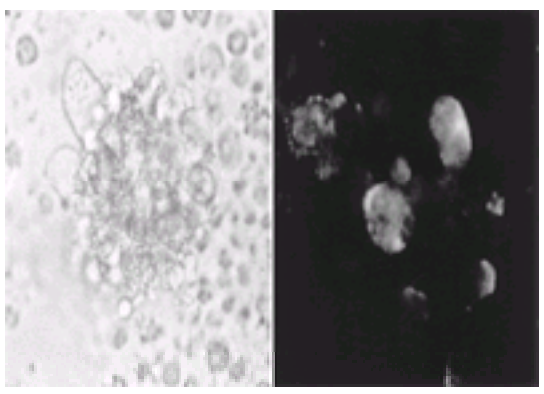

FIG. 2. Cytopathic effect by human herpesvirus 6. **A:** Balloon-like cells surround clumps of lymphocytes with positive staining by immunofluorescence antibody (IFA). **B:** Balloon-like cells stained by IFA using convalescent serum from exanthem subitum patient.

Although the rate appears to be low, primary infection of HHV-7 is similar to that of HHV-6 and causes ES or high fever (34). HHV-7 was isolated from PBMCs of an infant with typical ES. During the convalescent period of the patient, the titer of antibody to HHV-7 rose significantly, whereas the titer of antibody to HHV-6 remained negative. Some infants suffer a second episode of ES. Sera from children who had episodes of ES were tested for antibodies to HHV-6 and HHV-7, and five of seven patients had seroconversion to HHV-7 just after having typical symptoms of ES. The typical clinical case of ES caused by HHV-6 and then HHV-7 is shown in Figure 3. These results suggest that HHV-7 is one of the causative agents of ES. To define the clinical and virologic characteristics of primary HHV-7 infection and to compare these characteristics with those of primary HHV-6 infection, a prospective convenience sample study of 496 children aged less than 3 years old was recently attempted in more detail (34). Children with primary HHV-7 infection were identified and compared with children with primary HHV-6 infection detected during the same time period. All children were febrile, with no difference in the degree of fever, frequency of rash, or gastrointestinal complications between the groups. The median age of children with primary HHV-7 infection was 26 months, significantly older than that of children with primary HHV-6 infection (median, 9 months of age).

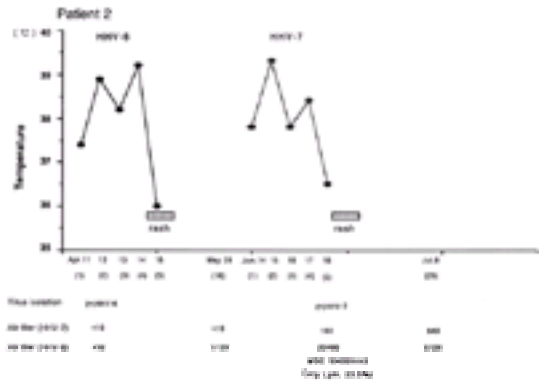

FIG. 3. The clinical course of an infant who had two episodes of exanthem subitum (ES). Human herpesvirus 6 and 7 were isolated from this infant at the first and second episodes of ES, respectively. Antibody to human herpesvirus 6 and 7 increased significantly after the first and second episodes of ES, respectively.

Associated Symptoms with Primary Infection

The most commonly reported severe symptom associated with ES is febrile convulsion, but its prognosis is not bad. The exact incidence of seizures occurring with ES is difficult to estimate. In a large study, Hall and colleagues (67) found that of the 160 infants and young children with acute HHV-6 infection, 21 (13%) were hospitalized, and 21 had seizures. The seizures often appeared late and were prolonged or recurrent. HHV-6 infections accounted for one third of all febrile seizures in children up to the age of 2 years. In this study, 7 (24%) of 29 CSF specimens were positive for HHV-6 by PCR, including 2 of 7 from children with convulsions. The detections of HHV-6 DNA were also reported in CSF from patients with neurologic manifestations at the time of primary infection of HHV-6 (33,145,178). HHV-6 persists within the CNS and has been reported to increase the risk for recurrence of febrile convulsions (90). However, a recently reported prospective study suggested that a first febrile seizure associated with an acute HHV-6 infection may be associated with a reduced risk for recurrent seizures (75). The seizures are mostly self-limited and benign; however, meningitis and encephalitis can happen, and residual deficits have been associated with HHV-6 infection. Cases of possible HHV-6–associated encephalitis in young children were also reported (14,114,178). Knox and associates (87) described an HIV-infected infant who developed fulminant encephalitis as a complication of HHV-6 infection and demonstrated that the virus present in the CNS tissue was predominantly the HHV-6A. Tang and colleagues (156) reported that a total of 60 CSF specimens from patients manifesting symptoms resembling viral CNS disease were examined for the presence of five human herpesviruses, including HHV-6, and the presence of DNA specific for two distinct herpesviruses in the same CSF specimen, providing molecular evidence that co-infection with this group of viruses may occur in the CNS.

Liver dysfunction is also associated with HHV-6 infection. Usually, liver dysfunction is mild, but fatal hepatitis and chronic hepatitis have been also reported. The first case reported was a fatal case of fulminant hepatitis, probably owing to HHV-6 (16). In another case, liver dysfunction was followed by ES, and HHV-6 was isolated from the peripheral blood of both patients (149). There have been several reports about idiopathic thrombocytopenic purpura, associated with primary infection of HHV-6 (83,138). The pathogenesis of the primary infection by HHV-6 is illustrated in Figure 4.

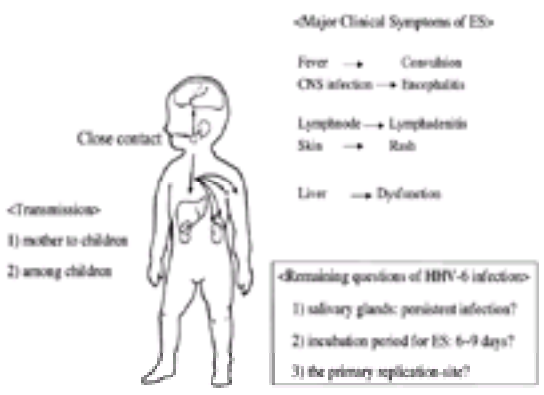

FIG. 4. Pathogenesis of human herpesvirus 6 infection.

The primary infection by HHV-7 can cause a highly febrile illness in childhood, complicated by seizures (34,159). It was reported in two ES children associated with CNS manifestations, such as by acute hemiplegia (159), suggesting that HHV-7 also infects the CNS.

Reactivation and Its Clinical Symptoms

Because herpesviruses persist in hosts after primary infection, they are important pathogens in immunocompromised hosts. Reactivation of HHV-6 occurs after bone marrow transplantation (BMT); solid organ transplantation, such as renal, liver, and heart transplantation; and AIDS.

Bone Marrow Transplantation

Asymptomatic HHV-6 reactivation appears to be common after allogeneic BMT (46), but HHV-6 reactivation with

symptoms such as bone marrow suppression, encephalitis, pneumonitis and acute graft-versus-host disease (GVHD) in bone marrow transplant recipients have also been recognized. Sixteen adults were studied for the first 100 days after allogeneic BMT to assess the pathogenic role of HHV-6 infection in patients with unexplained febrile illnesses. HHV-6 was directly isolated from the blood of six patients, and idiopathic marrow suppression occurred frequently in patients with concurrent HHV-6 viremia (52). Yoshikawa and colleagues (180) studied 25 pediatric patients who received BMT prospectively to determine the relationship between BMT and HHV-6 infection by the virus isolation from peripheral blood or bone marrow and by determining neutralizing antibodies to HHV-6 during the 2 months after BMT. HHV-6 was isolated from peripheral blood or bone marrow mononuclear cells in 40% of the 25 recipients between day 14 and day 22 of BMT, but not from any other day. Two additional recipients showed a significant increase in the antibody titer. Thus, infection with HHV-6 was confirmed in 12 (48%) of the 25 recipients. Four of the 12 developed skin rashes; 3 of these 4 had a febrile episode when the virus was isolated, whereas none of the remaining 13 developed the skin rash. These results suggest a frequent infection with HHV-6 only a few weeks after BMT and a close association between the infection with the virus and the development of skin rashes. Appleton and associates (9) recently investigated skin and rectal biopsy specimens from 34 allogeneic BMT recipients and 23 comparative autologous recipients. Twenty-eight (90%) of the 31 patients who engrafted developed clinical GVHD, which was mild in 5, moderately severe in 9, and severe in 14. Overall, HHV-6 DNA was detected in PBMCs in 74% of autologous recipients and 76% of allogeneic recipients, and in biopsy tissue in 48% of autologous recipients and 71% of allogeneic recipients. However, HHV-6 DNA was detected in skin or rectal biopsy specimens more frequently in allogeneic recipients with severe GVHD (92%) than in those with either moderate (55%) or mild GVHD (22%), suggesting that the presence of HHV-6 DNA in the skin or rectum may be a factor in determining GVHD severity.

The association of HHV-6 infection and pneumonitis was also reported, and the infected cells were primarily intraalveolar macrophages, although infected lymphocytes were seen (32). Cone and colleagues (45) also reported the possible role of HHV-6 infection in pneumonitis in immunocompromised patients by using quantitative HHV-6 PCR to study lung biopsy specimens from 15 patients with pneumonitis after BMT. In 15 immunocompetent subjects without pneumonitis, HHV-6 DNA was detected in lung tissue from all 15 patients, in 14 seropositive control subjects, and in none of the 7 seronegative control subjects. Six patients had levels of HHV-6 DNA in lung tissue that were 10 to 500 times higher than those in any of the other patients or control subjects. Increased levels of HHV-6 DNA correlated significantly with a decreased risk for death from pneumonitis, an increased severity of GVHD, and the presence of idiopathic pneumonitis. Their results suggested that the concentrations of HHV-6 genome in lung tissue and their relation to changes in serologic titers support an association between HHV-6 infection and idiopathic pneumonitis in immunocompromised hosts.

HHV-6 may also be a causative agent of encephalitis (52) and transient erythroblastopenia in immunocompetent children (125) because it can suppress the formation of erythroid burst-forming units and GM-CFUs *in vitro* and *in vivo* in HHV-6–infected patients who undergo BMT.

Recent studies have shown more rapid immune reconstitution after allogeneic peripheral blood stem cell transplantation (PBSCT) compared with allogeneic BMT. HHV-6 DNA was detected most frequently 3 weeks after transplantation, whereas HCMV and EBV DNA were detected later (2 to 3 months). Detection rates of HHV-6 DNA at 3 and 4 weeks after allogeneic BMT were significantly higher than those after allogeneic PBSCT. Furthermore, detection of HHV-6 DNA within the first 4 weeks was associated with delayed platelet engraftment after both allogeneic BMT and allogeneic PBSCT. These results suggest an advantage for allogeneic PBSCT over allogeneic BMT in terms of suppression of HHV-6 reactivation and prevention of subsequent complications (113).

Solid Organ Transplantation

Wade and associates (161) reported that children having no antibody to HHV-6 before transplantation rejected their kidneys early after transplantation. A relationship between rejection episode of kidneys and HHV-6 infection was reported (4,119). About 30% of renal transplant recipients showed a significant increase of serum antibody titer against HHV-6 after transplantation, and all these recipients suffered severe kidney rejection. Biopsy specimens of rejected kidneys were examined for the presence of HHV-6 antigens, and HHV-6 antigens were detected in the tubular epithelium as well as in infiltrating histiocytes and lymphocytes. These results suggested that HHV-6 can infect renal tissues and that the infection may be correlated with rejection or with immunosuppressive therapy (119). Another survey was attempted (181), and the infection with HHV-6 was confirmed in 55% of the recipients. The results indicate that the virus is activated in many cases in the early posttransplantation period and that HHV-6 establishes latency in the kidney tissue. However, there was no correlation between HHV-6 infection and acute rejection or the antirejection prophylaxis.

Singh and associates (137,138) reported the relationship of clinical features and HHV-6 infection in liver transplant recipients. HHV-6 infection occurred in four liver transplant recipients at a median of 50 days after transplantation. Severe cytopenia was observed in all patients. One of the four patients had interstitial pneumonitis due to HHV-6. These authors suggest that HHV-6 can be a pathogen in liver transplant recipients; idiopathic bone marrow suppression is its predominant clinical sequelae. They also described acute febrile illness characterized by life-threatening thrombocytopenia, progressive encephalopathy, and skin rash developed in association with invasive HHV-6B infection in a liver transplant recipient.

Because other herpesviruses can be also reactivated during the course of transplantation, a potential association between HHV-6 and HCMV after renal transplantation was explored by testing serial serum specimens for HHV-6 and DNA (49,129). HHV-6 reactivation occurred in 35 (66%) of 53 transplant recipients. HHV-6 reactivation was significantly associated with primary HCMV infection and HCMV syndrome and with trends for HCMV-related hepatitis, HCMV-related neutropenia, and serious HCMV disease. However, Osman and associates (123) also studied prospectively for 3 months or longer after transplantation by PCR for HCMV, HHV-6, and HHV-7. The relative risk for HCMV disease for patients with concurrent HCMV and HHV-7 was increased, whereas the association between HCMV and HHV-6 was inconclusive. HCMV disease was associated with rising antibody titers to HHV-7, and weakly so with HHV-6. Therefore, they concluded that in patients with HCMV DNAemia, concurrent infection and reactivation of HHV-7 is associated with an increased risk for progression to HCMV disease. Griffiths and colleagues (66) conducted a prospective study to see the possible relationship of HHV-6 and HHV-7 infection with the the clinical symptoms after liver transplantation. After

transplantation, 536 blood samples were tested by PCR, and active infection with HCMV was detected in 28 of 60 (47%), HHV-6 in 19 of 60 (32%), and HHV-7 in 29 of 60 (48%) patients. Although the virus load for HCMV was significantly greater than that for HHV-6 or HHV-7, HHV-6 and HHV-7 may be the cause of some episodes of hepatitis and pyrexia. From these results, HHV-6, HHV-7, and HCMV may cause some symptoms by reactivating doubly and triply.

Acquired Immunodeficiency Syndrome

Reactivation of HHV-6 is possibly associated with interstitial pneumonia, encephalitis, and retinal disorder in AIDS patients. The possible role of HHV-6 as a cofactor in HIV infection has been discussed because both viruses can infect CD4+ cells, and HHV-6 can transactivate the long terminal repeat of human immunodeficiency virus type 1 (HIV-1). Furthermore, the observation that HHV-6 can induce CD4 gene transcription and expression in CD4– cells was reported, and then HIV can infect those CD4+ cells. Lusso and Gallo (110) described the most important issue with respect to HHV-6–related disease in HIV-positive people as being not so much a direct effect on specific target organs as the putative cofactor role of HHV-6 in contributing to immune deficiency of the host.

Studies of serologic responses to HHV-6 in HIV-infected patients have shown different results. Comparisons between HIV-infected patients and uninfected controls have shown either no difference in seroprevalence and titer or higher or lower prevalence among those infected with HIV. The detection rate of HHV-6 DNA in PBMCs and saliva is also variable, depending on the investigators. One study found no correlation of HHV-6 seroprevalence with progression of AIDS (140), whereas another found that slow progressors had decreased HHV-6 seroprevalence compared with those whose disease advanced rapidly (38).

HHV-6–infected cells were detected in all lung, lymph node, spleen, liver, and kidney tissues obtained at necropsy from an unselected series of 9 patients with AIDS. Lung infection with HHV-6 was extensive enough in one patient to account for fatal pneumonitis. In other tissues, increased numbers of HHV-6–infected cells were related to the presence of lymphocyte infiltrates or residual lymphoid tissue, with lymphocytes being predominantly infected (84). The retinitis associated with AIDS and HHV-6 was also reported (127).

Because HHV-6 has been shown to be neuroinvasive, as described previously, HHV-6 may be important in the neuropathogenesis of AIDS in children. HHV-6 was more extensively disseminated in neural cells of brains of HIV patients, suggesting a contribution to the pathogenesis of AIDS encephalopathy (130). It was also reported that adult patients with AIDS had areas of demyelination in their CNS tissue at the time of death (86).

Recently, two reports appeared on the progression to AIDS by HHV-6 infection. The presence of HHV-6 in an organ is significantly associated with an elevated HIV-1 proviral load (53). Another study was done in Thailand in a total of 227 children born to HIV-seropositive mothers. When 22 HIV-carriers were studied for association of HHV-6 infection with progression of HIV disease, 5 of 12 patients (42%) without HHV-6 infection had no progression of HIV disease by 1 year of age, whereas all 10 (100%) children with HHV-6 infection progressed to HIV disease (91). These results suggest that there is an association between HHV-6 infection and progression of HIV disease and that HHV-6 may play a role as a cofactor in the HIV disease process.

Pityriasis Rosea

In 1998, Drago and colleagues (50) reported the association of pityriasis rosea (PR) with HHV-7 infection and proposed that PR is a clinical presentation of HHV-7 reactivation. PBMCs from PR patients showed ballooning cells and syncytia after 7 days in culture, whereas PBMCs from controls and recovered PR patients did not. PCR identified HHV-7 DNA in PBMCs, plasma, and skin from all patients with active PR, and only in the PBMCs 10 to 14 months later. However, controversial results were also reported. Watanabe and associates (163) reported that there were no significant differences in DNA and antibody tests between patients and control groups. Further experiments are necessary.

Possible Associated Diseases

Neoplasia

It has been reported that HHV-6 has a transforming capacity in mouse cells, but the oncogenic role of HHV-6 in human cancer has not been established.

HHV-6 has been demonstrated by detection of DNA in non-Hodgkin's lymphoma (73,76), Hodgkin's disease (158), and other neoplasias (40,102). The prevalence of HHV-6A and HHV-6B in carcinoma biopsy specimens from the mouth, salivary gland, larynx, breast, and cervix using variant-specific oligonucleotide probes was studied (10), and high prevalence was found in oral carcinoma tissue and salivary gland carcinoma tissue (167). The frequency of HHV-6 variants in certain tumors suggests a cofactorial role in multistep carcinogenesis. A possible specific association of HHV-6 with the unusual disorder S100-positive, T-cell chronic lymphoproliferative disease was also reported (26). As yet, there has been no conclusive demonstration that either HHV-6A or HHV-6B is involved in a causative way with any malignancy.

Chronic Fatigue Syndrome

There have been some reports on an association of chronic fatigue syndrome (CFS) and HHV-6 infection. CFS is an illness characterized by disabling fatigue associated with complaints of fevers, sore throat, myalgia, lymphadenopathy, sleep disturbances, neurocognitive difficulties, and depression.

More CFS patients than controls had elevated levels of HHV-6 early-antigen–specific IgM, perhaps indicating active replication of HHV-6 in CFS (124). However, there have been controversial studies (29), and further work is required to

determine whether HHV-6 contributes to the clinical manifestations.

Multiple Sclerosis and Other Neurologic Disorders

Multiple sclerosis (MS) is characterized clinically by neurologic signs and symptoms that wax and wane over time and involve multiple nerve pathways. Several studies have suggested an association between HHV-6 and MS. A DNA fragment that was the major DNA-binding protein gene of HHV-6 was detected in MS brains by representational difference analysis. Examination of 86 brain specimens by PCR demonstrated that HHV-6B was present in more than 70% of MS cases and controls and is thus a commensal virus of the human brain. Nuclear staining of oligodendrocytes using MAbs against HHV-6 virion protein 101K and DNA-binding protein p41 was observed in MS cases but not in controls; in MS cases, it was observed around plaques more frequently than in uninvolved white matter. MS cases showed prominent cytoplasmic staining of neurons in gray matter adjacent to plaques, although neurons expressing HHV-6 were also found in certain controls (36). Next, Soldan and colleagues (139) demonstrated increased IgM serum antibody responses to HHV-6 early antigen (p41/38) in patients with relapsing-remitting MS, compared with patients with chronic progressive MS patients with other neurologic disease, patients with other autoimmune disease, and controls.

Negative results, however, were seen in other reports. Fillet and associates (55) reported that there was no significant difference in detection of HHV-6 DNA in sera and CSF in groups of 32 MS patients, 21 patients with other neurologic diseases, and 13 controls. Furthermore, Coates and Bell (44) reported that there was no significant difference between MS patients and non-MS patients by staining brain immunocytochemically. Therefore, further experiments are needed.

Progressive multifocal leukoencephalopathy (PML) is a primary demyelinating disease of the CNS occurring almost exclusively in individuals with impaired cell-mediated immunity. The JC polyoma virus has been accepted as the etiologic agent of PML. Using a two-step *in situ* PCR procedure to amplify and detect genomic DNA of HHV-6 in formalin-fixed paraffin-embedded archival brain tissues, a high frequency of infected cells was consistently detected in PML white matter both within and surrounding demyelinative lesions, and HHV-6 genome was found mainly within oligodendrocytes. Lesser amounts of HHV-6 genome were detected in most tissues of patients with AIDS, patients with other neurologic disease, and controls. Immunocytochemistry for HHV-6 antigens showed actively infected nuclei of swollen oligodendrocytic morphology within the demyelinative lesions of PML but not in adjacent uninvolved tissue. In addition, no HHV-6 antigens were detectable in control tissues, including brain of patients with HIV-1 encephalopathy but without PML. Double immunohistochemical staining for JC virus large T antigen and HHV-6 antigens demonstrated co-labeling of many swollen intralesional oligodendrocytes in the PML cases. The evidence suggests that HHV-6 activation in conjunction with JC virus infection is associated with the demyelinative lesions of PML (116).

Drug Hypersensitivity

Drug-induced hypersensitivity syndrome is characterized by a severe, potentially fatal, multiorgan hypersensitivity reaction that usually appears after prolonged exposure to certain drugs. Clinical signs include a maculopapular rash progressing to exfoliate erythroderma, fever, and lymphadenopathy. Leukocytosis, atypical lymphocytes, liver dysfunction, and renal disturbance were also observed. Its delayed onset and clinical resemblance to infectious mononucleosis suggest that underlying viral infections may trigger and activate the disease in susceptible individuals receiving these drugs. Reactivation of HHV-6B, possibly in concert with HHV-7, can contribute to the development of a severe drug-induced hypersensitivity syndrome (148,157).

DIAGNOSIS

Virus Isolation and Assay

HHV-6 is easily recovered from PBMCs of ES patients during acute phase. The method of virus isolation from peripheral blood was described previously (173). Lymphocyte activation with either phytohemagglutinin (PHA) or antibody to CD3 and maintenance in IL-2 are required. CPE can be seen 7 to 10 days after cultivation, as shown in Figure 2. The refractile giant cells usually contain one or two nuclei, and after the occurrence of CPE, lytic degeneration of the cells takes place. Mononuclear cell–associated viremia caused by HHV-6 was detected in 66% of blood samples from ES children between days 0 and 7 of the disease. The rate of virus isolation from mononuclear cells was 100% on days 0 to 2 (just before appearance of skin rash), 82% on day 3, 20% on day 4, 7% on days 5 to 7, and 0% on day 8 and thereafter. The cell-free virus was also detected in blood in blood samples during the same period (13).

HHV-7 is sometime isolated from peripheral blood of ES patients as for HHV-6 (154), and frequently from saliva of individuals who have antibody to HHV-7 by using cord blood mononuclear cells, which are stimulated with PHA and IL-2 (23,164). In contrast, the isolation of HHV-6 from saliva is uncommon, although DNA is detectable there. The reason of the difference in virus isolation in these viruses is unclear.

Serologic Assays

Several serologic assays are available for HHV-6 studies, including IFA, ELISA, neutralization (NT), radioimmunoprecipitation, and immunoblot. Indirect IFA is the most commonly applied method for HHV-6 viral antigen and antibody detection. The HHV-6–infected cells are used as antigens for IFA. For detection of HHV-6–specific IgM, separation of serum IgM from IgG and IgA significantly increases the specificity. To remove interfering substances, density gradient columns, absorption by protein A from *Staphylococcus aureus* and anti-IgG treatment techniques can be applied. Another IFA test is anticomplement IFA (100). This assay is useful to reduce the nonspecific binding of fluorescein isothiocyanate–conjugated antibody. The NT test using chemically attached MT-4 cells (11) and by reading CPE (13) is used only in limited laboratories. The dot-blot neutralization assay was recently developed, and the neutralizing antibody titers appeared to correlate with the antibody titers determined by the indirect IFA test (160).

An enzyme-linked immunosorbent assay, immunoblot, and indirect IFA were developed for detection of HHV-7 antibodies

in human serum. Cross-absorption studies with ELISA or IFA using HHV-7 and HHV-6 antigens indicated that most human sera contain cross-reactive HHV-6 and HHV-7 antibodies and that the degree of cross-reactivity varies between individual serum specimens. Inhibition of homologous antibody activity by absorption with heterologous virus ranged from 0% to 57% by ELISA. However, for every sample tested, absorption with homologous virus removed more activity than did heterologous virus. An 85- to 89-kd protein was identified as an HHV-7–specific serologic marker by immunoblot (142). To detect antibody to HHV-7 specifically and sensitively, the p89/85 protein, encoded by open reading frames *U14* (85 kd) and *U11* (86 kd) of HHV-7, was expressed as recombinant protein in bacteria and developed for immunoblot kit. Activity to this protein was not removed by absorption with HHV-6 antigen. Of the three assays, the ELISA was the most sensitive, whereas the immunoblot was the most specific (24).

Genomic Detection by Polymerase Chain Reaction

HHV-6 DNA can be detected by hybridization and by PCR. Southern blot hybridizations can be useful for rapid screening of large numbers of specimens, but it is generally a less sensitive technique than PCR. Numerous PCR primer sets, which are sensitive and specific, have been described for HHV-6, and some of these sets allow easy discrimination of the variants (19,42,133,172). Variant-specific oligonucleotide hybridization is based on the amplification of two distinct regions of the HHV-6 genome, followed by hybridization of amplimers with variant-specific oligonucleotide probes. Variant-specific primer PCR is based on the amplification of each variant by using variant-specific primers (19). The putative coding region of immediate-early genes of HHV-6A was 2,517 nucleotides long, and two large additive regions of 108 and 228 base pairs were found in HHV-6B. PCR amplification using primers covering one of these regions results in PCR products with different molecular weights. This method is useful to differentiate HHV-6A and HHV-6B by PCR followed by staining with ethidium bromide (172). HHV-6 DNA is easily detectable by PCR in peripheral blood of ES patients during he acute phase, but appropriate precaution should be taken for contamination from saliva in laboratory for PCR. Detection of cell-free virus in serum or plasma by PCR offers the possibility of diagnosing active HHV-6 infections. Detection of HHV-6 DNA in plasma and a high virus load in whole blood had sensitivity rates of 90% and 100%, respectively, in diagnosing primary HHV-6 infection. However, both were occasionally found in patients with other infections, possibly associated with HHV-6 reactivation (41).

A new reverse transcription–PCR (RT-PCR) assay for HHV-6 was recently developed and validated that can determine the presence of HHV-6 in clinical specimens and differentiate between latent and replicating virus. The primers for amplification of messenger RNA (mRNA) of a major structural gene (*gp105*), which is expressed as a late gene with its mRNA having a spliced structure, were used. Therefore, the amplification of this gene has an advantage in detecting a replication of virus and readily distinguishing mRNA and residual DNA contamination. This method showed a low rate of false-positive results (1.2%) and a specificity of 98.8%. This RT-PCR assay can reliably differentiate between latent and actively replicating HHV-6 and should allow insight into the pathogenesis of this ubiquitous virus (118).

A quantitative competitive PCR assay for HHV-6 was also developed and demonstrated the persistence of a high HHV-6 load in the absence of apparent disease (43). It was recently reported that the primer sequences based on consensus sequences in the DNA polymerase gene of herpesvirus to detect herpesviruses by PCR were valuable in testing for six different herpesviruses simultaneously by a sensitive and straightforward technique rather than screening for only those viruses causing infection as suggested by clinical signs (115).

Qualitative and competitive-quantitative nested PCR assays were also developed for HHV-7. These assays amplify a DNA sequence encoding part of the HHV-7 *U42* gene (80). A multiplex PCR method was recently developed for the simultaneous detection of HHV-6 and HHV-7 in clinical samples, using primers that amplify a section of the HHV-6 *U67* gene and the HHV-7 *U42* gene. Comparison of the multiplex assay with the respective single PCR assays, using cloned HHV-6 and HHV-7 sequences as targets for amplification, showed equivalent sensitivity and specificity for the assays. It is proposed that this multiplex assay, in which HHV-6–positive samples may be typed directly from the reaction products, is an efficient and cost-effective approach to the analysis of large numbers of samples to determine the epidemiologic importance of HHV-6 and HHV-7 (81).

PREVENTION AND CONTROL

Few reports have been made concerning the response of HHV-6 to antiviral agents (6,8,31,143). Recently, the effect of several antiviral drugs against HHV-6 was evaluated, including phosphonoformic acid (PFA), 9-(2-hydroxyethoxymethyl)guanine (ACV), 9-[(1,3-dihydroxy-2-propoxy)methyl]guanine (DHPG), and (S)-1-[(3-hydroxy-2-phosphonylmethoxy)propyl]cytosine [(S)-HPMPC]. DHPG and (S)-HPMPC were more effective than the others. The sensitivity of HHV-7 to the guanine analogs was different from HHV-6, suggesting a difference in selectivity of specific viral enzymes (176). Prophylaxis with ACV did not prevent the occurrence of HHV-6–associated CNS disease after allogeneic BMT. The inhibitory effects of IFN-a and IFN-b on HHV-6 replication was also demonstrated *in vitro,* as described previously.

PERSPECTIVES

Although HHV-6 causes ES as an acute infection, its pathogenesis is still unclear. Although the main routes of transmission of HHV-6 and HHV-7 appear to be close contacts between infants and parents or siblings through saliva, it was reported that HHV-6 DNA was detectable in cord blood and PBMCs of infants at the early periods after the birth, suggesting possible vertical transmission in some cases. More interestingly, recent reports suggested that HHV-6 may integrate in the chromosome and transfer from mother to baby. The mechanism of integration into chromosome should be solved in future. Next, the detection rate of HHV-7 in saliva of adults is much higher than that of HHV-6, and even the isolation of HHV-7 is relatively easy from saliva, suggesting that the chance of transmission to infants should be high. However, the seroepidemiologic studies have indicated that the primary infection of HHV-7 also occurs during childhood, as for HHV-6, but the age of infection to HHV-7 appears to be later than that of HHV-6. HHV-7 has a narrow cell tropism for infection *in vitro,* such as in CD4+ cells, indicating the low chance of infection, but the real mechanism remains

unclear.

As for other herpesviruses, HHV-6 and HHV-7 infect latently after the primary infection. The possible sites of the latency of HHV-6 and HHV-7 are monocyte-macrophages and CD4+ T lymphocyte, respectively. However, the mechanism of the latency and its reactivation is not clear yet. It is extremely difficult to analyze the pathogenesis of HHV-6 and HHV-7 infection because the only known host for HHV-6 and HHV-7 is humans. We do not have a good animal model so far, and even the HHV-6– and HHV-7–related herpesviruses have not been found in animals. Animal models are also prerequisite for understanding the functions of the viral genes *in vivo.* For example, ES is a common disease among infants who show typical rash, but it is not clear whether virus exists in the skin.

The CNS infection by HHV-6 is one of the most serious problems among infants. Furthermore, HHV-6 and HHV-7 reactivate during immunosuppressive states, such as AIDS and transplantation, and the various clinical symptoms related to their reactivation are reported. Although the relationship between these clinical manifestations and their reactivation should be clearer, the prevention and treatment against these viruses should be developed in future.

Recently, the entire sequences of both viruses have been determined, accelerating the research of the molecular biology of these viruses. The functions of most viral gene products of HHV-6 and HHV-7 in the lytic and latent infections have not yet been elucidated. The development of recombinant virus systems is awaited for the detailed examination of functions of the viral genes in the context of the viral genomes.

CHAPTER 82 Kaposi's Sarcoma–Associated Herpesvirus

Patrick S. Moore and Yuan Chang

Kaposi's sarcoma-associated herpesvirus (KSHV), or human herpesvirus 8 (HHV-8), is the most recently discovered human tumor virus. There are currently only three proliferative diseases unambiguously associated with KSHV infection: Kaposi's sarcoma (KS), body cavity–based or primary effusion lymphoma (BCBL or PEL), and some plasma cell forms of multicentric Castleman's disease (MCD). KS is a tumor of endothelial cell origin, whereas PEL is a B-cell lymphoma, and MCD is a B-cell lymphoproliferative disorder. These tumors are most frequently found in immunosuppressed patients, particularly patients with acquired immunodeficiency syndrome (AIDS). KSHV also causes at least one non-plastic disease, acute bone marrow failure in transplant patients (186a).

KS was first described by Moritz Kaposi in the 1870s as an aggressive tumor affecting a younger age group than is commonly seen today, suggesting viral evolution in pathogenicity during the past century. Careful reading of Kaposi's initial description, however, shows that the clinical manifestations in Kaposi's time are not markedly different from those seen today (153). KS is frequently an indolent tumor affecting elderly men, occurring most commonly in Mediterranean and African populations. With the onset of the AIDS epidemic, a particularly aggressive form of KS appeared that can disseminate and cause death (6,147). KS in severely immunosuppressed people, such as transplant recipients, and in young children can also progress rapidly.

KSHV is one of several pathogens discovered by molecular biologic techniques (259). It was identified from an AIDS-KS skin lesion in 1993 using representational difference analysis (181), a polymerase chain reaction (PCR)-based subtractive hybridization procedure that isolated two small fragments of the viral genome (52). DNA-based detection of viral DNA allowed rapid extension of these results to HIV-unrelated forms of KS (3,34,60,70,87,170,211,276,297) as well as to PELs and MCD (47,289). Identification of infected cell lines derived from PEL tumors (48,165,262) in turn led to the development of first-generation serologic assays used in the characterization of the biology and epidemiology of this virus (115,116,159,173,203,212,262). Within 2 years of the initial discovery of the virus, the 145-kb coding region of the KSHV genome was sequenced from a PEL-derived cell line (269) and from a KS lesion (220).

One critical feature of KSHV is that it, like other rhadinoviruses (2,221,281,311), has captured a number of recognizable cellular cyclic DNAs (cDNAs) into its genome (“molecular piracy”). These genes play important regulatory roles in maintaining and propagating KSHV in the hostile environment of the host cell. Remarkably, although most of these pirated genes are unique to KSHV, close inspection reveals that they affect the same cellular signaling pathways modulated by viral proteins from other herpesviruses, particularly Epstein-Barr virus (EBV, or HHV-4) (210).

Knowledge about KSHV epidemiology and its involvement in immunosuppression-associated tumors has rapidly grown since its discovery (272). KSHV fulfills Hill's criteria (106,138) for causing KS (272), and the molecular basis for its pathogenicity is currently under active investigation. Humans are the only known host, and serologic assays now available can detect most cases of infection. Unlike most herpesviruses, KSHV is not ubiquitous, and only a small minority of people in most developed countries are KSHV positive. In some regions of the world, including large portions of Africa, however, most of the population has serologic evidence of past KSHV exposure. KSHV infection is characterized by a prolonged viral and clinical latency that is presumed to be lifelong. Thus, previously healthy, symptom-free carriers may develop KSHV-related tumors years after primary infection, particularly with onset of acquired immunodeficiency from human immunodeficiency virus (HIV) infection or immunosuppressive treatment to prevent transplant rejection. Although a role for KSHV in KS, PEL, and MCD is firmly established, reports of its involvement in other diseases, such as multiple myeloma, sarcoidosis, and posttransplantation skin tumors, have not been confirmed to date.

Despite rapid progress in the molecular biology and epidemiology of this virus, virologic characterization of KSHV has been hampered by difficulties in directly culturing KSHV *in vitro.* This has precluded performing reverse genetics experiments with deletion viruses, which have been successfully used to define the biology of other herpesviruses, such as HSV-1 and EBV, and little is known about interactions between multiple KSHV genes *in vivo.* Further, knowledge of cell-mediated immune responses critical for understanding viral pathogenesis and vaccine development is at a rudimentary stage. Despite these obstacles, KSHV provides an important new model for human tumor virology.

BASIC SCIENCE

Classification of the Virus

KSHV is a large, enveloped, double-stranded DNA virus sharing many characteristics of other herpesviruses (see Chapter 71). It belongs to the *Rhadinovirus,* or gamma-2 herpesvirus, genus within the subfamily *Gammaherpesvirinae* (Fig. 1). KSHV is closely related to herpesvirus saimiri (HVS) (saimirine herpesvirus 2) of squirrel monkeys, the prototypical and most extensively studied rhadinovirus before KSHV (2,22,83). It is also the only human rhadinovirus identified to date. The typical rhadinovirus genome consists of a single long unique region flanked by variable numbers of direct terminal repeats. Coding regions of rhadinoviruses contain conserved genome segments of structural and metabolic protein genes common to all herpesviruses interspersed with nonconserved clusters of genes related to latency and host cell regulation. These nonconserved regions diverge between even closely related species and frequently contain pirated genes originating from cellular cDNA. Rhadinoviruses do not encode a reverse transcriptase; hence, the mechanisms by which these viruses captured cellular cDNAs remain enigmatic (221).

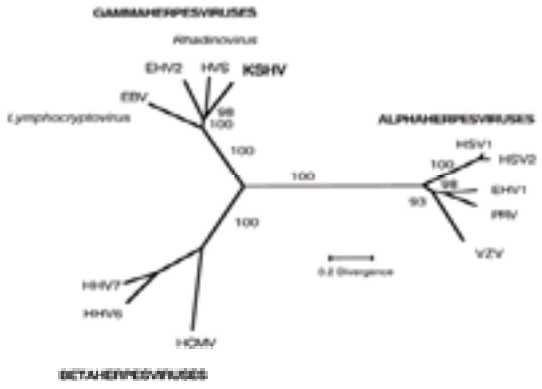

FIG. 1. Unrooted phylogenetic tree based on comparisons of nine conserved proteins showing the relationships between members of the alpha, beta, and gamma subfamilies of herpesviruses. Kaposi's sarcoma-associated herpesvirus (KSHV), like the Epstein-Barr virus (EBV), is a gammaherpesvirus but is the first rhadinovirus known to infect humans. It branches with H. saimiri (HVS), the prototypical rhadinovirus. A number of newly discovered rhadinoviruses (not shown) from Old World primates cluster together with KSHV. [Reprinted with permission (212).]

Related Rhadinoviruses

Since the discovery of KSHV, the list of newly discovered primate rhadinoviruses has rapidly expanded. Rhesus rhadinovirus (RRV) is a common infection of rhesus macaques that can be readily cultured in owl monkey kidney (OMK) cells like HVS (73). DNA fragments from two other rhadinoviruses associated with retroperitoneal fibromatosis of rhesus macaques (267) and two rhadinoviruses from African green monkeys (279) have been isolated, but these viruses have not been propagated *in vitro.* These discoveries suggest that the Old World primate progenitor was infected with two separate lineages of rhadinoviruses, which have subsequently evolved with their primate hosts (267,278). More recently, KSHV-like viruses have been identified in chimpanzees and gorillas (128b,165a). One primate virus lineage has genetic relatedness and *in vitro* culture properties similar to KSHV, whereas the other is RRV-like. For these nonhuman primate viruses, a nomenclature is being designed that will take into account the host monkey species and the viral lineage (KSHV-like versus RRV-like). Because the human RRV counterpart has not been discovered, there may be at least one more human rhadinovirus that has not yet been found and characterized.

The presence of rhadinovirus homologs to cellular proteins makes members of this genus uniquely suited for studies of virus–cell interactions. For example, scrutiny of rhadinoviral genomes (307) has led to the discovery of the corresponding cellular pathway proteins, such as FLICE-inhibitory proteins (FLIPs) (143). Murine MHV-68 is an important experimental rhadinovirus because both the virus and the host can be genetically manipulated, allowing a rigorous identification of host–virus determinants of pathogenicity (316). Further, many rhadinoviruses induce lymphoproliferative disorders when introduced into nonnative species, and rhadinoviruses serve as important but underexploited models for viral tumorigenesis (151). Herpesvirus saimiri and Herpesvirus ateles cause fulminant polyclonal T-cell lymphomas in nonnative host monkeys, and H. saimiri immortalizes human T cells.

KSHV Evolution and Strain Variability

The origin of KSHV and whether or not it recently entered into the human population are scientific questions that are being explored actively. Comparisons between conserved herpesvirus genes suggest that the KSHV-RRV lineage separated from the *H. saimiri* lineage about 35 My, corresponding to separation between their respective Old and New World monkey hosts (198,212). Phylogenetic examination of homolog genes allows a unique evolutionary analysis because both viral and host genes can be directly compared. For example, *vIL-6* genes are present in KSHV and RRV but not in *H. saimiri,* and sequence analysis lends support to the notion that the ancestral KSHV-RRV virus captured this gene after the split between New and Old World monkeys (198). Evolutionary assignments based on other homolog genes are less clear, in part because of the limited numbers of primate sequences available for comparison.

Phylogenetic and molecular epidemiologic studies of KSHV isolates have been difficult because the nucleotide sequence tends to be highly conserved. KSHV sequences from the BC-1 PEL cell line (269) and from a KS lesion (220) show that the central genomic regions have less than 0.4% nucleotide variation between these two isolates. Regions of higher variability are present at internal direct repeat regions, where repeats may be gained or lost (114a). Marked sequence variation, however, is also present at the right and left ends of the long unique region (LUR) adjacent to the terminal repeat sequences. Despite these regions of variability, the overall genomic integrity of KSHV appears to be high, and no clear genotypic strain variation has been found for different types of clinical isolates (333).

At least two major variants of KSHV can be distinguished based on sequence differences at the right end of the genome in the region between open reading frame 75 (*ORF75*) and the terminal repeat region. The two well-characterized variants are named the P and M alleles (246), and additional alleles (N and O) have been described (G. Hayward, unpublished observation) (246). Both P and M variants contain a *K15* gene encoding the highly spliced latency-associated membrane protein (LAMP), which is variable between isolates (124,246). M and P variants are found among widely dispersed KSHV clades and do not follow phylogenetic clusters, suggesting homologous recombination between viral strains after their dispersal into separate clades (333).

The left end of the genome also has a hot spot of genetic variability in the *ORF K1* gene locus (Fig. 2). *ORF K1* encodes a transmembrane protein with structural similarity to the immunoglobulin receptor family of proteins. The cytoplasmic region of K1 protein is relatively uniform, but the extracellular domain is highly variable between isolates, and multiple synonymous and nonsynonymous amino acid substitutions are common (166,172,226). Hypermutability in the K1 ectodomain probably reflects immunologic pressure exerted on infected cells expressing this protein. Viral sequences from different patients generally have different K1 sequences, whereas samples taken from the same patient over time (or from multiple sites) have identical K1 sequences (186a,333).

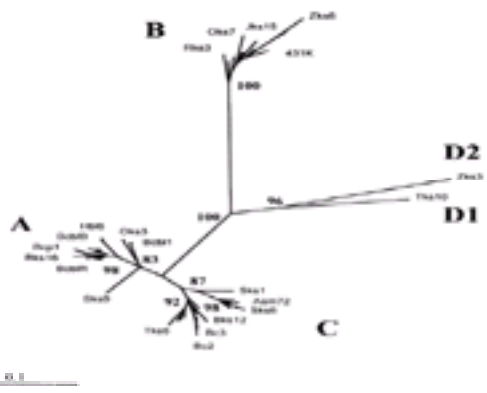

FIG. 2. Genotypic variation in ORF K1 protein sequences between 63 different geographic isolates shows that KSHV strains cluster into three distinct clades. Isolates from Africa and Asia predominate in the B and D clades respectively, while North American and European isolates are predominantly from the A and C clades (reprinted with permission (333)).

Based on variability at the K1 locus, KSHV can be divided into four clades (A to D) (333). African isolates frequently belong to the B clade, whereas the D clade is most common among Asian isolates (135,333). From these findings, it has been suggested that KSHV entered the human population before out-migration from Africa 100,000 years ago and is therefore a relatively ancient human pathogen (135). An alternative explanation, based on conserved sequences and the higher rates of infection in countries adjacent to Central Africa, is that KSHV entered the human population from a monkey host within the past several thousand years and has slowly spread locally to neighboring areas. Extreme sequence variability of K1 may reflect recent adaptations of KSHV to its new host (198). In either case, understanding the spread and evolution of KSHV requires taking into account its recent intercontinental dissemination before and during the AIDS epidemic (8,20,200).

Virion Structure and Replication

Virus Structure

KSHV virions have a target-like ultrastructural appearance (262), with an electron-dense nucleocapsid core surrounded by an amorphous proteinaceous tegument and a lipid bilayer envelope (Fig. 3). Three-dimensional reconstruction of the KSHV capsid imaged by electron cryomicroscopy shows size and structural organization similar to previously studied herpesviruses (309a,320a). Herpes-virus-like particles were found by electron microscopy in AIDS-KS lesions as early as 1984 (314). Recently, rare cells displaying intranuclear inclusions by light microscopy and containing KSHV virions have been documented in KS lesions (232). Little is known about the mode of cell entry or cellular receptor for KSHV because of difficulties in transmitting the virus *in vitro.* However, KSHV has structural glycoproteins (e.g., gB, gD, and gH) used by other herpesviruses for cell entry and virion replication (243).

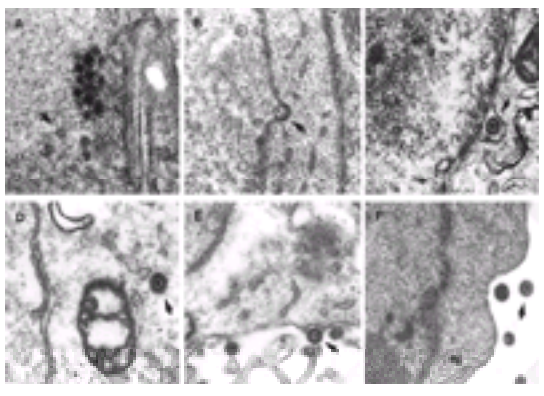

FIG. 3. KSHV virion maturation in the PEL-derived BCBL-1 cell line 48 hours after TPA stimulation. **A:** nucleocapsids forming in the cell nucleus, **B:** viral capsid budding through the nuclear membrane, **C:** virion in the perinuclear cistern after egress from the nucleus, **D:** complete encapsidated virion inside of a cytoplasmic vesicle, **E:** complete virions

budding at the cell membrane, **F:** free virus particles in the intercellular space (magnification 36,000x) Courtesy of Antonella Tosoni, L'Sacco Hospital, Milan.

Viral Replication and Infection of Cells

Like other herpesviruses, KSHV has two modes of replication: lytic, in which viral DNA is replicated by the virus-encoded polymerase and encapsidated into infectious virions; and latent, in which circular viral episomes replicate in tandem with host cell DNA using host cell replication machinery. Initiation of lytic replication results in cell killing (“lysis”) primarily through apoptosis (324), although the possibility of continued virion production without cell death has not been extensively studied.

Herpesviruses initiate lytic replication through highly choreographed transcriptional cascades in which a specific viral transactivator gene acts as a master control switch to turn on subsequent steps in lytic viral gene expression. Once the transactivator proteins are ex-pressed in response to cellular signaling, they in turn activate promoters of other viral genes in the lytic expression cascade. Viral genes needed for virus replication and encapsidation are sequentially activated either directly by the master transactivator or by secondary transcriptional regulators in a controlled series of early, delayed-early, and late waves of viral gene transcription. Individual KSHV genes, however, can also be regulated by tissue-specific cell-signaling pathways. Thus, some genes expressed during latency in some tissues may be up-regulated and expressed primarily during lytic replication in other cell types.

Two KSHV genes, *ORF K8* (129a,179) and *ORF50* (129,184,299), encoding the proteins K-bZIP and ART (activator of replication and transcription also called R4a or Lyta), respectively, are candidates for master lytic transactivators. These proteins are homologous to the well-studied EBV lytic transactivators Zta (ZEBRA) and Rta. The relationship between these KSHV lytic transactivators is not yet entirely clear, but Northern hybridization studies suggest that the ART may first transactivate the K-bZIP gene, *K8* (300), which subsequently acts at other viral promoters. In this case, expression of ART alone is sufficient to initiate all of the events leading to lytic replication (183). The DNA-binding elements in the promoters of KSHV genes responsive to ART have not yet been fully characterized.

Two putative lytic replication origins have been identified in the KSHV genome by sequence analysis that are the presumed initiation sites for genome replication (226). Like EBV, lytic replication can be triggered by chemical agents, including butyrate and the phorbol ester, 12- *O*-tetradecanoylphorbol-13-acetate (TPA or PMA) (202). TPA activates transcription through AP-1 signaling, whereas butyrate inhibits histone deacetylases involved in transcriptional repression. TPA also induces expression of histone acetyltransferases (195), suggesting that derepression of gene transcription is a critical factor in initiation of lytic replication. KSHV DNA is packaged into viral particle in the cell nucleus, and the virion is enveloped either in the Golgi apparatus or at the cell plasma membrane as it is exported out of the cell.

On entry into a new host cell, the linear KSHV genome recircularizes at its terminal repeat region to form the circular episome that will be replicated with the cell during latency. The membrane receptors allowing KSHV binding and entry into the cell are unknown. The episome is maintained in the replicating cell by the latency-associated nuclear antigen (LANA) encoded by *ORF73* (15). LANA is similar to the EBV EBNA1 protein (187,323). It binds the viral episome and tethers it to cellular chromosomes during mitosis, possibly through histone H1 interactions (66), resulting in segregation to daughter cells (15). The sites that LANA binds on the viral DNA, (the so-called origin-of-plasmid replication [ori-P]) have not yet been identified, although evidence suggests that the LANA-binding region lies within the terminal repeats (15a). This allows equal segregation of latent viral genomes to daughter cells during mitosis. During latency, KSHV gene expression is minimized, and the virus relies on the cellular nucleic acid replication machinery for survival. Silencing of viral genes during latency minimizes foreign antigen presentation to evade host immune responses.

The primary reservoir for persistent asymptomatic KSHV infection appears to be CD19+ B cells (3). Natural infection of endothelium, B cells, and possibly CD68+ monocyte-macrophage cells, prostate epithelia, and dorsal root sensory ganglion cells has been reported (3,29,63,74). Within KS tumors, virtually all spindle cells have detectable viral DNA and protein (33,86,255,292), but most cells are latently infected and do not generate encapsidated virus (232). Attempts to culture KSHV-infected tumor cells directly from KS lesions have been unsuccessful. Explanted KS spindle cells used in the past for studies on KS maintain PCR-detectable virus for only two to six passages, after which the virus is invariably lost from tissue culture (99,170). The spindle-like cells that grow out of explanted KS lesions may be uninfected endothelial progenitor cells or may be infected tumor cells that lose the virus with passage. In either case, the relationship of these tissue culture cell lines to KS tumors *in vivo* is unclear.

In contrast, KSHV can be readily cultured *in vitro* from PEL B-cell lymphomas and from peripheral blood cells from PEL patients (12,32,48,82,111,165,262). KSHV is maintained at high copy number in PEL cell lines (up to 50 to 150 genome copies per cell), and producer cell lines can be induced into lytic cycle replication by treatment with chemical agents to yield sufficient virus for purification by gradient centrifugation (218a,315,324).

In Vitro *Transmission*

Attempts to transmit the virus *in vitro* have until recently been limited to low-titered infection (104,201,212,260). Direct transmission from KS tumors and PEL cell lines to 293 cells demonstrates that tumor-derived virus is fully permissive for infection, although the achievable level of virus enrichment is low (104,260). Problems with virus transmission appear to be due to lack of appropriate recipient cell line rather than an inability to generate infectious virus. Nevertheless, extensive testing of dozens of established cell lines failed to identify appropriate recipient cells for transmission studies (260). Long-term infection and high-titered transmission have been recently described by Moses and colleagues (214). This was achieved using papillomavirus E6 and E7–immortalized dermal microvascular endothelial cells, which are

readily infected with supernatants from PEL cell lines. KSHV infection transforms E6 and E7–immortalized endothelial cells to grow on soft agar and lose contact inhibition. This occurs with only limited KSHV gene expression, suggesting that latently expressed genes are sufficient for complementing E6 and E7 in transformation. Confirmation of these results may allow more sophisticated analyses of KSHV genetics, assuming that deletion viruses can be generated and transmitted. Direct infection and transformation of primary bone marrow endothelial cells has also been reported, but like most other cell lines, high-titer infection is not sustained (101). These findings, however, are unique in that they suggest that paracrine effects from infected cells in maintaining endothelial cell proliferation may be important.

Genome Structure and Organization

The LUR of the KSHV genome is about 145 kb in length, contains at least 87 genes, and is flanked terminal repeat (TR) regions (Table 1). Varying numbers of TR units are present in each virus, and this variation may allow an assay of virus monoclonality within cells (150a,269). Each 801-bp repeat unit has high G+C content (85%) and contains putative packaging and cleavage signal sequences (269). The gene organization of the LUR (Fig. 4) is similar to that of H. saimiri, and KSHV genes are consecutively named after their H. saimiri counterparts, except for the first three H. saimiri genes, which are not represented in the KSHV genome (220,269). New genes, particularly spliced genes, continue to be described from transcription studies because the initial annotations of the genome were purposely conservative. KSHV genes that are not homologous to H. saimiri genes are given a K prefix (e.g., ORF K1 to K15) and include many of the cellular homolog genes. KSHV has no genes that encode proteins with direct sequence homology to known H. saimiri oncoproteins (STP and TIP) (152) or to EBV EBNAs and LMPs (see Chapter 74). As discussed in more detail later, some KSHV genes can functionally substitute for H. saimiri oncogenes (172) or are homologs of cellular genes induced by EBV oncogenes (210).

TABLE 1. *Features and functional properties of some KSHV regulatory genes*

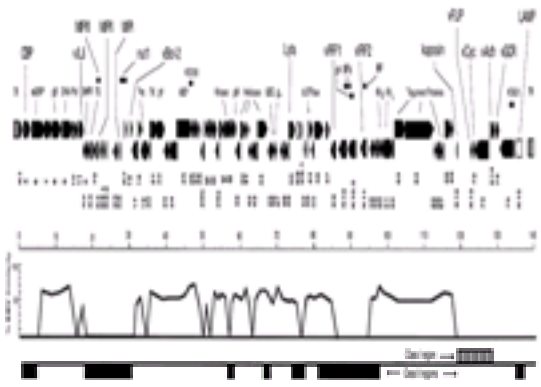

FIG. 4. Linear KSHV genome map showing open reading frames identified by sequence and transcript analysis. Genes are numbered after homologous H. saimiri genes or are given a K prefix if they have no apparent homology. Those loci in white have multiple alternative splice patterns. The middle panel shows the percentage amino acid similarity for each KSHV protein to the corresponding EBV protein, a measure of sequence conservation. Islands of highly conserved genes generally encode structural and replication proteins while intervening nonconserved regions frequently contain genes encoding proteins that alter host cell regulatory pathways. These blocks of conserved and nonconserved genes tend to have similar transcription patterns in PEL tissue culture cells (*bottom bar*). Class I genes are expressed constitutively (e.g. during PEL cell latency) and cluster at the right end of the genome (hatched box). Class II genes are expressed constitutively at low levels but are inducible during lytic replication (black boxes). These genes cluster in the nonconserved gene blocks. The remaining genes comprise class III genes (not shown for sake of clarity) corresponding to true lytic genes. These genes cluster in the conserved islands.

Viral Gene Transcription and Expression

Transcription Patterns in Cell Lines

Full-genome expression mapping has been performed using cDNA Southern hybridization of KS lesions (262), Northern blotting of the BC-1 cell line (271), and more recently by array hybridization (149). These techniques show that most viral genes are not expressed during latency, but are actively transcribed in lytic replication. Herpesvirus genes are usually classified into mutually exclusive categories of latent and lytic genes. Lytic genes can be further subdivided into immediate-early, early, and late expression patterns depending on the kinetics of transcription. This is a controversial

area of gene regulation because opinions differ on how individual genes should be classified and whether or not gene expression can be clearly divided between lytic and latent transcriptional programs.

KSHV has highly regulated transcriptional cascades like other herpesviruses. Initiation of lytic replication by ART results in specific genes being turned on to generate proteins ultimately involved in capsid formation and virus egress. Beyond this, several factors complicate classification of viral genes, such as differing expression programs occurring in different tissues, inability to use cycloheximide or polymerase inhibitors in tissue sections, and the unreliability of *in vitro* cell culture results when they are applied to *in situ* tumor sections (236). For example, some viral genes, such as *ORF K2* encoding vIL-6, are constitutively expressed in PEL cell cultures at low levels but are strongly induced by TPA treatment. This gene is constitutively expressed in hematopoeitic tumors but not KS lesions (209,237,291). Other genes, including *ORF K9* encoding vIRF, are expressed in cultured PEL cells but not the parental tumors from which these cells are derived (236). Finally, chemical inducing agents, such as TPA, may act on AP-1 sites in viral promoters that are not normally activated during natural lytic viral replication. In this case, viral genes would be activated by TPA treatment, which would not otherwise be activated in the course of lytic virus replication.

With these caveats in mind, PEL cells in culture provide an important model system for examining viral gene expression. Sarid and associates divided KSHV messenger RNA (mRNA) expression patterns into three broad classes using the BC-1 cell line that is under tight latent transcriptional control under unstimulated conditions (271). Class I transcripts are expressed constitutively and are not induced by phorbol esters, class II transcripts are expressed at low levels in unstimulated cells but are phorbol-inducible, and class III transcripts are detectable only after phorbol treatment. Class I genes correspond to latency genes, whereas class II genes appear to be expressed during both latency and lytic transcription. Interestingly, these classes of genes are least conserved with other herpesviruses and tend to be clustered together within the genome, forming “latency islands” of similarly regulated genes (see Fig. 4). Highly conserved genes involved in DNA replication and capsid formation also cluster and are expressed together during lytic reactivation (class III genes) (271). This implies that the evolutionarily successful architecture for the herpes virion has been conserved among herpesvirus species. In contrast, genes involved in herpesvirus latency are highly divergent and have evolved to match individual host cells for each herpesvirus.

The right hand cluster of latency genes (*ORF K13, ORF72,* and *ORF73*) is encoded on polycistronic messages expressed in most, if not all, infected cells and tissues (77,271,275,304). Latency transcript-1 (LT1) is a 6-kb message encompassing all three genes, whereas the 2-kb LT2 transcript initiates at the same start site as LT1 but has *ORF73* gene encoding the LANA spliced out. These transcripts (77,275,304) are constitutively expressed in PEL cells but are also cell cycle regulated, with highest transcription occurring in early G_1 phase (275). The KSHV cyclin protein, vCYC, encoded by ORF 72 has a long half-life relative to cellular D cyclins (P. J. Browning, personal communication); therefore, protein levels may not follow cell cycle kinetics. vCYC may also be encoded from a 1-kb transcript separate from LT1 and LT2 (77). LANA (*ORF73*) protein expression is constitutive and appears to be a reliable marker for the presence of the virus in all infected tissues and cells (86,236,255). An additional gene, *ORF K10.5,* lies outside of the right-hand latency cluster but is also constitutively expressed in PEL cells. Preliminary studies suggest that the *ORF K10.5*–encoded protein tentatively designated LANA2 is a B-cell–specific factor and is not expressed in KS tumors (265a).

Zhu and colleagues identified several immediate-early viral genes in PEL cells (belonging to Sarid's class II designation) that are resistant to the protein synthesis inhibitor cycloheximide after butyrate treatment, including *ORF50, ORF K4.2, ORF K8, ORF K8.2,* and *ORF4.5* (329) Based on the kinetics of their response to chemical agents and to the ART transactivator, Sun and colleagues (300) have designated a number of class II genes as early lytic and delayed-early lytic genes in PEL tissue culture cells. Examples of early genes include *ORF K2* (vIL-6), *ORF K3, ORF K4* (vMIP-II), *ORF K5, ORF K7* (polyadenylated nuclear transcript [PAN], formerly nut1, T1.1), and *ORF K8,* whereas delayed-early genes include *ORF2* (vDHFR), *ORF K6* (vMIP-I), *ORF16* (vBCL-2), *ORF K12* (kaposin), *ORF70* (vTS), and *ORF74* (vGCR). It is likely that proteins encoded by these genes play important early regulatory roles in preparing the cell for initiation of virus replication. Genes, such as K8 and K12, have alternatively spliced transcripts that belong to multiple classes of lytic gene expression (179,270).

The *K12* gene is an unusual and complicated locus that has both class I and class II transcription patterns in tissue culture (271). *K12* was originally named T0.7 based on the size of a 700-bp transcript isolated from a KS lesion (262). This transcript is now known to be an uncommon variant compared with most *K12* transcripts, which are 1.5 to 2.5 kb in length. *K12* encodes multiple proteins, termed kaposin A, kaposin B, kaposin C, and so forth, that use multiple alternative transcription and translation initiation start sites (270). In an intriguing study, Sadler and coworkers found that K12 protein translation occurs only infrequently at a predicted AUG start codon and more commonly begins at one of a series of upstream 5'-CUG codons. For most transcripts, translation then extends through the zppa repeat region but does so in different reading frames, depending on the initiation CUG codon used. Because the repeat unit (23 bp in length) is not divisible by three, each kaposin protein eventually encodes the same large internal acid repeat motif regardless of reading frame used* (Fig. 5). A small hydrophobic protein (kaposin A) encoded by the original T0.7 transcript but lacking the zppa repeat motif can transform Rat-3 cells (216), suggesting that some proteins encoded by this locus may be involved in cell proliferation. Because *K12* transcripts are abundantly expressed in all infected cells, they have been useful as *in situ* hybridization probes for KS lesions and related tumors (292).

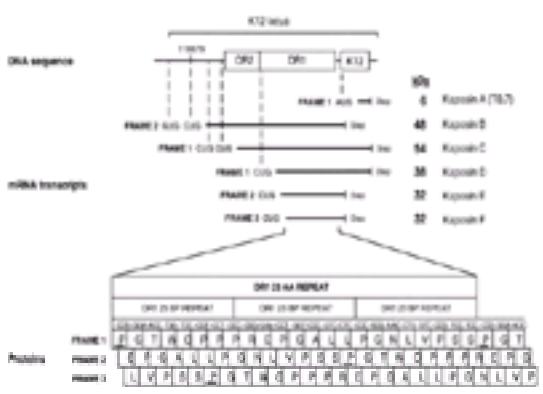

FIG. 5. Alternative transcription and translation start sites for proteins encoded by the K12 locus. Seven mRNA transcripts from this locus are shown encoding proteins with predicted sizes from 6 to 54 kDa. Except for the kaposin A (T0.7) transcript, these mRNAs initiate translation at noncanonical start codons (CUG or GUG instead of AUG) in different reading frames. Despite this, transcripts containing the zppa repeat region composed of two different direct repeat motifs (DR2 and DR1) produce peptides with the same repeating amino acid motif. An example is shown for the DR1 region which reoccurs in all three reading frames after 23 amino acids. The underlined proline is taken as an arbitrary start site for orientation purposes (modified from (270)).

ORF K7 encodes a second abundantly expressed 1.1-kb class II transcript called PAN that also has been used for *in situ* hybridization studies (261,298,327). PAN is primarily (but not exclusively) expressed after TPA treatment of PEL cells (271). Whereas *ORF K12* message is detectable in nearly all KS tumor cells as well as other KSHV-infected tissues, the *ORF K7* transcript has more limited expression compatible with lytic replication *in situ* (292).

Class III gene transcription in tissue culture cell lines is only detectable after lytic replication cycle activation. Typical class III genes include structural protein genes, such as the major capsid protein (*ORF25*) and the small capsomer-interacting protein SCIP (*ORF65*) genes. In general, transcription of these genes can be blocked by the viral DNA polymerase inhibitors phosphonoacetic acid or phosphonoformic acid that inhibit late gene transcription (100,300). Experimental results may differ between cell lines because different cells lines have differing proportions of cells spontaneously undergoing lytic replication. A small percentage of BCBL-1 cells (1% to 5%) continually enter lytic replication in culture, even in the absence of TPA or butyrate. BC-1 cells, in contrast, appear to be under tight latent control and do not express late lytic genes, such as the major capsid protein gene *ORF25* unless treated with phorbol esters (271).

KSHV Gene and Protein Expression in Human Tissues

Gene expression in infected tissues suggests different categories of KSHV latency that are reminiscent of those found for different types of EBV latency (see Chapter 74). In KS lesions, essentially all spindle cells are infected with KSHV, but the limited set of genes expressed includes LANA (*ORF73*), vCYC (*ORF72*), and kaposin (*T0.7, ORF K12*) (86,236). Rare tumor cells (about 1%) express the DNA processivity factor PF-8 protein (*ORF59*) and *T1.1,* indicative of lytic virus replication and virion production (50,155a,178,236). This expression profile is consistent with most KS cells being latently infected, whereas a minority cell population spontaneously undergoes lytic replication (232,292). vMIP-III protein (encoded by *ORF K4.1*), an angiogenic chemokine, has been found by immunoblotting KS tissues, but the cell types expressing this protein are not known (294). PEL tumors show a similar restricted pattern of gene and protein expression, with the exception that vIL-6 protein can be detected in 10% to 30% of cells (155a,236). In those PEL tumors co-infected with EBV and KSHV, EBV generally has a type I pattern of expression initiated from the Qp promoter, with EBNA1 being the only EBNA protein prominently expressed (142).

Infected cells in Castleman's disease lymph nodes have a strikingly different pattern of gene expression from PEL and KS tumors (155a,236). KSHV-positive cells comprise only a minority of cells in the Castleman's disease lymph nodes. These cells have features of immunoblastic B cells and are localized to 2% to 30% of cells in the mantle zone around reactive germinal centers (237). Although all these KSHV-infected cells express LANA, a substantial fraction also coexpress a variety of other proteins, including vFLIP, vIRF-1, vIL-6, PF-8 SCIP, K8-1, K10, and K11 proteins. It is unclear whether these cells are undergoing full lytic virus replication or have an expanded pattern of latent KSHV gene expression.

EPIDEMIOLOGY AND PATHOGENESIS

Diagnostic Assays

KSHV DNA can be detected in peripheral blood cells from only about half of infected persons using standard PCR protocols indicating that viremia is not prominent (88,213,317). Serologic assays for KSHV-specific antibodies are more sensitive than PCR for detecting either current or past infection with the virus. Improvements in assay formats are occurring rapidly, but current assays under optimal conditions can detect viral infection in more than 90% of infected patients. Antibody responses to LANA and other KSHV antigens appear to be lifelong in healthy adults; however, loss of detectable antibody occurs in 10% to 30% of end-stage AIDS patients with KS (116).

There are at least five serologic assays in current use, each with particular strengths and weaknesses. Indirect immunofluorescence assays (IFA) to detect LANA or lytic antigens are relatively inexpensive and simple but can be subjective. IFA is performed by incubating patient sera with infected PEL cells or isolated nuclei on microscopic slides, and specific antibody binding is measured using fluorescein-conjugated antihuman secondary antibodies. Patient sera with specific anti-KSHV antibodies fluoresce in characteristic patterns. LANA was the first serologic antigen identified by IFA (212), and this is still a standard assay because of its low rate of false positivity. A speckled nuclear pattern is seen in unstimulated whole cells (116) or isolated nuclei (157). The LANA IFA is very specific but generally less sensitive (about 80% sensitivity) than other assays. LANA can also be detected from Western blots of whole-cell lysates as a 226- to 232-kd doublet, although this procedure is more difficult owing to low protein electrotransfer (115).

Lytic antigen assays have higher sensitivity rates than LANA assays (more than 95%) but also carry the risk for cross-reactivity, especially at low serum dilutions. Cross-reactivity is the likely explanation of high human infection rates initially reported from lytic antigen assays compared with LANA testing (173). AIDS-KS sera are nonspecifically reactive to lymphocyte antigens at low dilutions (e.g., 1:10), which can be removed by adsorption with KSHV-negative lymphocyte lysates (116). Cross-reactivity in this assay can be markedly reduced by counterstaining with Evans blue and diluting

sera to 1:40 or more (287). Lytic IFA antigens have a diffuse cellular distribution after cells are treated with TPA or butyrate to induce virion protein synthesis (173,287). A purified whole virion enzyme-linked immunosorbent assay (ELISA) has been developed, which has similar characteristics as the lytic IFA (54).

Recombinant antigens from *ORF65* (180,284) and *ORF K8.1A* (51,177,249) used in an ELISA format show comparable sensitivity and specificity to the lytic IFA assays. SCIP (*ORF65)* is a small capsid antigen with some cross-reactivity to the homologous EBV antigen that can be eliminated by truncating the carboxyl portion of the protein (284) or through use of a peptide antigen (239). The *K8.1* gene encodes alternatively spliced glycoproteins termed *K8.1A* and *K8.1B* that may correspond to a 40-kd antigen identified by Western blotting BC-1 cells after butyrate treatment (203). *K8.1* can be examined in an ELISA or Western blot format. Other KSHV antigens have been examined but appear to be less appropriate for serologic screening owing to low sensitivity or cross-reactivity (4,168).

Evidence suggests that patient populations have heterogeneous serologic responses to defined KSHV antigens; therefore, combinations of antigen assays may achieve the best detection rates (168,284,329). Although early studies suggested wide differences in infection rates based on the type of antigen used (252), properly performed assays in standardized formats are actually highly concordant (284). These results are likely to be further improved with use of recombinant antigens (329), but conclusions based on early LANA IFA studies have been largely confirmed using the more refined antigen preparations (277).

Epidemiology

The existence of an infectious agent causing KS was predicted by the tumor's unusual epidemiology (21,123). Before the AIDS epidemic, “classic” KS was noted to have geographic clustering and occurred most frequently in elderly men of Mediterranean and Eastern European ethnicity. Evidence for an environmental (i.e., infectious) component to this disease comes from geographic differences in KS rates. More than 100-fold differences in classic KS rates occur in different regions of Europe. England and Wales have exceedingly low annual rates (0.14 cases per million), whereas rates in Sardinia and Sicily reach 24 to 30 cases per million per year. The United States has an intermediate rate estimated to be 3 cases and 0.7 cases per million men and women, respectively (144). Still higher rates of disease were present in Central African populations (“endemic KS”), where a particularly malignant form affects young children (13,61,330). The occurrence of KS is also increased among immunosuppressed transplant recipients and chemotherapy patients, particularly when the patient belongs to a high-risk ethnic group (241,247).

Regardless of the setting, country-wide incidence rates dramatically increased with the onset of the AIDS epidemic in the early 1980s. Evidence for an infectious etiology also became stronger with epidemiologic studies of AIDS patients because behavioral risk factors pointed toward a sexually transmissible agent (20). Homosexual male AIDS patients are 20 times more likely to have KS at AIDS diagnosis than comparably immunosuppressed male hemophilic AIDS patients (21). Studies also suggested that the agent spread internationally from the U.S. AIDS epicenters (New York, San Francisco, and Los Angeles) to Canadian and European homosexual communities (9,20,200). Having a bisexual male sex partner is also a risk factor for developing AIDS-KS among HIV-infected women. In contrast, people infected with HIV through blood transfusions rarely developed KS, indicating that HIV and the KS agent are not equally transmissible by blood-borne routes. Although HIV itself (particularly the tat protein) was considered a prime candidate for the KS agent before identification of KSHV, it could not be responsible for HIV-negative forms of KS, nor did it satisfactorily explain low rates of KS among HIV-infected hemophiliac patients and blood transfusion recipients.

Infection Rates in Various Populations

Isolation of KSHV DNA allowed use of PCR to test for the presence of the virus in both HIV-negative (classic, endemic, and immunosuppression-related) and HIV-positive forms of KS. Well more than 20 separate studies have demonstrated that viral DNA can be detected by PCR in at least 95% of KS tumors regardless of source. It is possible that a small percentage of KS lesions are free of KSHV infection, but it is now assumed that virus will always be detected in properly diagnosed and prepared specimens. The benefit of PCR in providing a simple and sensitive assay for infection is counterbalanced by its tremendous susceptibility to amplicon contamination. Some anomalous early studies resulted from undetected PCR contamination, which underscores the need for caution when using this technique in epidemiologic investigations. Confirmatory assays, such as direct Southern hybridization, should be used whenever possible. Serologic studies also support the near universal infection of KS patients with KSHV because specific antibodies are detectable in 70% to 90% of all KS patients and in almost 100% of KS patients who are not immunosuppressed (54,115,157,173,180,203,212,284,287,318,326).

Unlike most human herpesviruses, KSHV is not ubiquitous but is distributed according to a combination of geographic and behavioral risk factors (Table 2). KSHV infection rates generally parallel KS disease occurrence in different parts of the world. KS is uncommon in the United States, and KSHV seroprevalence among U.S. blood donors ranges from 0% to 10%, whereas seroprevalence rates above 50% occur in many African populations (10,19,35,116,121,136,173,196,230,284,285). Intermediate rates of infection are present for Italian blood donors (116,265,318) and other groups from Mediterranean countries where KS is more common (248,284). Two studies have demonstrated a gradient of KSHV seroprevalence along the Italian peninsula that matches local rates of KS disease occurrence. Highest rates of infection and disease are found in southern Italy—particularly Sardinia—and lowest rates are in northern Italy (43,318). Local population pockets having atypical KS rates such as in the Po valley also have high KSHV seroprevalence. In Japan, where KSHV seroprevalence among blood donors may be as low as 0.2% (109), KS is a rare tumor. Similar low rates of infection are present in HIV-seronegative people from Thailand (217), and KS is generally an uncommon opportunistic disease among AIDS patients in Asia. One unexplained finding is that KSHV infection rates are high in West Africa, although KS is reported to be uncommon (10,62). Data such as this suggests that other as-yet undescribed factors such as HLA (191), or other infectious cofactors may play a role in disease expression among people infected with KSHV.

KS incidence[a]	Regions	Population KSHV prevalence	Transmission	Risk groups
Low	North America, North Europe, Asia	<2%	Sexual	Homosexual men, STD attendees, transplant recipients
Intermediate	Mediterranean, Middle Eastern countries, Caribbean	5–20%	Sexual, nonsexual?	Homosexual men, STD attendees, transplant recipients, older adults
High	Africa, parts of Amazon basin	>80%	Nonsexual, sexual	Older adults, lower socioeconomic status

[a] AIDS-KS rates are highly dependent on local HIV infection rates and risk groups.

TABLE 2. *Patterns of KSHV infection and non–HIV KS*

KSHV seroprevalence in high-risk populations is dramatically higher than in the general population. Homosexual men can have asymptomatic infection rates approaching 40% (116,193,203), and KS is more frequent among HIV-negative homosexual men than the general male population (98,108). The only study from which population-based estimates of infection are available shows that 38% of homosexual men from San Francisco were LANA antibody positive in the early 1980s (193). Several studies record a dramatic decline in new KSHV infections since then, corresponding to declining KS rates that have been noted among AIDS patients (80,186,200,263). The reasons for this decline are not clear, but one explanation is that KSHV has low infectivity, and implementation of safe-sex practices effectively reduces its transmission in high-risk populations. Our current understanding of KSHV epidemiology helps to explain the long-standing mystery of why KS became a clinical hallmark for AIDS during the early manifestations of the epidemic. It is likely that the initial epidemic of AIDS-KS resulted from the collision between two simultaneous and independent viral epidemics of HIV and KSHV (200,227). It is therefore not surprising that homosexual men, who are independently at higher risk for HIV and for KSHV infection than heterosexual men, composed most AIDS-KS patients.

In many developed countries, women make up only 10% to 30% of the KS cases compared with men (26,130,140). Women are also less commonly infected than men in U.S. and Northern European KSHV serosurveys (126,157,319). Higher rates of infection generally occur among female sexually-transmitted disease clinic attendees, providing evidence that the virus might be heterosexually transmissible, but this mode is likely to be far less efficient than homosexual transmission (157,288). In Mediterranean and African populations, infection rates do not significantly differ between sexes (35,230,285,318), and a hormonal influence on disease expression seems likely because KS among people without HIV is still more common in men than women from these regions (117,145). Infection and disease are extremely rare among children in the United States and Europe, whereas it is far more common in parts of Africa (30,126,196,249).

Epidemiologic studies suggest that only a small percentage of healthy adults who are KSHV infected will develop symptomatic disease; therefore, KS is a rare tumor in countries with low infection rates. Symptomatic disease primarily occurs among people with acquired immunosuppression (for HIV-negative people, this may be due to advanced age or chemotherapy), resulting in loss of cell-mediated immune surveillance for virus-specific antigens (234). In contrast, KSHV prevalence was already high in some African countries before the introduction of HIV (230). Because of the African HIV epidemic, KS tumor rates have dramatically risen, and it is now the most frequently reported cancer in some African tumor registries, accounting for up to 50% of reported tumors among adult men (17,313). Public health efforts have not begun to address this problem, which is particularly important for African populations.

Transmission

Detailed knowledge of the epidemiology of KSHV transmission is currently limited; therefore, explanations of how KSHV infection occurs remain largely speculative. Seroepidemiologic studies suggest that KSHV has at least two major modes of transmission. Sexual transmission is the most common route of infection in low-prevalence, developed countries where infection is uncommon. In contrast, nonsexual routes of transmission predominate in endemic African regions where infection rates are high. The reasons for these differences and the precise mechanisms for human-to-human transmission are not known. Similarly, it is not yet clear whether sexual or nonsexual routes of transmission are the principal routes of infection in Mediterranean basin countries (Table 2).

KSHV can be shed into semen (reviewed in 28) and thus might be transmitted during vaginal or rectal intercourse. KSHV prevalence increases with the number of male homosexual contacts (193), and receptive anal intercourse has been found to be a risk factor for infection in some studies (200). However, virus can only be detected in semen samples from a minority of infected men, raising the possibility that shedding is episodic or that only a percentage of men are highly infectious. Shedding into the genital tract of infected women is uncommon; its significance for female-to-male transmission is unknown but probably low (42,319).

Infectious KSHV virions have also been detected in the saliva of KSHV-seropositive individuals, demonstrating replication of the virus in the oropharynx (164,239a,310). If KSHV is transmitted through oral secretions, the reasons that the virus has a sexual rather than an oral contact (e.g., kissing) transmission pattern are unclear (239a). Specific sexual practices such as oroanal and orogenital contact may help to explain this (131). Recent cohort studies point toward orogenital contact being a risk factor for transmission (84), although this does not fully explain why homosexual men have elevated infection rates.

Still less is known about how KSHV is nonsexually acquired in African countries, where infection can occur during childhood (154,230,285,331). Unlike developed countries, maternal–child transmission accounts for a portion of KSHV infections in highly endemic areas (196,286). This may not be due to vertical infection during the birth process because childhood infection appears common (188). KSHV infection continues to occur throughout childhood, and adolescence in

endemic regions (5,154,196) arguing for transmission through some form of casual contact. In this respect, KSHV epidemiology resembles that of hepatitis B virus (see Chapter 87), which has a low prevalence in developed countries, where it is principally sexually transmitted but is transmitted through unknown routes during childhood and adolescence in hyperendemic developing countries.

Transplantation-related KSHV transmission is an important preventable cause for KS. KS can be a complication of any form of transplantation, including bone marrow, cardiac, and renal transplantation. It develops in 0.1% to 1% of transplant recipients in low endemnicity settings (242) and in up to 5% of patients from Saudi Arabia, where KSHV infection is high (248). The risk for developing KS is significant for infected transplant recipients, with one study demonstrating 68% of KSHV-infected patients developing tumors during the course of follow-up (97). Recently, a new syndrome of bone marrow failure after transplantation due to KSHV infection has been described (186a). Disease can result from both reactivation of infection acquired before the transplantation (238) and *de novo* infection from the donated organ allograft (238,257,258). In contrast to organ transplantation, transmission from blood products is uncommon. KS rates are low among AIDS patients infected with HIV through blood transfusions, arguing for a low rate of transmission by this route. KHSV infection among intravenous drug users increases proportionally with frequency of drug use, suggesting that blood-borne KSHV transmission can occur but at lower rates than for other viruses, such as hepatitis C virus (45a).

Natural History of KSHV Infection

Characteristic clinical symptoms for primary KSHV infection have not been reported. Most primary KSHV infections are asymptomatic; however, in one well-documented case, an HIV-positive man developed a transient angioproliferative lymphadenopathy accompanied by a rise in LANA followed by a rise in *ORF65* antibody titers (229). Primary infection generates immunoglobulin M (IgM) and IgG antibody responses to LANA and lytic antigens. IgM titers are frequently transient, lasting for several months, although prolonged IgM responses can also be seen (258). Rising antibody titers may be predictive for KSHV-related disease (285), and the pattern of seroreactivity to specific antigens can evolve during the course of KS (128a,168).

The incubation period for disease caused by KSHV infection is primarily dependent on the immune status of the infected person rather than the length of time infected with KSHV. Examinations of transplant recipients receiving an infected organ give the most precise estimates for the minimum incubation period after infection. In one study, two patients developed KS within 26 months of receiving an organ from an infected donor (258); in another study, a patient developed MCD within 13 months and KS within 27 months after infection (238). Among HIV patients, risk for developing KS depends on patient CD4+ count rather than HIV viral load (263), and half of those destined to develop KS are infected at least 2 to 6 years before disease onset (115,263). Some patients, however, can develop clinical disease within months of primary KSHV infection. Longitudinal studies also suggest that those infected first with HIV and second with KSHV develop AIDS-KS more rapidly compared with KSHV-positive patients who later acquired HIV infection (263).

Immunologic control of KSHV infection in healthy adults is evident from clinical studies. HLA class I–restricted cytotoxic T-lymphocyte responses to proteins encoded by *K1, K8.1,* and *K12* are present in some infected patients but are lost with progression of AIDS-related immunodeficiency and onset of KS (234). Dramatic resolution of both KS and PEL tumors have been reported with highly active antiretroviral therapies in AIDS-KS patients (320). Similarly, posttransplantation KS can also resolve when patients are taken off immunosuppressive regimens. These findings are encouraging that preventative or therapeutic vaccines are achievable for controlling KSHV-related diseases.

Pathogenesis of KSHV-related Proliferative Disorders

The three neoplastic diseases associated with KSHV infection (KS, PEL, and some forms of MCD) represent a spectrum of proliferative disorders ranging from polyclonal hyperplasia to monoclonal neoplasia. Because of this, KSHV provides unique insights into the pathology of cell proliferation and its relationship to immune surveillance. All forms of cellular proliferation are considered tumors, but hyperplasia occurs through replication of normal, polyclonal cells operating from cytokine-driven regulatory mechanisms. Neoplastic proliferation implies dysregulated autonomous cellular expansion by abnormal cells that have undergone transformation. Prototypical cancers are aggressive, monoclonal conditions that rarely regress spontaneously. This does not imply that neoplastic disorders are cytokine independent, and in fact, neoplastic conditions characteristically show strong autocrine and paracrine cytokine dependence. Virus-induced cancers, however, can result from multiple independently infected cells undergoing clonal expansion, which resembles a polyclonal rather than a monoclonal disorder.

KS is a vascular tumor composed of proliferating spindle cells thought to be derived from an endothelial lineage, possibly from lymphatic endothelium (75,86). It frequently contains normal cells either as a result of infiltrative growth or inflammatory cell recruitment. Some studies suggest that KS tumor cells have a onoclonal cell origin as expected for a typical neoplasia (250,251,269), whereas others indicate that the tumor is a polyclonal hyperplasia (71,122). In part, these differences may be due to the admixture of normal and tumor cells, but it is also possible that KS lesions originate as polyclonal or oligoclonal diseases, which evolve into monoclonal disorders when single clones achieve growth advantage (113,150a,269). A more central issue to KS pathogenesis is whether or not KS spindle cell proliferation is caused by viral gene products or by external cellular inflammatory cytokines induced by infection. *In situ* localization studies show that most mature tumor cells contain virus (33,86,255,292). This implies that viral gene products directly impart a growth advantage within these cells, regardless of whether a tumor originated from a single clone or from a group of independently infected cells.

An alternate hypothesis states that an uninfected precursor lesion exists first, which secondarily attracts virus-infected cells through inflammatory cytokines (96,296). In this case, KSHV infection of KS lesions is a consequence rather than a cause of the disease. These conclusions are based on studies of early (patch) stage KS lesions in which only a minority of tumor cells have been found to be infected. The possibility of insensitive virus detection remains to be excluded, and it is difficult to reconcile this hypothesis with epidemiologic studies, indicating infection precedes onset of clinical disease

by up to 10 years (115,193,200,213,256,263,317).

Inflammatory cytokines, such as interferon-g, induce lytic KSHV replication as well as vasoproliferative cellular cytokines (208). Cellular cytokines, such as b-FGF, are likely to be central to maintaining tumor cells (93,95), but vigorous debate centers on whether b-FGF and other inflammatory cytokines induce KS lesions or are secondarily involved as an inflammatory response to viral infection of KS. HIV tat protein has also been implicated as a central mediator of KS pathogenesis (16,94,141,312), but clearly it is not involved in the development of HIV-negative KS, nor is HIV proviral DNA appreciably present in KS lesions (72). Although some angiosarcomas have been reported to be infected with the virus, pathologic discrimination between angiosarcoma and aggressive KS may be difficult, and these findings remain controversial (76,197,303,308).

In contrast to KS, PELs represent a more typical neoplastic process. PELs have unique clinical, immunophenotypic, and molecular characteristics. These B-cell lymphomas occur as malignant effusions in visceral cavities, although malignant cells can be found infiltrating adjacent visceral organs and in the peripheral circulation (32). Although most of these lymphomas are co-infected with EBV, dual viral infection is not invariable. In the setting of AIDS, the clinical course for most of these lymphomas is extremely aggressive, with a mean survival from diagnosis of 5 to 7 months (218). Implementation of highly effective antiretroviral therapy in cases has resulted in regression (320), which is atypical for a lymphoma. This “benign” course is reminiscent of that seen for PEL in HIV-seronegative individuals (295). Immunoglobulin rearrangements and surface expression of syndecan-1, coupled with lack of Bcl-6 expression, indicate that the KSHV-infected PEL cells are derived from preterminally differentiated post–germinal center B cells (46). PEL also express CD23, CD45, EMA, and other activation antigens. PEL cells, unlike cells from KS lesions, are fully transformed and tumorigenic in immunodeficient mice (32,245). A role for KSHV in other AIDS-related lymphomas, such as primary central nervous system lymphomas, has been proposed, but careful studies demonstrate that virus detection may be due to “spillover” of infected peripheral blood cells (47,110,112).

MCD is a reactive lymphadenopathy characterized by expanded germinal centers and proliferation of endothelial vessels within involved lymph nodes. Based on the microscopic features, MCD can be divided into two histologic subtypes: hyaline vascular and plasma cell variants. The former usually presents as a solitary, usually mediastinal, lesion that can be treated curatively by surgical excision; whereas the plasma cell variant tends to have a multicentric and malignant presentation. Although MCD is considered nonneoplastic, it often precedes development of non-Hodgkin's lymphomas (244). Dysregulated interleukin-6 (IL-6) production is the underlying abnormality that leads to the characteristic clinical and histologic manifestations of this disease (37). IL-6 signaling inhibits B-cell apoptosis by inducing BCL-XL (280), reducing B-cell turnover. IL-6 is also an autocrine growth factor for some B-cell neoplasias (1). KSHV-related forms of MCD appear to be caused by vIL-6 secretion (237), whereas KSHV-negative MCD probably results from local cellular IL-6 hypersecretion through other mechanisms. Most MCD tumors in AIDS patients have detectable KSHV infection, but only half of HIV-negative MCD patients are KSHV positive (289). KSHV-related MCD is more commonly the plasmacytic variant (64) and is clinically severe, with most patients dying within 2 years from a variety of disorders, including autoimmune hemolytic anemia associated with gammopathy (237).

Scattered KSHV-infected B cells are present in the mantle zone of germinal centers of KSHV-positive MCD tumors (237). These cells express a wide range of KSHV proteins, including early lytic gene products (155a,236). Whether the small percentage of KSHV-infected cells in an MCD germinal center are themselves neoplastic (analogous to EBV-positive Reed-Sternberg cells of Hodgkin's disease) remains to be determined, but monoclonal expansions of B cells have been found in some MCD cases (133,134,253). KSHV-infected cells in MCD germinal centers have been reported to have a lambda light-chain restriction pattern (85). vIL-6 secretion is most likely responsible for the B-cell hyperplasia surrounding uninfected B cells. Other viral and human cytokines may also contribute to MCD pathogenesis, particularly neoangiogenesis (7,14,31,306).

Attempts have been made to generate animal models of KSHV-induced proliferative disorders using whole virus or individually expressed viral genes. Primate infections with KSHV have not thus far led to clinically apparent disease. When KSHV is injected into human fetal liver and thymus implants in SCID mice, the virus replicates at low level before establishing a prolonged latency (78). No appreciable pathology was found in the infected tissues. Implantation of PEL cell lines into immunodeficient mice leads to lymphoma formation with local angiogenic hyperplasia (32,245). NIH3T3 cells overexpressing vIL-6 causes cell transformation and tumor formation, but also mouse B-cell hyperplasia and neoangiogenesis (7). One of the most convincing animal models for KS has recently been described using transgenic expression of the viral G-protein–coupled receptor (vGCR) under control of a B-cell promoter (322). These transgenic mice develop angioproliferative lesions that closely resemble KS lesions, suggesting an important role for vGCR in KS pathogenesis, presumably acting through paracrine mechanisms.

Molecular Piracy of Cellular Regulatory Genes

The most prominent feature distinguishing KSHV from other human tumor viruses is its extensive array of pirated regulatory genes (Table 1). Although the KSHV genome is unique because of these readily identifiable genes, other viruses frequently have functional equivalents (210). This is most clearly seen for EBV in which there is close correspondence between cellular genes induced by EBV infection and cellular homologs encoded by KSHV (Table 3). The recognizability of many KSHV genes make this virus a highly transparent model for understanding commonalities among tumor viruses. Other viruses modulate some of the same cell regulatory pathways, and it remains to be seen how far this correspondence principle can be extended to unrelated tumor viruses.

KSHV Genes	Effect	Cell protein induced by EBV	Responsible EBV proteins
ORF 4 (vCRP)	Complement inactivation?	C3bi/vCP2	EBNA2
ORF 42 (vIL6)	Growth factor	IL-6	gp350/220, LMP1
ORF 16 (vBCL2)	Anti-apoptosis	BCL2	LMP1
ORF K9 (vIRF)	IFN inhibition CBP/p300 binding		EBNA2
ORF 72 (vCYC)	Cell cycle control	Cyclin D2	EBNA2, EBNA-LP
ORF 74 (vGCR)	Cellular proliferation	EBI-1	EBV induced
ORF K1, K15 (LAMP)	Immunoreceptor signaling	–	LMP1, LMP2
ORF 50 (Lyta)	Lytic transactivator	–	BRLF (Rta)
ORF K8 (b-ZIP)	Lytic transactivator	–	BZLF (Zta, ZEBRA)
ORF 73 (LANA)	cis-P-binding protein	–	EBNA1

KSHV, Kaposi's sarcoma–associated herpesvirus; EBV, Epstein-Barr virus; IFN, interferon; CBP, CREB-binding protein.

TABLE 3. *Correspondence between KSHV and EBV regulatory genes*

Cytokines and Cytokine Receptors: vMIP-I, vMIP-II, vMIP-III, vIL-6, and vGCR

There are at least four secreted cytokines and a G-protein–coupled receptor encoded by KSHV. The cytokine genes (*ORF2, ORF4, ORF4.1,* and *ORF6*) cluster in a nonconserved 10-kb region on the left end of the genome between base pairs 17,000 and 27,000, whereas the G-protein–coupled receptor gene (*ORF74*) is at the far right-hand end of the genome (base pair 119,000).

*Viral Chemokines (*ORFK4, ORF4.1, *and* ORF6*)*

KSHV encodes three chemokines (chemoattractant cytokines) belonging to the macrophage inflammatory protein family. This group of related chemokines initiate signaling by binding to G-protein–coupled receptors and have a central dicysteine (CC) motif, which distinguishes them from CXC chemokines that include IL-8. The viral proteins encoded by *ORF K6, ORF4,* and *ORF4.1,* respectively, are termed vMIP-I (or vMIP1a), vMIP-II (or vMIP-1b), and vMIP-III (or BCK), based on their sequence similarity to cellular macrophage inflammatory protein (MIP) chemokines. Virus-encoded chemokines were initially considered to be unique to KSHV (209,225) and molluscum contagiosum virus (282), but functional chemokines have since been found in HHV-6 (334), human cytomegalovirus (CMV), and mouse CMV (189,240).

Although it was initially thought that the vMIPs might have a broad antagonist function to inhibit inflammatory responses (163), it has become clear that each vMIP binds to a specific receptor and initiates chemotactic signaling. Nonetheless, all three may share a similar functional activity in blunting the helper T-cell subtype 1 (T_H1) immune response (290). For example, vMIP-II specifically activates CCR3, the eotaxin receptor for eosinophils, while binding other receptors at low affinities (31). This broad receptor-binding range may be related to vMIP-II being a monomer in solution unlike most CC chemokines (182). vMIP-II also chemoattracts T_H2 lymphocytes that express CCR3, and this property may serve to inhibit recruitment of T_H1 lymphocytes during a nascent immune response. vMIP-I and vMIP-III bind CCR8 (67,92) and CCR4 (294), respectively, which are also T_H2 lymphocyte chemotaxis receptors. vMIP-II, like vMIP-I, binds CCR8 with high affinity, but results are contradictory as to whether this inhibits or activates (290) signaling. Only vMIP-III is actively synthesized and secreted in KS lesions (294). In contrast to KSHV, EBV encodes an IL-10–like cytokine, which may also serve to polarize immune responses toward a T_H2 profile.

Both vMIP-I and vMIP-II prevent HIV entry into cells by blocking the chemokine coreceptors used by both macrophage- and lymphocyte-trophic strains of HIV (31,209). Whether these proteins have significant activity at the concentrations achievable in patients is unknown, but they may serve as molecular starting points for generating synthetic broad-spectrum coreceptor inhibitors. All three viral chemokines are also highly angiogenic in chorioallantoic membrane assays, an unusual property for CC chemokines (31,294).

Viral G-Protein–coupled Receptor (vGCR, ORF74*)*

Like H. saimiri KSHV encodes a functional seven-transmembrane–spanning G-protein–coupled receptor with sequence similarity to the IL-8 receptor (49,132). vGCR is encoded on a bicistronic transcript, together with *ORF K13* (vAdh or vOX-2), as an early lytic gene in PEL cell lines (162). Stable vGCR expression induces cell transformation and secretion of the angiogenic vascular endothelial growth factor (VEGF) in NIH3T3 cells (11,14), but this gene has limited expression in KS lesions (162). KSHV vGCR is constitutively active in stably transfected cells in culture (11) and can be further activated by IL-8 and GRO-a binding (120,268). In contrast, the interferon-induced chemokine IP-10, which acts as a chemoattractant for T_H1 cells, inhibits vGCR signaling, as does vMIP-II (119). Activation of the receptor results in a Ca^{2+} influx and mitogen-activated protein kinase (MAPK) pathway activation, which may be responsible for cell proliferation induced by this viral gene (11). Transgenic vGCR expression in mice results in an angioproliferative disorder strongly resembling KS (322).

*vIL-6 (*ORF K2*)*

This secreted viral cytokine has 62% amino acid sequence similarity to its cellular counterpart (209,219,225). huIL-6 is an inflammatory cytokine that binds to a specific high-affinity receptor (IL-6Ra or gp80) and the low-affinity gp130 signal transducer molecule (reviewed in 139). IL-6 binding to gp130 leads to Jak-STAT pathway activation and activation of other pathways, such as MAPK, through the protein tyrosine phosphatase SHP-2 (161). Like the vGCR, constitutive overexpression of vIL-6 induces secondary VEGF secretion and promotes NIH3T3 cell transformation (7). vIL-6 is active in IL-6 bioassays, although it has a lower specific activity than the human cytokine (39,209,225). One important difference between the human and the viral cytokine is that vIL-6 can directly initiate signaling through the gp130 receptor without

use of the IL-6Ra co-receptor (206). Unlike haIL-6, vIL-6 makes contact with gp120 through hydrophobic interactions to induce reception dimerization-activation (57a). This may lead to activation of cells normally unresponsive to IL-6. Despite this, there is no clear indication that downstream signaling pathways differ between the two cytokines (233).

PEL cells are autocrine dependent on vIL-6 and huIL-10 (81,150). If vIL-6 inhibits an apoptotic B-cell responses initiated as a defense against KSHV infection, this results in the unusual situation whereby KSHV sets up a cross-species autocrine loop in which host cells become dependent on a parasite-derived cytokine. EBV does not encode an IL-6–like cytokine, but EBV LMP-1 induces huIL-6 secretion (90), and EBV-infected lymphoblastoid cell lines are autocrine dependent on huIL-6 (309). KSHV-infection and vIL-6 elaboration were proposed to play a role in multiple myeloma (23,264), but subsequent studies have failed to confirm this association (231).

Immune Regulatory Proteins: vIRF-1 and vIRF-2

KSHV vIRF-1 and vIRF-2 have low but significant homology to the interferon regulatory factor (IRF) family of transcriptional factors possessing a conserved amino-terminal DNA-binding domain (DBD) and a carboxyl-terminal transcriptional activation or repression region. The amino-terminals region of vIRF-1 corresponding to the DBD is poorly conserved and does not appear to bind specific DNA sequences (209). Two other genes and potential pseudogenes with even lower IRF homology are clustered with *ORF K9* in the midregion of the genome between base pairs 83,000 and 94,000.

The putative function of vIRF-1 is to inhibit interferon signaling in infected cells by blocking both class I and II interferon–regulated transcription (102,114,175,332). The mechanism by which this occurs is still under active investigation, but vIRF-1 does not compete directly with cellular IRFs for binding to interferon-stimulated response element (ISRE) sequences in interferon-responsive promoters. Interferon, which has an antitumor as well as an antiinfective role, induces cell cycle arrest, and up-regulates the cyclin-dependent kinase inhibitor, p21. vIRF-1 can reverse both of these interferon-induced effects, and expression of vIRF-1 in NIH3T3 cells results in a transformed phenotype (114,175).

One clue for the action of vIRF-1 comes from the adenovirus E1A protein, which inhibits interferon signaling by binding the CH3 domain of the transcriptional histone acetyltransferase coadaptors p300 and CBP (CREB-binding protein) involved in interferon-related transcription (25,325). vIRF-1 also binds p300 and CBP in the CH3 region (40). This provides a straightforward explanation of how vIRF-1 inhibits interferon-induced transcription. Transcriptional coadaptors, such as p300 and CBP, are recruited to promoters by transcription factors to acetylate core histones at the transcription start site. Histone acetylation relaxes condensed chromatin at the promoter, allowing RNA polymerase access to the start site and facilitating gene transcription. Therefore, the ability of vIRF-1 to interrupt this process could inhibit transcription of genes activated by interferon-pathway transcription factors.

The clinical significance of these effects is unclear because vIRF-1 is not expressed in KS or PEL tumors (236). These findings are nonetheless important in revealing the interactions between immune and cell proliferation signaling pathways.

A second IRF-like protein, designated vIRF-2 putatively encoded by *ORF K11.5,* has been described. vIRF-2, unlike vIRF-1, appears to be constitutively expressed at low levels in PEL cells and binds NF-kB enhancer DNA elements but not ISRE (41). vIRF-2 inhibits NF-kB–mediated transcription as well as activation of the interferon-a promoter by IRF1 and IRF3, which cooperatively activate this promoter together with NF-kB. Both vIRF-1 and vIRF-2, therefore, have potential to abrogate antiviral responses initiated by innate immune signaling pathways. If this strategy fails, evidence suggests that inflammatory cytokines, such as interferon-g, activate lytic virus replication, perhaps allowing the virus to escape to another uninfected cell or to a new host (208). A third protein with homology to cellular IRFs has recently been described. It is transcribed from the *ORF K10.5* gene as a spliced product and has low but detectable homology to human IRF4, primarily in a putative activation domain region (265a). This protein (LANA2) has generated interest because it is expressed constitutively in hematopoietic tissues and inhibits p53-induced apoptosis, thus serving as a primary candidate for contributing to B-cell transformation.

Antiapoptotic Proteins: vBCL-2 and vFLIP

Two KSHV genes, *ORF16* and *K13,* encode the vBCL-2 and vFLIP proteins, respectively, which have roles in preventing cellular apoptosis. BCL-2–like proteins are also encoded by EBV and H. saimiri, and primarily expressed during lytic replication, whereas EBV induces cellular BCL-2 during latent infection (137). KSHV vBCL-2 effectively inhibits apoptosis initiated either by Sinbis virus infection or by overexpression of the pro-apoptotic Bax protein (55,273), but study results are conflicting regarding whether it achieves this effect by heterodimerization with a cellular BCL-2 family partner protein. BCL-2 is minimally expressed in KS lesions and is markedly induced by TPA treatment of PEL cell lines.

vFLIP (FLICE-inhibitory protein) is encoded by *ORF K13* on latency-expressed polycistronic transcripts together with vCYC and LANA. Translation of vFLIP occurs through an internal ribosome entry site (IRES) present in the ORF72 gene, thus allowing protein to be made from polycistron C transcripts (25a,131a,182a). Other gammaherpesviruses, including *H. saimiri,* equine herpesvirus 2, and some poxviruses, encode similar proteins (24,307). Unlike KSHV vFLIP, the *H. saimiri* vFLIP is expressed as an immediate early gene during lytic replication (307). Cellular and viral FLIPs possess a single death-effector domain required for caspase-8 interaction but cannot interact with downstream signaling components and therefore act as dominant-negative inhibitors of caspase-mediated apoptotic signaling pathways (reviewed in 59). KSHV vFLIP inhibits Fas-mediated apoptosis (79), indicating that it may play an important role in preventing NK cells from killing KSHV-infected cells.

Cell Cycle–Regulatory Protein: vCYC

vCYC (*ORF72*) has well-conserved homology with cellular D-type cyclins, particularly in the region of the “cyclin box”

responsible for interactions with cyclin-dependent kinases (CDKs) (49,53). vCYC is constitutively coexpressed together with vFLIP on the LT2 transcript and with both LANA and vFLIP on the LT1 transcript. vCYC mRNA transcription is cell cycle dependent, with highest expression during early G_1 phase (275), but the protein lacks PEST sequences regulating cyclin protein turnover, resulting in a long protein half-life (P. Browning, unpublished observation).

Cellular D-type cyclins interact with CDK4 and CDK6 to direct phosphorylation of the tumor suppressor retinoblastoma (RB1) checkpoint protein involved in the G_1- to S-phase transition (44,185,301). RB1 is directly targeted by viral proteins from several small DNA tumor viruses and is probably indirectly inactivated by others (210). RB1 sequesters E2F transcriptional factors required for entry into S phase of the cell cycle and inhibits E2F-dependent promoters by recruiting histone deacetylases. D-type cyclins reverse this by phosphorylating RB1 and inhibiting its function, allowing transit across the G_1- to S-phase checkpoint. Overexpression of cyclin D1 (PRAD1, BCL-1) by chromosomal translocation overrides this tumor suppressor checkpoint and contributes to some B-cell and parathyroid tumors (215). Other cyclin–CDK complexes (e.g., cyclin B/CDK2) are involved in cell cycle regulation at other checkpoints.

Although KSHV vCYC complexes with CDK6 to phosphorylate RB1, leading to its inactivation and unscheduled S-phase cell cycle entry (53,125,176), the vCYC–CDK6 complex shows several important differences from the cellular CYC D–CDK6 holoenzyme. The vCYC–CDK6 complex is resistant to the cellular CDK inhibitors p16, p21, and p27 (302) and has a more promiscuous substrate specificity because it can direct phosphorylation of histone H1, which is not a substrate for cellular D cyclins (125,176). The vCYC–CDK6 complex also phosphorylates the CDK inhibitor (CDKI) p27 to induces its degradation (91,190) and induces the cyclin A promoter through E2F activation, but does not phosphorylate the RB-related protein, p107 (89). Thus, the KSHV-encoded cyclin can escape from CDKI regulation and may have substrate specificity that allows it to abrogate other cyclin- and CDK-regulated checkpoints beyond those targeted by cellular D-type cyclins. Overexpression of vCYC is toxic to cells and has not been directly assessed as a transforming viral protein.

Immunoreceptor Proteins: KSHV ITAM-Based Signal Transducer (KIST) and Latency-Associated Membrane Protein (LAMP)

KSHV encodes two membrane proteins, KIST and LAMP, which affect B-cell receptor (BCR) signaling (68). The K1 protein acts as a constitutively activated BCR, whereas LAMP inhibits some BCR signaling pathways. KIST is the first recognizable ORF in the KSHV genome and encodes a small transmembrane glycoprotein possessing a cytoplasmic immunoreceptor tyrosine activation motif (ITAM). The KIST ITAM is tyrosine-phosphorylated *in situ,* allowing recruitment of SH2 domain proteins, Syk pathway activation, and intracellular calcium mobilization (167,171). KIST overexpression causes transformation of Rat-1 fibroblasts and, when substituted for the *STP* oncogene in recombinant HVS virus, it can immortalize primary T lymphocytes and induce lymphomas in marmoset monkeys (172). KIST spontaneously forms multimeric complexes through cross-linking of the cysteine-rich external region. Aggregation of KIST, like BCR cross-linking, may be necessary for initiating its immunoreceptor signaling activity. Although the ectodomain of this transmembrane protein is highly variable between KSHV isolates, there is no current evidence that different KIST strain types have altered signaling activity or ability to induce proliferation.

ORF K15 encoding the latency-associated membrane protein (LAMP) is the last recognizable ORF on the opposite end of the genome from *ORF K1* (124,246). It lies in the highly divergent P and M variant regions, but *K15* genes from both P and M virus subtypes have a similar organization of eight exons, which generate a family of alternatively spliced transcripts. Surprisingly, the largest versions of the P and M subtype proteins are predicted to have only 29% amino acid identity to each other. LAMP proteins may consist of up to 12 transmembrane domains, depending on varying donor-acceptor splice site usage. Although numerous combinations of exons have been detected, all LAMP proteins have a hydrophilic C-terminal cytoplasmic tail encoded by exon 8, possessing protein motifs similar to those found in EBV LMP2A and LMP1 proteins. This region contains both a group III tyrosine motif and an src phosphotyrosine kinase SH2-binding motif present in the cytoplasmic domain of EBV LMP2A. It also possesses a PFQPADE motif similar to the TRAF-binding motif of LMP1, and protein–protein interaction assays demonstrate that it, like the corresponding region of LMP1, binds TRAF1, TRAF2, and TRAF3 (124). Further, epitope-tagged LAMP proteins also show membrane patching. In contrast to KIST, LAMP overexpression blocks calcium influx in response to BCR activation from cross-linking antibodies. This response is similar to EBV LMP2A (57). Taken together, the KIST and LAMP proteins appear to have many of the properties of EBV LMP1 and LMP2A. Future studies are needed to determine whether KIST and LAMP antagonize each other or whether they differentially affect different arms of BCR signaling pathways.

DNA Synthesis Enzymes

DNA synthetic enzyme genes, such as those found in the KSHV genome, are a central feature of herpesviruses (see Chapter 71). Rhadinoviruses have the most extensive sets of these genes among the herpesviruses (2,220,269). The corresponding cellular genes are under E2F transcriptional regulation controlled by the RB1 tumor suppressor protein (reviewed in 169,222, and 321). This leads to the possibility that the KSHV enzymes not only supplement enzymatic activities that may be rate limiting within the cell but also may overcome cellular mechanisms to regulate DNA synthesis. The KSHV DNA synthesis enzyme genes are generally expressed during initiation of lytic replication (271).

Most currently available antiherpesvirus drugs act by inhibiting the viral DNA polymerases, encoded by *ORF9* in KSHV. This may require phosphorylation of a prodrug by a viral thymidine kinase or phosphotransferase to generate the active drug. *In vitro* studies suggest that KSHV replication is most sensitive to cidofovir and foscarnet (phosphonoformic acid), with intermediate sensitivity being present for ganciclovir and relative resistance for acyclovir (45,156,199,223). Drugs such as penciclovir and BVDU show limited activity *in vitro.* Using recombinant viral proteins expressed in cell lines, Cannon and colleagues demonstrated that the KSHV phosphotransferase (*ORF36*) has higher activity than the viral thymidine kinase (*ORF21*) in phosphorylating ganciclovir, which converts it to an active form while the opposite is true for penciclovir (45).

Patient studies are largely consistent with these results in that patients at risk for AIDS-KS develop the disease at lower

rates after treatment with foscarnet for CMV retinitis (205,266). One study of high-dose oral ganciclovir for prevention of CMV retinitis demonstrated a 75% reduction in the rate of new KS lesions among high-risk AIDS patients (192). Little is known, however, about the activity of antiherpesvirus drugs on established KS lesions.

Several other KSHV enzymes are particularly worth noting because they may be unique targets for existing chemotherapeutic drugs (see Chapter 15). KSHV is the only human virus to encode a dihydrofolate reductase (*ORF2*), a potential therapeutic target for methotrexate and sulfonamide derivatives (58). The viral thymidylate synthase (*ORF70*) is another potential target for specific inhibitors.

Other KSHV Genes

The complement-binding protein or complement control protein homolog (vCBP or CCPH, *ORF4*) and the viral adhesion protein (vADH or vOX2, *ORF K14*) genes have not been experimentally examined. The protein encoded by *ORF4* is similar to the CR2 complement receptor (CD21). Other viruses, including poxviruses and HVS, possess similar proteins that inhibit C3 convertase activity and prevent activated complement deposition (103,194). vADH is predicted to be a transmembrane protein belonging to the immunoglobulin superfamily expressed together with vGCR on a bicistronic transcript (162,271,304). It possesses sequence similarity to adhesion molecules, such as N-CAM, and is highly homologous to the rat cell surface antigen OX-2 that inhibits T_H21 immune responses (128). HHV-6 and HHV-7 possess similar proteins that are not recognizably similar to vADH but are homologous to OX-2 and may have been independently acquired (127,224).

Some KSHV genes, such as *ORF K3* and *K5,* have counterparts only to uncharacterized human expression sequenced–tagged (EST) transcripts. An important clue to the functions of the K3 and K5 proteins was discovered by Coscoy and Ganem (65). Because other herpesviruses have specific mechanisms to inhibit class I major histocompatibility complex (MHC) peptide antigen presentation, these investigators surveyed the *K* genes in retrovirus vectors to find KSHV proteins that down-regulate class I MHC cell surface expression. They found that both K3 and K5 proteins sequester class I MHC to the endoplasmic reticulum from the plasma membrane through a unique mechanism. This has been confirmed by other groups (146,293) and may contribute to the reduced cytotoxic T-lymphocyte killing of PEL cell lines (36). K5 protein also downregulates the B7.1 and ICAM-1 immune accessory proteins. This may inhibit NK cell responses to cells lacking surface MHCI (145a.)

One gene that is not homologous to known cellular genes but deserves mention is the *ORF73* gene encoding LANA (158,160,255). *ORF73* is 4.5 kb and encodes a protein with a long internal acidic repeat region ending in a leucine zipper motif, flanked by basic regions at both the amino and carboxyl ends. The corresponding EBV EBNA1 repeat region inhibits peptide processing required for cytotoxic lymphocyte responses against EBNA1 antigen (174). In addition to its role in maintaining the viral episome (15), LANA may have a broader role in cell regulation during latency. LANA effectively inhibits p53-dependent transcription and apoptosis; thus, it is likely to be a major contributing factor to KSHV-induced cell transformation (107). LANA-1 also binds and inhibits RB1 (254a). In this regard, LANA has functional similarities to viral oncoproteins from other tumor viruses, such as SV40 T antigen. LANA directly binds histone H1 as well as the ubiquitin conjugating enzyme UBC9 and SUMO-1 (274).

Model for Viral Oncogenesis

Tumorigenesis alone is an unlikely reason for tumor viruses to encode oncogenes. Although tumors increase total infected cell burden, thereby increasing virus numbers, the virus is generally in a nontransmissible latent or defective state. This is particularly disadvantageous to the virus because tumors shorten the host's lifespan without increasing the opportunity of transmission to a new host. Tumor formation frequently occurs when a tumor virus infects a dead-end, nonnative or immunocompromised host and, therefore, is not likely to be an essential stage in the viral life cycle (210,221). This leads to the conclusion that virus-induced cancers, like nonviral cancers, are biologic accidents. What, then, are the benefits that some viruses derive from having conserved oncogenes?

The answer to this question may come from examining cellular targets of viral oncogenes. Most tumor viruses cause cell transformation by directly or indirectly inhibiting at least two major tumor suppressor proteins, RB1 and p53, which balance each other to prevent tumor cell formation (Fig. 6) These two pathways are functionally linked through feedback loops involving p14ARF (p19ARF in the mouse) and CDKIs. Inhibition of RB1 induces p14ARF, which in turn inhibits MDM2-mediated degradation of p53, resulting in increased p53 activity in cells in which RB1 has been inappropriately deleted or shut off (18,207,235,254,283). Activation of p53 leads to apoptosis through activation of pro-apoptotic signaling molecules, such as Bax. If this feedback loop is interrupted by a viral inhibitor, p53 drives the infected cell into apoptosis (27). However, in cells with intact RB1, p53 can also induce cell cycle arrest at the G_1- to S-phase and G_2- to M-phase checkpoints by inducing p21 and other CDKIs (38,56). Viral inhibition of RB1 therefore requires simultaneous inhibition of p53 for the virus-infected cell to survive.

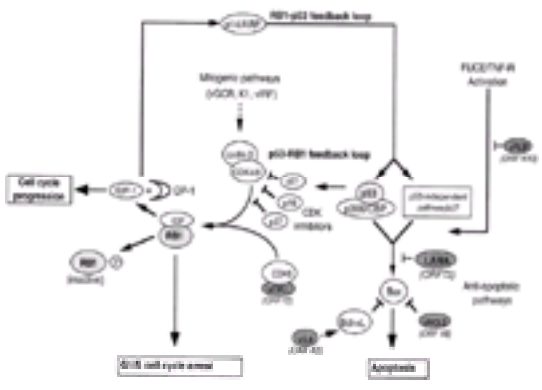

FIG. 6. Interrelationship between the RB1 and p53 tumor suppressor pathways commonly inhibited by tumor viruses.

Inhibition of the G1/S checkpoint protein RB1 leads to activation of p53, which controls apoptotic signaling, through a feedback loop mediated by p14ARF. p53 activation can in turn either arrest the cell by activating the cyclin dependent kinase inhibitor p21 or initiate apoptosis (cellular suicide). Sites of potential interaction with KSHV proteins demonstrated by experimental studies are indicated (potential but not proven interactions shown with dashed lines).

At least in broad outlines, KSHV possesses the machinery expected for a tumor virus (see Fig. 6 and Table 3). Despite the number and variety of viral genes capable of contributing to KSHV tumorigenesis, they are functionally similar to oncogenes found in well-established model tumor viruses. vCYC and LANA-1, for example, inactivate RB1 and possibly other cell cycle checkpoints. From a functional standpoint, this is similar to E1A and E7 oncoproteins. Other known *in vitro* transforming KSHV proteins (vGCR, K1, vIRF-1) may also provide mitogenic signals that complement or substitute for vCYC activity, depending on the tissue infected. vCYC activity could be expected to cause apoptosis, and this has been found to be the case when vCYC is expressed together with its kinase partner, CDK6 (228). Apoptosis through this vCYC mechanism is inhibited by vBCL-2 but not cellular CL-2. Because apoptosis also occurs in SAOS-2 cells, an osteosarcoma cell line homozygously deleted for both RB1 and p53, p53-independent apoptotic signaling pathways may be activated by vCYC as well.

The p53-inhibitory properties of LANA-1 make this protein the leading candidate to inhibit RB1-induced apoptosis (107), analogous to E1B and E6. Other KSHV proteins, including vBCL-2, vIRF-1, and vIL-6, also prevent apoptosis under specific circumstances, but LANA is ubiquitously expressed and regulated together with vCYC in all KSHV infected cells. KSHV gene analysis has proved valuable in uncovering new pathways that may be critical in cell transformation. Discovery of vFLIP led directly to identification of cellular FLIPs regulating Fas pathway apoptosis that may play a role in regulating tumor cell formation (143). Further, vIL-6 and vGCR experiments revealed that autocrine and paracrine cytokine processes play important roles in mitogenesis and inhibition of apoptosis.

What are the likely reasons that tumor viruses target these tumor suppressor checkpoints? There are at least two hypotheses, both of which have experimental support. One widely accepted explanation is that viral oncoproteins promote a proliferating state in the cell, allowing viral nucleic acids to be synthesized for virion replication (148). Under conditions in which nucleic acid synthesis is a limiting factor, RB1 inhibition drives infected cells into S phase, thereby priming cellular resources for virus replication. Viral proteins that inhibit apoptosis delay cell death so that optimal maturation and release of infectious virions can be achieved. Expression of viral oncoproteins would then result in two important preconditions of cancer cell transformation: dysregulated cell proliferation and blockade of cell death through apoptosis.

The alternative hypothesis, which does not exclude the possibility that viral oncoproteins also optimize virion production, is based on the idea that cells use tumor suppressor pathways to prevent and eliminate viral infections (210). Activation of innate immunity induces an antiviral state in the infected cell in part by activating key tumor suppressor checkpoints (Fig. 7). The p21 promoter, for example, is induced by interferon signaling as well as by p53 activation. By arresting cells from entering S phase through RB1 activation and *cMYC* repression, interferon signaling could thus effectively limit viral nucleic acid replication. Interferon signaling also sensitizes cells to p53-mediated apoptosis (305), which might kill virus infected cells. Other innate immune signaling pathways, such as the Fas-Fas ligand signaling pathway used by natural killer cells to kill virus-infected cells, initiates apoptosis using pathways shared with tumor suppressor control proteins. Thus, inhibition of innate immune pathways by a virus might inadvertantly initiate cell transformation (210). This is particularly appealing for KSHV because many of the proteins that have proliferative or antiapoptotic activities directly affect these immune pathways. Support for this idea also comes from the fact that proteins such as vCYC and LANA are expressed during virus latency and hence do not appear to be directly required for lytic virion production.

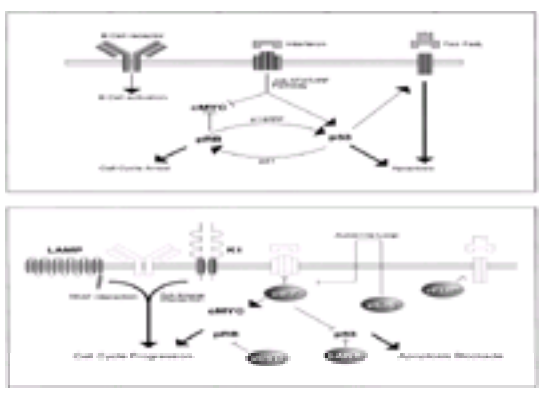

FIG. 7. Interactions of KSHV proteins, that may contribute to cell transformation and carcinogenesis, with innate immune signaling pathways. Innate immune signaling pathways act on tumor suppressor pathways to induce cell cycle arrest and apoptosis as a nonspecific response to viral infection. KSHV proteins involved in cell proliferation may therefore primarily serve to blunt these responses by blocking upstream innate immune signaling pathways, such as Fas and interferon pathways, or downstream effectors including RB1, p53, cMYC and Bax. B cell receptor (BCR) signaling can lead to either pro- or antiapoptotic responses. K1 mimics constitutive immunoreceptor signaling through Syk kinase interactions, whereas LAMP actually blocks some BCR signaling pathways through TRAF interactions possibly inhibiting pro-apoptotic BCR signaling.

Caution is required in applying this paradigm to human disease, particularly in the case of KSHV because of the atypical nature of the KSHV-related tumors. Detailed studies have not yet been performed to determine the effects of

combinations of KSHV genes expressed at levels that can be expected during natural infection. Many of KSHV genes involved in proliferative and antiapoptotic pathways are not expressed in KSHV-related tumors and do not directly contribute to disease pathogenesis. We now know that we have all the working parts for an automobile, but how they go together determines whether it will be a sports car or a city bus. Although PEL is an unambiguous lymphoma in which KSHV is likely to be contributing to the transformed tumor cell phenotype, the mechanisms for cell proliferation in KS lesion is more murky. Further, MCD is a hyperplasia rather than a neoplasia, and yet many of the suspected KSHV oncogenes are only naturally expressed in this disorder. Despite these reservations, the rapid advances that have been made already in KSHV research indicate that this virus promises to make a unique contribution to our understanding of tumor viruses and viral oncogenes.

---

*A musical analogy to this is found in the composer Tom Johnson's piece, “Rational Melodies,” in which a 6-note melody is repeated in a 37-note rhythmic pattern. Each iteration of the pattern displaces the melody by one beat but the phasing of the melody returns after six iterations and the same piece is eventually played regardless of which note the piece is started on. According to the music commentator John Schaefer, similar rhythmic devices are common in medieval musical pieces.

CHAPTER 83 Cercopithecine Herpesvirus (B Virus)

Richard J. Whitley and Julia K. Hilliard

B virus, endemic in macaque monkeys, has the unique distinction of being the only one of nearly 35 identified nonhuman primate herpesviruses that is highly pathogenic for humans. B virus has been positively linked with more than two dozen human deaths since its discovery. Five of those deaths occurred in the last 12 years, resulting from exposure to macaques with active viral infection. The unique biology of B virus includes its neurotrophism and neurovirulence. Untreated human B virus infections are associated with an extremely high mortality rate and, consequently, present unique and potentially lethal challenges for individuals handling macaques or macaque cells and tissues. Infection in humans is associated with breach of primary skin or mucosal defenses and subsequent contamination of the site with virus. Fomites and contaminated particulates or surfaces can serve as a source of virus infection as well. In one case, human-to-human transmission was noted and attributed to a shared tube of medication that resulted in virus infection at the broken skin site when a contaminated antiviral cream was applied to treat the patient's bite wound. Later, the same patient autoinoculated an eye. Of 25 human cases occurring during the 1980s and 1990s, out of a total 46 documented cases since 1933, 80% of individuals have survived infection because of the advent of antiviral therapies. In contrast, there is an 80% rate mortality in untreated patients. Timely antiviral intervention is an effective means of reducing B virus–associated morbidity and preventing a fatal outcome.

HISTORY

In 1932, a young physician (WB) was bitten by a monkey and later developed localized erythema at the site of the animal bite. This apparent localized infection was followed by lymphangitis, lymphadenitis, and, ultimately, a transverse myelitis. The demise of WB was ascribed to respiratory failure. At the time of WB's death, tissue specimens were obtained for laboratory investigation. Gay and Holden reported that an ultrafilterable agent recovered from neurologic tissues of WB was similar to herpes simplex virus (HSV) (48). The isolate was initially designated as “W” virus. Gay and Holden noted that it caused similar disease in rabbits infected by either intradermal or intracranial routes of infection. A rhesus macaque exposed to this virus showed no evidence of illness. These studies were expanded with the observation that B virus, deadly in this patient, caused disease strikingly different from HSV.

Within a year of this first report, Albert Sabin independently found an ultrafilterable agent that he identified as “ B” virus from tissues of this same index patient (101), naming the virus by the initial of the patient's last name. Thus, the virus subsequently has been called *herpes B virus, herpesvirus simiae, Cercopithecine herpesvirus 1,* or more simply, *B virus.* The lethality of B virus infection in rabbits was described by Sabin, who showed that infectivity was independent of route of inoculation. Experimentally infected dogs, mice, and guinea pigs showed no susceptibility, regardless of the route of inoculation (101). Both groups observed that B virus induced immunologic responses in an infected host similar to HSV-1 (97). The virus was also noted to share similarity with pseudorabies as well as with other viruses, including SA8 and two additional herpes nonhuman primate alphaherpesviruses recently described, HPV-2 and Langur herpesvirus (20,21,39,97,98 and 99).

By 1959, B virus had been identified as having caused 12 fatalities and 5 recognized survivors (18,68,91), suggesting for the first time that this infection may not always end in fatality for humans. Additionally, investigators reported antibody titers in a number of individuals with no clinical symptoms but a history of working with macaques (113). However, because serologic assays could not unequivocally distinguish HSV antibodies from those to B virus, the existence of seropositive humans without disease was difficult to substantiate. Once differentiation of humoral immune responses induced by these closely related viruses was possible, Freifeld and colleagues reported that, in a high-risk group of 325 subjects, antibodies were rarely, if ever, present in the absence of clinical symptoms (46). Since this report, a different cohort of individuals with no HSV antibodies has been found to have high B virus titers by enzyme-linked immunosorbent assay (ELISA) and Western blot (J.K. Hilliard, unpublished results). Thus, it remains controversial as to whether B virus infection in humans can occur in the absence of clinical symptoms.

During the decades since the initial reports of B virus infection, investigators have learned a great deal about the molecular biology of this virus and the illness it causes in humans and nonhuman primates, including its natural host, the

macaque monkey. Because of the neurovirulence this virus demonstrates in a foreign host, it is considered by some to be one of the most dangerous occupational hazards for those who work directly with macaques or their tissues or with monkeys who have been in contact with macaques.

DISTRIBUTION IN NATURE

B virus is endemic in macaques, one of the Old World monkeys widely distributed throughout Asia. All species of macaques tested thus far are able to serve as natural hosts. The virus can infect other nonhuman primate species; but in such cases, the infected animal is considered a foreign host, and the infection generally results in death within a relatively short time after onset. Transmission of virus can occur by direct contact between members of the *Macaca* genus, from infected animal to human, from virus-contaminated surfaces, or, in one case, from human to human, as extensively reviewed (27,35,41,42,43 and 44,64,69,70,73,74,90,117,122).

Prevalence estimations of B virus infection, using different serologic methodologies and sampling approaches in both wild and captive macaque colonies, have been noted to be variable (118). Spread of infection correlates with onset of sexual activity, which facilitates transmission of the virus among animals (106,120). Crowding of animals during transportation seems to accelerate the spread of infection as well (106).

B virus infection in the macaque species is mild and seldom associated with death of the animal, unless conditions prevail that facilitate generalized systemic infections (29). The frequency of active infections has been reported to be slightly more than 2%. These observations suggest that virus is only transiently present. This thought has prevailed because monkeys frequently had lesions only during a primary infection. Later, antibody-positive animals were found to shed virus periodically from mucosal membranes, including the eyes (65,106,118,120). Thus, isolation of virus from asymptomatic animals has been established (15,45,77,82,114,115 and 116).

THE VIRUS

Isolation and Growth Properties of B Virus

Because B virus causes fatal human disease in 80% of untreated cases, the Centers for Disease Control and Prevention (CDC) has published agent summary statements for laboratory studies using B virus. Growth of the virus is recommended in a BL-3 laboratory, whereas propagation should be strictly confined to a BL-4 facility (112). Initial isolation of B virus was achieved using rabbits for passage of the virus (47,48,101). Within a decade of discovery, the virus was grown on chorioallantoic membranes of embryonated eggs (20).

In 1954, B virus was reported to be present in rhesus kidney tissue that was used for preparation of poliomyelitis vaccines (124) and from rhesus central nervous system tissue (84). Subsequently, cultured cells, derived from monkey kidney and chick embryo, were found to support the replication of B virus (78,94). Infection of cells resulted in the development of large syncytial similar to those seen in Figure 1. The virus is relatively stable in cell culture media stored at 4°C and can be maintained for long-term storage at –80°C but not at –20°C. The virus has growth properties similar to HSV *in vivo* (20,97,98,99 and 100,102). Vero cells appear to be the best system for replication of virus.

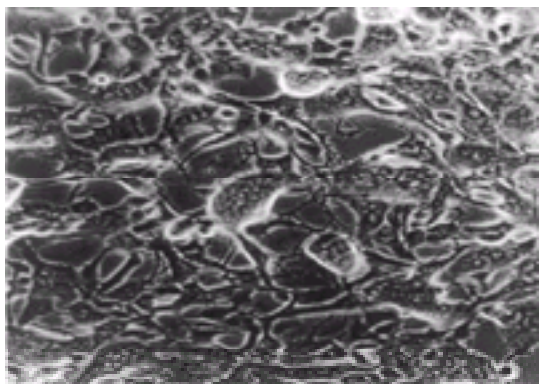

FIG. 1. Vero cell monolayer infected with B virus.

Replication kinetics of B virus follows a time course similar to HSV-1 and HSV-2 in cell cultures. Virus adsorbs to the surface of a susceptible cell within 30 to 60 minutes after infection. Host cell machinery is halted once the virus enters the cell. An eclipse of cell and viral activities is noted during the first 2 to 3 hours after infection, followed by synthesis of polypeptides early during infection. By 4 hours after infection, DNA synthesis increases dramatically and in parallel with the synthesis of viral polypeptides. Morphogenesis of the virus is also similar to HSV, as shown by electron microscopic studies (96). Infectious virus is detectable within 6 to 10 hours after infection, and both extracellular and intracellular virus levels plateau about 24 to 28 hours after infection, declining thereafter (56,94). B virus, like HSV, has been observed to express sequential classes of proteins, that is, immediate-early, early, and late proteins (56), and to possess glycoproteins and other structural proteins that were studied in detail with respect to their antigenic relatedness to HSV-1 and HSV-2 and later to other nonhuman primate alphaherpesviruses (36,55,81,88). B virus replicates to high titer in cell lines of Old World monkey origins, particularly in Vero, African green monkey, and vervet kidney cells, as well as rabbit kidney, BSC-1, and LLC-RK cells (62,65). Although B virus replication in cultured cells usually results in syncytial formation, as illustrated in Figure 1, some primary isolates produce cell rounding. Generally, cells balloon, fusing into polykaryocytes that expand outwardly as more cells become infected. In this manner, virus infection spreads through the entire cell monolayer, destroying cells. Eosinophilic intranuclear inclusions (Cowdry type A) can be visualized after fixation and staining infected cell monolayers; however, these inclusions are observed consistently neither in infected

animals nor in some humans with zoonotic infection (34,61). Thus, the presence of characteristic intranuclear inclusion bodies is not a reliable diagnostic marker of infection.

The B Virus Genome

B virus contains a double-stranded DNA genome of about 162 kb. One strain of virus originating from a cynomolgus monkey has been mapped and subcloned by Harrington and associates (52). The genome contains two unique regions (UL and US) flanked by a pair of inverted repeats, two of which are at the termini and two internally located, an arrangement that results in four sequence-orientated isomeric forms, as occurs with HSV. Figure 2 shows the comparative genome organization of B virus and HSV-1, as established by using HSV-1 genes to identify and locate specific B virus homologs (52). The overall size of the genome is slightly larger than HSV-1 (152 kb) and HSV-2 (155 kb). The guanosine and cytosine (G+C) content of the DNA has been calculated to be 75% based on the buoyant density of viral DNA. Eberle and Hilliard have published data that define the presence in B virus homology to HSV-1 and HSV-2, specifically for the genes of the glycoproteins gB, gC, gD, gE, and gG (38). Further examination of the sequences of the nine major glycoproteins showed that the 75% of the G+C content is conserved within most glycoproteins. Harrington and associates (52) have also shown that the location of genes within the UL regions of HSV and B virus was colinear. One gene rearrangement was described in an isolate that originated in a cynomolgus macaque. Homologs of HSV *US9* and *US10* genes are located upstream of the US glycoprotein gene cluster. This is in contrast to the downstream location of these genes in the HSV US region. This rearrangement was based on hybridization data and the proposed physical map of Harrington and associates (52). Sequence analysis (unpublished) of the prototype strain (E2490), which originated from a rhesus macaque, however, showed that B virus DNA is colinear in these same regions with the HSV-1 genomic arrangement (L.M. Perelygina and colleagues, 2000, unpublished data).

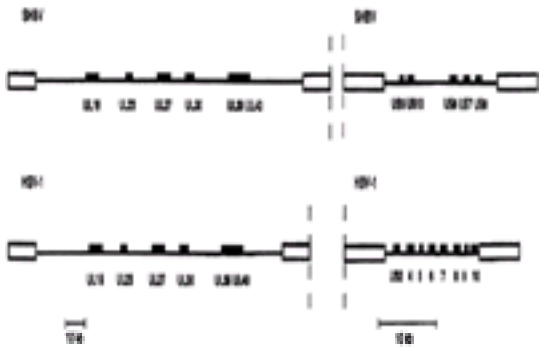

FIG. 2. Physical map of B virus as proposed by Harrington and colleagues (52).

To date, sequences for only a few B virus genes have been submitted to GeneBank, that is, homologs of gB, gD, gC, gG, gJ, and gI, largely covering the sequence of the US region (9,76,108). Because a number of laboratories are engaged in the sequencing of this virus, the entire genome should be sequenced within a short time. Each of the glycoproteins for which sequence information is available, except gG, has about 50% identity with HSV, slightly higher for HSV-2 than HSV-1. B virus gG is a homolog of HSV-2 gG and is closer in size to gG-2 (699 kb) than gG-1 (238 kb) (108). Glycoprotein sequences demonstrated that all cysteines are conserved, as are most glycosylation sites. This conservation suggests that B virus glycoproteins have similar secondary structure to that of HSV. Sequence analyses also suggest that B virus and HSV types 1 and 2 probably diverged from a common ancestor during the evolution of these pathogens.

Using restriction-length polymorphisms (RLPs) as a guide, several investigators have shown intrastrain variation among both human and nonhuman primate–derived isolates, the significance of which remains to be defined (57,59,109). Eberle and colleagues (40) postulated the possible existence of B virus isolates, which vary with respect to pathogenicity for nonmacaque species, based on the existence of three distinct B virus genotypes. These genotypes were found when collected data were analyzed phylogenetically; however, this postulate must be studied in a suitable animal model. In zoonotic infections, unfortunately, usually little is actually known about the species of the source animals. Where data are available, many rhesus macaques have been identified (90), targeting this species as the source of a unique, highly pathogenic strain that can cause zoonoses. Published case summaries that implicate other macaque species, and in one case a baboon, are difficult, if not impossible, to confirm (90).

Synthesis of Viral Proteins

About 23 major polypeptides have been identified by electrophoresis in denaturing polyacrylamide gels (Fig. 3), but more than 50 different polypeptides have been identified by immunoblot analysis. Each has been assigned an infected cell polypeptide number as an initial reference point (56). This number may be an underestimate of the total synthesized, but it serves as a basis for comparison in ongoing studies. The size of these infected-cell polypeptides ranges from about 10,000 to 250,000 daltons. More than 75% of the expected coding capacity of the viral DNA is accounted for by these infected cell polypeptides. At least nine bands from electrophoresed infected cell polypeptides containing viral glycoproteins have been thus far identified (Fig. 4). Many of these glycoproteins have been cloned and sequenced recently by two laboratory groups (9,10,40). The proteins encoded were mapped to genes by the US region, which was largely colinear to the HSV glycoproteins gD, gI, gJ, and gG, as previously described. Sequence analysis of selected genes showed that B virus is most closely related to herpesvirus papio 2 (HVP-2) (37). Although there are protein homologs in herpesviruses of New World monkeys, very little, if any, cross-reactivity exists between B virus and the New World monkey herpesviruses.

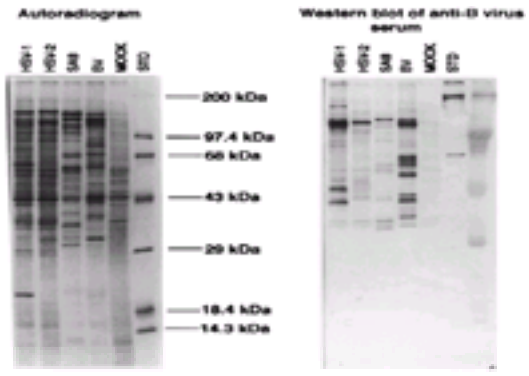

FIG. 3. Infected cell polypeptides of B virus–infected Vero cells electrophoresistically resolved on SDS-polyacrylamide gel electrophoresis and transferred nitrocellulose. **Left:** Result of autoradiography following electrophoresis of metabolically ^{35}S-methionine–labeled B virus–infected Vero cells 4 to 24 hours after infection. **Right:** Result of immunoblot of the exposed membrane using a rhesus sera pool of anti–V virus antibodies.

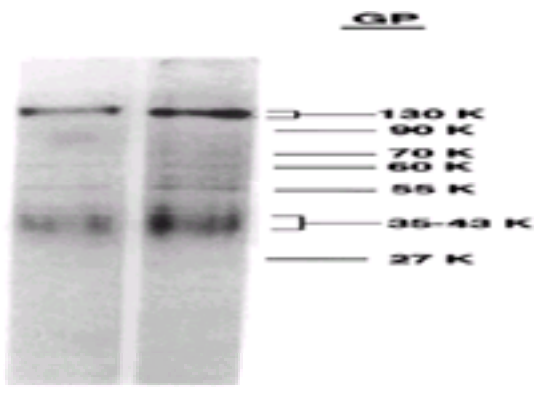

FIG. 4. ^{3}H-glucosamine, metabolically labeled B virus–infected cell glycoproteins. 20 µCi/mL of radiolabeled sugar was added to cells 4 hours after infection. Twenty-four hours after infection, monolayers were harvested and analyzed on SDS-polyacrylamide gel electrophoresis. Gels were subsequently exposed to Kodak RP X-Omat film for 24 to 72 hours for autoradiography.

The kinetics of protein and glycoprotein synthesis in infected cell culture are similar to that observed for HSV, although infectious virus was detectable slightly earlier—appearing 6 hours after infection. Both host cell DNA and protein synthetic activities appeared curtailed during the first 4 hours after infection, as shown in Figure 5. The polypeptides of B virus–infected cells, summarized in Table 1, may represent an overestimate of the primary gene products of the virus; however, this summary should serve as a fairly complete listing of B virus–induced polypeptides for future reference. As for glycoproteins, only glucosamine and some mannose are incorporated during the infection *in vitro.* B virus polypeptides and glycoproteins can be grouped into classes that differ in their relative rates of synthesis at different times throughout the virus replication cycle, as is characteristic of alphaherpesviruses (56).

PATHOLOGY AND PATHOGENESIS

During the course of B virus infection, several observations are common to the natural host, the experimentally infected host, and infected humans. Those common factors are discussed initially, then specific details for each of these groups are provided. First, there are various pathogenetic outcomes in infected hosts. Evidence deduced from the literature suggests that route of infection has an important role in disease pathogenesis. Specific details must be studied further, but, in general, there are several common observations. The route of inoculation predicts differences in the time course of infection, development and spread through the central nervous system and visceral organs (e.g., spleen, adrenal, kidney, and, in some cases, even heart). There are routes of infection that are obviously unique to each of the categories of hosts: natural, experimentally infected, and human zoonotic infections. For example, venereal transmission of the virus is common in macaque hosts, whereas an intranasal route of virus delivery defines an experimental rabbit model or, in the case of human zoonotic exposure, accidental aerosolization of virus. However, these routes share one common feature: all require exposure of mucosal membranes to infectious virus.

The cells that come into contact with the virus initially are also important to the permissiveness of the infection. For example, nasal mucosa has been found to be a less ideal site for virus replication than lung (6,7 and 8,28,69). However, nasal mucosa is not entirely resistant because increasing titers of virus can be isolated from these sites. Another important consideration in B virus infection is the dose or quantity of the virus introduced initially into a host. The role of dose remains a challenging question for exploration. Both dose and route of inoculation are important factors with respect to the onset of pathogenesis. For example, a far greater quantity of virus is required to infect rabbits by aerosolization than by an intradermal route of inoculation, although practically, it remains unconfirmed whether these routes and doses are paralleled in human or nonhuman primates. Also, the dose may be an important factor in determining associated morbidity and mortality. The commonality of successful infection is the requirement of mucous membrane exposure early in infection. Another common feature of natural, experimental, or zoonotic infection is that B virus can be found in the central nervous system shortly after the onset of acute infection. But the distribution of virus and its consequences differs widely in natural infection as compared with infection failure of susceptible foreign hosts.

The Natural Host

The macaque monkey suffers little or no morbidity as a consequence of infection. Exceptions occur rarely and appear to involve specific accompanying factors, such as immunosuppression (29,107,125). Infection is self-limiting (1,11,73,74,120,121). Virus can replicate at the site of inoculation and induce a localized erythema. There is also evidence of a limited focal infection of liver and kidney in some macaques (73,74). Virus travels through the peripheral nerves from the site of inoculation to the representative dorsal route ganglia. Latent infection is established in the ganglia with intermittent reactivation of the virus throughout the life of the macaque (14,15,43,79,102,115,118). In rare cases, viremia has been observed (22,83,107). Virus has also been recovered from urine as well as multiple organs of animals. Reactivation from latency occurs in the natural host as judged by increasing antibody titers, recovery of virus by co-cultivation of sensory ganglia, and isolation of virus in the absence of detectable lesions (29,51,82).

During active B virus replication, isolation of virus can be readily accomplished from buccal, conjunctival, or genital mucosa sites (1,33). The frequency of active infection among seropositive macaques has been observed to be low, with relatively short time periods for successful virus recovery from mucosal sites (118,120).

Mucosal ulcers extend down to the papillary layer of the dermis. Two distinct zones have been described, namely a central area of necrosis and a surrounding zone of ballooning degeneration. Around the lesion, “normal” epithelium exists. An eosinophilic polymorphonuclear infiltration characterizes the histopathology of the lesion. Postmortem histopathologic examination of monkey tissues from animals euthanized at the time of active virus shedding reveals perivascular lymphocytic cuffing in sections of spinal cord. Examinations of latently infected but healthy animals failed to detect virus excretion from peripheral sites routinely, but virus can still be recovered from sensory ganglia (14).

Experimental Infections

Rabbits, mice, rats, guinea pigs, and chickens have been studied as B virus models, as previously mentioned (47,97,102). Disease is not a uniform consequence following B virus inoculation into mice and guinea pigs; however, several strains of B virus that have increased virulence for the mouse have been identified. One strain, identified as E2490, was avirulent for white rats and chickens; nonetheless, antibody developed after infection (64). Cotton rats infected by either intraperitoneal, subcutaneous, or intracerebral routes succumbed to infection with selected strains. Rats had typical hind leg paralysis secondary to transverse myelitis similar to symptoms in the rabbit. Reagan and colleagues selected by serial passage human isolates of B virus strains capable of infecting mice, hamsters, and white

chicks (92,93). With respect to experimental infections, review of the literature suggests that the rabbit is perhaps the most useful small animal model because virus replicates to high titers, making it a particularly good model for testing antiviral agents.

Using the rabbit or the mouse model, investigators have demonstrated that viral dose was important, depending on the route of inoculation, as would be predicted. Experimentally infected animals inoculated with low doses of virus intradermally developed only erythema that disappeared within a few days and was not associated with further apparent symptoms. In contrast, animals receiving a larger dose developed a necrotic lesion that was generally followed by central nervous system invasion (49,50). B virus subsequently appeared in the regional lymph nodes late after infection. These nodes drained the area of initial infection, and with time, necrosis of the infected nodes occurred, as seen upon postmortem examination. In the central nervous system, focal lesions are evident in pons, medulla, and spinal cord virus. Spread is most often facilitated by travel through the peripheral nerves, but, in rare cases, hematogenous route of spread in experimentally or inadvertently infected hosts can occur (29,49,50,98,111).

Cervical spinal cord and medulla oblongata are the primary sites of postmortem virus recovery. With time after infection, virus is also found in olfactory regions of the brain that may have been due to movement of the virus centripetally through the nerves innervating nasal mucosa. Perivascular cuffing and glial infiltration are characteristic histopathologic findings upon examination of brain tissue. Hepatic congestion is accompanied by infiltration of polymorphonuclear and mononuclear cells seen in the periportal areas of the liver. Scattered foci of necrosis can be found throughout the lobes of the liver. The presence of inclusions is visualized mainly in the regions of inflammation, around pyknotic or karyorrhetic hepatocytes. When lesions are present on skin, the depth of the involved tissue is significantly greater than that of mucous membranes, explaining perhaps the reason B virus can be recovered weeks or months later from these sites (34,60,61).

Development of animal models has been limited by the lack of antiviral drugs or a protective vaccine designed specifically to treat or prevent this infection. Because there is grave concern for individuals with this neurovirulent virus, should an accident occur, even when BL-4 laboratories are available, appropriate management protocols must be available.

Human Infection

Human B virus infection generally occurs through an occupational exposure to a macaque monkey shedding virus at a site that comes into contact with broken skin or mucosal membranes of the susceptible human. Several cases in which monkey contact had not occurred in years suggest that virus can be reactivated.

Review of all confirmed cases of B virus in humans can be summarized as follows. The most striking characteristic of human B virus infection is the involvement of the central nervous system, specifically the upper spinal cord and brainstem. These areas are the principal sites for virus replication, as observed from clinical, laboratory, and postmortem data. Initially, the infected individual experiences an influenza-like syndrome followed by numbness or parenthesis around the site of inoculation. An ascending transverse myelitis occurs during the final stages of the infection in humans, resulting ultimately in respiratory failure. Virus can be recovered at skin sites of inoculation for extended periods of time, and viral DNA can be detected generally in cerebrospinal fluid (CSF) by the time neurologic symptoms are experienced. CSF antibodies can also be detected. Generally, death is associated with complications of sustaining respiration with a ventilator. Cutaneous vesicular lesions are a source of virus isolation, even late in infection (85). Edema and degeneration of motor neurons are prominent. Even with advanced disease, Cowdry type A eosinophilic intranuclear inclusions can be found in only a few cases, and certainly not uniformly. Gliosis and astrocytosis are late histopathologic findings; thus, there can be evidence of myelitis, encephalomyelitis, or encephalitis, or combinations of each of these conditions (90).

Pathogenesis of B virus infection has been studied for each of the reported fatal cases and a few of the surviving cases (34,47,48,61,68,85,101). With fatal disease, generally, central nervous system lesions are localized within the upper cervical spinal cord, sometimes extending into the medulla and pons. In some cases, hemorrhagic infarcts are visualized in these areas, whereas in other cases, damage appears minimal despite the fact that the patient succumbs after prolonged ventilatory support. Discontinuing ventilatory support is nearly always followed by respiratory failure. In some cases, patients are alert but paralyzed, and in other cases, patients remain comatose. Surviving cases vary with respect to the level of morbidity, ranging from little or no neurologic impairment to more extensive central nervous system involvement (2,18,19,46). Some survivors experience slow neurologic decline, whereas others report few if any long-term effects. Several infected individuals have subsequently given birth to healthy children with no ill effects in either mother or infant. Monitoring of the vaginal canal for virus shedding in these individuals before delivery has produced negative results. In several reports, the ocular effects of B virus infection have been reported (86,95). Histopathologic examination of the eye revealed a multifocal necrotizing retinitis associated with a vitritis, optic neuritis, and prominent panuveitis. Herpes-like viral particles were identified in the involved retina by electron microscopy in one case. Postmortem vitreous cultures taken from both eyes and retinal cultures taken from the right eye in the later case were positive for B virus. From these observations, B virus can produce infection and destruction of retinal tissue similar to that of other herpesviruses. Ophthalmic zoster–like symptoms have been reported as well (45), and in one particular case, reactivation of latent infection was postulated.

To summarize human pathogenesis, the tissues and organs that become infected by B virus vary, perhaps according to the route of inoculation. If skin is the primary site of infection, the virus usually, but not always, replicates in the skin, resulting in localized erythema. Knowledge of the site of initial replication is useful for the development of guidelines for disease prevention and also for retrieval of a virus isolate that then allows unequivocal diagnosis. Subsequently, lymphangitis and lymph node involvement are observed. Although viremia has been documented in rabbits and monkeys, it has not been proved to occur in humans, although with the application of more sensitive assays (e.g., polymerase chain reaction [PCR]), more details of infection can be uncovered. Certainly, with lymphatic involvement, virus can spread, particularly to abdominal viscera, where it has been isolated previously. Nevertheless, spread through neuronal routes is the fundamental route of transmission of the virus, as it is with HSV, given the involvement of the spinal cord

and central nervous system. Visceral organs, including heart, liver, spleen, lungs, kidneys, and adrenals, demonstrate congestion and focal necrosis with variations in the extent of involvement from patient to patient. Recent human cases failed to demonstrate necrosis, but virus was isolated from adrenal, kidney, lung, and liver tissue collected at autopsy (34,61). In cases in which B virus infection is suspected, medical personnel should follow published guidelines at the time of injury or observation of symptoms of possible infection (23,24,25 and 26).

LATENCY

A characteristic of all herpesviruses is the ability to establish latency and to reactivate when provoked by the proper stimulus. B virus is no exception. Reactivated infection has been described in both wild macaques and established captive colonies (82,117,118,119 and 120). Unequivocal evidence of latent B virus infection in macaques came with studies on frequency of recovery of virus in monkey kidney cell culture systems. Wood and Shimada obtained six isolates from 650 pools of monkey kidneys, suggesting that at least 1% of macaque kidneys contain latent virus that can be reactivated in cell culture (124). Virus was also isolated from rhesus tissues by Boulter and Grant (14,15) as well as by co-cultivation from a variety of neuronal tissues, including gasserian ganglia, trigeminal ganglia, dorsal route ganglia, and spinal cord (116). Latent virus has also been isolated by co-cultivation of tissues from experimentally infected rabbits (116), further supporting the rabbit as a potentially acceptable animal model for B virus infections. Latency likely occurs after human infection.

As with human HSV infections, a prominent factor associated with reactivation of B virus in macaque monkeys appears to be stress, particularly that associated with the capture and shipment of animals from the wild to captivity. Shedding of virus after reactivation also occurs with illness and during the breeding season of the natural host. No information is yet available on the state of the viral DNA during latency or on the molecular or biochemical events associated with the establishment and reactivation of latent virus.

EPIDEMIOLOGY

Natural Hosts

Macaques

Most adult wild macaques are seropositive for B virus (106). However, colonies of animals exist in the wild that have been found to be predominantly seronegative. Each of these colonies was established apart from original natural habitats to meet escalating needs for seronegative animals by the scientific community. Thus, the epidemiologic pattern of virus infection was modified by human intervention. The seroprevalence in wild macaques, in addition to the noted high infectivity (118) and low morbidity within captive colonies (20), initially confirmed the macaque as the natural host. Recent studies among macaques belonging to captive breeding colonies demonstrated a high seroprevalence, a seroprevalence that increases after the onset of puberty (118,119). Increasing seroprevalence appears to be associated with sexual transmission within the colony (111,119). Infants and juveniles have a very low incidence of infection, judged by low prevalence of specific B virus antibodies (118). Despite antibody levels reflecting presence of maternal transplacental antibodies in young animals, it is of importance to note that all age groups have been found to be virus positive, indicating that routes of transmission other than sexual activity exist (1).

No particular species of macaque appears to be excluded as a natural host for B virus infection, although there are minimal or no data available from certain species. Although presence of antibodies has been confirmed in most of the different species of macaques, there has been speculation that virus isolated from certain species is less neurovirulent or less neurotropic than virus shed by rhesus macaques (12). Differences in the restriction endonuclease profiles of the different isolates from different macaque species have been reported, but the lack of available data on the types of macaques involved with each of the documented human cases does not permit rigorous evaluation of this hypothesis.

Virus shedding during either primary or recurrent infections has been noted to occur. Analysis of available data support that, in general, macaques shed virus for a longer duration during primary infection and, for short periods, even hours with reactivated infections. Levels of virus, as measured from mucosal swabs, range from 10^2 to 10^3 plaque-forming units (PFU).

Humans

B virus is an infection that humans rarely contract, but when they do, 80% of untreated cases result in death, as noted previously. Epidemiologic analysis indicates B virus is usually acquired through zoonotic transmission from either a macaque or infected cells or tissues from the animal. There is, however, one documented case of transmission from human to human, as previously noted, supporting the assumption that B virus can be transmitted similarly to HSV-1 or HSV-2. A recent fatal case resulted from exposure of ocular membranes to virus from a monkey in the process of being transported. This tragedy has refocused attention on an earlier report implicating this type of transmission in the epidemiologic analysis of zoonotic transmission of the virus (78). Interestingly, current case analyses suggest that categorization of risk levels with regard to the severity of injury is not useful. The low incidence of B virus infection in humans makes it difficult to reach statistical conclusions, but analyses of cases occurring during the 1990s supported the observation that immediate medical attention ameliorates, if not prevents, disease. Only minimal disruption of the protective skin layer or instillation directly to a mucosal membrane can result in initiation of infection. The level of virus required to initiate infection in humans remains unknown. Where data are available, rhesus macaques were most frequently implicated as the source of infectious virus in the known human cases, but alone, this is insufficient to conclude that rhesus-derived virus is uniquely important in the establishment of zoonotic infections. Other species of macaques, including baboons, have been linked to fatal zoonotic infections (90).

The incidence of zoonotic infections has been correlated retrospectively with periods of increased usage of macaques for biomedical research. Evaluation of past cases underscores that transmission of the virus is often associated with no

more than a superficial scratch or puncture, suggesting that once virus gains entry into a host, the ability to initiate disease is perhaps dose independent, at least in some cases. Again, however, this point remains unsubstantiated. Dose and route of entry are topics that require more study to clarify importance in zoonotic infection. Likewise, incidence and prevalence of zoonotic infections must be estimated cautiously because few data regarding the virus source are available from clinically recognized cases.

HOST IMMUNE RESPONSE

B virus antibodies have been studied in both the natural and the foreign hosts by a variety of methods, including serum neutralization with or without complement, competitive radioimmunoassay (RIA), multiple types of ELISA including competition ELISA, and Western blot. Limited serial observations have been available from both the natural and foreign host, but comparison of available data has been useful in that a relatively consistent response is induced in both hosts (3,4 and 5,63,66,67). The natural history of antibody development has been measured in wild macaques, captive colony populations, individually imported animals, experimentally infected macaques, zoonotically infected humans, and even vaccine trial recipients. The ELISA methodologies provide a rapid diagnostic tool with increased sensitivities of detection, and with enhanced specificity when competition protocols were used. The antibodies that develop in response to B virus infection in both humans and nonhuman primates are capable of neutralizing HSV-1 and HSV-2 as well as nonhuman primate alphaherpesviruses. Interestingly, the antibodies from HSV infections are not able to neutralize B virus, indicating the presence of virus-specific antigens unique to B virus (16,103). Sequence data have been useful in confirming the existence of B virus–specific epitopes (9,76,108).

The humoral immune response that develops after a B virus infection has a characteristic pattern (34,61,79). The glycoproteins induce antibodies early in the course of infection. Antibodies begin to appear within 7 to 10 days after the infection and consist of immunoglobulin M (IgM). Within 14 to 21 days after the onset of acute infection, IgG antibodies were present. In rare cases, the infected host remains persistently antibody negative despite virus isolation. The pattern of the immune response is somewhat altered in the cases of humans who have had a previous infection with HSV-1 or HSV-2 because viral antigens that are shared among the three viruses induce an anamnestic response toward shared protein or glycoprotein sequences. Neutralizing antibodies develop in both the natural and foreign host, but at significantly lower levels in the foreign host. The nature and specificity of the humoral responses make it possible to design enhanced serologic testing strategies to identify detectable antibodies rapidly and to provide the basis for future diagnostic strategies.

CLINICAL MANIFESTATIONS OF DISEASE

Observations of the clinical pattern of disease are important for rapid diagnosis of B virus infection in both macaques and humans. In the natural host, recognition of early infection allows removal of infected monkeys from captive colonies that are being established as B virus free. In B virus–free colonies, it is important to remove seropositive animals and isolate animals with equivocal results to prevent infection of other colony members, or in seropositive colonies to minimize risk to humans who have to handle them. Macaques are not treated with antivirals because the high prevalence of infection makes it cost prohibitive. In the case of human illness, early recognition of disease facilitates treatment with antivirals, principally such nucleoside analogs as acyclovir, valaciclovir, or famciclovir, a course that appears to lower the morbidity and mortality (34,61). Notably, immunosuppression (e.g., administration of corticosteroids) is often associated with reactivated disease, often mild, in the natural host (125), whereas other agents appear to be capable of facilitating systemic B virus disease culminating in death (27).

Humans exposed to B virus demonstrate clinically variable signs of disease. Most often, illness is apparent within days to weeks, but in some cases, there appears to be a delay in development of acute disease. The reasons for this delay are unknown and, although rare, delays may even range from months to years, making diagnosis difficult. Once symptoms appear, the clinical progression is associated with relatively consistent symptoms, including influenza-like illness, lymphadenitis, fever, headache, vomiting, myalgia, cramping, meningeal irritation, stiff neck, limb paresthesias, and urinary retention with an ascending paralysis culminating in respiratory failure, requiring ventilatory support. Cranial nerve signs, such as nystagmus and diplopia, are common in most published cases. Sinusitis and conjunctivitis have been observed in some (34,61). The array of symptoms may be related to the dose of virus with which the individual was infected or the route of inoculation. A summary of descriptions of human cases can be found in two comprehensive reviews (90,117).

A summary of reported cases indicates that the highest percentage of deaths occurs within a few weeks after onset of disease. In some cases, however, life was prolonged artificially for months or years. Incubation times from identifiable exposures to onset of clinical symptoms ranges from days to years, but most cases occur within days to months. Virus has been recovered from throat, buccal, and conjunctival sites as well as from lesions, vesicles, or injury sites as late as weeks to months after infection. Most clinical cases are associated with bites (50%), fomites, (8%) saliva (<5%), and aerosols (10%).

DIAGNOSIS

Nonhuman Primates

Macaques

B virus infection in macaque monkeys is identified by virus isolation, the presence of specific antibodies, or both (30,59,75). The neutralization antibody test was the predominant diagnostic tool in macaques and humans for many decades. The time required for the results of this test was often a drawback, and a more rapid test was required. Thus, the dot-blot, RIA, ELISA, and Western blots were developed (13,32,53,54,71,72,87). Three of these techniques (dot-blot, ELISA, and Western blot) rely on the use of monoclonal antibody. The results of these tests can be acquired in less than 1 day. These tests are available through commercial laboratories as well as through a national resource laboratory

subsidized through National Institutes of Health (NIH) National Center for Research Resources. All of these assays use B virus–infected cells for antibody detection, making such tests more effective than other types of assays that rely on HSV-1 (89). This is a particularly important point with respect to diagnostic tools used to identify signs of infection for the establishment of B virus–free colonies. Currently, there are no serologic tools that identify uninfected macaques; however, there are promising assays being developed for diagnosis of HSV-2 infections in humans that may be adapted for identification of B virus infection in macaques. When selecting an assay for detection of antibodies, the sensitivity and specificity of the test for a specific species of macaque should be known and considered in the final evaluation of the results. Tests dependent on monoclonal antibodies or recombinant reagents should have defined sensitivity and specificity for each macaque species to be tested. Finally, evaluation of a macaque is only optimal when analysis is performed on multiple samples at different dates, especially in cases in which antibody titer is low (less than 1:50). A constellation of different tests for deployment at varying time points after infection may be necessary in some cases to determine correctly the status of an animal with a very low antibody titer, particularly when such an animal is housed in a B virus–free colony (58).

Virus isolation is the gold standard for diagnosis of infected macaques. Unfortunately, virus isolation is not a particularly sensitive diagnostic tool, with the possibility of many false-negative results. Nonetheless, standard cell culture for virus isolation remains a valuable tool for the colony manager and for the veterinarian. Virus-positive cultures can be easily recognized with the unique cytopathic effect, but unequivocal confirmation requires either electrophoretic analysis of infected cell polypeptides or restriction endonuclease–digested DNA. More recently, several PCR tests have been described that can be used to verify the identity of the virus; however, this diagnostic tool for colony management is costly. Nonetheless, when a possible zoonotic infection must be confirmed, PCR may be beneficial for identification of B virus in macaques.

Nonmacaques

Other species of monkeys infrequently become infected with B virus, as previously discussed. These are usually animals that have been co-housed or housed in close proximity to B virus–infected macaques at some time. Because many, if not all, nonhuman primates harbor indigenous alphaherpesviruses, the important diagnostic point is to differentiate specific antibodies from cross-reactive ones. Euthanasia is generally advised in the case of a B virus infection in a nonmacaque monkey because it is likely that the animal will succumb and, in the meantime, would pose a great risk to anyone attempting to treat the infection. B virus has been identified in the patas monkey and colobus monkey (80,110,123). In each case, there was a major concern for the people responsible for care of the animal, particularly because these animals often have severe morbidity and are shedding virus. Currently, the most effective assay for diagnosis of B virus in a nonmacaque monkey would be a competition ELISA to facilitate discrimination between specific and cross-reactive antibodies similar to the challenge faced when diagnosing infection in humans.

Humans

The evaluation of clinical symptoms associated with an antibody- or virus-positive case is the gold standard for diagnosis of B virus infection in an exposed individual. Both serologic and virologic techniques are available for diagnosis of B virus–infected humans. The CDC has published specific guidelines for recognition and treatment of such infections (61). In the case of a suspected infection, several emergency resources are available. Contact with the CDC or laboratories recommended by the CDC (see guidelines) can expedite laboratory assistance for the clinician suspecting B virus infection. Generally, a rise in B virus–specific antibodies over several days during acute infection substantiates B virus as the etiologic agent. However, in other cases, data are equivocal, and decisions with regard to patient management must be based on a complex decision table collectively using all diagnostic tools, including clinical symptoms. Virus isolation remains the gold standard for diagnosis; however, virus isolation is frequently not possible even under the best of circumstances. Serologic diagnosis of B virus in humans is a complex task when an individual with a suspect infection has detectable antibodies as a result of a previous HSV-1 or HSV-2 infection. As discussed previously, significant cross-reactivity exists among these viruses. In the absence of these cross-reactive antibodies, diagnosis is rapid and straightforward, with confirmation using the neutralization assay, Western blot, or both. This was not the case before the development of rapid diagnostic competitive ELISAs and RIAs (71,72). The diagnostic tests for humans are performed currently by only a few facilities that have been licensed and have access to BL-4 containment laboratories for the preparation of B virus antigen.

Virus identification can be accomplished by isolation using conventional cell culture and, in clinical emergencies, by PCR (104). The identity of isolates should be confirmed by electrophoretic analysis of infected cell polypeptides or restriction endonuclease–digested DNA (56). The application of PCR is most helpful in the symptomatic patient if virus cannot be recovered. PCR is also a useful tool for monitoring the efficacy of antiviral interventions.

CONTROL OF B VIRUS INFECTION

Multiple levels of prevention can be used to prevent B virus infection in both humans and nonhuman primates, ranging from attempts to eliminate virus from colonies to designing methods to work safely in environments where there is increased risk for contracting this agent. The CDC has published detailed guidelines for maximizing protection of individuals working with macaque monkeys (23,25). Further, the NIH National Center for Research Resources has funded the development of B virus–free colonies for NIH-funded research involving these animals in an attempt to eliminate this virus from colonies used for biomedical research. Nonetheless, B virus–infected monkeys are plentiful and require handling that can be done safely if strict guidelines are followed, including barrier precautions.

When B virus is detected, it can be inactivated with either heat or formaldehyde (91). Other virus inactivators include detergents and bleach, but individuals who are working in a decontaminated area should still be alert for injury prevention. Minimizing fomites, however, decreases worker risk and reduces virus spread among animals. One B virus infection in a human was acquired from a cage after sustaining a scratch (61), underscoring that surface decontamination

can play an important role in infection control.

As early as the 1930s, attempts were made to identify an effective vaccine for protection of individuals who could be exposed to this virus while working with macaques or their cells or tissues. Limited vaccine trials have been performed in human volunteers (66,67); and although short-term antibody was induced, it was observed to wane quickly. Thus, the vaccine was not pursued further. Recently, a recombinant vaccine was tested and found to induce antibodies in macaques, but the duration of antibody persistence and efficacy remain to be assessed (10).

Antiviral therapy has been recognized as an effective prevention of infection prophylactic in human and animal trials, when administered early after exposure (17,31,34,61,126). Acyclovir and the related family of nucleoside analogs were noted to be effective when given in high doses (60), for example, acyclovir at 10 mg/kg intravenously three times daily for 14 to 21 days. Efficacy of therapy in cases of infection in humans has been monitored by inhibition of peripheral virus shedding in some cases and by reduction in cerebrospinal fluid antibodies or viral DNA load in others (34,61,105). Some physicians follow intravenous therapy with long-term oral suppression (acyclovir, valaciclovir, or famciclovir). Ganciclovir has a greater efficacy *in vitro* and thus was used in a few cases since 1989 with success. Interestingly, before 1987, in at least five retrospectively recognized cases, individuals fared well in the absence of antiviral therapy, but overall, the use of one of these nucleoside analogs is recommended by CDC. Generally, antiviral therapy is uniformly used in humans with clinical disease. Moreover, it is also used by an increasing number of facilities for postinjury prophylaxis or after laboratory results indicate an animal may have been actively infected around the time of the exposure. Postinjury prophylaxis has been performed with famciclovir or valaciclovir, and both have demonstrated efficacy *in vitro.* Recommendations and guidelines have been published by the CDC, as discussed previously, and can be readily accessed (60). Only a handful of physicians have had experience in the treatment of B virus zoonosis, and their participation and expertise has been important in the development of the CDC guidelines. There are other compounds that show a high degree of efficacy against B virus *in vitro,* but their clinical usefulness in the treatment of infections in humans must be further investigated owing to the toxicity of the compounds. Toxicity may be averted by lower doses of these compounds, but safety trials in animals are not complete.

Finally, with respect to prevention, the value of first aid after a potential exposure due to a bite, scratch, splash, or other suspicious injury is very important. Guidelines for wound cleaning are described in detail by the CDC. Every institution working with macaques should have an injury protocol with immediate availability of first aid, a secondary care plan, and last but not least, an infectious disease specialist who is a member of the institution's prevention and care response team.

CONCLUSIONS

B virus is usually a rapidly progressive, devastating disease that can be interrupted by effective use of antiviral therapies if deployed sufficiently soon after infection. The guidelines for treatment and prevention are widely published and can be rapidly accessed either through the CDC or the diagnostic resource using the World Wide Web address www.gsu.edu/bvirus. Other web sites are beginning to spring up as well and can be useful in learning more about B virus infections in both humans and nonhuman primates. Diagnostic techniques are rapidly improving to support clinical diagnosis and information regarding sample collection. Evaluation is available at any time to clinical care centers in case of emergencies.

With the newer diagnostic techniques, sensitivity of detection is improving, and the barriers posed by the high degree of cross-reactivity among this family of viruses are rapidly being diminished.

Because of the risk of human disease, precautionary methods must be followed in the workplace. Proper attention to the details of housing, management, and handling of macaque monkeys and organized exposure response measures using the CDC guidelines can minimize B virus zoonotic infections. Rapid identification of infection is essential for early initiation of antiviral drug therapy, which can prevent further mortality associated with this very interesting alphaherpesvirus.

CHAPTER 84 *Poxviridae:* The Viruses and Their Replication

Bernard Moss

The *Poxviridae* comprise a family of complex DNA viruses that replicate in the cytoplasm of vertebrate or invertebrate cells. These viruses are of special interest because of their unique biologic properties and impact on human health. Two members of the family—variola virus and molluscum contagiosum virus—are obligate human pathogens, and many others can be transmitted to humans from other animal hosts (see Chapter 85). Variola virus can cause smallpox, a once common and devastating disease that altered human history. Smallpox was eradicated in 1977, nearly two centuries after the introduction of prophylactic inoculations with cowpox and vaccinia virus, through a dedicated effort spearheaded by the World Health Organization. Vaccination contributed to present concepts of infectious disease and immunity. Moreover, vaccinia virus was the first animal virus seen microscopically, grown in tissue culture, accurately titered, physically purified, and chemically analyzed. A once prevalent view of virus particles as packets of nucleic acid was revised after the discovery of RNA synthetic activity in purified vaccinia virions. This finding stimulated investigations that led to the discovery of transcriptase and reverse transcriptase activities in RNA viruses and to the elucidation of structural features of viral and eukaryotic messenger RNA (mRNA), including the 5' cap and 3' poly(A) tail. Recombinant DNA technology eliminated obstacles to working with these large viruses, and considerable progress has been made in elucidating the cycle of virus replication (Fig. 1). Discoveries of virus-encoded proteins that affect cell growth and modulate immune defense mechanisms provided new insights into virus–host relationships. In addition, the development of vaccinia virus as a live recombinant expression vector provided a powerful tool for immunologists and biochemists as well as an alternative approach to the development of vaccines against a variety of infectious agents.

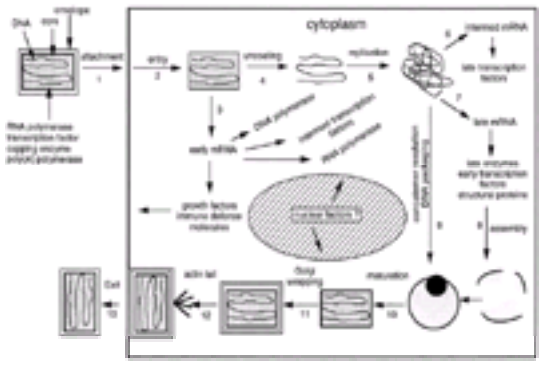

FIG. 1. The replication cycle of vaccinia virus. Virions, containing a double-stranded DNA genome, enzymes, and transcription factors, attach to cells (*1*) and penetrate the cell membrane, releasing cores into the cytoplasm (*2*). The cores synthesize early mRNAs that are translated into a variety of proteins, including growth factors, immune defense molecules, enzymes, and factors for DNA replication and intermediate transcription (*3*). Uncoating occurs (*4*), and the DNA is replicated to form concatemeric molecules (*5*). Intermediate genes in the progeny DNA are transcribed, and the mRNAs are translated to form late transcription factors (*6*). The late genes are transcribed, and the mRNAs are translated to form virion structural proteins, enzymes, and early transcription factors (*7*). Assembly begins with the formation of discrete membrane structures (*8*). The concatemeric DNA intermediates are resolved into unit genomes and packaged in immature virions (*9*). Maturation proceeds to the formation of infectious intracellular mature virions (*10*). The virions are wrapped by modified Golgi membranes, are transported to the periphery of the cell (*11*), and acquire actin tails (*12*). Fusion of the wrapped virions with the plasma membrane results in release of extracellular enveloped virus (*13*). Although replication occurs entirely in the cytoplasm, nuclear factors may be involved in transcription and assembly.

CLASSIFICATION

The general properties of *Poxviridae* include: a large complex virion containing enzymes that synthesize mRNA; a genome composed of a single linear double-stranded DNA molecule of 130 to 300 kilobase pairs (kbp) with a hairpin loop at each end; and a cytoplasmic site of replication. The *Poxviridae* are divided into two subfamilies, *Chordopoxvirinae* and *Entomopoxvirinae*, based on vertebrate and insect host range (Table 1). DNA sequencing has confirmed the genetic relationship between the two subfamilies. African swine fever virus shares some properties with poxviruses but is morphologically and genetically distinct and separately classified.

Subfamilies	Genera	Member viruses	Features
Chordopoxvirinae	Orthopoxvirus	Cowpox, vaccinia, ectromelia, monkeypox, raccoonpox, skunkpox, *Uasin Gishu, **vaccinia, *variola, volepox	Brick-shaped virion, DNA ~200 kbp, G + C ~35%, wide to narrow host range, variola (smallpox), vaccinia (smallpox vaccine)
	Parapoxvirus	*Bovine stomatitis, *Orf, pseudocowpox, paripox of deer, *sealpox	Ovoid virion, DNA ~140 kbp, G + C ~64%
	Avipoxvirus	Canarypox, *fowlpox, juncopox, mynahpox, pigeonpox, psittacinepox, quailpox, *peacockpox, *penguinpox, sparrowpox, starlingpox, turkeypox	Brick-shaped, DNA ~260 kbp, G + C ~30%, limited, arthropod transmission
	Capripoxvirus	Goatpox, lumpy skin disease, *sheeppox	Brick-shaped, DNA ~150 kbp, ungulates, arthropod transmission
	Leporipoxvirus	Hare fibroma, **myxoma, rabbit fibroma, squirrel fibroma	Brick-shaped, DNA ~160 kbp, G + C ~40%, leporids and squirrels
	Suipoxvirus	Swinepox	Brick-shaped, DNA ~170 kbp, narrow host range
	Molluscipoxvirus	*Molluscum contagiosum	Brick-shaped, DNA ~190 kbp, G + C ~60%, human host, localized tumors, contact spread
	Yatapoxvirus	Tanapox, *Yaba monkey tumor	Brick-shaped, DNA ~145 kbp, G + C ~33%, primates and T rodents
Entomopoxvirinae	Entomopoxvirus A	*Melanoplus melanoplus	Ovoid virion, DNA ~380–570 kbp, Coleoptera
	Entomopoxvirus B	**Amsacta moorei, *Melanoplus sanguinipes	Ovoid, DNA ~236 kbp, G + C ~18%, Lepidoptera and Orthoptera
	Entomopoxvirus C	*Chironomus solitor	Brick-shaped, DNA ~250–360 kbp, Diptera

*Probable member of genus.
**Biological member.
†Completely sequenced.

TABLE 1. *Family* Poxviridae

The *Chordopoxvirinae* consist of eight genera: *Orthopoxvirus, Parapoxvirus, Avipoxvirus, Capripoxvirus, Leporipoxvirus, Suipoxvirus, Molluscipoxvirus,* and *Yatapoxvirus* (see Table 1). Members of the same genus are genetically and antigenically related and have a similar morphology and host range. The orthopoxviruses have been studied most intensively. The prototypal member, vaccinia virus, has an unknown origin (41) and no known natural host, although it has been isolated from buffalo that probably contracted it from humans (149). DNA sequencing revealed that the genes common to vaccinia, variola, and cowpox viruses are greater than 90% identical (186,311,456,457), whereas limited data on orthopoxviruses indigenous to the Americas (e.g., raccoonpox virus and volepox virus) indicate that they are more genetically divergent (263). There are much less comparative data for individual members of the other poxvirus genera.

The *Entomopoxvirinae* have been divided into three genera based on the insect host of isolation (20). The prototypal members are listed in Table 1. The recent complete sequence analysis of the *Melanoplus sanguinipes* and *Amsacta moorei* viruses suggest that the Orthopteran and Lepidopteran members of genus B should be split into separate genera (1,40).

VIRION STRUCTURE

Morphology

Poxvirus virions are larger than those of other animal viruses and are discernible by light microscopy. The ultrastructural appearances of the particles varies according to the preparation methods. Vaccinia virions are visualized as smooth, rounded rectangles of about 350 × 270 nm by cryoelectron microscopy of unfixed and unstained vitrified samples (148) (Fig. 2). A 30-nm, membrane-delimited surface layer surrounds a homogenous core. Using the same technique, cores

produced by treating virions with a detergent, reducing agent, and deoxyribonuclease appear to be studded with 20-nm spikes. Two types of particles, C and M, are seen by negative staining of whole virions (359,546). The C form has a smooth exterior similar to the particles viewed by cryoelectron microscopy, whereas the M form has a beaded or tubular appearance also noted by freeze-etching (321). Incubation of virions with a nonionic detergent converts the M forms to C forms, but otherwise, the morphology appears unchanged (154). Further treatment with a reducing agent leads to removal of the outer coat, suggesting that disulfide-bonded proteins hold the latter together (154,422). Negatively stained images of cores, isolated by treatment with a detergent and reducing agent, have a rectangular shape; the wall of the core appears to be composed of an outer layer of cylindrical subunits 10 nm in length and 5 nm in diameter and an inner 5-nm thick smooth layer (154). Trypsin-sensitive structures called *lateral bodies* remain associated with cores prepared in this manner. In fixed and stained thin sections of virions, the core frequently appears dumbbell-shaped, with the lateral bodies in the concavities (126) (Fig. 3). It has been suggested that the surface tubules and the dumbbell-shaped cores result from nonisotropic drying because they are most clearly seen in dehydrated samples (148). Even so, an underlying structure must contribute to the acquisition of this highly characteristic appearance. Cylindrical elements that may take an S shape, or more complex flower-like structures, presumably representing nucleoprotein, have been visualized within poxvirus cores (227,390).

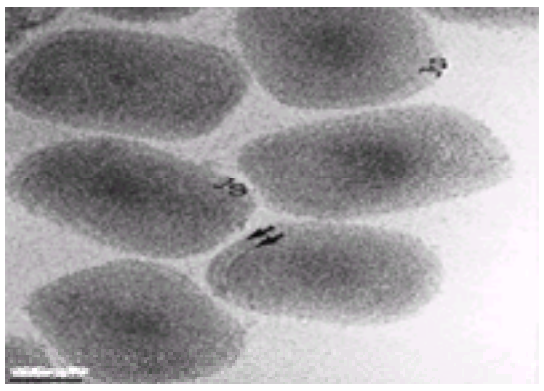

FIG. 2. Vitrified suspension of intracellular mature vaccinia virus particles observed by cryoelectron microscopy. The 30-nm thick surface domain (*S*) is delimited by arrows. (From ref. 148, with permission.)

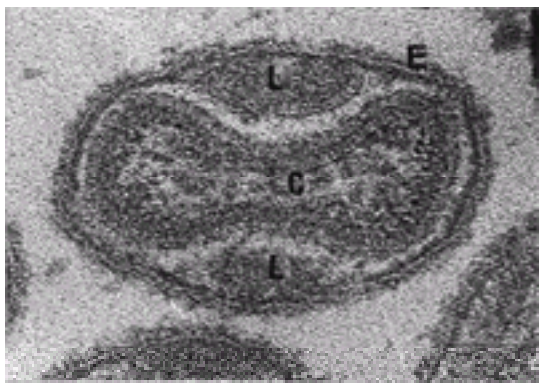

FIG. 3. Electron-microscopic image of a thin-sectioned intracellular mature vaccinia virus particle showing core (*C*), lateral bodies (*L*), and external membrane (*E*). (From ref. 393, with permission.)

The preceding descriptions apply to cytoplasmic infectious particles that are called *intracellular mature virions* (IMVs). *Extracellular enveloped virions* (EEVs), isolated from the tissue culture medium, contain an additional somewhat fragile lipoprotein envelope and have a lower buoyant density than IMVs (378,422). Thus far, EEVs from only vaccinia virus have been analyzed.

Chemical Composition

The large size of poxvirus virions facilitated their isolation by low-speed centrifugation and permitted accurate chemical determinations in the early 1940s (483). The principal components of vaccinia virions are protein, lipid, and DNA. These account for 90%, 5%, and 3.2%, respectively, of the dry weight (575), which has been estimated to be about 5×10^{-15} g (484). In contrast, about one-third of fowlpox virions is lipid (298). The lipid components of vaccinia virions are predominantly cholesterol and phospholipids (492,498), whereas fowlpox virions also contain squalene and cholesterol esters (298). Carbohydrate is present in the EEV as a constituent of glycoproteins. Spermine and spermidine (278) and trace amounts of RNA (420) have also been found in vaccinia virions, but their significance has not been established.

Genome

Poxviruses have linear double-stranded DNA genomes that vary from 130 kbp in parapoxviruses to about 230 kbp in avipoxviruses. All poxviruses examined have *inverted terminal repetitions* (ITRs), which are identical but oppositely oriented sequences at the two ends of the genome (176) (Fig. 4). The ITRs include: an A+T-rich, incompletely base-paired, hairpin loop that connects the two DNA strands (36); a highly conserved region of less than 100 bp that contains sequences required for the resolution of replicating concatemeric forms of DNA (136,324); variable-length sets of short, tandemly repeated sequences (557); and up to several open reading frames (ORFs). The ITRs are variable in

length owing to deletions, repetitions, and transpositions.

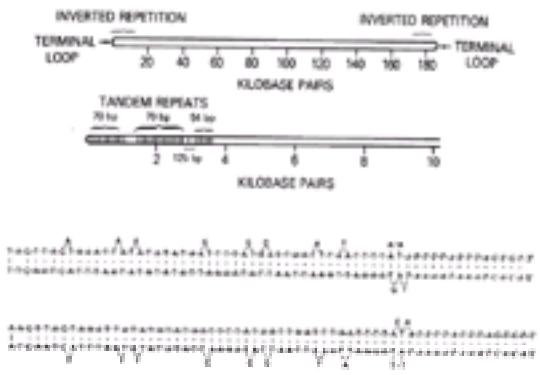

FIG. 4. Structural features of vaccinia viral DNA. A representation of the entire linear double-stranded DNA genome and an expansion of the 10,000-bp inverted terminal repetition are shown in the *upper part.* The nucleotide sequences of the inverted and complementary forms of the terminal loops are *below.* (From refs. 36 and 347, with permission.)

Complete genome sequences have been reported for six chordopoxviruses—vaccinia virus (19,186), variola virus (311,456), molluscum contagiosum virus (450), myxoma virus (89), Shope fibroma virus (552), and fowlpox virus (2)—and for two entomopoxviruses (1,40). There are about 100 ORFs that are represented in all chordopoxviruses and about 50 that are shared by chordopoxviruses and entomopoxviruses. Several generalizations can be made: ORFs are largely nonoverlapping, tend to occur in blocks pointing toward the nearer end of the genome, are usually located in the central region if highly conserved and concerned with essential replication functions, and are usually located in the end regions if variable and concerned with host interactions. The arrangement of the central genes is remarkably similar in all chordopoxviruses. The convention for naming orthopoxvirus ORFs was adopted before obtaining the complete genome sequence and consists of using the HindIII restriction endonuclease DNA fragment letter, followed by the ORF number (from left to right) within the fragment, and L or R, depending on the direction of the ORF. An exception to this rule was made for the HindIII C fragment; the ORFs were numbered from right to left to avoid starting at the left end of the genome, which is highly variable. For reference, the physical order of the 16 HindIII fragments of vaccinia virus is C, N, M, K, F, E, P, O, I, G, L, J, H, D, A, B. With the other poxviruses, the convention has been to number the ORFs continuously starting from one end.

Polypeptides

Consistent with their size and complex structures, poxvirus virions are composed of a large number of polypeptides. About 30 bands are readily resolved by one-dimensional polyacrylamide gel electrophoresis of vaccinia virus virions that have been purified from infected cells and disrupted with sodium dodecyl sulfate and a reducing agent, and considerably more can be detected by two-dimensional analysis (240). Twelve polypeptides have been localized near the exterior of the IMV by one or more of the following procedures: surface-specific labeling, sensitivity to proteases, extraction with nonionic detergents, and reactivity with virus-neutralizing antibodies (Table 2). Some of these proteins may form a disulfide-bonded matrix because both a reducing agent and a nonionic detergent are required for their release (233). There is evidence for physical association of the A17L, A27L, and A14L polypeptides in a complex (418). The L1R polypeptide is myristylated (405), and the A14L and A17L proteins are phosphorylated (55,143). Many of the IMV membrane proteins have unusual topologies: the A17L protein crosses the membrane twice with both the N- and C-terminal ends in the cytoplasm (54). The D8L (434) and the H3L (120) proteins are anchored by N- and C-terminal hydrophobic domains, respectively.

TABLE 2. *Nonenzymatic vaccinia virion components*

After IMVs are treated with a nonionic detergent and reducing agent, the cores can be recovered by low-speed centrifugation. Disruption of the core with deoxycholate releases a soluble enzyme fraction (described in the next section) from insoluble structural proteins. Four of the latter proteins, encoded by the F17R, L4R, A3L, and A10L ORFs, account for about 70% of the viral core by weight (see Table 2). The F17R 11-kd phosphoprotein and the L4R 25-kd polypeptide bind DNA and may correspond to nucleoprotein constituents (233). The mature G7L, L4R, A3L, A10L, and A12L proteins are processed from larger precursors at Ala-Gly-Ala/Ser motifs during morphogenesis (343,536). Vaccinia virus EEVs have a lower buoyant density than IMVs because of the additional lipid membrane and contain several unique

glycosylated proteins with type I or II topologies encoded by the A33R, A34R, A36R, A56R, and B5R ORFs (see Table 2) and by F13L, a nonglycosylated phospholipase (Table 3).

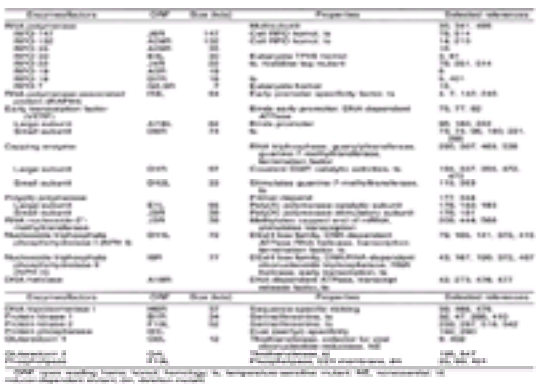

TABLE 3. *Vaccinia virion enzymes and factors*

Enzymes

Infectious poxvirus particles contain a transcription system (248,354) that can carry out *in vitro* synthesis of mRNAs that are polyadenylylated (247), capped, and methylated (544). A large number of virus-encoded enzymes and factors are packaged in the virus particle (see Table 3). Many of these, including the RNA polymerase, RNA polymerase-associated protein of 94 kd (RAP94), vaccinia early transcription factor (VETF), capping and methylating enzymes, poly(A) polymerase, and nucleoside triphosphate phosphohydrolase (NPH) I are directly involved in the synthesis and modification of mRNA. Additional enzymes may also be involved in synthesis of RNA or in virus assembly, protein processing, or DNA packaging.

VIRUS ENTRY

Studies of poxvirus entry into cells are complicated by the existence of multiple infectious forms that may use different and still unidentified cellular receptors and viral proteins (381,530). Although IMVs are commonly used by investigators to infect cells, they are only released by cell lysis; EEVs (68,380), and particularly the related *cell-associated enveloped virions* (CEVs) (61), are important for efficient cell-to-cell spread. IMVs are generally thought to enter cells by fusion with the plasma membrane or vesicles formed by surface invaginations (98,124,146,238). The inhibition of IMV entry by cytochalasin B and D suggests a role for actin filaments (381,530). In contrast to IMVs, some data suggest that EEVs enter cells by a mechanism that involves endocytosis followed by low pH disruption of the EEV outer membrane and fusion of the released IMV with endosomal membranes (228,530). The fusion of infected cells to each other, mediated by short exposure to a low pH, may mimic the latter process by disrupting the outer membrane of virus particles on the cell surface (146,187).

Poxvirus Receptors

A virus receptor is usually defined as a component on the cell surface to which a virus specifically binds and that mediates virus internalization. Because vaccinia virus can enter virtually all cell lines tested, there must be either many receptors or one that is ubiquitous. Thus far, however, no receptor has been unequivocally identified for any poxvirus. A virus-binding site, in contrast to a receptor, allows virus attachment but not necessarily entry. Evidence that IMV and EEV have different binding sites includes the efficiency with which the two virus types bind to different cell lines, differential effects of cell surface digestion with proteases, and the specific effect of a monoclonal antibody on binding of IMV (101,532). Heparin sulfate binds to vaccinia IMV and can inhibit infection by IMV of several orthopoxviruses and leporipoxviruses, suggesting that cell surface proteoglycans could serve as general mediators of poxvirus infection (106). It will be important, however, to rule out the possibility that heparin sulfate binding is an adaptation to passage in tissue culture. A candidate cell surface receptor was identified with a monoclonal antibody that blocked binding of IMV to cells (101). A suggestion that the epidermal growth factor (EGF) receptor serves as a portal of entry for vaccinia virus (305) has not been generally accepted (225). An exciting, albeit short-lived, proposal that poxviruses use chemokine receptors was based on studies with Shope fibroma virus (277). However, recent data (G. McFadden, personal communication) does not support this hypothesis.

Poxvirus Entry Proteins

Information about which viral proteins mediate cell entry and penetration is limited. At least four vaccinia IMV proteins—L1R, A27L, D8R, and H3L—have been implicated. Monoclonal antibodies to the L1R (231,561) and A27L (414) proteins neutralize the infectivity of IMV. In addition, the A27L protein plays a critical role in low pH–mediated cell-to-cell fusion, and an N-terminal domain binds heparin sulfate (187,217,537). The H3L protein also binds heparin sulfate, and a deletion mutant was reported to bind less efficiently to cells under some conditions (286), but not others (121). A role for the D8L protein was suggested by its ability to bind to cell surface chondroitin sulfate and by decreased binding of virions with a mutation in the *D8L* gene (218,274). Treatment of vaccinia virions with proteases increases infectivity, apparently by enhancing cell penetration (232).

A difficulty in studying entry of EEV is that purified preparations may contain damaged particles with exposed IMV membranes. In addition, deletion or repression of some genes encoding EEV membrane proteins may affect formation of the membrane, precluding an analysis of their role in entry. Repression of the *A34R* gene, which encodes a glycoprotein with a putative lectin domain, however, leads to increased production of EEV with reduced infectivity (319). Whether this

reduction is due to a defect in cell binding or later steps has not been determined. The B5R protein has also been implicated in cell entry because polyclonal antibodies to its extracellular domain neutralize EEV (173). Nevertheless, the extracellular domain does not appear to be essential for infectivity (203,312). Mutations of the hemagglutinin or the K2L glycoprotein result in the fusion of infected cells (448,524). However, neither the mechanism of fusion inhibition nor the roles of these proteins are understood.

Cell-to-cell spread is mediated most efficiently by CEVs, which resemble EEVs except that they are still attached to the plasma membrane of the parental cell (61). Vaccinia virus strains, such as WR, that produce mostly CEV form large, round plaques; whereas those that release large numbers of EEVs, such as IHD, form long comet-like plaques on cell monolayers under a liquid overlay. The different plaque phenotypes were mapped to a single amino acid substitution in the putative lectin domain of the A34R glycoprotein (62). Most orthopoxviruses have the WR-like sequence, suggesting that increased EEV may be an adaptation to spread in tissue culture. The extracellular domain of the B5R protein may also have a role in release of cell-associated virions (312). The efficient spread of CEVs is facilitated by their location at the tips of long microvilli that form by attachment of actin tails to the viral particles (119,499). Deletion of the *A34R, A33R,* or *A36R* gene prevents actin tail and microvillus formation and reduces the efficiency of virus spread (423,437,559,563). Presumably, the CEVs have the same outer membrane as EEVs, and details regarding their entry will be similar. A further discussion of these topics appears in a later section on EEV.

UNCOATING

After entry into the cytoplasm, virus cores are transported to juxtanuclear locations where they synthesize mRNA and undergo a second uncoating step. Electron microscopic images suggest that the nucleoprotein complex passes out through breaches in the core wall (123). Susceptibility of the virion DNA to treatment with deoxyribonuclease has been used as biochemical evidence of uncoating (241). Prevention of the uncoating process by inhibitors of transcription or translation (242) indicates a requirement for either a virus-induced or virus-encoded protein. A putative 23-kd uncoating protein with trypsin-like activity was partially purified from infected cell extracts (383). Viral particles in intermediate stages of disassembly have been isolated, and the polypeptide compositions have been analyzed (382).

GENE EXPRESSION

Programmed Expression of Poxvirus Genes

Studies primarily with vaccinia virus have led to a general understanding of how the DNA genomes of poxviruses are expressed within the cytoplasm of infected cells (see Fig. 1). A complete early transcription system is synthesized late in infection and packaged within the core of an infectious poxvirus particle, providing a mechanism for the initial synthesis of viral mRNAs. These early mRNAs encode enzymes and factors needed for transcription of the intermediate class of genes that in turn encode enzymes and factors for late gene expression (Table 4).

Stage	Factor	ORF	Promoter	Properties	Selected references

TABLE 4. *Stage-specific transcription factors encoded by vaccinia virus*

Regulation of Early-Stage Transcription

Vaccinia virus early mRNA is detected within 20 minutes after infection and accumulates to maximal levels in 1 to 2 hours (28) (Fig. 5). About half of the vaccinia virus genome is transcribed before DNA replication (65,371), including genes encoding proteins involved in host interactions, viral DNA synthesis, and intermediate gene expression. When uncoating of the core is prevented by protein synthesis inhibitors, early mRNA synthesis is increased and prolonged (28,564), suggesting that under normal conditions, core disassembly leads to the disruption of the early transcription apparatus. By comparison, DNA replication inhibitors do not prevent uncoating and prolong early transcription to a limited extent. The rapid decline of steady-state early mRNA levels cannot be explained solely by cessation of transcription and is consistent with an enhanced rate of degradation of all classes of mRNA after virus infection (28,366). Rapid mRNA turnover may be a mechanism for eliminating cellular and viral mRNAs at the end of each temporal stage.

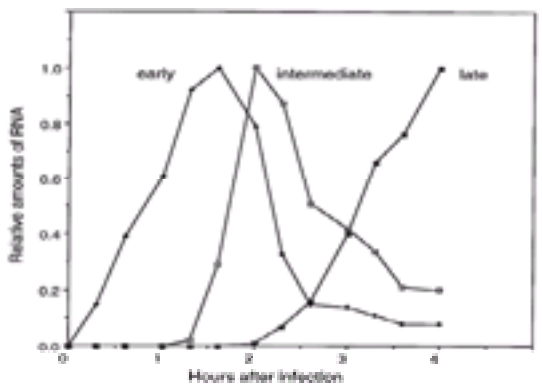

FIG. 5. Steady-state levels of representative early-, intermediate-, and late-stage messenger RNAs (mRNAs) in vaccinia virus–infected cells. Total RNA was isolated from infected HeLa cells at various times after infection and hybridized to antisense RNA probes specific for the 5' ends of mRNAs encoded by the C11R (early), G8R (intermediate), or F17R (late) open reading frames (ORFs) (28). After ribonuclease digestion, the protected probe fragments were analyzed by polyacrylamide gel electrophoresis and the radioactivity quantified. The numbers were normalized to the peak value in each case.

Early-Stage Promoters and Termination Signal

The transcription of an early gene is determined by an A+T-rich sequence located immediately upstream of the RNA start site. Saturation mutagenesis of a vaccinia virus early promoter defined a critical core region, from nucleotide –13 to –27, in which many single substitutions have a drastic effect on expression (131) (Fig. 6). A consensus core sequence AAAAAATGAAAAAA/TA is close to the optimal one defined by mutagenesis. Transcription initiation occurs with a purine, predominantly 12 to 17 nucleotides downstream of the core region. The intervening DNA, between the core and RNA start site, appears to have a spacer role, and there are no evident sequence requirements upstream of the core or downstream of the initiation site. Promoter sequences are conserved between poxvirus genera, partially explaining the phenomenon called *nongenetic reactivation,* which consists of rescue of a heat-inactivated poxvirus by co-infection with a second poxvirus (169,200). Thus, the heat-killed poxvirus provides the template and the second poxvirus provides the enzymes for transcription.

VACCINIA VIRUS PROMOTER SEQUENCES

	CORE			INITIATOR
EARLY	AAAA	T	GAAA TA	A/G
INTER	T	TT	AAA AA	TAAA
LATE	A/T-rich			TAAATG/A
	-30	-20	-10	+1

FIG. 6. Early-, intermediate-, and late-stage promoter sequences. Nucleotides that have a strong positive effect on transcription are shown. Positions of nucleotides in the nontemplate strand are relative to the RNA start site (+1). (From ref. 340, with permission.)

The 3' ends of vaccinia virus early mRNAs occur 20 to 50 bp downstream of the sequence TTTTTNT (574). Such termination sequences are present near the ends of most viral early genes but only rarely in their middle. When absent, the mRNA may extend through the next early gene downstream. *In vivo* studies suggested that the efficiency of termination is about 80% (152), although in some cases, it is much less, probably because of RNA secondary structure (282,296). TTTTTNT sequences have been noted near the ends of putative early genes in other poxvirus genera, suggesting a similar role in termination. As discussed later, the TTTTTNT sequence is actually recognized as UUUUUNU in RNA (474).

Enzymes and Factors for Early-Stage Transcription

A complete early transcription system is packaged within the core of an infectious poxvirus particle (248,354). Soluble extracts of vaccinia virus virions can transcribe an early promoter template *in vitro* to generate properly initiated and terminated mRNAs (421) and therefore provide a source of materials for characterization of the relevant enzymes and factors. The virion RNA polymerase is eukaryotic-like with regard to its size and subunit complexity (35). The subunits, ranging from 7- to 147-kd, are encoded by at least eight viral genes (see Table 3). There is a single copy of each large subunit, but the stoichiometry of the small subunits has not been accurately determined, partly because of polypeptide heterogeneity caused by alternative transcriptional and translational start sites. RPO147 and RPO132 are homologous to the corresponding large subunits of cellular RNA polymerase and resemble those of eukaryotes and archae (20% to 30% amino acid identities over the entire proteins) slightly more than those of bacteria. The vaccinia virus RPO30 subunit is about 23% identical in sequence to eukaryotic transcription elongation factor SII (TFIIS); RPO7, the smallest vaccinia virus RNA polymerase subunit, is about 23% identical in amino acid sequence with the smallest eukaryotic RNA polymerase subunit. Although the functions of the individual viral RNA polymerase subunits have not been investigated,

the large ones are likely to catalyze nucleotide addition based on homology with the cellular enzymes. Temperature-sensitive (ts) mutants with defects mapped to RNA polymerase subunits have been isolated (213,514). Mutant virions, propagated at the permissive temperature, generally contain active RNA polymerase, and early gene expression occurs even when cells are infected at the nonpermissive temperature. The phenotype of these mutants is a block in late gene expression, probably caused by aberrant assembly of the multisubunit enzyme.

An additional polypeptide is associated with RNA polymerase molecules in vaccinia virions (4,7,142). This RAP94 is specifically required for transcription of early promoter templates in conjunction with the VETF. RNA polymerase lacking RAP94 can transcribe single-stranded DNA nonspecifically or double-stranded intermediate or late promoter templates with the corresponding transcription factors. It seems likely that RAP94 interacts with VETF, although this has yet to be demonstrated. Synthesis of RAP94 occurs late, at the time of virion assembly, consistent with its exclusive role as a virion-associated early transcription factor. In this regard, RAP94 is distinct from the RNA polymerase subunits that are synthesized throughout the infectious cycle for intermediate and late transcription.

Transcriptional activity can be reconstituted *in vitro* with RNA polymerase and VETF, a heterodimer of 82 and 70 kd subunits (82,180). VETF, like RAP94, is synthesized only at late times after infection. The protein binds to the core region of early promoters and to DNA downstream of the RNA start site, thereby altering the conformation of the DNA (75,96). Single nucleotide substitutions in the core sequence of the promoter that decrease transcription also abrogate specific DNA binding (573). A DNA-dependent adenosine triphosphatase (ATPase) activity associated with the small subunit of VETF is not required for promoter binding but is essential for transcription, possibly through a promoter clearance mechanism (71,77,283). Complexes of VETF and RNA polymerase have been detected, suggesting that VETF may recruit RNA polymerase to the promoter (27,80,251,284). The elongation complex has a 3' RNase activity that permits resumption of transcription by stalled polymerase (197). A role for RPO30 has been suggested because the latter RNase activity is similar to one exhibited by eukaryotic RNA polymerase II in the presence of TFIIS, an RPO30 homolog.

A physical complex of RNA polymerase, VETF, capping enzyme, and NPH I (a DNA-dependent ATPase) can accurately terminate, as well as initiate, transcription on DNA templates containing an early promoter and TTTTTNT sequence (80,574). Although RNA polymerase and VETF can reconstitute the transcription initiation and elongation activities, capping enzyme and NPH I are needed to release nascent mRNA containing a UUUUUNU sequence from the transcription complex in an adenosine triphosphate (ATP)-dependent reaction (105,141,469,474). The physical interaction of NPH I with RAP94 may explain the specificity of this termination system for early transcripts (334). NPH I also serves as a polymerase elongation factor to facilitate read-through of intrinsic pause sites (141).

Because early viral transcripts made *in vivo* or *in vitro* are capped (64,544) and polyadenylylated (247), they structurally and functionally resemble eukaryotic mRNAs. RNAs synthesized by virus cores contain a cap I structure that consists of a terminal 7-methylguanosine connected by a triphosphate bridge to a 2'- *O*-methylribonucleoside. The N^7-methylguanosine component of the cap is required for mRNA stability and for binding of vaccinia virus mRNA to ribosomes, whereas the role of ribose methylation is undetermined (355). Capping occurs during transcription when the nascent RNA chains are about 30 nucleotides long (196). The steps in cap formation are: (a) removal of the terminal phosphate of the triphosphate end of the nascent RNA to form a pp(5')N-terminus, (b) transfer of a guanosine monophosphate (GMP) residue from guanosine triphosphate (GTP) to form G(5')ppp(5')N-, (c) transfer of a methyl group from *S*-adenosylmethionine to produce m^7G(5')ppp(5')N-, and (d) transfer of a second methyl group to form m^7G(5')ppp(5')Nm. The first three reactions are catalyzed by the virus-encoded 127-kd heterodimeric capping enzyme (307,308,538). The fourth step in cap formation, ribose methylation of the penultimate nucleoside, is mediated by a separate viral enzyme (34). The capping enzyme large subunit forms a covalent lysyl-GMP intermediate (114,362,431,472). The RNA triphosphatase and guanylyltransferase activities reside in an N-terminal segment of the large subunit (357,473), whereas a complex of the C-terminal part of the large subunit and the small subunit contains the N^7-methyltransferase activity (205,304). The nucleoside 2'-methyltransferase is a 39-kd protein that exists as a monomeric species and as a subunit of the poly(A) polymerase (444). High-resolution x-ray crystal structures of the nucleoside 2'-methyltransferase complexed to its methyl donor and mRNA cap have been determined (209,210). Viral mRNAs synthesized *in vivo* have additional base and ribose methylations that are catalyzed by cellular enzymes (64).

The enzyme that catalyzes poly (A) tail formation is a heterodimer of virus-encoded 55- and 39-kd subunits called VP55 and VP39, respectively (178,344). VP55 binds to uridylate sequences near the end of the RNA chain and catalyzes the processive addition of 30 to 35 adenylate residues before changing to a slow and nonprocessive mechanism (140,183). VP39 binds poly(A) and stimulates VP55 to add additional adenylate residues (181). Thus, VP39, which is present in an excess over VP55, serves as a processivity factor for the poly(A) polymerase as well as a methyltransferase. The two activities are independent because mutated forms of VP39 that lack methyltransferase but retain adenylyltransferase stimulatory activity *in vitro* have been produced (445,458). Genetic and biochemical studies indicate an additional role of VP39 as an RNA elongation factor for intermediate and late RNA synthesis (279,568), discussed later. The finding that the capping enzyme and termination factor and the ribose methyltransferase and poly(A) polymerase processivity factor function at the 5' and 3' ends of the mRNA is intriguing. Whether the association of such apparently disparate functions in the same enzymes provides a specific advantage or represents an economical use of proteins is unknown.

The minimal components for synthesis of correctly initiated, terminated, capped, and polyadenylylated mRNA were defined by *in vitro* reconstitution assays. However, additional enzymes may be needed within the virus core. One example is NPH II, an enzyme with RNA-dependent RNA nucleoside triphosphatase and RNA helicase (372,468) activities. Permeabilized mutant virions lacking NPH II have diminished transcription activity and produce longer than normal RNAs that remain virion associated, suggesting a role in transcription termination or extrusion (191). Studies with ts mutants suggest that the A18R DNA helicase has a role in early, as well as late, transcription (476,477). Biochemical studies indicate that the A18R protein, along with an unidentified cellular component, acts a transcript release factor (273). Virions deficient in the H1L serine-tyrosine phosphatase have low transcription activity, suggesting a regulatory role along with that of the virion-associated protein kinases (290).

Regulation of Intermediate-Stage Transcription

DNA replication precedes a shift in viral gene expression. Amino acid labeling (346,385) and transcription (28,541) studies indicated the existence of an intermediate class of genes that are expressed after DNA replication but before expression of the late genes (see Fig. 1). After synchronous infection, intermediate mRNAs were detected at 100 minutes, the time of peak early mRNA accumulation (see Fig. 5). Intermediate mRNAs reached their peak values soon after and then declined in quantity. Only seven vaccinia virus genes belonging to the intermediate class have been identified thus far (253,271,541), although additional ones exist (580). Three of these (*A1L, A2L,* and *G8R*) encode transactivators of late gene expression (253), and one (*I8R*) encodes the RNA helicase NPH II (467). Two have both early and intermediate promoters; of these, I3L is a single-stranded DNA binding protein that interacts with ribonucleotide reductase (130,521), and K2L (also called SPI-3) is a member of the serine protease inhibitor (SERPIN) superfamily with an unknown role (523,524).

The DNA replication requirement for intermediate gene expression may result from the inaccessibility of the genome within the infecting particle to the newly synthesized RNA polymerase and transcription factors. This hypothesis is consistent with transfection experiments showing that the DNA isolated from purified virus particles can serve as a template for intermediate and late transcription in the absence of DNA replication (253). The proposed inaccessibility of the parental DNA could be nonspecific owing to remaining virion proteins or to putative specific repressor proteins.

Intermediate-Stage Promoters

Mutagenesis of intermediate promoters indicated two important regions: a 14-bp core element separated by 10 or 11 bp from a 4-bp initiator element (29). The intermediate core element resembles that of early promoters in A+T richness but differs in specific sequence (see Fig. 6). The tetranucleotide TAAA serves as an initiator element of intermediate promoters. Intermediate-stage RNAs are initiated within the AAA triplet, but as discussed later, they contain additional A residues incorporated by a polymerase slippage mechanism. With a slight adjustment, early and intermediate promoter motifs can be accommodated within a single, dual-function, synthetic early-intermediate promoter (28), raising the possibility that such dual promoters occur naturally.

Analysis of some intermediate mRNAs by agarose gel electrophoresis indicated diffuse bands, equal to and longer than the coding regions, suggesting preferred sites of 3'-end formation that did not correlate with early gene transcriptional termination signals (28).

Enzymes and Factors for Intermediate-Stage Transcription

Intermediate promoter templates can be transcribed by extracts prepared from cells infected with vaccinia virus in the presence of an inhibitor of DNA replication (541). Further studies indicated a role for both viral and cellular proteins. The viral proteins (see Table 4) include capping enzyme, which acts by a cap-independent mechanism (202,539,540); VITF-1, which is encoded by the gene for RPO30, a viral RNA polymerase subunit with homology to eukaryotic transcription elongation factor TFIIS (426); and VITF-3, a heterodimer composed of polypeptides encoded by ORFs *A8R* and *A23R* (439). Unlike the early transcription factor, neither VITF-1 nor VITF-3 has ATPase activity or exhibits sequence-specific DNA binding. It is uncertain which component corresponds to the promoter melting factor (539). The cellular component, VITF-2, was extracted from the nucleus of uninfected HeLa cells but was distributed within the cytoplasmic and nuclear fractions of infected cells (427). Whether vaccinia virus infection induces transit of VITF-2 out of the nucleus, activates a cryptic cytoplasmic factor, or depends on newly synthesized VITF-2 has not yet been determined. A relationship between VITF-2 activity and certain examples of host range restriction has been suggested (503). One intriguing possibility is that VITF-2 provides a gate-keeper role between the prereplicative and postreplicative phases of the virus cycle by signaling whether a quiescent cell has been activated to allow optimal replication.

Genetic studies have provided evidence for positive and negative regulators of intermediate or late transcriptional elongation. Initial experiments pointed to similar effects on RNA metabolism of vaccinia virus mutants that mapped to the *A18R* gene, now known to encode a DNA helicase, and those produced by the antiviral drug isatin-b-thiosemicarbazone (IBT) (369). Subsequent experiments indicated that IBT-resistant mutants of vaccinia virus mapped to the RNA polymerase subunit RPO132 (111), whereas IBT-dependent mutants mapped to G2R, a protein of unknown function (322). The story became more intriguing when it was discovered that mutations in the *A18R* gene increased transcriptional readthrough of downstream gene sequences (571), whereas mutations of the *G2R* gene produced decreased-length mRNAs (57). Remarkably, *G2R* mutants rescued *A18R* mutants (113), and physical interactions between the proteins encoded by *G2R, A18R,* and *H5R* (a late transcription factor) were demonstrated (58,314). Recent biochemical studies suggest that the *A18R* helicase is a transcript release factor and acts in conjunction with an unidentified cellular protein (273). Similar genetic approaches led to the identification of the product of the *J3R* gene, which also serves as the cap 2'-*O*-methyltransferase and as a subunit of the poly(A) polymerase, as an mRNA elongation factor (279,568).

Regulation of Late-Stage Transcription

The transcription of late genes follows that of intermediate genes (see Fig. 1). In HeLa cells, late-stage RNA is detected at 140 minutes after synchronous infection with vaccinia virus and continues for about 48 hours (see Fig. 5). The persistent synthesis of late proteins reflects continued transcription because the half-life of late mRNAs has been estimated to be 30 minutes or less (366). Many late proteins, including the major virion components, accumulate in large amounts during this long period. Other late proteins include the factors that are specifically required for transcription of early genes, such as VETF and RAP94, as well as certain other virion enzymes (see Table 3). Although distributed throughout the genome, the late-stage genes cluster in the central region.

Late-Stage Promoters and RNA Processing Signal

Late-stage promoters may be considered in terms of three regions: a core sequence of about 20 bp with some consecutive T or A residues, separated by a region of about 6 bp from a highly conserved TAAAT element within which transcription initiates (132) (see Fig. 6). A synthetic promoter with exclusively T residues forming the core sequence was stronger than tested natural late promoters. Any mutations of TAAAT severely decreased transcription. G or A usually follows the late promoter TAAAT sequence; in the former case, the TAAATG transcription initiation sequence and the ATG translation initiation codon overlap. The seeming absence of an untranslated RNA leader in this situation was puzzling, until it was found that late mRNAs have a 5'-capped, heterogeneous-length, poly(A) sequence formed by RNA polymerase slippage (6,376,446). Poly(A) leaders are also present on mRNAs of a few early genes that have a TAAAT initiation site (5,235) as well as on intermediate mRNAs (28), suggesting that slippage on an AAA sequence is an intrinsic property of the viral RNA polymerase.

Most late transcripts are long and heterogeneous and lack defined 3'-ends (117,303). The early termination signal is not recognized by the late transcription system; consequently, TTTTTNT is frequently present within the coding region of late genes. Terminal heterogeneity, combined with transcription from both DNA strands, explains the ability of late transcripts to self-anneal or anneal with early transcripts to form ribonuclease-resistant hybrids (66,109). The vaccinia virus–encoded double-stranded RNA-binding protein (100) or RNA helicase (467) may prevent deleterious effects of the double-stranded RNA, although this idea is entirely speculative. Alternatively, the 5' poly(A) leader could compensate for the complementary RNA by providing a single-stranded binding site for initiation factors and the 40s ribosomal subunit, which would then move unimpeded by antisense RNA to the first AUG codon where ribosome assembly and translation occur.

An exception to the general 3' heterogeneity of late mRNAs was discovered (18). The cowpox virus late mRNA encoding the A-type inclusion protein has a 3' end corresponding to a precise site in the DNA template. The DNA sequence at this position encodes an RNA cis-acting signal for RNA 3'-end formation that can function independently of either the nature of the promoter or the RNA polymerase responsible for generating the primary RNA (214). There is evidence for induction or activation of a specific endoribonuclease that cleaves this RNA, which is then polyadenylylated. The number of late mRNAs that are processed in this manner remains to be determined. Therefore, poxviruses employ at least two mechanisms of RNA 3'-end formation. The first, operative at early times in viral replication, terminates transcription downstream of an RNA signal, whereas the second, operative at late times, involves RNA site-specific cleavage.

Enzymes and Factors for Late-Stage Transcription

Templates containing late promoters can be transcribed by extracts prepared from cells at the late stage of vaccinia virus infection (567). Late transcription factors were identified by the systematic screening of cloned DNA fragments: ORFs *A1L, A2L,* and *G8R* were necessary and sufficient for transactivation of a transfected late promoter reporter gene in vaccinia virus–infected cells that were blocked in DNA replication (253). An intermediate promoter regulates each of these late transcription factor genes (see Table 4), which is consistent with a cascade model of regulation. *In vitro* studies confirmed that the products of the *G8R, A1L,* and *A2L* genes are vaccinia virus late transcription factors (223,255,375,565,566), and they have been named VLTF-1, VLTF-2, and VLTF-3, respectively (see Table 4). In addition, ts and repressible mutations of *A1L* and *G8R,* respectively, block late gene expression under nonpermissive conditions (92,580). Both VLTF-2 and VLTF-3 can bind zinc (254), and yeast two-hybrid studies indicate interactions of VLTF-1 with itself and with VLTF-2 (314). *In vitro* studies indicated that the product of the early *H5R* gene, named VLTF-4, stimulated late transcription several-fold (269). Evidence has been obtained for a cell-derived late transcription factor that binds late promoters (193). Other studies demonstrated that the cellular transcription factor YY1 is found in the cytoplasm of infected cells and can bind to at least two late promoters (76), but it remains to be shown that this protein has a role in vaccinia virus transcription. Several studies have been cited as evidence for a role of host RNA polymerase II in late vaccinia virus gene expression (122), but this has not been demonstrated directly.

Posttranscriptional Regulation of Viral Gene Expression

Poxvirus mRNAs are made in the cytoplasm, and no evidence of splicing has been reported. As noted earlier, accelerated mRNA degradation induced by vaccinia virus facilitates rapid changes in viral mRNA populations (see Fig. 5), although the basis for this effect is unknown. The finding that intermediate and late mRNAs contain 5' poly(A) sequences, whereas such sequences are uncommon on early mRNAs, raises the possibility that this structural feature enhances translation. However, critical experiments to test such a hypothesis have not been reported.

DNA REPLICATION

General Features

Poxvirus DNA replication takes place in the cytoplasm, a characteristic shared only with African swine fever virus, and has been reported to occur in enucleated cells (386,398). Discrete cytoplasmic foci of replication, termed *factory areas,* were discerned by light and electron microscopic autoradiography and microscopic procedures (88,201,249).

Enzymes Involved in DNA Precursor Metabolism

Some poxviruses encode enzymes involved in the synthesis of deoxyribonucleotides, evidently to enhance DNA replication in cells with suboptimal precursor pools; whereas other poxviruses lack some or all of these enzymes and are dependent on the host. In orthopoxviruses, these enzymes include a thymidine kinase (26,216), thymidylate kinase (489), ribonucleotide reductase (478,510), and dUTPase (72). In addition, there is an incomplete guanylate kinase (488), raising the possibility that an intact form might be found in some other poxvirus. Leporipoxviruses are missing genes encoding the large subunit of ribonucleotide reductase, thymidylate kinase, and remnants of the guanylate kinase

(89,552); whereas molluscum contagiosum virus has no known enzymes involved in nucleotide precursor formation (450). Fowlpox virus encodes a protein related to human deoxycytidine kinase that is not present in the other poxviruses (266). The completely sequenced genome of the entomopoxvirus *Melanoplus sanguinipes* lacks all of the previously described poxvirus genes involved in nucleotide metabolism but has a thymidylate synthetase homolog (1). However, a homologous thymidine kinase gene is present in *Amsacta moorei* (40) and other entomopoxviruses.

The thymidine kinases encoded by orthopoxviruses, avipoxviruses, suipoxviruses, capripoxviruses, leporipoxviruses, and some entomopoxviruses are 20 to 25 kd and related in sequence to corresponding eukaryotic enzymes (35% to 70% amino acid identity), but not to the pyrimidine kinase of herpesviruses. The thymidine kinase gene is regulated by an early promoter, as befits its role in increasing the precursors for DNA replication. The vaccinia virus enzyme exists as a tetramer, has ATP- and Mg^{2+}-binding domains, and is susceptible to feedback inhibition by dTDP or dTTP (59). Although the thymidine kinase gene is not required for virus growth in tissue culture cells, deletion mutants are attenuated *in vivo* (86).

Thymidylate kinase catalyzes the next step in thymidine monophosphate (TMP) metabolism. The vaccinia virus gene encodes a 23.2-kd protein that can complement *Saccharomyces cerevisiae* mutants deficient in the homologous enzyme (224). The protein is expressed early in infection and is not required for virus replication in tissue culture.

The synthesis of ribonucleotide reductase, an enzyme that converts ribonucleoside diphosphates to deoxyribonucleoside diphosphates, occurs soon after vaccinia virus infection (480). Both the small catalytic subunit and the large regulatory subunit closely resemble their eukaryotic counterparts both structurally (70% to 80% identity) and functionally (215,479). Catalytic activity is inhibited by hydroxyurea, and drug-resistant mutants generate direct tandem repeats of the gene encoding the catalytic subunit (482). Mutation of the large subunit prevented induced ribonucleotide reductase activity in tissue culture cells without affecting replication (104). However, the mutant virus was mildly attenuated in a mouse model.

The hydrolysis of dUTP by the vaccinia virus dUTPase provides dUMP, an intermediate in the biosynthesis of thymidine triphosphate (TTP), and might also minimize dUTP incorporation into DNA (72). The protein is synthesized early in infection (481) and is nonessential for virus replication (388).

DNA Synthesis

The time of onset of DNA synthesis varies with different members of the poxvirus family and to some extent with the multiplicity of infection and cell type. In cells synchronously infected with vaccinia virus, DNA replication begins 1 to 2 hours after infection and results in the generation of about 10,000 genome copies per cell, of which half are ultimately packaged into virions (243,435). Studies depending on thymidine incorporation instead of hybridization for DNA quantification generally underestimate the length of the replication period, probably because of a decline in the activity of the viral thymidine kinase used for incorporation of the radioactive precursor through the salvage pathway.

A plausible model for poxvirus DNA replication begins with the introduction of a nick near one or both of the hairpin termini, followed by nucleotide addition to the free 3' end, strand displacement, and concatemer resolution. Nicking is supported by changes in the sedimentation of the parental viral DNA (394) (although the cleavage site remains to be defined), and labeling studies suggested that replication begins near the ends of the genome (396). The presence of single-stranded DNA is consistent with a strand-displacement mechanism, and the report of small DNA fragments covalently linked to RNA primers suggests lagging strand synthesis (158,159 and 160,395), but this needs further investigation with current methods. The presence of transient concatemeric DNA intermediates were demonstrated by the presence of junction fragments (37,352) and high-molecular-weight DNA (135,329).

Efforts to locate a specific poxvirus origin using a plasmid replication assay in transfected cells led to a surprising conclusion that any supercoiled plasmid replicated in cells infected with Shope fibroma (137) or vaccinia virus (330). The absence of any stimulatory effect of vaccinia virus DNA sequences resulted in speculation that poxviruses, unlike nuclear DNA viruses, do not require specific origin sequences. Recently, however, more specific results were obtained by transfecting a linear DNA molecule containing vaccinia virus hairpin ends (147). With this assay, an enhancing effect was found when the template contained the terminal 200 bp of the viral genome.

Viral Proteins Involved in DNA Replication

Several complementation groups of ts mutants that express vaccinia virus early proteins but are impaired in DNA synthesis have been found (112,317). One group contains mutations in the DNA polymerase, which has a mass of about 110 kd, an associated 3' exonuclease activity and sequence similarities with other eukaryotic and viral DNA polymerases (97,153,316). Certain codon substitutions confer resistance to inhibitors of DNA synthesis, providing information regarding the active site of the polymerase (134,153,505,506,519).

The second DNA-negative complementation group maps to the *D5R* gene, which encodes a 90-kd protein with a nucleic acid–independent nucleoside triphosphatase activity (163,165,429). An abrupt cessation of DNA synthesis occurred upon a shift to the nonpermissive temperature of cells infected with one of the *D5R* mutants, suggesting a direct but still unknown role in replication (164). The third DNA-negative complementation group was mapped to the *B1R* ORF, which encodes a serine-threonine protein kinase that is expressed early in infection, and is packaged in virions (32,288,410). An early protein encoded by the *H5R* gene has been shown to be a substrate for the B1R kinase (47), and interactions between these proteins was demonstrated by the yeast two-hybrid system (314). Although the H5R protein appears to be involved in late transcription (58,269), it has no known role in DNA replication. Two human homologs of B1R have been identified, but their functions are unknown (361).

Another vaccinia virus ts mutant impaired in DNA replication was mapped to the *D4R* ORF (331). A mutant with a deleted *D4R* gene was also impaired in DNA replication but could be propagated in a transfected cell line stably transfected with *D4R* (212). Both the *D4R* ORF and its Shope fibroma virus homolog encode functional uracil DNA glycosylases

(502,528). Because these enzymes remove uracil residues that have been introduced into DNA, either through misincorporation of dUTP or through the deamination of cytosine, a DNA-negative phenotype was surprising.

Additional ts mutants impaired in DNA replication were derived by directed mutagenesis of the *A20R* gene (264). The protein encoded by this gene interacts in the yeast two-hybrid system with the DNA glycosylase and the D5R protein, both of which are involved in DNA replication (314). Traktman (517) cited evidence that the A20R protein is the DNA polymerase processivity factor previously detected in infected cell extracts (315).

Vaccinia virus encodes a functional ATP-dependent DNA ligase that is not essential for viral replication in tissue culture, although it affects virulence as well as sensitivity to DNA-damaging agents (110,256). Whether DNA ligation is unnecessary for replication or this requirement is fulfilled by the cellular homolog is unknown.

Three of the putative replication proteins encoded by orthopoxviruses (the DNA polymerase, nucleoside triphosphatase, and DNA glycosylase) have homologs in all sequenced poxvirus genomes pointing to their central roles. B1R protein kinase homologs are present in all sequenced poxviruses except for molluscum contagiosum virus; putative processivity factor homologs are present in all except entomopoxviruses; an ATP-dependent DNA ligase is encoded by leporipoxviruses but not by either molluscum contagiosum virus or entomopoxviruses. *Melanoplus sanguinipes,* however, encodes a putative NAD^+-dependent DNA ligase (1).

Concatemer Resolution

The replication of the poxvirus genome involves the formation of concatemeric intermediates and their resolution into unit-length molecules. The concatemer junction consists of a precise duplex copy of the hairpin loop present at the ends of mature DNA genomes (see Fig. 4). Studies with ts mutants of vaccinia virus, as well as specific inhibitors, indicate that concatemeric forms of DNA accumulate when late gene expression is prevented (135,329). Resolution occurs upon allowing late proteins to be made, providing evidence that the concatemers are replicative intermediates.

Circular plasmids containing vaccinia virus (328) or Shope fibroma virus (138) concatemer junctions are converted into linear molecules with hairpin termini when transfected into poxvirus-infected cells. Using this assay, the structural and sequence requirements for resolution of concatemer junctions were determined by site-directed mutagenesis (136,318,324,327). The minimal requirement for resolution is two copies of the sequence T_6-$N_{7–9}$-T/C-A_3-T/A present in an inverted repeat orientation on either side of an extended double-stranded copy of the hairpin loop. Structurally and functionally similar resolution sequences are present in at least four poxvirus genera: *Orthopoxvirus, Leporipoxvirus, Capripoxvirus,* and *Avipoxvirus* (Fig. 7). The sequence of the intervening region, destined to form the hairpin loop, is not highly conserved but must be palindromic and less than 200 bp long. Further studies suggested that resolution is accomplished either by conservative site-specific recombination and oriented branch migration (325) or by nicking and sealing of an extruded cruciform structure (318).

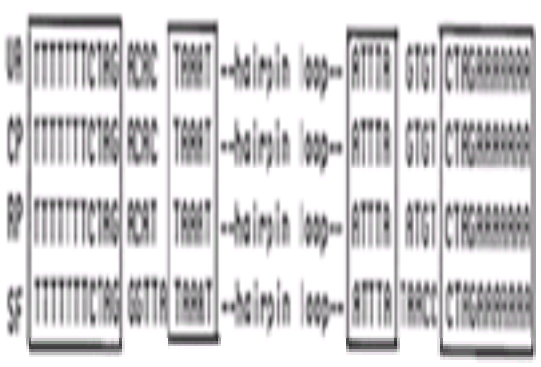

FIG. 7. Concatemer resolution sequence. The *boxed regions* represent conserved sequences necessary for concatemer resolution. Extended palindromic hairpin loop sequences are indicated. VA, vaccinia; CP, cowpox; RP, rabbitpox; SF, Shope fibroma.

Data showing that all conditional lethal mutants of vaccinia virus that are blocked in late gene expression are also defective in concatemer resolution at the nonpermissive temperature were interpreted as indicating a requirement for a specific viral late protein (135,329). However, the resolution sequence contains a functional late promoter (374,501) (compare Fig. 6 and Fig. 7). Therefore, it is unclear whether transcription of the resolution sequence, the translation product of a late transcript, or both are required.

There are at least three viral late proteins that might be components of a resolvase. One is a type 1 topoisomerase that structurally and functionally resembles its eukaryotic counterpart (39,261,470,475), except for a specificity for the sequence C/TCCTT (465). Similar sequence-specific topoisomerases are encoded by orf virus (260), entomopoxvirus (272,391), Shope fibroma virus (370), and molluscum contagiosum virus (226). Despite extensive biochemical analyses and evidence that the gene is essential for virus replication (466,471), its biologic role remains uncertain. The ability of poxvirus topoisomerases to resolve Holliday junctions, a key intermediate in both homologous and site-specific recombination, and generate hairpin ends suggest that this enzyme might be involved either in resolving concatemer junctions or in general recombination (370,449).

A 50-kd homodimeric DNase with nicking and joining activity (275,326,409) was recently identified as the product of the *K4L* ORF (M. Merchlisky, Food and Drug Administration, personal communication) and is present in vaccinia virus cores. The nicking and joining reaction requires no energy cofactor and generates 3'-P- and 5'-OH-termini. When the purified

enzyme was incubated with concatemeric junction fragments, cleavage occurred at the apex of the cruciform instead of at the base, which would be necessary for telomere formation (409).

Most recently, a bacterial-type Holliday junction resolvase was found to be encoded by the *A22R* gene of vaccinia virus and homologs are present in all poxviruses (174). *In vitro,* the recombinant A22R protein can resolve synthetic Holliday junctions or cruciform structures extruded by a supercoiled plasmid. Furthermore, a vaccinia virus mutant in which the *A22R* gene was repressed is defective in concatemer resolution (175).

Homologous Recombination

High rates of recombination occur within poxvirus-infected cells (168). Recombination has apparently occurred naturally between two leporipoxviruses—Shope fibroma virus, which produces benign fibromas in rabbits, and myxoma virus, the agent of myxomatosis—to form malignant rabbit fibroma virus (63), and between individual capripoxviruses (179). Recombination between the terminal sequences of poxvirus DNA may explain variations in the number of tandem repeats and translocations. Most extraordinarily, field and vaccine strains of fowlpox virus carry a nearly full-length and apparently infectious integrated avian retrovirus genome (204).

Recombination can also occur between virus-derived genomic DNA and transfected subgenomic DNA fragments, and this has been exploited to map and construct mutations and to insert genes for expression. Viral genomes rapidly eliminate direct repeats with the formation of intramolecular and intermolecular recombination products (31). Single- and double-crossover products, resulting from recombination between transfected plasmids and viral genomes (497), and intermolecular and intramolecular plasmid or bacteriophage DNA recombinants (162,373) have been detected in poxvirus-infected cells. Recombination does not require late gene products, and there appears to be a strong connection between recombination and replication (323,551). After phage lambda DNA was transfected into Shope fibroma virus–infected cells, heteroduplex formation coincided with the onset of both replication and recombination, suggesting that poxviruses make no clear biochemical distinction between these processes (170). Evidence for DNA strand exchange catalyzed by proteins from vaccinia virus–infected cells has been reported, and a derivative of the T4-replication–primed recombination model has been suggested (576). The roles in recombination of the poxvirus encoded topoisomerase and Holiday junction endonuclease, discussed in the previous section, remain to be determined.

DNA Replication Model

Although there are large gaps in our understanding of poxvirus DNA replication, the unique terminal structure of the poxvirus genome, evidence that initiation occurs near the ends of the molecule, and the presence of concatemer junctions in replicating DNA suggest a model similar to that proposed for replication of single-stranded parvovirus DNA. As depicted in Figure 8, a hypothetical nick occurring at one or both ends of the genome provides a free 3' end for priming. The replicated DNA strand then folds back on itself and copies the remainder of the genome. Concatemer junctions form by replication through the hairpin; very large branched concatemers can arise by initiating new rounds of replication before resolution occurs. Recombinational strand invasion may further contribute to the formation of complex multibranched molecules. After the onset of late-stage transcription, unit-length genomes are resolved, and the incompletely base-paired terminal loops, with inverted and complementary sequences, are regenerated.

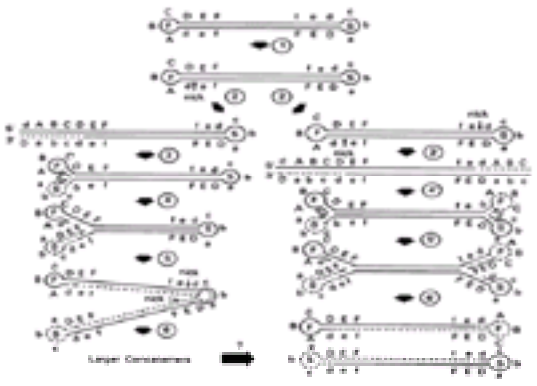

FIG. 8. Self-priming model for vaccinia virus DNA replication. *F* and *S* refer to the difference in electrophoretic mobilities of the two alternative inverted and complementary hairpin sequences present at the ends of the vaccinia virus genome. The scheme *on the left* assumes that the replication of a single DNA molecule is initiated at one end and continues to the other end to form a concatemer, whereas *on the right,* initiation occurs at both ends without concatemer formation. VIRION ASSEMBLY, MATURATION, AND RELEASE

Intracellular Mature Virions

Assembly begins in circumscribed, granular, electron-dense areas of the cytoplasm. The first morphologically distinct structure is a crescent (or cupulae in three dimensions) consisting of a membrane with a brushlike border of spicules on the convex surface and granular material adjacent to the concave side (Fig. 9, *panel 1*). Electron micrographs showing a single bilayer membrane with no apparent continuity with cellular organelles have been published by several groups (125,189,211). How such a membrane could form *de novo,* however, is unclear. One unprecedented and highly speculative possibility is the assembly of a protein lattice or scaffold with hydrophobic domains into which lipids could be deposited. An alternate view, more in line with cell biology, is that the viral membrane is composed of two tightly apposed membranes derived by a wrapping mechanism from the intermediate compartment between the endoplasmic reticulum

and Golgi network (434,492). A third scheme, in which vesicles bud from cellular organelles and then coalesce to form the viral membrane, is suggested by the accumulation of small vesicles in the viral factory area when morphogenesis is blocked by repression of the *A17L* (418,560) or *A14L* (419,520) genes. In subsequent stages of development, the crescent membranes are transformed into circular (or spherical in three dimensions) immature virions with a dense nucleoprotein mass embedded in a granular matrix (see Fig. 9, *panels 2 and 3*). Occasional electron-microscopic pictures suggest that the nucleoprotein enters the immature envelopes just before they are completely sealed (336). Further steps in maturation are inferred from selected images (see Fig. 9, *panels 4 to 6*).

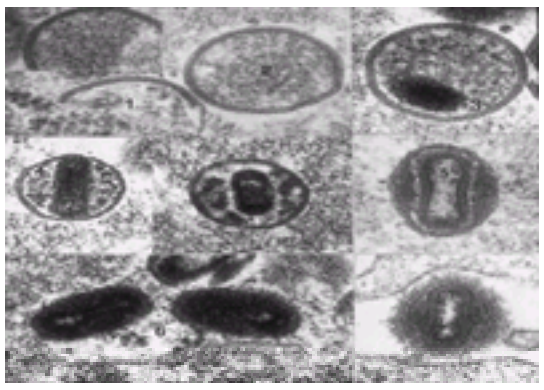

FIG. 9. Electron micrographs of developing and mature virus particles in thin section. (Courtesy of P. Grimley, Uniformed Services University of the Health Sciences.)

Studies of the early stages of morphogenesis have been facilitated by the combined use of drugs or conditional lethal mutants to arrest assembly and immunoelectron microscopy to locate viral proteins in the abortive structures. No viral membranes can be detected at their usual time of formation when viral DNA replication is stringently inhibited, consistent with the finding of late promoters on the membrane proteins. The earliest defect in morphogenesis occurs with a ts F10L kinase mutant (518,542). At the nonpermissive temperature, late viral proteins were made, but recognizable viral membranes were not seen. A similar phenotype was also described for a ts mutant in the *H5R* gene (139), which was surprising because other studies had indicated a role for this protein in RNA synthesis. When synthesis of the A17L or A14L proteins, which associate with each other, is repressed, small vesicles accumulate instead of a continuous membrane (418,419,520,560). There is, however, some difference in the locations of the vesicles that form with the two mutants and the block appears to be more stringent with the A17L mutant. Both the A17L and A14L proteins are phosphorylated apparently by the F10L kinase (55,143). In the presence of the antibiotic rifampicin, irregular viral membranes that lack spicules accumulate (345,358) (Fig. 10) Within minutes after removal of the drug, the membranes become spicule coated and assume a regular crescent shape (see Fig. 10), even in the presence of inhibitors of RNA or protein synthesis, suggesting that rifampicin directly interferes with assembly (189). The gene responsible for resistance of mutant viruses to rifampicin has been mapped to the *D13L* ORF, which encodes a 65-kd protein (30,509) that rapidly associates with the rifampicin body membranes after drug removal (332,493,534). When expression of the *D13L* ORF is repressed, morphogenesis of the viral envelope is blocked at the same stage as occurs with rifampicin (578). The 65-kd protein appears to concentrate on the inner side of the membrane, perhaps serving as a scaffold. A block at later stages, in which crescents and circular immature virus particles accumulated, occurred when expression of the A9L (572), L1R (406), or H3L (121,286) membrane protein was repressed.

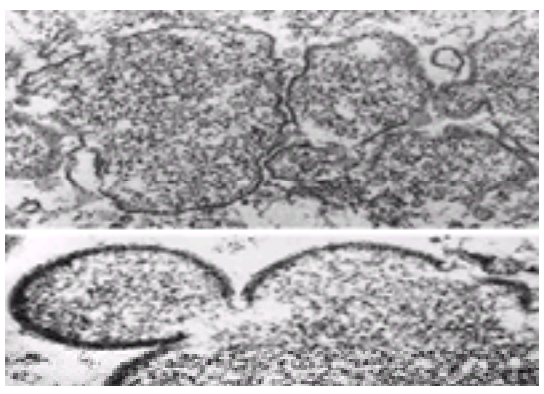

FIG. 10. Electron micrographs of thin sections of cell infected in the presence of rifampicin. **Upper panel:** HeLa cells were fixed and sectioned at 8 hours after infection in the presence of rifampicin. **Lower panel:** Cells were fixed and sectioned at 10 minutes after removal of rifampicin. (From ref. 189, with permission.)

Several vaccinia virus major core proteins have been detected within the immature particles visualized by immunoelectron microscopy (412,534) or isolated by sedimentation (442,535). Pulse-chase experiments indicated that several late polypeptides, including major structural proteins of the core, undergo proteolytic processing (343) at Ala-Gly-Ala/Ser motifs (280). Processing of the major structural proteins is coupled to virus assembly because their cleavage is prevented by rifampicin or mutants that interfere with early steps in morphogenesis (252). Repression of synthesis of certain core proteins, such as the F17R phosphoprotein or the I1L DNA-binding protein, halts assembly at an immature particle stage and prevents proteolytic processing (262,579). Under nonpermissive conditions, ts mutants with substitutions in the *I7L* ORF appear to be blocked at a slightly earlier stage, but protein processing was not examined (246). Repression of the *A32L* gene, a predicted ATPase, interfered with the packaging of DNA and led to the

formation of aberrant particles (95). The question of how the transcription apparatus becomes enclosed within the core of the assembling virus particle is intriguing. It seems unlikely that each enzyme has its own targeting signal. A clue to possible mechanisms was obtained by examining the noninfectious virus particles that formed when synthesis of RAP94, the RNA polymerase-associated protein that confers specificity for early promoters, was repressed. Such particles contained an apparently complete set of structural proteins as well as the early transcription factor VETF but lacked the viral RNA polymerase, poly(A) polymerase, capping enzyme, topoisomerase, NPH I, and NPH II (577). Such a specific effect could result if these proteins formed a complex that associates with promoter-bound VETF through RAP94. Evidence for an interaction between NPH I and RAP94 has been obtained (334). Reduced amounts of RNA polymerase in virions formed with a ts mutation in VETF (285) is also consistent with the latter model. Repression of synthesis of either subunit of VETF, however, leads to a more severe defect with accumulation of immature virus particles (221,222).

Because disulfide bonds usually form in the endoplasmic reticulum, the presence of intramolecular and intermolecular disulfides in cytoplasmic vaccinia virus core and membrane proteins (229,291,416,561) raise the possibility that poxviruses encode novel thiol oxidoreductases. Proteins with predicted C-X-X-C redox motifs include the vaccinia virus O2L and G4L glutaredoxins, which have been shown to have thiol transferase activities *in vitro* (9,195), and the E10R protein, a member of the eukaryotic ERV1/ALR family (450). Of these, the G4L and E10R proteins are conserved in all poxviruses and are essential for morphogenesis (452,547). Recent data suggest that the E10R and G4L proteins are components of a cytoplasmic disulfide bond pathway (453).

Occluded Virions

The IMV of some *Chordopoxvirinae* (e.g., cowpox, ectromelia, and fowlpox) become occluded in a dense protein matrix referred to as *A-type inclusions* to differentiate them from the sites of virus replication and assembly, which are sometimes called *B-type inclusions* (250). Presumably, the A-type inclusions are released into the environment after degeneration of infected cells. The major A-type inclusion protein of cowpox virus is a 160-kd species that may represent up to 4% of the total cell protein at late times after infection (172,377). Some cowpox virus mutants form inclusions without virions, implicating a role for the IMV-specific protein 4C (461,525). Although vaccinia virus does not form A-type inclusions, a smaller homologous protein is made because of a frameshift mutation (17,133). Both the cowpox and vaccinia virus inclusion proteins are myristylated (306).

The virions of *Entomopoxvirinae* are also occluded to protect them from the environment (51). After ingestion by a new larval host, infectious particles may be released in the alkaline pH of the gut. The sequences of homologous occlusion proteins, called *spheroidin* or *spherulin,* have been deduced from the ORFs of several entomopoxviruses (1,33,198,199,441). These proteins are cysteine-rich, about 100 kd, and lack homology to fusolin, the abundant 50-kd spindle-body protein of entomopoxviruses (127), the A-type inclusion protein of chordopoxviruses, or the polyhedrin protein of baculoviruses.

Extracellular Enveloped Virions

The movement of IMV out of the assembly areas to the cell periphery is microtubule dependent and requires the A27L membrane protein (438). The IMV become wrapped by additional membranes, derived from the trans-Golgi or early endosomal network, that contain viral proteins (206,230,336,443,516). Studies with mutant vaccinia viruses indicate that wrapping requires expression of at least one IMV membrane protein, the A27L 14-kd protein (417), and two EEV membrane proteins: the F13L 37-kd phospholipase (25,60,424) and the B5R 42-kd glycoprotein (156,558). Fusion of the wrapped particles with the plasma membrane results in the externalization of the virus, with loss of the outermost Golgi-derived membrane. Only some of the externalized virions are found in the medium as EEV, whereas the rest adheres to the cell surface (CEVs). The ratio of adherent to released virions varies with different cell hosts and different vaccinia virus strains (379), largely because of a single amino acid difference in the putative lectin-binding domain of the membrane protein encoded by the *A34R* ORF (62). The extracellular virions are important for virus dissemination (68,380). On cell monolayers, the CEVs can mediate efficient cell-to-cell spread and plaque formation, whereas the EEVs provide long-range dissemination (61).

The efficient cell-to-cell spread of CEVs appears to be due to their location at the tip of motile, actin-containing microvilli that have been visualized by fluorescence and electron microscopy (119,207,499). When the *A33R, A34R,* or *A36R* ORFs are not expressed, actin-containing microvilli are not formed, resulting in a small plaque phenotype (423,436,559,563). Nucleation of the actin tails depends on tyrosine phosphorylation of the A36R protein by Src-family kinases: the phosphorylated A36R protein interacts with the adaptor protein Nck, which results in the recruitment of the Ena/VASP family member N-WASP to the site of actin assembly (171).

VIRUS–HOST INTERACTIONS

Inhibitory Effects on Host Macromolecular Synthesis

Infection of tissue culture cells with vaccinia virus or other orthopoxviruses results in profound cytopathic effects (21), changes in membrane permeability (93), and inhibition of DNA, RNA, and protein synthesis. The effects on protein synthesis are dramatic (161,346). It seems likely that several factors may lead to the switch from host to viral protein synthesis and that the relative contribution of each factor may depend on the virus multiplicity, cell type, time of analysis, and use of metabolic inhibitors. Some experiments suggested that inhibition of host protein synthesis could occur in the absence of viral gene expression, thereby implicating a protein in the vaccinia virus particle. Candidate inhibitors are the surface tubules (313), the F17R phosphoprotein (389), and the B1R protein kinase (49). There is indirect evidence that some viral early proteins may allow translation of viral mRNA to continue under conditions that inhibit host protein synthesis (48,342). Other studies suggested that viral transcription is necessary for inhibition of host protein synthesis. For example, high concentration of actinomycin D and cordycepin prevented this inhibition (22). Also, in some cell lines, inhibition of host protein synthesis remains incomplete until after DNA replication. An inhibitory role for small poly(A)-containing RNA molecules was originally proposed to explain the effects on host protein synthesis that occur in

the presence of actinomycin D or by ultraviolet-irradiated virus (184,430). Subsequent reports, however, suggested that small poly(A)-containing RNAs may have an inhibitory role during normal virus infection (23,24,87). After several hours, most of the mRNA present in the cytoplasm of infected cells is viral, accounting for the predominance of viral protein synthesis regardless of translational effects (65,116). The shift in mRNA species results from the short half-life of all mRNAs following vaccinia virus infection (50,447), coupled with very active virus transcription and inhibition of host RNA synthesis and transport. Rapid degradation of actin and tubulin mRNAs has been demonstrated (411). Viral inhibitory effects on the synthesis or processing of cellular RNAs have been reported (50,239,447). This inhibition involves all classes of RNA and requires vaccinia virus protein synthesis; heated or ultraviolet irradiated virus was ineffective (384). The inhibition was correlated with the transit of RNA polymerase II activity from the nucleus to the cytoplasm (338,554). However, whole cell extracts of vaccinia virus–infected cells were no longer able to transcribe genes regulated by eukaryotic RNA polymerase II promoters, although they were still able to transcribe a polymerase III promoter (399). Nuclear DNA replication is also inhibited (144,244). Under certain nonpermissive conditions of vaccinia virus infection, the inhibition of host macromolecular synthesis may be accelerated. These situations include the restricted growth of vaccinia virus in Chinese hamster ovary cells, which can be overcome by the cowpox virus gene encoding a 77-kd protein (494); host range mutants of rabbitpox virus (351); and vaccinia virus K1L deletion mutants (185,387,503).

Stimulatory Effects on Cell Growth

Many poxviruses induce hyperplastic responses and even tumors in the skin of infected animals. These effects are pronounced with fowlpox virus (103), Shope fibroma virus (464), Yaba virus (364), and molluscum contagiosum virus (397). In the case of orthopoxviruses, the hyperplasia is due to secretion of a homolog of EGF (83,84,500). Leporipoxviruses have structural and functional homologs of EGF that are nonessential for replication in tissue culture but contribute to virulence (102,289,368). A gene encoding a mitogenic polypeptide with homology to mammalian vascular endothelial growth factor is present in the orf virus genome (555).

Viral Defense Molecules

Host immune responses can halt the spread of viruses and eliminate them. Immediately after virus invasion, nonspecific mechanisms involving interferons (IFNs), complement, cytokines, and natural killer cells predominate; subsequently, cytotoxic T cells and antibodies assume importance in defense (85). In response to these selective pressures, poxviruses encode multiple proteins that interfere with the induction or activity of complement and the principal cytokines (Table 5). The inhibitory proteins fall into three main classes: virokines, which are secreted from infected cells and resemble host cytokines or soluble immune regulators (268); viroceptors, which are altered cellular receptors that have lost their transmembrane anchor sequences and consequently are secreted from infected cells and sequester ligands (526); and intracellular proteins that interfere with signaling or effector pathways (407).

Virus protein	Role	Virus/Gene	Selected references
Secreted complement binding protein	Binds C4B, C3B; inhibits complement activation	Orthopox (VAC C3L)	236, 267, 268, 320, 433
Soluble IFN-γ receptor	Binds and antagonizes IFN-γ	Orthopox (VAC B8R); Leporipox (MYX M-T7)	12, 349, 350, 527
Soluble IFN-α/β receptor	Binds and antagonizes IFN-α/β	Orthopox (VAC B18R)	108, 504
Soluble TNF receptor	Binds and antagonizes TNF-α	Orthopox (CPV cmv5); Leporipox (MYX M-T2)	219, 293, 301, 485, 486, 526
Soluble IL-1β receptor	Binds and antagonizes IL-1β	Orthopox (VAC B15R)	10, 11, 496
Secreted IL-18–binding protein	Binds and antagonizes IL-18	Molluscipox (MC54L); Orthopox (ECTV v013/16)	67, 490, 569, 570
Secreted chemokine–binding protein	Binds and antagonizes CC chemokines	Orthopox (VAC 35 kD, Leporipox (M-T1)	13, 91, 186, 487
Secreted chemokine homolog	Binds and antagonizes CCR8	Molluscipox (MC148)	129, 279, 297
dsRNA-binding protein	Prevents activation of protein kinase PKR and 2,5A synthetase	Orthopox (VAC E3L)	45, 96, 190, 455
EIF-2α homolog	Inhibits protein kinase PKR	Orthopox (VAC K3L)	46, 54, 170
Caspase inhibitor	Inhibits caspase 1 to prevent processing of IL-1β and IL-18 precursors and procaspase 8 to block TNF and Fas-induced apoptosis	Orthopox (CPX crmA); Leporipox (MYX SERP2)	237, 265, 392, 407, 511, 581
Serine protease inhibitor	Inhibits serine proteases	Leporipox (MYX SERP1)	392, 393
FLIP (FLICE-like inhibitory protein)	Binds FADD and procaspase 8 to prevent TNF and Fas induced apoptosis	Molluscipox (MC159)	52, 220, 310
Glutathione peroxidase	Hydrolyzes peroxides from inflammatory cells or UV rays	Molluscipox (MC66)	469
Class I MHC homolog	Binds β2-microglobulin	Molluscipox (MC80R)	451

IFN, interferon; TNF, tumor necrosis factor; IL, interleukin; dsRNA, double-stranded RNA; EIF, eukaryotic translation initiation factor; FADD, Fas-associated death domain protein; FLICE, FADD-like IL-1β converting enzyme; MHC, major histocompatibility complex.

TABLE 5. *Poxvirus immune defense molecules*

Complement Regulatory Protein

One of the major secreted proteins of vaccinia virus consists largely of four, tandem, inexact copies of a 60–amino acid sequence known as the *short consensus repeat* (SCR) that is found in complement regulatory proteins (268). This vaccinia viral protein, called VCP, inhibits the classic and alternative pathways of complement activation through its ability to bind and inactivate both C4B and C3B (267,320,433) and contributes to virulence (236). B5R, an EEV membrane protein of vaccinia virus also has SCRs, but there is no evidence that it has complement inhibitory activity. Host proteins incorporated into the EEV membrane could also inhibit complement activation (531).

Inhibitors of Interferon and Interferon Transduction Pathways

Secreted proteins that bind to type I or II IFNs are encoded by poxviruses of several different genera. The IFN-g–binding proteins of myxoma virus (M-T7) and orthopoxviruses (vaccinia B8R) are similar in sequence to the extracellular domain of the IFN-g receptor and consequently bind IFN-g (12,350,527). Deletion of the gene encoding the IFN-g–binding protein of myxoma virus greatly attenuates disease in European rabbits (349). A protein from the supernatant of cells infected with tanapoxvirus has been reported to bind IFN-g and also interleukin-2 (IL-2) and IL-5 (157).

A type I IFN inhibitor is present in the supernatants and on the surfaces of cells infected with vaccinia and other orthopoxviruses (108,504). The protein has some sequence similarities with regions of cellular type I IFN receptor and binds IFN-a with high affinity but less species specificity than the receptors. Vaccinia viruses with a deletion of the type I IFN-binding protein gene are attenuated in mice, suggesting that the protein is a virulence factor.

Orthopoxviruses encode a double-stranded RNA-binding protein (e.g. vaccinia virus E3L) that prevents the activation of the IFN response protein kinase (PKR), which inhibits translation initiation (99,100,455). Vaccinia virus E3L deletion mutants show host range restriction and enhanced apoptosis, RNA degradation, and IFN sensitivity (45,258). Orthopoxviruses also encode a homolog of the translation initiation factor eIF-2a (e.g., vaccinia virus K3L) that inhibits eIF-2a phosphorylation by PKR (94,129). Deletion of K3L increases the IFN sensitivity of vaccinia virus (46). Therefore, the E3L and K3L proteins have overlapping roles in blocking IFN action.

Interleukin-18–Binding Proteins

IL-18 induces IFN-g production, acts in synergy with IL-12 to induces natural killer (NK) cell activation, T-cell activation and helper T-cell type 1 response polarization, and can protect mice from vaccinia virus infection (508). molluscum contagiosum virus (MCV) and orthopoxviruses encode secreted proteins that are homologous to the mammalian IL-18–binding protein and that bind IL-18 and block IFN-g production (67,490,569,570). An ectromelia deletion mutant induced elevated intraperitoneal NK cell activity and cytokine production and decreased virus replication compared with wild-type virus (67).

Tumor Necrosis Factor Receptor Homologs

Tumor necrosis factor (TNF) binds to its cognate receptors and induces proinflammatory responses or death of virus-infected cells. Leporipoxviruses (301,485,526) and orthopoxviruses (219,293,486) encode one or more soluble type II TNF receptor homologs that can block TNF-a–mediated cytolysis *in vitro* and attenuate virulence.

Interleukin-1 Receptor Homologs

IL-1b mediates a broad response to virus infection by binding to a high-affinity cellular receptor and triggering a signal transduction pathway. Orthopoxviruses encode homologs of the IL-1 receptor that bind IL-1b (11,496). Depending on the route of inoculation, deletion of the gene can reduce or enhance virulence (10,496). Frameshift mutations in the variola homolog preclude synthesis of an active protein.

SERPINS and Inhibitors of Cytokine Processing

IL-1b and IL-18 are produced by caspase-1 cleavage of inactive precursors. CrmA (also called SPI-2), a member of the SERPIN superfamily encoded by cowpox virus, was identified by its antiinflammatory properties and shown to inhibit caspase-1, a cysteine aspartic protease, and activation of IL-1b (265,407). An effect on activation of IL-18 is presumed, although it has not been shown directly. Further studies showed that CrmA protects cells against apoptosis by inactivation of additional caspases (581). Other orthopoxviruses and leporipoxviruses also encode CrmA homologs that inhibit caspase-1 (257,392). Attenuation of cowpox or rabbitpox viruses results from deletion of the *crmA* gene (515).

Orthopoxviruses and LeporIpoxviruses encode additional members of the SERPIN superfamily. SPI-1 and SPI-3 have been shown to complex with certain proteinases *in vitro,* but whether these proteinases are important targets *in vivo* is unknown (335,523). Deletion of SPI-1 causes a host range effect and nuclear changes but not other signs of apoptosis (335,462). Deletion of the *SPI-3* gene induces fusion of infected cells, but this activity does not require the SERPIN active site (523). Another SERPIN (SERP-1), encoded by leporipoxviruses, is secreted from infected cells, interferes with inflammation, and is required for virus-induced disease in rabbits (302). SERP-1 inhibits a number of serine proteases (plasmin, urokinase, tissue plasminogen activator, and a member of the complement cascade) *in vitro*, but whether any or all of these are significant biologic targets *in vivo* is unknown (292).

Chemokine Inhibitors

MCV encodes a CC chemokine homolog (MC148) that is predicted to be an antagonist based on the absence of the conserved N-terminal region (450). MC148 was found to bind specifically to the CCR8 chemokine receptor and to inhibit competitively the binding of I-309, the natural ligand (297). Other reports, based mainly on chemotaxis assays, suggest a broader activity (128,270).

Secreted proteins that bind to CC chemokines but lack sequence similarity to chemokine receptors are encoded by leporipoxviruses (M-T1) and orthopoxviruses (35-kd proteins) (13,91,188,487). These proteins prevent activation and chemotaxis of leukocytes. An influx of inflammatory cells into tissues infected with a rabbitpox virus 35-kd protein deletion mutant was described (188), although no difference in virulence was detected (309).

M-T7, the myxoma virus IFN-g receptor–binding protein, also interacts with chemokines but with low affinity through the heparin-binding site, suggesting that it could alter their tissue localization (276). The influx of leukocytes into tissues infected with a M-T7 deletion mutant could be due to loss of either the chemokine or IFN-g–binding activities.

Genes encoding homologs of seven transmembrane receptors have been identified in swinepox and capripox viruses (90,310), although their ligand-binding properties are unknown.

Apoptosis Inhibitors

CrmA was described previously as an inhibitor of caspase-1, the IL-1b–converting enzyme. However, CrmA and other orthopoxvirus homologs also block apoptosis activated through the Fas and TNF receptors (145,333,512) and potently inhibited caspase-8, the apical caspase in these pathways (581). CrmA also binds granzyme B, a serine protease associated with lytic granules released by cytotoxic T lymphocytes (CTLs) (400). It is difficult to evaluate the specific roles of CrmA during a natural infection. CrmA can protect target cells against Fas-mediated lysis by alloreactive CTLs

(300,512), but wild-type cowpox or ectromelia virus–infected target cells are not protected against lysis by class I major histocompatibility complex restricted CTLs (353). Although *crmA* deletion mutants replicate normally in most cell lines ithout inducing apoptosis, a cowpox *crmA* deletion mutant induced apoptosis in a pig kidney cell line but without affecting the virus yield (299,408). The effect on virulence caused by deletion of *crmA* or *SPI-2* has varied in different animal models (257,515).

MCV encodes two proteins with death effector domains (DEDs) (450). DEDs are also present in FADD and procaspase-8 and mediate their interaction after the binding of TNF or FasL to their receptors. One of these MCV proteins, MC159, binds FADD and protects transfected cells against death effector filament formation and apoptosis induced by Fas and other members of the TNF receptor superfamily (52,220,513,522). The role of the second DED-containing protein, MC160, is uncertain.

MCV encodes a selenocysteine-containing protein, MC66, that is homologous to cellular glutathione peroxidase and that can protect cells against the cytotoxic effects of hydrogen peroxide and ultraviolet (UV) irradiation (450,463). Peroxides may be formed by activated inflammatory cells and by UV light. A putative glutathione peroxidase is also encoded by fowlpox virus (2).

Ectromelia virus encodes a protein called p28 that contains a really interesting new gene (RING) finger motif that is required for virulence in mice (454) and that acts upstream of caspase-3 to block UV-induced apoptosis (69). Overexpression of the Shope fibroma virus RING finger protein N1R can also block apoptosis induced by UV light (70).

Several unrelated myxoma virus proteins prevent apoptosis. The protein encoded by the *M11L* gene localizes in the mitochondrial membrane and is required for virulence, to block myxoma-induced apoptosis of primary rabbit monocytes and staurosporine-induced apoptosis activation of caspase-3 (166,367). The M-T4 protein localizes to the endoplasmic reticulum of infected cells and is required for virulence and to prevent induction of apoptosis in a rabbit CD4+ T-cell line or primary rabbit lymphocytes (38,208). The M-T5 protein has a single ankyrin motif, is related to orthopoxvirus host range genes, and is required to prevent apoptosis in a rabbit CD4+ T-cell line (348).

CHOhr is a host range gene of cowpox virus that is disrupted or deleted from vaccinia virus strains and that is required for vaccinia virus replication in Chinese hamster ovary (CHO) cells (494). In the absence of the host range gene, there is a rapid cessation of host and viral protein synthesis and accelerated apoptosis in vaccinia virus–infected CHO cells (234,365,404). Apoptosis was induced at an unidentified viral postbinding step (403) and could be prevented by expression of the adenovirus *E1B-19K* gene or *Bcl2* gene in RK-13 (107,234).

The *E3L* gene of vaccinia virus was described previously as a double-stranded RNA-binding protein that protects against the action of protein kinase PKR and provides resistance to the action of IFN. *E3L* deletion mutants induced apoptosis in HeLa cells through failure to inhibit PKR (258,281).

EXPRESSION VECTORS

Several attributes of poxviruses have led to their extensive use as expression vectors (339). These include relative ease of formation and isolation of recombinant viruses, capacity for large amounts of DNA, relatively high expression, and wide host range. Expression has been achieved either by using poxvirus promoters or by employing bacteriophage RNA polymerases and cognate promoters. Recombinant viruses have been used for the synthesis of proteins *in vivo* or *in vitro* and as vaccine candidates.

CONCLUSIONS

The poxviruses are among the largest and most genetically complex of all animal viruses. Unlike most other DNA viruses, they replicate in the cytoplasm and encode many proteins that permit transcription and replication to occur outside of the nucleus. Gene expression is stringently regulated by a cascade mechanism, and virion assembly is a complex process that involves the formation of multiple membranes. Viral proteins are used for evasion of the host immune defense system.

CHAPTER 85 Poxviruses

Joseph J. Esposito and Frank Fenner

The *Poxviridae* family comprises two subfamilies of double-stranded DNA cytoplasmic viruses that infect arthropods (*Entomopoxvirinae*) or vertebrates (*Chordopoxvirinae*). Vertebrate viruses are brick-shaped or ovoid (Fig. 1). Currently, there are eight recognized genera of vertebrate poxviruses (Table 1), which lack immunologic cross-protection (158). Species within each genus have distinctive biologic traits and genome sequences and may differ in geographic distribution and host range. Some vertebrate viruses may spread systemically, producing generalized dermal lesions after aerosol droplet infection of the respiratory epithelium or infection of the skin by contact; others produce single or multiple localized skin lesions after contact with infected animals or humans, mechanical transmission by insects, or exposure to contaminated fomites.

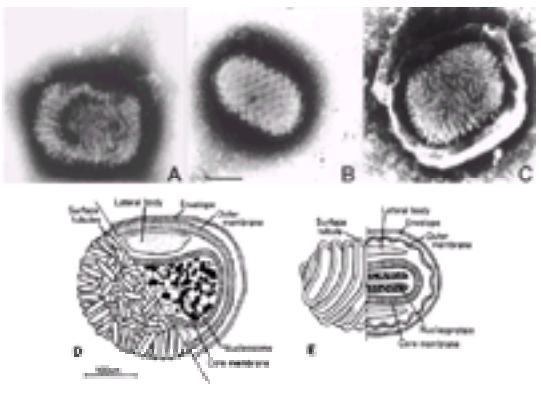

FIG. 1. Virion structure of orthopoxviruses (**A**), parapoxviruses (**B**), and yatapoxviruses (**C**) by negative staining and by diagram in **D** and **E.** The virion morphology of orthopoxviruses and yatapoxviruses is similar to the molluscipoxvirus (MCV; not shown)—intracellular mature virions (IMVs) are knobby and brick-shaped. Clinical material containing the yatapoxvirus tanapox virus often shows extracellular enveloped virions (EEV) (**C**); IMVs are more commonly seen in clinical material containing orthopoxviruses (**A**) or MCV. Parapoxviruses are ovoid and smaller, with a distinctive regular surface tubule that gives a criss-cross appearance (**B**). **D:** Drawing of brick-shaped virion, for example, vaccinia virus. Viral genome DNA and several proteins within the core are organized as a nucleosome. The core has a 9-nm thick membrane with a regular subunit structure. By negative staining, the virion core assumes a dumbbell shape with large lateral bodies occupying the concavities. The core and lateral bodies are enclosed within a lipoprotein shell, the outer membrane, which is about 12-nm thick. The outer membrane surface appears to consist of irregularly arranged surface

tubules, which produce the knobby or mulberry-like form. Most orthopoxvirus and MCV particles remain cell- associated and may be released by cytolysis; however, some virions may be released enclosed in an envelope (EEVs) composed largely of host cell Golgi membrane material associated with virus-specific proteins. **E:** Drawing of ovoid virion, for example, orf virus. The outer membrane consists of a single long tubule that appears to be wound around the particle. Negative-stained virions often show a criss-cross filament pattern as in **B**, because the opposing faces of the particle filament are visualized. The envelope is usually closely applied to the surface of the outer membrane (bars = 100 nm). (**A** courtesy of F.A. Murphy; **B** to **E** from ref. 73, with permission.)

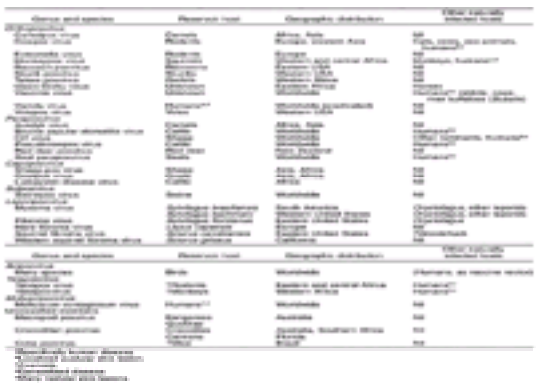

TABLE 1. *Host range and geographic distribution of genera and unclassified members of the subfamily Chordopaxvirinae*

Four genera contain species that may infect humans: *Orthopoxvirus, Parapoxvirus, Yatapoxvirus,* and *Molluscipoxvirus.* Four *Orthopoxvirus* species, three of which are zoonotic, may infect humans (162): (a) variola virus, the cause of smallpox, which is eradicated, is a strictly human pathogen producing a febrile pustular rash illness (72); (b) monkeypox virus, which is reported from nine West and Central African rainforest countries, mainly the Democratic Republic of Congo (DRC, formerly Zaire), is a zoonotic agent of a smallpox-like illness of low interhuman transmissibility (110); (c) cowpox virus is rodent-borne and indigenous to rodents in several European and a few western Asian countries, where humans appear to acquire a localized pustular skin infection by contact with infected rodents, or more likely, intermediate hosts, such as pet cats, cows, or other animals (9,40); and (d) the vaccinia virus subspecies buffalopox virus, which occurs mainly on the Indian subcontinent, causes localized oral or skin lesions after contact with infected dairy animals or drinking their milk (59,128). In addition, vaccinia virus strains used for smallpox vaccination form a dermal pustule and may cause postvaccinal side effects.

Members of the other two genera, *Parapoxvirus* and *Yatapoxvirus,* infect humans, usually as a zoonosis, and cause localized skin nodules. Three *Parapoxvirus* species may infect humans occupationally worldwide: (a) orf virus, which is transmitted by infected sheep, goats, or wild artiodactyls; (b) pseudocowpox virus (paravaccinia virus), which is transmitted by infected dairy cows, causing milker's nodule; and (c) bovine papular stomatitis virus, which is transmitted by infected beef cattle (192,193). Two species of *Yatapoxvirus,* tanapox virus and Yaba monkey tumor virus (YMTV), cause fever and localized single or multiple lesions after transmission, possibly by insects from infected African primates (57,109,198). Finally, molluscum contagiosum virus (MCV), the sole *Molluscipoxvirus,* is a strictly human virus that occurs worldwide, causing papular skin lesions by contact, sometimes sexually, and is an opportunistic infection in acquired immunodeficiency syndrome (AIDS) (13,183).

ORTHOPOXVIRUS INFECTIONS IN HUMANS

History

Smallpox

Fenner and colleagues (72) have provided a comprehensive description of smallpox and its eradication, and Hopkins (98) has described the historical, social, and political impact of the disease. Smallpox appears to have emerged some 5,000 years ago, presumably from wild animals, possibly by adaptation to an increasing human population of a rodent cowpox-like virus through an intermediate host such as cattle, which were domesticated some 12,000 years ago. The genome sequences of recent cowpox virus isolates appear to be the antecedents of those in other orthopoxviruses (204); including b-1 phylogeny inference of sequences for the hemagglutinin protein (Fig. 2). Moreover, a sign that the progenitor of variola virus was rodent-borne, like cowpox virus, appears in its DNA sequences (145), which encode three orthologs of the murine interstitial A-particle, long terminal repeat-promoted, placental-expressed (MIPP) protein.

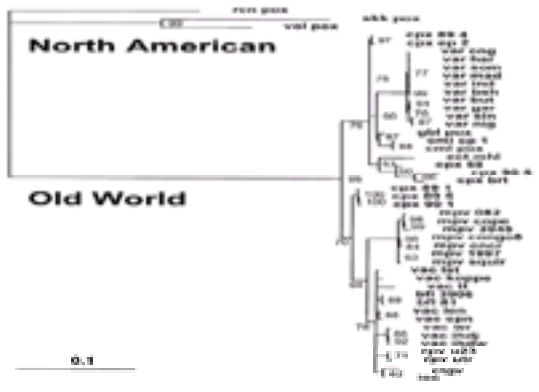

FIG. 2. Inferred phylogeny of orthopoxviruses. The open reading frames (~971-bp) coding for the hemagglutinin (HA) protein of different orthopoxviruses were compared by constructing an unrooted tree (S. Ropp, J. Esposito, et al., unpublished) using aligned (ClustalX) base sequences for input into the maximum likelihood software Puzzle 4.02 (218), opting for the Hasegawa model of substitution, neighbor-joining, a uniform rate heterogeneity model, raccoon poxvirus as the outgroup, and 100,000 tree-puzzling steps to obtain quartet maximum likelihood trees and a quartet puzzling tree with statistically significant taxon partition frequencies; the scale represents relative genetic distance. Virus sequences used for the analysis were the North American isolates raccoon poxvirus (*rcn-pox*); skunk poxvirus (*skk-pox*); and volepox virus (*vol-pox*), and the following strains or isolates of Old World orthopoxviruses: ectromelia mousepox Mill Hill (*ect-mhl*); cowpox from animals or humans (*cpx-89-1, cpx-89-4, cpx-89-5, cpx-90-1, cpx-90-5, cpx- ep-2, cpx-58*), and cowpox Brighton (*cpx-brt*); human monkeypox from West Africa (*mpv-082, mpv-3945, Congo-8, mpv-1997*), from an African squirrel (*mpv-squir*), strain Copenhagen (*mpv-cope*), and a red pock mutant of Congo-8 (*mpv-cncr*); vaccinia strains Lister (*vac-lst)*, Statens Serum Institute Copenhagen (*vac-koppe*), Lenny (*vac-len*), Copenhagen GenBank No. M35027 (*vac-cpn*), Western Reserve (*vac-wr*), International Health Department vaccinia variants (*vac-ihdw* and *vac-ihdj*), Chinese TianTan (*vac-tt*), rabbitpox Utrecht (*rpv-utr*), mutant rabbitpox (*rpv-u23*), buffalopox isolates (*bfl-3906* and *bfl-81*), the Brazilian smallpox vaccine strain (*ioc*), and a recent vaccinia-like isolate from Brazilian cattle and infected farmers (*ctgv*); variola virus isolates Congo (*var-cng*), Harvey (*var-har*), Madagascar (*var-mad*), Somalia (*var-som*), Bangladesh (*var-bsh*), India (*var-ind*), Butler (*var-but*), Brazil-Garcia (*var-gar*), Nigeria (*var-nig*), Sierra Leone (*var-sln*); Dahomey, Africa *Tatera kempii* gerbilpox (*gbl-pox*), and camelpox from Somalia (*cml-pox*) and Iran (*cml-cp-1*). Except for ioc and ctgv (sequences courtesy of N. Moussatché), the origins of the viruses are described elsewhere (62,125,154,181,196).

The earliest descriptions of smallpox date to western Asia and India about 3,000 years ago. By 700 A.D., smallpox had spread to China and Japan in the East and Europe and Northern Africa in the west. New World colonization provided for devastating transmission among Amerindians after introduction of the disease into the Caribbean by African slaves in 1518, with spread to Mexico and Peru by 1524, and its independent introduction from Africa into Brazil in 1555. From 1617, there were repeated introductions into North America from Europe and to a lesser extent from Africa, where slave trade had spread smallpox south of the Sahara in the 16th and 17th centuries. In 1713, infected travelers on a boat from India introduced smallpox into South Africa, and in 1789, Macassan visitors to northern Australia were likely the source of an epidemic among Aboriginals near the first European settlement in Sydney a year after the First Fleet arrived (32).

About 1000 A.D., smallpox spawned one of the first effective preventative measures for an infectious disease—immunization by intranasal insufflation of dried smallpox scab material in China, and in India the more popular practice of “inoculation” or “variolation,” which used pustule fluid or scab material applied variously into the skin. Such operations produced smallpox if the material contained active virus, but for unclear medical reasons, the consequent illness produced case fatalities of up to 2% rather than fatalities of up to 30% after natural infection usually acquired by aerosol droplet. The incubation period of variolation smallpox was much shorter than the 12 to 14 days normally associated with the appearance of the rash after a natural infection, and the rash often resolved more rapidly. Variolation did not change the virulence of the virus because contacts of mild cases of inoculation smallpox may have had severe illness and died. Despite the risks, the small-scale practice of variolation, which was used for several centuries in China, India, and western Asia, was introduced into Europe by the early 1700s and became common in some countries, notably England.

In 1798, following on folk medicine, which recognized that milkmaids who acquired cowpox were resistant to smallpox, Edward Jenner demonstrated protection from variolation by prior inoculation using cowpox lesion material, or as he called it, *variolae vaccinae* (smallpox of the cow) (108). The milder procedure, termed *cowpoxing,* was at first renounced by entrepreneur variolators, but it eventually became popular. By the late 19th century, vaccinia virus became the component virus in vaccine used virtually everywhere, but the historical details that changed the immunizing agent and the origin of vaccinia virus are obscure (8,92).

In time, health services improved and vaccine production became more scientific. By the 1950s, most industrialized countries had eliminated endemic smallpox by using vaccine prepared on the skin of cattle or sheep and suspended in bactericidal concentrations of glycerol. By the middle of the 20th century, freeze-dried vaccine became available. The availability of such a vaccine facilitated vaccination programs in remote smallpox-endemic countries, which was a key element of a Russian proposal by Viktor Zhdanov at the 1958 World Health Assembly (WHA) that the World Health Organization (WHO) should intensively pursue global eradication by mass vaccination (72).

Although smallpox was eliminated in several developing countries by 1965, it became clear that something more was needed, especially for the Indian subcontinent and sub-Saharan Africa. In 1966, WHO launched an intensified eradication program that paid special attention to vaccine quality control, surveillance and containment, a capacity for reliable diagnosis, and further research. Eradication was greatly enhanced by increased use of the surveillance and containment method, as eloquently demonstrated by William Foege and colleagues in West Africa. The method is sometimes referred to as *ring* vaccination, by which known and potential contacts of identified cases are immunized to contain an outbreak instead of using the more resource-demanding mass vaccination (54). By the mid-1960s, the use of the bifurcated needle for intradermal vaccination led to more efficacious vaccination by unskilled health workers and further augmentation.

By setting eradication priorities, the disease was gradually eliminated, country by country, continent by continent. The global collaborative efforts, especially those of Donald A. Henderson and colleagues, who facilitated the WHO program, saw the last natural case (a cook, Ali Maow Maalin) in Somalia in October 1977, and in 1979, the world was declared smallpox free (238). Routine smallpox vaccination of civilians was discontinued worldwide by 1982, although in the United States, routine vaccination of civilians had been stopped by 1971, except for travelers who could receive vaccine

until the late 1970s if going to endemic countries, and the U.S. military, which ended vaccination of recruits in 1990.

With smallpox eradicated, and after a tragic episode in 1978 involving an accidental lethal infection of Janet Parker, a medical photographer at the University of Birmingham, England, WHO initiated an effort to prevent reappearance of the disease by recommending that research on variola virus in laboratories, the only known source of the virus, should stop, and that all known variola virus samples should be sent to selected reference centers or destroyed (240). Beginning in 1982, a succession of recommendations were put forth by WHO to destroy the known variola virus samples after WHO had validated that the only known collections were at WHO Collaborating Centers in Atlanta at the Centers for Disease Control and Prevention (CDC) and in Moscow at the Research Institute for Viral Preparations (in 1994, the Russian government moved the samples from Moscow to the State Center for Virology and Biotechnology in Koltsovo). WHO itself delayed destruction several times, recommending that DNA cloning and sequencing of selected strains should be done to archive the genetic information of variola virus.

In the late 1980s, opposition to destruction surfaced, and WHO decided that the proposition should be vetted in the biomedical arena. As destruction issues were debated, they gained increasing public visibility, and intelligence agencies, mainly in the United States and the United Kingdom, voiced concerns that the collections would be needed for defensive research, because of a potential for bioterrorism that used possible clandestine sources of the virus. The probability of clandestinely held virus specimens was disclosed by a Russian official, Kanatjan Alibekov, who indicated after his defection that until the early 1990s, a civilian agency known as the Biopreparat in the former Soviet Union worked with the virus and the Russian military had weaponized the virus in a secret offensive biowarfare program (6). There are suggestions that Russia and some other countries may secretly retain the virus (6,93).

Essentially two scenarios developed over the WHO proposition for eliminating the known variola virus samples. Destruction proponents (141) raised the specter of undoing eradication by asserting that the risk of retaining the specimens in an unvaccinated world far outweighed any medical benefits from research using the virus, which produces its true pathologic effects only in humans; that the repository samples could be targeted by terrorists; and that the virus had a record of infecting laboratory workers, posing a biohazard. To address the possibility of bioterrorism, they argued that destroying the samples under aegis of the WHA would send a signal that such reprehensible acts are intolerable by all governments.

Destruction opponents (113,194) submitted that retention would offer otherwise unattainable advances, including more fully understanding the molecular basis of variola virus infection, which would allow development of antiviral drugs, particularly for immunocompromised people who could not be vaccinated if smallpox somehow reemerged. They contended that a broader knowledge would provide the best strategies to defend against malevolent use of the virus and that working with the virus in maximum containment facilities using vaccinated staff minimized the biohazard risk. In light of the smallpox bioterrorism potential, a pivotal argument for retention came to be antiviral drug research, which was fueled by an observation that some of the acyclic nucleoside phosphonates, including, 1-[(S)-3-hydroxy-2-(phosphonomethoxy)-propyl] cytosine (Cidofovir, Vistide), a DNA-polymerase inhibitor sponsored by the U.S. Food and Drug Administration to treat cytomegalovirus infection, suppressed variola virus growth in culture and inhibited certain orthopoxvirus diseases in experimentally infected animals (22,104). On the other hand, proponents advanced the position that rebuilding stockpiles of smallpox vaccine and human vaccinia immune globulin (VIG) and destroying the specimens would virtually eliminate the biothreat potential (93).

Although the United States had supported a WHO recommendation for destruction in 1996, on April 22, 1999, President William Clinton announced that the specimens at CDC would be retained for research that may help save lives should the disease somehow reemerge. The announcement followed an analysis by various U.S. government agencies and publication of a study by the U.S. National Academy of Sciences, Institute of Medicine, entitled “Assessment of the future scientific needs for live variola virus,” which recommended areas for research using live variola virus, considering the biothreat potential (104).

In May 1999, the 52nd WHA recommended postponement of destruction (240). Although destruction of all variola virus samples remains the goal of WHO and all WHA Member States, the destruction of the collections was delayed by the WHA to enable further internationally approved research on antiviral agents and improved vaccines and to permit high-priority investigations of variola virus genetic structure and its pathogenesis, in monkeys, a yet unproven surrogate system. In December 1999, poxvirus experts from several WHO regions assessed U.S. and Russian variola virus research agendas with the aim of reaching a global consensus on the timing of destruction, and early in 2000 and 2001, specific studies began using live variola virus in maximum containment laboratories of the WHO Collaborating Centers in Atlanta and Koltsovo, respectively.

Many experts on terrorism agree that the chance of smallpox reappearing is miniscule, but the consequences of a reappearance in humans would be enormous (93). In this light, the United States and several other countries set out to increase public awareness, revamp national policies, and improve the public health and emergency response infrastructure by strengthening national, state, local, and military defenses and promoting global condemnation of the malevolent use of variola virus and other agents of biologic and chemical terrorism.

Cowpox

Years before Edward Jenner's observations, cowpox was regarded as a sporadic disease of European cows, occurring as ulcers that could be transmitted from the teats onto the hands of milkers. Jenner's observation that milkmaids who had recovered from cowpox did not contract smallpox led to the practice of cowpoxing as a specific prophylactic against smallpox (108) until it was superseded by vaccination using vaccinia virus. Since the early 1970s, observations of cowpox in large cats in the Moscow Zoo in Russia and Whipsnade Park in England, and in domestic cats in England, led to conclusions that the cow is an ancillary host of cowpox virus and that cows, cats, foxes, and various zoo animals are sporadically infected from a rodent reservoir (40). Moreover, humans are probably infected by contact with intermediate infected animals, especially domestic cats, and not the rodent source (9). Support for indigenous rodents being the

reservoir derives from serosurveys of rodents, cattle, and humans, the fact that the virus remains indigenous to Eurasia, and that it has never appeared in exported cattle as has pseudocowpox, which is maintained by the bovine reservoir.

Vaccinia

The term *vaccination* (vacca, Latin for cow) was introduced in Plymouth in 1803 by Richard Dunning to describe the Jennerian method, and in 1881, Louis Pasteur honored Jenner by adopting the term to refer to *all* immunization methods. Jenner's writings indicate that although he had used cowpox lesion material initially, he also succeeded using lesion material from a now extinct equine disease “grease” because even then, cowpox rarely occurred. Over time, whichever virus it was that he and other vaccinators had used became passaged many times and in many ways, including in various animals and arm-to-arm in humans, probably also in smallpox patients; the passaging led to what is now regarded as a different species, vaccinia virus. Eventually, the selection of vaccinia strains that caused less fever, pain, and complications led to the strains now used (8,88,92,188,236). Sequencing of cowpox, variola, vaccinia, and monkeypox virus genome DNAs has substantiated that cowpox virus contains the most comprehensive set of genes, thus is the likely progenitor of contemporary orthopoxviruses, but it has not shed much light on the origin and derivation of vaccinia virus.

Lyophilized smallpox vaccine had several properties that made it one of the most successful vaccines in history, including its relative stability, ease of production and administration, and capacity to induce durable cellular and humoral immunity. Although recombination of DNA from one poxvirus into another had been reported beforehand, in 1982, marker rescue by recombination and expression of rescued sequences of other organisms by using vaccinia virus was described (139,173). The publications set the stage for development of vaccinia and other poxviruses into genetically engineered expression vectors, which have become widely used experimental tools, particularly in immunology and vaccinology (12,34,77,156,157,174,185).

Currently, in the United States, it is recommended that laboratory and health care workers at high risk for infection by human orthopoxviruses should be vaccinated within 10 years of their use (37; update available at http://www.cdc.gov/). In the United Kingdom, the decision to vaccinate is made on a case-by-case basis (2). Other countries have devised recommendations based on the U.S. and U.K. versions.

On teats of milking buffalo and dairy cows, a vaccinia subspecies, buffalopox virus, causes lesions that are similar to cowpox ulcers. Human skin lesions appear more like vaccinia pustules rather than the more severe lesions of human cowpox; oropharyngeal lesions also occur in humans, mainly by drinking unpasteurized milk from infected animals (128). DNA studies have suggested that buffalopox virus is related enough to vaccinia virus that it is a subspecies (59). Presumably, buffalopox emerged as a result of mass vaccination by transmission of human vaccinia to milking animals; outbreaks still occur in milking buffalo and cattle on the Indian subcontinent (161). Another vaccinia subspecies is rabbitpox virus, which has caused outbreaks of generalized disease in laboratory rabbits (171).

Monkeypox

Jezek and Fenner have extensively described monkeypox (110). In 1958, during days when subhuman primates from various parts of the world were mixed together in holding facilities to fill demands for polio vaccine, monkeypox was first reported as a disease of Asian cynomolgus monkeys. Monkeypox outbreaks with animal fatality rates of 3% to 48% continued to occur in several holding facilities during the 1960s, but no infections were reported among animal handlers, likely because they had preventative smallpox vaccination.

In 1970, the African origin of the disease became apparent when it was recognized that monkeypox virus caused a smallpox-like disease in humans in the DRC, and no such disease occurred in Asia. Since then, the illness has been observed as a rare zoonosis with low interhuman transmission among inhabitants of small villages in tropical rain forests in West and Central Africa. Because of the close resemblance between smallpox (Fig. 3) and human monkeypox (Fig. 4), following the declaration of smallpox eradication and recommendation to stop smallpox vaccination, WHO conducted a largely prospective intensified surveillance in the DRC from 1981 to 1986 that was aimed at determining whether human monkeypox could replace smallpox and pose a threat to eradication. The study identified 338 cases (86% under 10 years of age), including 33 deaths in five DRC provinces; 72% of cases were suspected to have acquired the disease from animals (Fig. 5). The number of first-generation cases among contacts not vaccinated against smallpox, which is protective, indicated a secondary attack rate of 7.5%, compared with the substantially higher 60%-on-average, secondary attack rate of smallpox. Ecological and serologic studies suggested that monkeypox virus has a broad host range, humans and primates being fortuitously infected, and that squirrels (*Funisciurus* species and *Heliosciurus* species), a usual food of the inhabitants, are involved significantly as wildlife hosts of the virus. It was concluded that monkeypox was a rare zoonosis that did not jeopardize eradication, primarily because of the relatively low secondary attack rate, the apparent low percentage of secondary cases (28%), and an infrequent finding of clusters of cases. Thus, monkeypox virus seems to be like cowpox virus, which is geographically confined to indigenous animals and not well adapted for interhuman spread.

FIG. 3. The rash of smallpox. The “smallpox recognition card” used during the Intensified Smallpox Eradication Programme of the World Health Organization, showing the nature and distribution of the rash of discrete, ordinary-type smallpox. (From ref. 72, with permission.)

FIG. 4. Human monkeypox. Front and rear views of a 7-year-old girl from the Democratic Republic of Congo with monkeypox, on the 8th day after the appearance of the rash. Note the enlargement of the cervical and inguinal lymph nodes, a feature not seen in smallpox. (From ref. 23, with permission.)

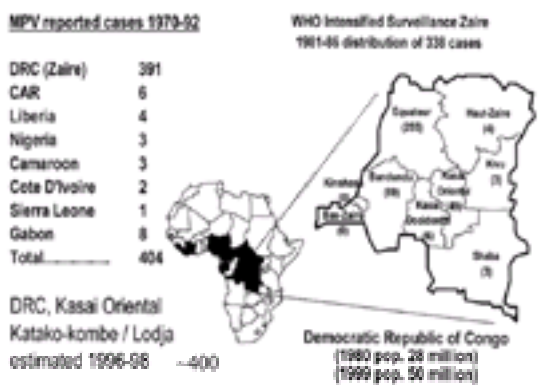

FIG. 5. Geographic distribution in West Africa rainforest countries of human monkeypox showing the location and number of cases verified mostly prospectively between 1970 and 1992. No cases were reported from 1993 to 1996 before limited retrospective studies in 1997 and 1998 in 78 villages of the Katako-Kombe and Lodja health zones, Kasai Oriental Province, DRC.

Few cases were reported after the intensified surveillance; however, in 1996, from February to August, 71 suspect cases, including 6 deaths, were reported from the DRC Kasai Oriental Province during heightened civil and military unrest in the country (159). Because of the unrest and consequent difficulty of obtaining prospective data, WHO conducted only three brief surveys using retrospective surveillance methods to obtain incidence estimates, two in 1997 and one that provided little data in 1998 (38,39,96). A review of the studies (241) indicated that retrospective case determination was obscured by a lack of surveillance continuity, use of disparate case definitions with attendant recall prejudices, and biases in case selection, ascertainment, and classification, particularly because of co-circulation of chickenpox, which is variably confused with human monkeypox. Given the limitations of such studies, laboratory test results of clinical samples from surveys in February and October, 1997 provided an estimate that just over half of 511 reported cases with febrile vesicular rash illness between February 1996 and October 1997, which were mostly children under 16 years of age, were most likely monkeypox. A secondary attack rate of 8% was estimated that was very much like the rate reported for 1981 to 1986. The review (241) concluded that human monkeypox is increasing in the region for various reasons, but the disease continues to be unsustainable by interhuman transmission and depends on repeated introductions from the animal reservoir; monkeypox still poses no threat to smallpox eradication. In addition, prospective intensified studies were encouraged, realizing that this would require a better public health system in the DRC and development of more specific and sensitive diagnostics. As in the 1980s, continued health education, and not reintroduction of smallpox vaccination, was recommended for disease prevention.

Infectious Agents

Several books and monographs about orthopoxviruses are available (12,49,74,143,227) (see Chapter 84). Descriptions of the biologic properties and the lineages of several vaccinia and variola virus strains are also available (68,88,188,236,237); most research is done using vaccinia virus.

Orthopoxviruses are large, brick-shaped particles (see Fig. 1) that replicate in the cytoplasm to produce intracellular mature virions (IMVs), which are released upon cytolysis. Some species (cowpox, ectromelia, raccoonpox, skunkpox, volepox) also occlude virions within cytoplasmic acidophilic-type inclusion (ATI) bodies, which may be protective. Poxviruses also have a method of viral dissemination from the cell in which a small proportion of IMVs become wrapped in an additional lipoprotein layer and released as extracellular enveloped virions (EEVs). Additionally, poxviruses may spread by enabling cell fusion, a feature that is influenced in orthopoxvirus-infected cells by several components,

including the viral hemagglutinin (HA) and a protein, termed SPI-3, with amino acid sequences resembling serine protease inhibitors.

To initiate infection, an IMV attaches to a cellular receptor, and the viral outer membrane fuses with the plasma membrane bilayer to enable release into the cytoplasm of the viral core complex containing the genome. During penetration of the virus into the cytoplasm, in the first stages of virion uncoating, a virion-associated RNA polymerase complex initiates transcription of the genome. Most cell functions shut down as the core elements become further dissociated and virus components become established in a cytoplasmic region of granular endoplasm termed the *viroplasm* or “viral factory,” which is devoid of ribosomes and organelles. In the viroplasm, the genome is replicated and progeny are assembled; the region comprises a basophilic inclusion. On the other hand, EEVs appear to attach to a distinct receptor and enter the cell by endocytosis or engulfment, forming a plasma membrane endosome in which the EEV tegument dissolves. In the endosome, the outer membrane of the tegument-less virion, like IMV, fuses with the enclosing plasma membrane, releasing the core into the cytoplasm (212).

As viral proteins become synthesized, morphogenesis of progeny virions initiates in the viroplasm by the formation of cup-shaped lipid bilayers (crescents in two dimensions) that contain, on the convex surface, spicules of viral protein. The membrane finally closes to form the outer membrane of a spheroidal immature particle (IV). For several years, the cup-shaped membrane was believed to originate by *de novo* synthesis because extensive electron microscopy studies indicated no connections between the lipid bilayer and cellular membranes (49). Recently, the outer membrane was suggested to originate from a tightly opposed pair of cell membranes in an intermediate compartment that is situated between the Golgi apparatus and the endoplasmic reticulum (213). The membrane pair was suggested to form the outer membrane by wrapping around the core and overlapping itself, like a macaroni shell. More recently, however, the seminal data (49) were substantiated by high-angle tilt electron microscopy observations of discontinuity between the viral and cellular membranes and detection of IV formation distal to the intermediate compartment, including in the nucleus (97).

The IVs mature into more complex structures containing a distinct nucleoprotein core that is not enclosed by a separate membrane (97) and appears dumbbell shaped in thin sections (49). Fully developed IMVs contain about 100 viral proteins, are infectious, and eventually are released by cytolysis. Before cytolysis, a minor portion of IMVs in the trans-Golgi network or tubular endosomes become further wrapped in a double lipoprotein layer. This production of intracellular enveloped virions (IEVs) appears to enable cellular actin polymerization behind the IEV, producing virus-tipped comet-shaped structures, which move erratically to the cell surface, where individual virions can be seen moving into separate microvilli (47). A microvillus may connect to an adjacent cell enabling virus transfer. The Golgi-derived lipid bilayer envelope of the IEV may also fuse with the plasma membrane in an exocytotic process that releases EEVs wrapped by the proximal layer. A portion of the EEVs may adhere to the plasma membrane as cell-associated enveloped virions (CEVs) (16). IEVs without actin tails may also reach the cell surface to become EEVs or CEVs, and some IMVs may become enveloped in some cells by budding (226). The envelope of the EEV contains about a dozen proteins, including viral and host complement control proteins that may inhibit virolysis. The envelope contains an HA glycoprotein, which is also intercalated into the plasma membrane of infected cells and antigenically distinguishes orthopoxviruses from other genera (206,212).

Neutralizing antibodies, as measured by standard pock- or plaque-reduction tests, block penetration of IMVs into cells, but these antibodies are ineffective in preventing EEV spread. Several studies have emphasized the importance of EEVs for spreading virus in culture and throughout the body, and the distinctive role of antibodies against envelope proteins, which are antibodies that aggregate rather than neutralize EEVs, preventing their release from the cell surface. Such antibodies may protect EEVs from IMV-neutralizing antibodies, but *in vivo,* the antibodies may augment cell-mediated clearance (212).

Orthopoxviruses, like other genera, contain a covalently closed, double-stranded DNA genome. Orthopoxvirus DNAs range in size from 170 to 240 kilobase pairs (kbp) and are composed of 34% G+C. DNA restriction mapping (62,138) has shown that 90 kbp composing the central region of the genome is highly conserved among species and strains and that the terminal regions are varied. DNA sequencing has shown that central region genes mostly specify virion structural components and enzymes associated with viral mRNA transcription and DNA replication. The terminal regions primarily specify genes associated with virus survival in the host, for example, genes for modulating immunopathogenesis and host range. To date, GenBank contains all or nearly all of the genome DNA sequences for several orthopoxviruses (in parentheses—accession number; reported sequences), including vaccinia strains Copenhagen (M35027; 191,737 bp), Tian Tan (AF095689; 189, 274bp), and Modified Virus Ankara (U94848; 177,923 bp), variola strains Bangladesh-1975 (L22579; 186,103 bp, fully sequenced), India-1967 (X69198; 185,575 bp), and alastrim Garcia/Brazil-1966 (Y16780; 186,986 bp). Additionally, large DNA segments of cowpox virus GRI-90 are reported (Y11842, Y15035, X94355), as are significant portions of other variola strains (U18337, U18338, U18339, U18340, U18341) and vaccinia strain Western Reserve (WR).

Among poxviruses, only members of the genus *Orthopoxvirus* produce an HA protein. Based on this trait, Esposito and colleagues have used HA sequences of several species and strains to estimate the phylogeny of orthopoxviruses (see Fig. 2). The estimate agrees well with phylogeny assessments based on dissimilarities of restriction maps (72,110) and coincides with the organization of orthopoxviruses by biologic criteria. The phylogram in Figure 2 shows a considerable divergence (75% sequence identity) between Old World orthopoxviruses and isolates from North America. The Old World species are 95% identical in sequence. The tree suggests that vaccinia and monkeypox viruses are more closely related to ectromelia virus, which itself appears related to a major clade of cowpox virus. Tatera gerbilpox, camelpox, and variola viruses appear more related to another major clade of cowpox viruses.

In the diagnostic laboratory, several of the biologic properties of human orthopoxviruses (Table 2) are useful for identifying and differentiating virus in lesion material (73), although polymerase chain reaction (PCR) amplification with or without restrictase cleavage of amplicons is proving to be more rapid and sensitive for routine diagnostic purposes (195). In experimental animal systems, infection by one orthopoxvirus species usually leads to protection against the others because of high antigenic similarity; the sera of animals infected with orthopoxviruses cross-react extensively.

Cross-absorption of immune sera against one species with antigen preparations of one or two other species has been used to resolve type-specific antigens (63,82,83,102,246); in one study (64), a predominant 73-kd viral protein was detected in variola-, vaccinia-, or monkeypox-specific immunoprecipitates.

Property	Variola	Monkeypox	Vaccinia	Cowpox
Host range	Narrow	Broad	Broad	Broad
Pocks on the chorioallantoic membrane (CAM)	Small, opaque, white	Small, opaque, hemorrhagic	Strains vary; large, opaque, white or hemorrhagic	Large, hemorrhagic
Ceiling growth temperature on CAM (°C)	37.5–38.5	39	41	40
Rabbit skin lesion	Small, transient, nontransmissible	Indurated, hemorrhagic	Strains vary; indurated nodule, sometimes hemorrhagic	Large, indurated hemorrhagic
Lethality for:				
Mice	Low	High	High to very high	Variable
Chick embryo	Low	Medium	Very high	High
A-type inclusion bodies	No	No	No	Yes
B-type inclusion bodies	Yes	Yes	Yes	Yes
Genome DNA size (kbp)	186	191	192	220

TABLE 2. *Biologic properties of orthopoxviruses that can infect humans*

Pathogenesis

In experimental monkey infections, variola and monkeypox viruses may induce systemic illness with fever and rash, generally resembling that in humans (see Fig. 3 and Fig. 4), although virulent human variola strains often produce an attenuated infection with reduced transmissibility (72,110). Cowpox and vaccinia viruses usually produce a localized dermal lesion with rare systemic complications after infection, the cowpox lesion being more severe in humans (74).

Generalized Infections with Rash

The developmental phases and physical appearance of smallpox is described in several publications (54,72,186,190). Our understanding of some details in the course of events can be derived from studies of monkeypox in monkeys with generalized disease (42), rabbitpox infection of rabbits (171), and ectromelia virus in mice (70). Careful autopsies of people who died of other causes during early-stage smallpox were rarely performed, and it was difficult to assess from postmortem examinations of acutely fatal cases the location(s) in the body that the virus multiplied before secondary viremia and concomitant prodrome symptoms began. The pathogenesis of monkeypox in humans probably is similar to that of smallpox, except that viral entry in primary infections from a wildlife source probably occurs through small lesions on the skin or oral mucous membrane, or by the respiratory route in cases of person-to-person infection (110).

Viral Entry and Incubation Period

During the smallpox rash stage, people with active disease may have transmitted virions by dissipation from the mouth simply by speaking or coughing. The inhalation of aerosol droplets from an erupting oropharyngeal enanthem passed the virus to the oropharyngeal and respiratory mucosa of a susceptible individual. Infection from fragmented dermal scab material, which consisted of inspissated virus, was probably responsible for the much lower transmission rates associated with crusted smallpox scabs. Initial infection of the mouth, trachea, and lungs produced no symptoms or local lesions that could be recognized clinically or by autopsy of people who died soon after infection. Whatever cells were initially infected passed the virus to respiratory tract macrophages, which by about day 3 would have entered the bloodstream and lymphatics, thereby reaching regional and draining lymph nodes by day 4 to 10. Infection was not contagious during the week or two of incubation before the development of the oropharyngeal enanthem and skin rash exanthem.

Spread Through the Body

As virus traveled into the most likely sites for early viral multiplication, the lymphoid organs (spleen, bone marrow, and lymph nodes), a prodrome of influenza-like symptoms with a fever of about 40°C developed quickly. As the fever descended from its peak, an oropharyngeal enanthem developed that involved the pharynx, uvula, larynx, and tongue, and less frequently the trachea and bronchi, from which virus was secreted for about a week. Cell-associated virus also localized to small dermal blood vessels, producing an exanthema. The rash developed over 3 days into pustules that felt velvety and “shotty,” as if filled with a birdshot, and eventually became umbilicated and may have fused with other pustules, causing skin sloughing.

Cell-associated virus was likely in the form of infected monocytes, which migrated from dermal vessels into the epidermis, where they transmitted the infection to cells of the basal layer. Sebaceous glands were particularly susceptible, and necrosis and edema followed, sometimes with splitting of the dermis. As part of the inflammatory response, polymorphonuclear cells migrated into the lumen of developing vesicles, rendering the contents pustular. Pustules then progressed to dried-up crusts, or scabs, within about 2 weeks. A phenomenon known as the *centrifugal spread* of the rash occurred by an unknown process that enabled distribution of more lesions on the extremities than on the trunk.

Patients were extremely toxemic and dehydrated at the peak of the rash, which was the critical time, resulting in life or death. At the peak of the rash stage, intestinal involvement may have led to vomiting, diarrhea, and severe dehydration, requiring fluid hyperalimentation. If skin lesions were confluent, with sloughing of the skin, it was difficult to administer intravenous fluids using a peripheral vein; central intravenous access was often attempted with variable success. Some physicians recount a fetid odor of variola major smallpox patients, but the reason or mechanism of its genesis is

unknown.

The Immune Response

After infection by most viral pathogens, infected macrophages and lymphocytes induce the production of interferon, which stimulates natural killer (NK) cell activity to permeabilize and kill virus- infected cells independent of conventional immunologic specificity (see viral immunology chapters in this book). Activation of the complement cascade also serves as a first-line host defense. Macrophages and dendritic cells process antigens into peptides that complex with products of the major histocompatibility complex (MHC) to present antigens to thymus-derived lymphocytes, of which there are several subclasses. CD8+ T lymphocytes (CTLs) respond promptly by specific clonal expansion to clear infected cells quickly. Type 1 CD4+ helper T lymphocytes play a role in inducing lasting CTL activity, and type 2 CD4+ helper T lymphocytes interact with B cells to produce the antiviral neutralizing and aggregating immunoglobulins that prevent subsequent infection. CTLs recognize antigen presented in conjunction with class I MHC, whereas the CD4+ helper cells recognize antigen presented in conjunction with class II MHC. CTLs recognize predominantly cytosol-derived proteins processed by antigen-presenting cells, such as dendritic cells, macrophages, and B cells, whereas helper T cells recognize exogenous antigens processed and presented by these same cells.

It is likely that variola virus infection of the oropharyngeal and respiratory mucosa led to infection of macrophages, and their lodgement in lymph nodes, bone marrow, and spleen provided for the network of T-cell interactions that stimulated the CTL-mediated killing of infected cells and the subsequent humoral immune response that produced neutralizing and other antibodies against a large assortment of viral antigens. Current evidence for other viruses suggests that NK cells and CTLs also play a subsequent role in antibody-dependent cellular cytotoxic killing of infected cells by mechanisms that may involve complement (ADCC response). The production of an array of cytokines and chemoattractant cytokines (chemokines) and concomitant receptor interactions are responsible for signal transduction processes that regulate the immune network. Classic experiments demonstrating cell-mediated immunity in the recovery of mousepox (44) and passive immunization protection from mousepox (67) and rabbitpox (18) substantiate the vital role of the cell-mediated response as crucial for viral clearance and the humoral response as important for resistance to subsequent infections with the same or related viruses.

In generally healthy individuals who became infected, a vigorous cellular immune response usually resulted in development of ordinary-type smallpox. However, if the cellular immune response was grossly deficient, the case may have presented as flat smallpox with skin lesions lacking a pustular infiltrate. Hemorrhagic smallpox was a rare form that occurred in patients with a defective immune response, which led to extensive virus multiplication in the bone marrow, where megakaryocyte destruction caused blood coagulation defects, and in the spleen.

Death or Recovery

The outcome of smallpox was either death or recovery with no persistence of the virus in the body. Pockmarks, the most common sequela, were the result of granulation tissue filling necrotic lesions. Lesions could occur all over the body, including on the soles and palms, which is a feature that is uncommon in chickenpox, a pustular rash illness sometimes confused with smallpox and human monkeypox. Smallpox lesions were usually most profuse on the face because of the large number of sebaceous glands there and the deeper pitting associated with their involvement (20). Blindness was an important but rare complication, usually occurring in cases in which there was malnutrition or secondary bacterial infection. Recovery was accompanied by prolonged immunity to reinfection with variola virus. In contrast, heterologous immunity, such as from vaccination, was less durable, especially in cases of variola minor alastrim virus infection.

Localized Infections

Infections with cowpox or vaccinia viruses ordinarily cause localized lesions at the site of their introduction into the skin, by inoculation or multiple puncture as in deliberate vaccination, or through small abrasions as with cowpox virus. Cowpox is generally more painful and produces somewhat larger lesions. The draining lymph node becomes swollen, and there is a brief viremia sometimes accompanied by a low-grade fever. Secondary lesions and complications occur sporadically, usually in individuals with immune deficiencies.

The Immune Response

Current knowledge indicates that macrophages, and very likely, Langerhans cells (11,94,163) in the skin, transport cowpox and vaccinia viruses to the draining lymph nodes, and there present viral antigens to immunocompetent lymphocytes. Specific antibodies, formed by B lymphocytes after interaction with type 2 CD4+ T lymphocytes, can prevent infection of susceptible cells by the virus. In contrast, CTLs provide the major mechanism for controlling and clearing any infection initiated by virus that escaped neutralization by preexisting antibody (e.g., after vaccination). Type 1 CD4+ T lymphocytes play a major role in inducing a lasting CTL response. In a naive host, the CTL response occurs first and is primarily responsible for clearing an infection (1,15), although antibodies formed soon thereafter may sometimes be important for preventing released virus particles from reaching sites not easily accessible to CTLs, such as the skin.

Experience with smallpox vaccination has indicated the importance of cell-mediated immunity in recovery from infection. For example, progressive vaccinia, the most dreaded complication, occurred in infants with defective cell-mediated immunity. In contrast, vaccinees with agammaglobulinemia but a normal cellular response recovered normally (78,79). Although shown for mousepox some time ago (15), production of vaccinia-specific CTLs in human vaccinees was recently demonstrated (61,197).

Pustulation following inoculation and migration of polymorphonuclear cells into the lumen of the vaccinal lesion have been shown to be reasonably good markers of smallpox vaccine capacity to induce cellular and humoral responses (148). The absence of virus replication of inactivated smallpox vaccines in the vaccinees, which led to absence of EEV

opsonizing antibodies and a less-than-comprehensive cell-mediated response, explains the failure of killed and component vaccines to fully protect and induce a durable long-lasting response.

Molecular Basis of Orthopoxvirus Pathogenicity

The collective viral and host molecular mechanisms in smallpox and human monkeypox that sometimes ended in death are largely unknown. Smallpox (and monkeypox) patients experienced a fever and toxemia that conceivably produced sufficient physiopathologic shock to induce fatal respiratory failure and heart attack, or encephalitides, which were usually fatal and affected smallpox cases somewhat more often than as a complication of smallpox vaccination. Such outcomes might have been influenced by the virus strain, secondary bacterial infection, immune complexes, the inflammatory response, malnutrition, or other factors likely operating concurrently.

For several decades, mousepox, caused by ectromelia virus in mice (70), has served as a paradigm of pathogenesis and immunology of an acute viral infection, including smallpox. However, in contrast to mousepox, in which death is from hepatic infection and decimation, autopsies of smallpox cases usually indicated that no vital organs were destroyed by variola virus infection (46) (no autopsies on human monkeypox patients are reported beyond characterization of skin lesions).

Poxviruses have adopted general and specific strategies to enable their growth in their hosts. General strategies include shutoff of cellular transcription, which is supervised by virus-controlled synthesis of its own components; the production of particles with different surfaces (e.g., IMVs, CEVs, and EEVs), which enhances viremia and augments attachment to and infection of different cell types; and the production by some species of virus-containing ATIs, which may ensure a concentrated inoculum and protect virus particles.

More specifically, sequencing and structure–function studies have indicated that vertebrate poxviruses have exploited their hosts by adopting cellular genetic information and adapting it to modulate aspects of infection, such as tissue and host range and the inflammatory reactions that lead to clearance mechanisms *in vivo.* How poxviruses acquire the cellular sequences is unknown, but the discovery of a reticuloendotheliosis retrovirus DNA integrated into fowlpox virus DNA (95) has suggested that both viruses may infect the same cell type, and there the retrovirus reverse transcriptase may produce provirus and copy cellular mRNAs for subsequent recombination into fowlpox virus DNA. Because no other poxviruses have been reported with retroviral sequences, other integrative mechanisms may be involved. Nevertheless, a viral strategy that usurps host inflammatory and other immune modulators suggests that the toxemia and fever are due to discordant reactions of cytokines, chemokines, cell adhesion molecules, growth factors, and other immunologic components.

Inflammation and Other Immune Modulators

The literature on poxvirus immune modulators and other elements involved in virus survival in the host is fast growing (5,30,48,66,149,166,182,209,211,215,232). Although many of the poxvirus modulators may react with their presumed substrates *in vitro,* providing functional information, the dynamic interactions of such components in the context of a naturally infected host are largely unknown.

Genome DNA analysis has indicated that orthopoxvirus species and strains differ in the extent of sequences specifying potential modulating proteins. Such sequences may be deleted without affecting virus growth in culture, but the encoded proteins are likely to be rather essential *in vivo* because they are directly related to surviving sufficiently in the host to produce progeny. Most hosts recover from poxvirus infections; hence, it is reasonable to assume that a prime purpose of viral expression of such modulators is to deal with antigen presentation in conjunction with class I and class II MHC and its consequences, the viral clearance process and immunologic memory.

There are no data on the capability of poxviruses to abrogate class II MHC presentation directly other than by shutoff of cellular transcription. However, myxoma virus has been shown to down-regulate the proportion of surface class I MHC epitopes, and there is evidence that some poxviruses can induce measurable, although less severe, down-regulation of surface class I MHC epitopes. Observations of early or late gene expression using recombinant vaccinia viruses have indicated a potential defect in presenting some foreign antigens that depends on the epitope and is antigen-specific, which has suggested that vaccinia virus can somehow compromise MHC-restricted antigen presentation, possibly by influencing proteosome function, or there may be class I MHC synthesis inhibitors or other competitive viral components.

Host processing of viral proteins is coordinated with up-regulation of class I and II MHCs in their respective antigen-presenting cells and association of infiltrating CD8+ and CD4+ T cells into the site of virus replication. The indication that poxviruses, including orthopoxviruses, are targeting antigen presentation stems from discoveries that some poxviruses encode secreted soluble receptors for interferon-g (IFN-g) and a variety of receptors for members of the tumor necrosis factor (TNF) superfamily, including TNF-a and lymphotoxin-a (LT-a) (5,166,211). IFN-a is a cytokine produced by CD8+ T cells and NK cells and potentiates IFN-a and -b, and TNF-a and LT-a are multifunctional cytokines usually specified by CD4+ T cells, NK cells, macrophages, monocytes, neutrophils, and B cells. The viral receptors mostly appear secreted from infected cells, except for a surface-associated TNF receptor of vaccinia strain Lister, which suggests that such proteins are extracellular decoys modifying host recognition of infected cells, rather than being intercalated into the plasma membrane, like cellular TNF receptors, to modulate signal transduction. At least one cowpox strain contains sequences for five different isologs of cellular TNF receptors (204), other orthopoxviruses may contain a lesser number or may have a truncated correlate, and some contain two copies by virtue of being in the DNA inverted terminal repeat. The time of expression of viral TNF receptors may be early or late after infection, and some may be produced much more abundantly by one virus than another (3,100,134,208).

Another viral homolog of a cellular receptor, or “viroceptor,” that appears rather significant for immune evasion is an interleukin-1b (IL-1b) receptor correlate known to be encoded by cowpox and some vaccinia strains, but not by variola and some vaccinia strains associated with high fever (4). The protein is soluble and secreted and thus is a probable

decoy *in vivo* for IL-1b, a cytokine produced by neutrophils, monocytes, and macrophages, which upon binding to its receptor, actuates signal transduction and production of other cytokines, including IL-2.

More than a dozen genes in orthopoxviruses specify proteins that contain ankyrin repeats. Because eukaryotic genes for ankyrin are located very close to genes encoding IL-1 and TNF receptors, which through their signal transduction processes can modulate nuclear factor-kB (NF-kB)-directed transcription, it is reasonable to consider that viral genes for proteins containing ankyrin might have been acquired to interface with cytosolic NF-kB (which itself derives from ankyrin-containing precursors) and its inhibitor, IkB (which also contains ankyrin). The interfacing may influence NF-kB translocation to the nucleus, where subtypes of NF-kB regulate transcription of various cellular genes for immune-modulating components (17,132).

Several orthopoxviruses express a soluble secreted homolog of the cellular receptor for IFN-a and -b (43,220), cytokines that can influence expression of class I MHC. IFN-a is produced by lymphocytes and occurs as approximately 15 different isologs, and IFN-b is a fibroblast glycoprotein. IFN-a can activate PLC-2A, which enables release of diacylglycerol and a precursor of proinflammatory prostaglandins and leukotrienes, arachidonic acid (31). The viroceptor for IFN-a and -b appears to block by interacting with moieties on the amino and carboxyl termini of IFN-a and -b (210,211), but the counterpart cellular receptor interacts only with the amino terminus and appears to function secreted and at the cell surface. The viroceptor may compete with the cellular IFN-a and -b receptor in its role as an inhibitor of signal transduction and prevent transcription of IFN-a–responsive genes.

At least two orthopoxvirus gene products have been implicated in modulating the antiviral effects of IFN-a and -b (81,106,107). One such protein encoded by most orthopoxviruses binds double-stranded RNA and inhibits the activation pathway associated with IFN-a induction of transcription of cellular 2',5'-oligo-A synthetase into isomers that can activate RNAseL, which may inhibit protein synthesis and protect the host from viral takeover by inducing apoptosis. Another comprises a homology of eukaryotic translation initiation factor eIF-2a that protects eIF2-a from P1/eIF2-akinase, which phosphorylates and inactivates eIF2 required by ribosomes for translation initiation, thereby inhibiting protein synthesis and reinforcing the 2',5'-oligo-A synthetase mechanism.

Associated with immune-modulating function of several poxviruses, including cowpox and vaccinia viruses, is an apparently multifunctional element, cytokine response modifier A (CrmA), which has been shown to inhibit caspase-1 (136,182,187). Caspase-1 is a cysteine protease involved in cleaving pre-IL-1b to IL-1b, which is produced mainly by monocytes and neutrophils, and possibly in blocking enzymatic cleavage of pre-IL-18 to IL-18 (211), an IFN-g–inducing inflammatory cytokine that is produced mainly by migrating macrophages, that activates NK cells, and that is needed for a type 1 helper CD4+ cell response. Regarding IL-18, some poxviruses, including orthopoxviruses, also produce at least one IL-18–binding protein (168,242).

CrmA may also interfere with proinflammatory leukotriene synthesis by interfering with an enzyme in the lipoxygenase pathway involved in producing 14,15-dihydroxyeicosate-traenoic acid from arachidonic acid, which is released upon membrane permeabilization (30,172). Further, CrmA and related proteins may also play a role in retarding CTL-mediated apoptosis by inhibiting the serine protease granzyme-B (184), which, along with perforin, is produced by CTLs in granules that help permeabilize infected cells and leads to antigen presentation and infected cell destruction.

In this regard, another apoptosis inhibitor encoded by orthopoxviruses appears to be a protein, designated CHO-hr, that influences viral infection of Chinese hamster ovary cells. The CHO-hr protein was first described as an effector of cowpox virus host range (214). CHO-hr contains ankyrin repeats and appears functionally similar to myxoma virus M11L protein (137), which may inhibit inflammatory signal generation resulting from apoptosis and has been shown to inhibit apoptosis in conjunction with the myxoma virus TNF-binding protein in primary rabbit peripheral mononuclear cells and RL5 rabbit CD4+ T cells.

A protein with amino acid sequences resembling the family of serine protease inhibitors termed serpin-1 or SPI-1, which is related in sequence to CrmA (also designated as the 38-kd protein or SPI-2) and is present in some orthopoxviruses, has also been implicated in apoptosis inhibition. More specifically, SPI-1 may interface with CrmA in Fas-mediated apoptosis (25); however, the *in vivo* effects of SPI-1 vary with the virus strain and animal model (121,222).

A 35-kd protein, which is similar in sequence to the superfamily of regulators of complement activation, is secreted by various orthopoxviruses and binds complement components C3b and C4b, thereby blocking antibody-dependent and alternate pathways in the complement cascade and inhibiting complement-augmented neutralization of virus particles (99,200). A protein in the envelope of EEVs is described that also resembles the superfamily members, but it may not bind complement (135); however, a few host complement control proteins have also been detected that are associated with the envelope of EEVs, which may provide resistance to virolysis (230).

Chemokines comprise a large family of low-molecular-weight secreted proteins that bind to specific seven-transmembrane G-protein–coupled receptors belonging to the rhodopsin superfamily. By a regulated electrostatic process of chemotaxis, chemokines recruit leukocytes into infected or injured sites in the host (10,117,178). Based on the number and arrangement of cysteines, the family consists of CXC chemokines, which attract neutrophils, lymphocytes, or fibroblasts or augment mitogenesis of fibroblasts; CC chemokines, which attract monocytes, B cells, T cells, eosinophils, and basophils; CX3C chemokines, which play a role in leukocyte adhesion and attract monocytes and T cells; and the C chemokine lymphotactin, which is chemotactic for lymphocytes but not monocytes. A wide variety of orthopoxviruses have been shown to secrete a soluble 35-kd protein that principally binds CC chemokines (210); other poxvirus genera may produce similar binding components, chemokine receptor-like molecules, or chemokine receptor antagonists (33,50,127,150). Myxoma virus, which is nonpermissive in mouse 3T3 cells, grows in 3T3 cells engineered to express certain chemokine receptors, particularly CCR5 (129), but this mechanism remains to be elucidated.

In addition to the immune modulators mentioned previously, some orthopoxviruses have a gene for a semaphorin-like protein that appears to bind to a B-cell 200-kd plexin-like transmembrane glycoprotein receptor containing a semaphorin

subdomain and may up-regulate intracellular adhesion molecule 1 (ICAM-1), induce CD-54, and reduce IL-6 production on human monocytes (45). Also, among the various TNF receptor–like proteins of cowpox virus (204) is a soluble secreted protein that binds CD-30 (D. Pickup, personal communication), a TNF-like ligand found on activated B and T cells, macrophages, and cultured NK cells that may modulate aspects of both the humoral and cellular immune responses.

Relative to controlling virus or host gene expression, various orthopoxviruses express zinc-finger proteins, phosphatases, and other kinases that probably play concerted roles in defining virus pathogenicity, including dUTPases, which may influence both neural and immunologic aspects of pathogenesis (116,229). Ectromelia virus expresses a zinc-finger–containing protein, p28, that may modulate viral replication and spread in macrophages (203). Several poxviruses, including orthopoxviruses, are predicted by sequencing or known to secrete a homolog of cellular epidermal growth factor, which may bind epidermal growth factor (EGF) receptor for roles, such as up-regulating macromolecular synthesis to facilitate cytoplasmic viral growth, inducing hyperplasia around foci of infection to provide virus susceptible cells, and affecting immune responses through affecting signal transduction (27,29,31). Vaccinia and other poxviruses express a 3b-hydroxysteroid dehydrogenase speculated to facilitate expression of immunosuppressive glucocorticoids (211). Finally, variola virus contains a correlate of the open reading frame C7L of vaccinia virus that influences the ability of vaccinia virus to grow in primate cells; however, amino acid 24 is changed in variola virus, creating an arg-gly-asp (RGD) motif (145), which is a feature of cellular adhesion proteins that bind integrins that modulate immune responses, including migration of lymphocytes across endothelial cells. Clearly, the plethora of determinants of poxvirus pathogenesis are not all discovered, and the complexity of their dynamic interplay in the host challenges our ability to molecularly define the pathogenicity of different poxviruses.

Pathology

Cytoplasmic inclusion bodies are a characteristic histopathologic feature of poxvirus infections. There are two types (Fig. 6): basophilic inclusions, or Guarnieri bodies (see Fig. 6A and Fig. 6B), which are made by all poxviruses and constitute the viroplasm or virus factory; and ATIs (see Fig. 6C and Fig. 6D), which may have an eponym and are produced by certain orthopoxviruses, cowpox (Downie body), ectromelia (Marchal body), raccoonpox, volepox, and skunkpox viruses (125), and some avipoxviruses, particularly fowlpox virus (Borrel body) (224). The five orthopoxviruses produce an ATI protein of 130- to 160-kd, which appears to provide a critical amino acid composition to form the inclusion; other orthopoxviruses produce a truncated polypeptide of 90 kd and do not form ATIs. The sequence variability of the orthopoxvirus ATI gene region has enabled development of a species-specific PCR assay (195).

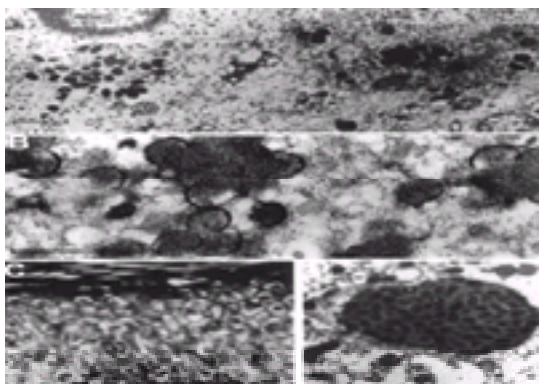

FIG. 6. Cytoplasmic inclusion bodies produced by poxviruses. **A** and **B:** Electron micrographs of viral cytoplasmic "factories"—B-type inclusion bodies that are produced by all poxviruses (B-type inclusions are basophilic by hematoxylin and eosin (H&E) staining.) **A:** Low-power electron micrograph of immature virus particles (IVs) on the *right* and nonenveloped intracellular mature virions (IMVs) on the *left.* **B:** Higher-power micrograph showing viroplasm containing the cupules of developing particles and immature particles. **C** and **D**: A-type inclusion bodies (ATIs), which appear late in the replication cycle of a few poxviruses, including the orthopoxviruses cowpox, ectromelia, raccoonpox, volepox, and skunkpox viruses and the avipoxvirus fowlpox virus; ATIs are eosinophilic by H&E staining. **C:** A-type inclusion body in cells in the skin of a mouse infected with ectromelia virus (H&E stain). **D**: Low-power electron micrograph of mature cowpox virions occluded within an ATI; some mutants show no occluded virions, and others show virions clustered around the outside of the inclusion body (103) (**A** from ref. 177, with permission; **B** from ref. 217, with permission; **C** from ref. 69, with permission; **D** courtesy of Y. Ichihashi.)

Smallpox

Hematoxylin and eosin stained sections of early-stage lesions in the skin and oropharyngeal mucous membranes of smallpox cases often showed B-type inclusions as round or oval, faintly basophilic bodies lying in the cytoplasm, usually close to the nucleus. In more advanced lesions, suitably stained sections showed faintly acidophilic granular inclusions occupying a large part of the cytoplasm of infected cells. These are seen particularly well in the epithelial cells at the base of vesicles and pustules.

The vesiculopustular skin rash, which appeared just after the viremic and toxemic prodrome, was the most outstanding pathologic feature of smallpox. Bras has described the evolution of the skin lesions (20; see also 54,72,186, and 190). The earliest change was dilation of the capillaries in the papillae of the corium, with swelling of the lining endothelium and infiltration of lymphocytes and histiocytes. Changes then appeared in the overlying epidermis. At first, a few cells in the middle layer of the epidermis became enlarged and vacuolated, and then great thickening of the epithelial layer occurred as cells in the malpighian layer proliferated and swelled. As the process of degeneration spread to neighboring cells in the middle layer, there was edema, the cell membranes ruptured, and a vesicle was formed, which was loculated,

with septa formed by the remains of incompletely destroyed cells. Polymorphonuclear leukocytes entered the vesicle from the dermis to produce a pustule, and the septa, which previously crossed the vesicle, disappeared. Fluid was absorbed from the pustule, drying the contents. Epithelial cells from the sides of the cavity grew under the residual mass of the exudate, so that finally a crusty scab was left, which consisted of degenerated epithelial cells, leukocytes, and cellular debris. Pockmarks, which were most severe on the face, were caused by destruction of sebaceous glands, followed by organization and subsequent shrinking of granulation tissue.

Because of the absence of an impervious keratin layer in oropharyngeal tissue, damaged epithelial cells, which were shed from oropharyngeal lesions that formed just as the fever began subsiding and immediately before the skin rash, produced highly infectious oropharyngeal excretions. There were few specific lesions in other organs, although small hemorrhages often occurred in the heart and liver, and endothelial cells throughout the body often showed hyperplasia and degenerative changes (21). In hemorrhagic, or “black,” smallpox, hemorrhages occurred under the serosa in the pericardium, pleura, and peritoneum; in the lungs, kidneys, liver, bladder, uterus; and occasionally in the bone marrow (170).

Human Monkeypox

Histologic examination of a papulonecrotic lesion from autopsy skin material from human monkeypox indicated that the skin lesions were like those in smallpox (216). In contrast to smallpox, generalized lymphadenopathy is a relatively common feature of human and simian monkeypox. No lymph nodes or other tissues from human monkeypox have been examined by histology to date, but in simian monkeypox, lymph nodes showed hyperplasia, medullary edema, dilation of sinuses, and occasionally degeneration and necrosis of cells in germinal centers; immunofluorescent staining showed large amounts of viral antigen in the necrotic foci (42,233).

Vaccinia and Cowpox

Vaccinia and cowpox skin lesions show some similarities to smallpox lesions. There is greater epithelial thickening and less rapid cell necrosis in cowpox than in vaccinia, and there is a greater involvement of mesodermal tissues. The most striking feature of cowpox is the presence of two types of cytoplasmic inclusions in virus-infected cells: rather faint, irregular, B-type inclusions; and several often large and somewhat homogenous ATIs (Fig. 6), which were first described by Downie (55). Some orthopoxviruses produce irregularly shaped ATIs (125) or ATIs with or without virions (103).

Clinical Features

Smallpox

The clinical features of smallpox are described with excellent photographs in several publications (54,72,186,190). Since the late 19th century, two varieties of smallpox have been distinguished on the basis of the severity of the disease and the mortality rate: variola major, the conventional disease of earlier times; and variola minor (called *alastrim* in South America), which was endemic along with variola major in the Americas and Africa. Although the rash was often quite extensive, alastrim produced a much less severe toxemia and a case-fatality rate among unvaccinated subjects of less than 1%, compared with 5% to 30% fatality rates for contemporary variola major outbreaks. DNA sequencing (144,146,205) has indicated distinct differences within the genome terminal regions of virus isolates from cases categorized clinically and epidemiologically as either variola major or minor, confirming earlier restriction mapping observations (60,62) that alastrim variola minor virus is a distinct subspecies. Alastrim spread through the Americas and Europe beginning early in the 20th century. On the other hand, some strains designated as variola minor viruses, such as that which occurred in Somalia in 1977, were not true alastrim virus by DNA analysis (62,146), but were much more like variola major virus, and probably represent attenuated variants.

The incubation period of ordinary smallpox was 10 to 14 days (Fig. 7). The onset of symptoms, or prodrome, was acute, with fever, malaise, headache, and backache. This phase, which was toxemic, lasted about 5 days; in pale-skinned subjects, onset of symptoms was sometimes accompanied by an erythematous rash or rarely a petechial rash, both of which were distinct from the vesiculopustular rash. On about the 3rd day after symptom onset, the rash began to form, first on the buccal and oropharyngeal mucosa, then on the face, the forearms, hands, and lower limbs, and then, within a day or so, on the torso. In contrast to chickenpox, in which periodic crops of rash arise, with the first crop appearing exactly at the peak of fever, smallpox lesions cropped up simultaneously just as the fever began to subside. On any part of the body, smallpox lesions were at the same stage of development, whereas in chickenpox, the lesions are at different stages. Smallpox lesions often arose on the soles and palms, which is uncommon in chickenpox.

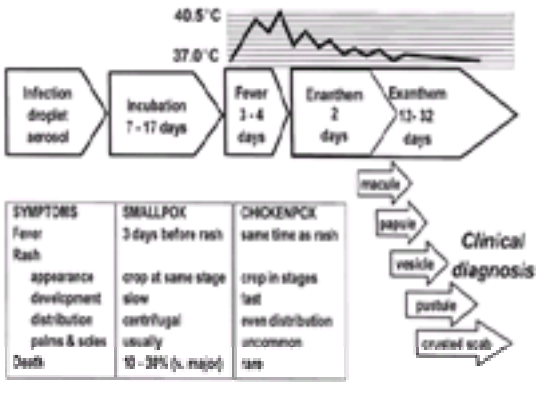

FIG. 7. The development of discrete ordinary smallpox. After aerosol droplet infection and incubation period, a prodrome, which includes a febrile response, is followed by development of an oropharyngeal enanthem and, soon thereafter, a dermal exanthem (the skin rash). The stages of rash development and a comparison of smallpox and chickenpox

symptoms are shown.

Smallpox lesions began as macules, which soon became firm papules, and then vesicles, which quickly became opaque pustules that were raised from the skin, tense, velvety, and firm to the touch as if filled with a small bead. About 8 or 9 days after rash onset, the pustules became umbilicated and then dried up, becoming crusty scabs by day 14 to 16. Within 4 days, most scabs had separated, except those on the palms and soles, which fell off last. The distribution of the rash, as well as its evolution, was a highly characteristic centrifugal spread, usually most profuse on the face and more abundant on the forearms than the upper arms and on the lower legs than the thighs, but relatively sparse on the trunk, especially the abdomen (see Fig. 3).

The previous description relates to what was called *ordinary* smallpox, which was by far the most common clinical form produced by both variola major and minor viruses. According to the severity of the rash on the face and upper limbs, ordinary smallpox was subdivided into confluent, semiconfluent, and discrete types (186). Alastrim was nearly always discrete, ordinary smallpox; however, the toxemia was much less, the individual lesions were generally less severe and smaller, and the rash healed quicker than in variola major.

Three other clinical types of smallpox were recognized: *flat*, *hemorrhagic*, and *modified*. Hemorrhagic smallpox was rare and associated with dermal petechia, bleeding from the conjunctiva and mucous membranes, very severe toxemia, and early death, often before skin lesions developed. Flat smallpox, which was also rare and mostly fatal, was characterized by intense toxemia and delayed appearance and slow evolution of skin lesions, which were usually flat and soft and nonsuppurative. The physiopathologic mechanisms and concurrent factors that influenced these rare forms are unknown, but they were not due to more virulent virus strains because infected case contacts usually developed ordinary smallpox. Hemorrhagic smallpox was more common in pregnant women than in other adults; flat smallpox was probably associated with particular defects in cell-mediated immunity. Modified smallpox, which was usually nonfatal, was seen in people who had been vaccinated, usually many years earlier; the rash evolved quickly, and the lesions were often more variable in size than in discrete, ordinary smallpox and were sometimes rather sparse.

Human Monkeypox

The clinical features of human monkeypox (see Fig. 4) are generally indistinguishable from those of ordinary smallpox, except there is often a much more pronounced enlargement of cervical and inguinal lymph nodes than in smallpox (110). Syndromes resembling flat-type smallpox have not been seen in human monkeypox, and what appeared to have been hemorrhagic-type monkeypox with liver and spleen involvement has been reported for two cases in Gabon (153).

Vaccinia

When vaccinia virus is deliberately introduced into the skin for vaccination, a papule appears at the site in 3 to 4 days, and by 2 to 3 days, this progresses to a typical umbilicated and multilocular *Jennerian* vesicle (Fig. 8). As with a smallpox lesion, the contents of a vaccination lesion rapidly become turbid upon infiltration of inflammatory cells, and the center becomes surrounded by erythema and induration, reaching maximum diameter by approximately day 11. At this time, the draining lymph nodes in the axilla may appear enlarged and tender; many patients develop mild fever. The pustule dries from the center outward, and the brownish crusted scab falls off in about 3 weeks, leaving a scar, which historically was used as the epidemiologic marker of vaccination, recognizable for many years.

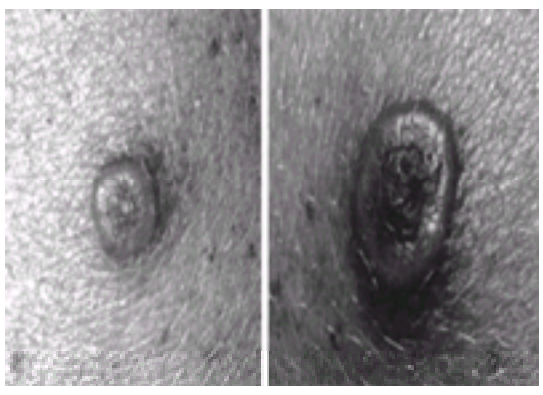

FIG. 8. Primary response to vaccination; typical vesiculopustular response, maximal at 8 to 11 days. **Left:** At 7 days. **Right:** At 11 days. (Courtesy of J. R. L. Forsyth.)

Complications of Vaccination

The occasional serious complications from smallpox vaccination (Fig. 9**A**, Fig. 9**B** and Fig. 9**C**) were more important than the slight morbidity that occurred from side effects, such as fever, lymphadenopathy, allergic skin reactions (Stevens-Johnson syndrome and urticaria), and auto-inoculation of some part of the body distant from the inoculation site, particularly ocular. From 1963 to 1968 in the United States, ocular vaccinia (see Fig. 9**D**) was observed in 348 people, including 259 vaccinees and 66 contacts (199); 22 cases showed corneal involvement, and 11 had residual visual defects.

FIG. 9. Severe complications of vaccination. **A:** Eczema vaccinatum in the unvaccinated contact of a vaccinated sibling. **B:** Progressive vaccinia (vaccinia necrosum), which was fatal, in a child with a congenital defect in cell-mediated immunity. **C:** Generalized vaccinia, 10 days after primary vaccination; benign course, no scarring. **D**: Ocular vaccinia after autoinoculation. (From ref. 72, with permission.)

Two large surveys of postvaccinal complications were reported (130,131) on the basis of vaccination as practiced in the United States in 1968 using vaccine manufactured by scarifying the skin of calves with the New York City Board of Health (NYBH) strain of vaccinia virus. Vaccination using this strain produced the following serious complications:

- Progressive vaccinia (vaccinia gangrenosa) (see Fig. 9**B**), which usually affected people with cell-mediated immunologic problems (78,79), occurred at a rate of about 1 per million vaccinations or revaccinations, and thus, congenital or acquired immunodeficiency diseases and pharmacologic immune suppression remain absolute contraindications to vaccination.
- Eczema vaccinatum (see Fig. 9**A**), which appeared only in people who had a history or suffered from eczema, a contraindication to vaccination, occurred at rates of 66 cases and no deaths among 14.5 million vaccinees, and 60 cases with one death among their several million contacts (vaccination under cover of VIG or treatment of established cases with VIG sometimes eased the severity of this complication).
- Generalized vaccinia, which may produce a rash covering the entire body (see Fig. 9**C**), occurred in 141 cases (no deaths) at 6 to 9 days after vaccination among 14.5 million vaccinees. The lesions resembled that at the inoculation site or sometimes varied in size; the prognosis was good because this side effect was not associated with immunodeficiency.
- Postvaccinial encephalitis, which was an unpredictable complication, occurred with widely differing frequencies in different countries (72,235).

In addition to these specific side effects, general encephalopathy was associated with a high viremia, particularly in infants younger than 1 year old; 4 cases with 3 deaths occurred among 614,000 vaccinees in this age group in the U.S. study. However, in older people, pathologic findings resembled other types of encephalitides, principally perivenular inflammation and demyelination (112). The incidence of this complication, which could not be predicted on the basis of preexisting disease in the vaccinee, was influenced by the virus strain used and was lowest with the calf skin Wyeth seedlot of the NYBH strain in the formulation; the U.S. survey showed 12 cases with one death among some 13 million vaccinees. Studies in the Soviet Union from 1968 to 1979 suggested generally higher side-effect rates in older primary vaccinees, including 313 cases of neurologic complications per million in people older than 5 years of age (87). Further information on complication rates outside the United States is available (88,188).

Attenuated or Recombinant Poxvirus Vaccines

During the latter days of eradication, attempts had been made to develop so-called priming vaccines, which were attenuated vaccinia strains that could be given before the standard vaccine to people who needed protection from smallpox but who were at risk for complications because of eczema or other contraindications. For example, safety tests were conducted in thousands of healthy people using variants of standard vaccinia strains that had been passaged hundreds of times on the chorioallantoic membrane (CAM) of chick embryos (e.g., the NYBH variant CV-I-78 in the United States and the modified virus ankara [MVA] strain in Germany) or adapted to grow at 30°C and plaque purified (e.g., the Lister variants LC16m0 and LC16m8 in Japan) (118,147,219). As eradication became a reality, further development of such strains as smallpox vaccines was virtually abandoned; however, as recombinant poxvirus vaccine technology developed, two of these strains emerged as potentially useful substrates for human vaccines: MVA, which replicates fully in avian cells and shows abortive infection in most mammalian cell lines and humans (34); and LC16m0, which is replication competent in most cell lines and shows high attenuation in experimental animals (219). In addition, a wide variety of other genetically engineered mutants with various attenuation traits and gene expression properties have been constructed for reasons of versatility. Several reviews on vaccinia recombinant vaccine candidates are available (77,133,156,157,174,180). Since the first recombinant vaccine candidates were produced in 1982 (139,173), no recombinant poxvirus vaccine has been sanctioned by regulatory agencies for routine use in humans, although a vaccinia rabies vaccine is being used to control wildlife rabies in several countries (24,175).

Cowpox

Downie (55) described lesions on people infected with cowpox virus from infected cows; lesions on humans appear similar to those evidently acquired from other cowpox-infected animals, commonly cats in Europe (9). One or more lesions usually appear on the hands; the thumbs, the first interdigital cleft, and the forefinger are quite vulnerable. Scratches or abrasions of the skin may determine localization of the lesions elsewhere on the hands, forearms, or face. Lesions resemble those of primary vaccination, passing through stages of vesicle and pustule before a scab forms. Local edema may be more pronounced than in vaccination, and lymphangitis, lymphadenitis, and often fever may persist for a

few days. There is virtually no encephalitis, but there may be multiple primary lesions, and generalized rash may occur. Children may have a more severe infection than adults.

Diagnosis

Differential Diagnosis

Smallpox

When smallpox was endemic, the diagnosis of most cases could be made easily from the distribution and evolution of the rash (54,72,186). Difficulties arose in outbreaks associated with importations into nonendemic countries, especially in cases of hemorrhagic smallpox, which were confused with meningococcal septicemia or acute leukemia. In situations in which their occurrence was not expected, modified-type variola major and ordinary-type variola minor were often confused with chickenpox, but the evolution and the distribution of the rash in the two diseases were usually distinguishable (see Fig. 7). More rarely, on first examination of a case, erythema multiforme or secondary syphilis might cause difficulties in diagnosis.

Human Monkeypox

Human monkeypox cannot be routinely differentiated from smallpox clinically, although enlargement of the cervical and inguinal lymph nodes is usual in human monkeypox and was virtually unknown in smallpox. With smallpox eradicated, the geographic localization of cases to African rainforest countries and other epidemiologic features help in making a clinical diagnosis; however, chickenpox, which is not uncommon in these countries, may easily be confused with monkeypox by local health care workers. Confirmation can be made by identifying the virus in skin lesions, such as by PCR (195), or by genus-specific antibody tests because no other orthopoxvirus is known in the endemic areas. Monkeypox-specific antibody tests, which use serum cross-absorption, have been employed to screen sera (102,165), but a gold standard species-specific test for orthopoxviruses has not been developed.

Vaccinia

Clinical diagnosis could be problematic for contact cases, but a history of contact with a recently vaccinated person or a laboratory source of vaccinia virus should arouse suspicion; the diagnosis can be confirmed by recovery and characterization of the virus. Buffalopox virus infection of humans has been reported from countries with domesticated river buffalo (*Bubalis* species). Since 1980, only India has reported infections in milking buffalo and dairy cattle, although horses and goats may sometimes become infected (59,128). Human infections are generally acquired occupationally or by drinking unpasteurized milk. The incubation period is about 7 days before vaccinia-like lesions appear on the hands or in the throat; there is virtually no interhuman transmission. Lesions usually heal by day 15 after infection. In some cases, differential diagnosis from infection by parapoxviruses must be made.

Cowpox

Cowpox in humans was traditionally associated with milking infected dairy cows in Europe, but many cases gave no history of contact with cattle; domestic cats now constitute a more important source of human infection (9). Occupationally acquired parapoxvirus infection sometimes must be differentiated from cowpox; parapoxviruses produce nonulcerating nodules, and cowpox virus causes pustular lesions (Fig. 10).

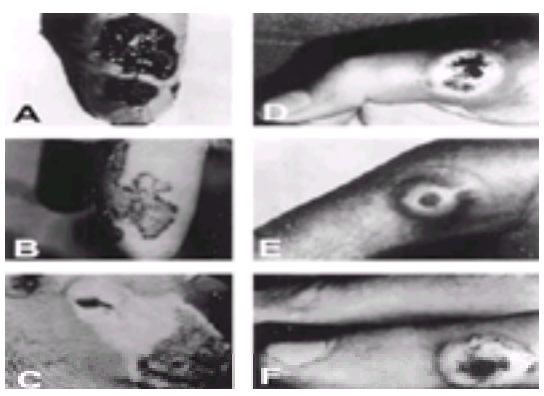

FIG. 10. Cowpox, pseudocowpox, and orf virus infections of animals (*left*) and lesions caused by these viruses on the hands (*right*). **A:** Cowpox ulcer on teat of cow, 7 days after onset of symptoms. **B:** Pseudocowpox (milker's nodule) virus infection of teat of cow. **C:** Orf virus scabby mouth in a lamb. **D:** Cowpox. **E:** Milker's nodule. **F**: Orf. (**A** and **B** courtesy of E. P. J. Gibbs; **C** courtesy of A. J. Robinson; **D** courtesy of A. D. McNae; **E** and **F** courtesy of J. Nagington.)

Laboratory Diagnosis

Laboratory methods for confirmation of orthopoxvirus infections are available (73,165,195). Laboratory diagnosis of an active infection is by discovery of characteristic virions in lesion material (see Fig. 1) and verification of genus and species by biologic or molecular tests, such as PCR assays. Histologic staining of viral inclusions in cells at the base of lesions may be used for diagnosis, but such methods are being displaced by techniques that use antibodies, PCR, or hybridization to detect virus *in situ.* Retrospective identification of infection uses convalescent-phase sera in various

assays, including enzyme-linked immunosorbent assay (ELISA), Western blot, and virus neutralization assays.

Clinical recognition of human monkeypox was made simpler by the eradication of smallpox from West and Central Africa; confirmatory diagnosis requires characterization of the virus in vesicle fluid or scabs and differentiation from chickenpox, usually by PCR. Cowpox is clinically distinctive, although laboratory confirmation by differential assays is important because of the rarity of the disease. Apart from buffalopox, vaccinia infections ordinarily do not need laboratory confirmation because the source of infection (vaccination) is usually known.

Treatment

Experimental orthopoxvirus infections of cell cultures and animals are variably susceptible to certain thiosemicarbazones; however, such drugs were found to be impractical for treating smallpox (72) and presently are not recommended to treat any other orthopoxvirus infection or postvaccinal complication. Presently, VIG is the usual treatment for eczema vaccinatum, accidental autoinoculation with vaccinia virus, and some cases of progressive vaccinia, although it has not been useful for treating postvaccinial encephalitis, and it may be contraindicated in auto-inoculation ocular vaccinia with keratitis (37,179). More recently, acyclic nucleoside phosphonates, like Cidofovir (Vistide) (51), and the antiviral ribavirin (120) have been used to inhibit growth in cell culture and animals of some orthopoxviruses, including variola virus in cell culture (104). Although no controlled clinical trials were performed, vaccination within 4 days after exposure to smallpox appeared to be an effective treatment (93).

Around the world, most institutions working with human orthopoxviruses (variola virus is restricted to WHO Collaborating Centers in the United States and Russia) usually vaccinate staff at risk for infection by administering their country's standard smallpox vaccine. If vaccination policies exist in different countries, they are generally patterned after recommendations used in the United States, which advise vaccination within 10 years for laboratory and health care workers who handle human orthopoxviruses (37; updates at http://www.cdc.gov/), and the United Kingdom, which advise obligatory vaccination for people handling monkeypox virus; otherwise, a case-by-case decision is made (2).

Epidemiology

Smallpox

Variola major case-fatality rates in outbreaks in the past millennium sometimes approached 30%, with considerable variations in different geographic regions that were probably influenced by concurrent factors such as nutrition status or quality of health care. During the WHO Intensified Smallpox Eradication Program (1967–1980), fatality rates were about 10% in African countries and about 20% in Asian countries, which suggested that the virus strain also played a role in the outcome of infection. In this regard, alastrim, which emerged in the late 19th century, was associated with a case-fatality rate of 1% or less in all affected countries (72).

Unvaccinated people of all ages were susceptible to smallpox, but mortality was highest in the very young and the elderly. Age incidence of infection depended on epidemiologic circumstances; where it was endemic in large population groups, smallpox was a disease of childhood. In rural populations, the disease might have been absent for many years, but then on its reappearance, people of varying ages would be susceptible, and an epidemic would ensue. When smallpox was introduced into virgin-soil communities in North, Central, and South America, in Central and South Africa, and in Australia, enormous epidemics ensued with very high mortality rates, in part owing to a breakdown of the social system because of simultaneous illness of so many adults in subsistence societies without food reserves.

One attack of smallpox provided solid immunity to reinfection. Vaccination with a potent vaccine gave complete protection against smallpox for about 5 years and varying degrees of protection after that. Before eradication, to provide an adequate margin of safety, the WHO Committee on International Quarantine specified that valid vaccination certificates for international travelers required successful vaccination to have been performed within the previous 3 years.

Human Monkeypox

The epidemiology of human monkeypox is quite different from that of smallpox; the disease is a rare zoonosis limited to tropical rainforest villages of West and Central Africa (110). Between 1970 and 1995, about 400 cases, most of which had been clinically diagnosed and verified by laboratory tests, were reported from eight African countries (see Fig. 5), mostly from the DRC (former Zaire). Of these, 338 cases, including 33 (9.8%) deaths, were discovered in five DRC provinces (1980 population, 5 million) during a largely prospective, intensified WHO surveillance from 1981 to 1986 that covered all of the DRC (1980 population, 28 million). In this study, 67% of the cases were substantiated by virus isolation, 30% by serology, and 3% by strong clinical data. Query data indicated that 72% of the 338 cases acquired the disease from wild animals, likely including infected squirrels caught to eat; and the secondary attack rate for people lacking cross-protective smallpox vaccination was estimated to be 7.5%. The study results indicated few clusters of cases and a dependence on an animal reservoir to sustain human infection, primarily because of the low (28%) interhuman transmissibility of monkeypox virus. Incidence modeling indicated that in an unvaccinated population, interhuman circulation of virus would not continue beyond a cascade of 14 human-to-human transmissions.

From February to September in 1996, 71 human monkeypox cases, including 6 deaths, were reported from the DRC (1999 population, 55 million). The reports prompted three WHO-sponsored, multiagency, short-term missions in 1997 to 1998 to identify cases, mostly retrospectively, because of heightened civil unrest. Although data from a 1998 mission was fragmentary, results from two epidemiologic surveys in 1997 suggested that a high proportion of cases (~75%) reported acquiring disease from another case, and there were several clusters of cases (38,39,96,159,239). In 1997, the survey teams visited 78 villages in the Katako-Kombe and Lodja areas (population, 0.6 million) in the Kasai Oriental Province in central DRC; 511 suspected active and retrospective cases were recognized (308 cases, including 6 active cases, were reported from the 1998 mission, but query data on only 50 cases were obtained). Of 42 cases in the rash stage that were discovered during the three missions, 26 were verified as monkeypox by virus isolation and PCR assays, in contrast to

the 1980s prospective study in which 227 of 338 cases were verified by virus isolation. The limitation to retrospective methods in the recent studies was compounded by a relative lack of expertise in clinically identifying monkeypox and differentiating it from chickenpox; 7 of the 42 active rash cases showed varicella virus by PCR assay. The missions were limited by a lack of surveillance continuity, use of disparate case definitions with attendant recall prejudices, and selection, ascertainment, and misclassification biases. Moreover, a critical weakness was dependence on invalidated serologic tests to confirm cases that met the epidemiologic case definition.

Despite the problems, some estimates were made. As found in the 1980s, the disease occurred mostly in children under 16 years of age, and the illness reported in 1996 to 1998 seemed no more severe than in the 1980s. A secondary attack rate was estimated to be about 8%, like that in the 1980s, which indicated a relative genetic stability of the virus over the years. DNA mapping and limited sequencing substantiated the close relationship of selected isolates from the DRC since 1970. In the 1997 to 1998 surveys, most reported cases occurred between June and September, a seasonality that was less clear in the 1980s study. The increased proportion of secondary cases, about 75% (28% in the 1980s), was attributed to reduced herd immunity caused by cessation of smallpox vaccination in the country by 1982. Misdiagnosed chickenpox was suspected to be responsible for some of the cases.

The limitations of the retrospective studies were likely insufficient to explain the increased number of monkeypox cases per capita compared with the 1980s. During a review at the WHO in 1999 (241), it was surmised that at least half of the 800 suspected cases in the Kasai Oriental that reported onset between February 1996 and July 1998 were monkeypox, and the rest were mostly chickenpox. WHO recommended that intensified prospective studies should be carried out as soon as possible to better define the estimated increased incidence since the 1980s and to understand the virus in the animal reservoir.

Vaccinia

Vaccinia virus ordinarily has no epidemiologic distinction because of little capacity to spread between humans; nowadays, it is mostly used for research. Vaccination was practiced during the eradication era on such a large scale that sometimes domestic animals, including cows, pigs, rabbits, and buffaloes, were accidentally infected with the virus, and humans were, in turn, infected from lesions on domestic animals (72). Unexpectedly, vaccinia virus was isolated in 1999 from farmers and dairy cattle in Northern Brazil (N. Moussatché, personal communication). During the latter days of the smallpox eradication era, certain strains of vaccinia virus (e.g., Lister, NYBH, and Tian Tan) became predominant for human vaccination as the rate of side effects for various vaccine strains in use became known (88,188).

Buffalopox

The most important veterinary infection with vaccinia virus is caused by buffalopox virus, which was thought to be a distinct species but is now regarded as a vaccinia virus subspecies as a result of DNA restriction endonuclease mapping of some isolates (59). During the WHO smallpox eradication program in the 1970s, buffalopox occurred in India, Egypt, and Indonesia, where water buffaloes, *Bubalis bubalis* (there are over 50 million in India), are used as domestic animals, and in certain countries had been used for vaccine manufacture (128). The disease has persisted in India since cessation of smallpox vaccination (161). Buffalopox is characterized by pustular lesions on the teats and udders of milking buffaloes and dairy cows; occasionally, especially in calves, a generalized disease is seen. Lesions may occur on milker's hands and face and in the mouth of people who drink unpasteurized milk from infected animals. Smallpox vaccination most likely had been protective. Several of the more recently isolated strains appear to have been maintained in nature by serial infection of buffaloes and dairy cows or possibly some wild animal host. Most isolates have somewhat different restriction maps compared with vaccinia strains used in India in the days of smallpox vaccination, although the differences observed were no greater than differences between a variety of vaccinia strains (59).

Cowpox

Cowpox virus is rarely contracted by humans directly from ulcers on the teats of infected dairy cows (see Fig. 10**A** and Fig. 10**D**); even in Jenner's day, “spurious cowpox,” which is caused by a parapoxvirus, was relatively much more common (36) and still is. Various studies have indicated that cowpox virus is transmitted inadvertently to humans, mainly by animals that acquire the disease from wild rodents that are indigenous to Europe and some adjoining Asian countries. Baxby and colleagues have studied cowpox epidemiology extensively over the years and have concluded that cowpox virus is restricted geographically to a region bounded by Norway, Northern Russia (includes Moscow), Turkmenia, Northern Italy, France, and Great Britain, probably because of limited ability of the virus to adapt beyond certain indigenous animals that constitute the reservoir (40). Moreover, based on their own studies and other reports, they concluded that the reservoir includes the following: bank voles (*Clethrionomys glareolus*), field voles (*Microtus agrestis*), and possibly wood mice (*Apodemus sylvaticus*) in Great Britain (except Ireland) and conceivably all of Europe; Turkmenian susliks (*Rhombomys opimus*) and gerbils (*Citellus fulvus*); Russian root voles (*Microtus oeconomus*) and possibly Russian (Georgian) gerbils (*Meriones libicus*); and Norwegian lemmings (*Lemmus lemmus*). Cowpox virus has also been isolated from Russian laboratory rats and humans who have handled infected rats and from zoo animals, but Baxby and colleagues have reasoned that the virus is not enzootic in rats, or else it would be found worldwide. It appears that domestic cats play a major role as intermediate hosts that transmit cowpox from rodents to humans, and possibly to horses, dogs, foxes, and various zoo animals, which may also be intermediate inadvertently infected hosts (9).

PARAPOXVIRUS INFECTIONS IN HUMANS

History

Humans acquire the following parapoxvirus infections, usually occurring as localized epithelial lesions contracted occupationally from infected animals and rarely from fomites: (a) orf, which is transmitted by sheep, goats, and several wild artiodactyls (e.g., bighorn sheep, mountain goats, reindeer), and is referred to in animals as orf, contagious pustular dermatitis, contagious ecthyma, or scabby mouth; (b) milker's nodule, which is transmitted by dairy cattle, and is referred

to as paravaccinia or pseudocowpox in these animals; and (c) bovine papular stomatitis, which is transmitted by beef cattle and possibly gazelles, and designated bovine papular stomatitis in these animals. Skin lesions on humans and some of the animals infected with these viruses are shown in Figure 10.

Reviews on parapoxvirus infections are available (90,152,179,192,193,244). Orf was first described as a disease of sheep in 1787, of goats in 1897, and of humans in 1934. Pseudocowpox lesions on the teats of cows constituted one of the forms of spurious cowpox about which Jenner cautioned should not to be used for smallpox vaccination (108). On rare occasions, humans have been infected with parapoxviruses of seals or possibly camels. In camels, parapoxvirus disease is termed *contagious ecthyma, amru,* or *ausdyk* (192,193). Camels may also acquire a rather severe generalized rash illness termed *camelpox,* which is caused by the orthopoxvirus camelpox virus, but the disease is not transmissible to humans (111).

Infectious Agents

Parapoxvirus virions are distinctive ovoid particles (see Fig. 1) that vary in size from 260 nm long by 160 nm wide (orf virus) to 300 nm by 190 nm (pseudocowpox virus). The outer membrane contains a tubular, threadlike structure, 10 to 20 nm wide and perhaps 1,000 nm long, that spirals around the particle, giving a characteristic cross-hatched appearance when opposing surfaces are viewed by negative-stain electron microscopy. Infectivity is resistant to ether and chloroform and is destroyed by heating at 58°C for 30 minutes. Orf virus is viable for long periods in dried scabs, which is an important feature for maintaining enzootic infection in sheep under field conditions.

The genome of parapoxviruses consists of a covalently closed, linear, double-stranded DNA of about 135 kbp and a 63% G+C (152,158,193). Within the genus, restriction patterns of DNAs of different parapoxviruses are more heterogeneous than DNAs of different orthopoxviruses (152), although Southern blot restriction mapping has indicated extensive sequence homology of different parapoxvirus DNAs within about 80 kbp of the central region and that the terminal region sequences are rather diverged and species specific (80). There is considerable synteny in the physical arrangement of parapoxvirus genes and the arrangement of orthopoxvirus genes; promoters and the function of several viral proteins are related, although the sequences are diverged. The demonstration (75) of nongenetic reactivation between parapoxviruses and orthopoxviruses—infection of cells with orthopoxviruses that are heat inactivated (which probably inactivates virion transcription enzymes) and reactivating their growth using parapoxviruses killed with ultraviolet light (which inactivates DNA)—has indicated that members of both genera have complementary components. Parapoxvirus promoter sequences can regulate transcription if they are inserted into orthopoxvirus DNA (152). Immune-modulating proteins specified by parapoxviruses include a vascular endothelial growth factor homolog that may effect angiogenesis in lesions, correlates of ovine IL-10 and an IFN-induced kinase inhibitor, and a secreted inhibitor of granulocyte-macrophage colony-stimulating factor (52,90).

Pathogenesis and Pathology

Parapoxvirus epidermal lesions are markedly proliferative. There are different incubation periods for orf virus in humans (3 to 14 days) and sheep (2 to 4 days), and the primary lesions differ clinically and histologically. Lesions in sheep appear as plugs penetrating the dermis (rete formation) and contain a massive accumulation of class II MHC-positive dendritic cells. Lesions in humans typically show a central umbilication with an erythematous margin and infiltration with monocytes and lymphoid cells more prominent around hyperemic capillaries and venules. Infection of endothelial cells may produce endothelial proliferation. The different lesions in humans and sheep suggest different viral clearance mechanisms (89,90,243,244).

The humoral immune response is generally similar in sheep and humans, although the durability of the response may be more in humans than sheep, and secondary infections producing milder lesions may occur in sheep. Early changes in proliferating keratinocytes include nucleolar enlargement and focal lysis of keratin fibrils (124). Extreme swelling of the cells results in ballooning degeneration, which, when accompanied by B-type cytoplasmic inclusion bodies and nuclear shrinkage, is pathognomonic of orf lesions. In humans, cellular and humoral immunity is significantly protective, although exceptions exist, such as among abattoir workers who may acquire repeated infections (193). In sheep, the cellular immune response appears more transient than in humans, and there appear to be different levels of susceptibility to reinfection of the udder, hind limb, and coronet of the hoof than other body parts—factors that might sometimes contribute to annual orf outbreaks in the same flock (193,244).

Clinical Features

Parapoxvirus lesions on humans, which occur through skin abrasions, are localized on the hands, sometimes on the face. Orf lesions on humans are 1 to 3 cm in diameter, and occasionally they are multiple. The lesion progresses from maculopapular to bullseye-like (red center, white ring, red halo) to a vascularized ulcerated nodule with central umbilication (see Fig. 10**F**), and finally to a crusted eschar with regenerating epidermis. The surrounding skin is inflamed, the lesion is painful, and there may be swelling of draining lymph nodes and low-grade fever.

Milker's nodule (see Fig. 10**E**) appears 5 to 7 days after exposure as a hemispherical, cherry-red papule that gradually enlarges to a firm, elastic, purple, and smooth hemispherical nodule that may reach 2 cm diameter and may be umbilicated when fully developed. Lesions are relatively painless but may itch. They are highly vascular, which explains the purple color, but they do not ulcerate. The granulation tissue makes up the mass of the nodule and gradually becomes absorbed; lesions disappear in about 5 weeks. The only evidence of a systemic effect is occasional slight swelling of draining lymph nodes.

Bovine pustular stomatitis lesions occur in and around the mouth of calves. Human infection, usually on the hands, is less common than orf or milker's nodule, probably because the physical contacts between animal handlers and beef cattle are less than between shearers and sheep and between milkers and dairy cattle (35).

Diagnosis

Diagnosis of human parapoxvirus infections is generally based on clinical and epidemiologic features, notably a history of contact exposure to infected animals. Laboratory verification is by observation of characteristic cross-hatched ovoid virions (see Fig. 1**B**) in lesion material; other laboratory diagnostic methods exist (73,165,195). Parapoxviruses do not produce pocks on the CAM, but they can be cultured from human lesion homogenates in primary bovine or ovine fetal kidney cells, primary ovine testis or muscle cells, or primary human amnion cells. Once in culture, the isolate usually can be passaged into established cell lines, such as human embryonic fibroblasts or monkey kidney cells. DNA restriction assay may be used for virus differentiation (80,152); efficacious, reproducible, type-specific PCR tests are not yet reported. Serologic cross-reactivity is demonstrable between parapoxviruses and certain orthopoxviruses and capripoxviruses, but cross-protection occurs only among members of the same genus. Western blot assays may be used to discern antibodies against parapoxvirus from other genera, and panels of monoclonal antibodies are described that may be useful for development of species-specific serologic assays.

Epidemiology

Orf is a common disease of sheep and goats worldwide, causing papules and vesicles sometimes around the nostrils and eyes and often on the skin of the lips of lambs and kids, which can lead to emaciation, infection of the udder of nursing ewes and dams, and consequent economic problems on farms. Human orf is a nonfatal occupational disease of animal handlers, including veterinarians, farmers, and shearers; thus, the disease is of industrial importance in countries where these animals are raised. Primary lesions on animals and humans cause more morbidity than lesions acquired by reinfection. Healing in humans and animals occurs in about a month, without scarring. Repeated infection of flocks and herds is largely due to the extended viability of virus in scabs that fall on pasture plants and the soil. In some countries, vaccination of lambs or kids with live, nonattenuated vaccine is practiced, which may lead to outbreaks on farms and human infections. Orf may be transmitted to humans from farmed or wild herds of musk-oxen and reindeer and by various other artiodactyls and wild ungulates, including deer, serow, chamoi, gazelles, bighorn sheep, and mountain goats (192). Humans have been infected by host animals kept as pets in petting zoos.

Pseudocowpox (paravaccinia) occurs in dairy herds in all parts of the world. The epizootiology of the disease in cows indicates that infection may be enzootic in cattle and may persist in small herds, in contrast to cowpox, which is sporadic (193). Milkers' nodules are contracted by contact with infected animals, and animals may be infected from the milkers' lesion through small abrasions on the teats or by mechanical transmission through teat cups of milking machines. Immunity sometimes appears to be short-lived. Cyclical waves of reinfection may occur in herds, especially in autumn and spring. Chronic lesions may occur, which are seen as mild scabbing. Beef cattle calves may transmit bovine papular stomatitis from lesions on their muzzles to their mothers' teats, which also occurs with pseudocowpox; lesions may also be chronic.

YATAPOXVIRUS INFECTIONS IN HUMANS

History

The genus *Yatapoxvirus* contains two species of African origin, tanapox virus and Yaba monkey tumor virus (YMTV); in monkeys, tanapox virus is designated Yaba-like disease virus (YLDV). Tanapox was first observed in epidemics of acute febrile illness associated with localized skin lesions in 1957 and 1962 among inhabitants of the flood plain of the Tana River in Kenya (58). The disease is endemic in this area and in the DRC (109). Epizootics of YLDV occurred in 1966 in macaques in three primate centers in the United States in which animal handlers were infected, apparently through skin abrasions (57).

YMTV was first recovered from subcutaneous tumors in captive rhesus (Asian) monkeys in Nigeria (167), but naturally occurring YMTV infections of humans have not been found in the field in Africa or Asia. Experimental subcutaneous or intradermal injection of YMTV into humans or monkeys, but not other tested animals, produced histiocytomas in the skin (85).

Infectious Agents

Tanapox virions (see Fig. 1**C**) in human lesions resemble orthopoxvirus particles, although most are enveloped (73). The yatapoxvirus genome DNA is ~145 kbp; the YLDV genome is sequenced (GonBank No. AJ293568; 144, 575 bp). DNAs of tanapox virus from Zaire and Kenya and YLDV from a monkey showed very similar restriction digest electropherograms. The patterns were rather different compared with YMTV DNA, although DNA of these viruses cross-hybridized extensively (122,126). YMTV has been used to reactivate orthopoxviruses nongenetically (225), indicating equivalent transcription components. A secreted 38-kd glycoprotein of tanapox virus binds to human IFN-g, IL-2, IL-5, and TNF-a (65,176).

Monkeys, but no other common laboratory animal, are susceptible to experimental infection with yatapoxviruses. Cross-protection tests and serologic assays have indicated that tanapox virus is related to YMTV (57). Neither species grows on the chick embryo CAM, but most strains grow in and form plaques in primate cell lines, such as CV-1 cells, producing distinctive focal lesions characterized by intense granularity, lipid vacuoles, and cell rounding; most isolates grow well at 33.5°C (58,73,126,165).

Pathogenesis and Pathology

Human tanapox lesions show marked epidermal thickening with extensive ballooning and degeneration of the prickle cell layer. The cytoplasm of swollen epidermal cells is filled with large, pleomorphic, granular, eosinophilic, B-type inclusions.

Nuclei are also swollen, with peripheral concentration of the chromatin and large nucleoli (57).

After subcutaneous or intradermal inoculation of humans or monkeys, YMTV produces histiocytic tumors that become suppurative. No true neoplastic proliferation occurs, and the lesions regress as the immune response develops (84).

Clinical Features

A detailed analysis of the clinical and epidemiologic features of tanapox as seen in 264 cases in the DRC has been reported (109) in which the diagnosis was confirmed by electron microscopy. The natural incubation period in humans is unknown, but in a person inoculated intradermally with 100 infectious particles, erythema and central thickening appeared by day 4 (57). Most patients have a mild fever before lesions erupt, sometimes accompanied by severe headache and backache, often with itching at the skin lesion site.

The appearance and evolution of a tanapox skin lesion is depicted in Figure 11. Initially, there is a small nodule without central abrasion, like an insect bite, which soon becomes papular and gradually enlarges to about 15 mm diameter by the end of week 2. An edematous zone and a large erythematous areola surround the nodule. The draining lymph nodes are enlarged and tender from about the 5th day after the appearance of the lesion, which may remain nodular, but usually ulcerates by the 3rd week and gradually heals within 5 to 6 weeks, leaving a scar. In Kenya, observed lesions were almost always solitary and on the upper arm, face, neck, and trunk (58); however, in the DRC, 22% of patients usually had two, and sometimes three or more, lesions, the maximum on one patient being 10 (109). Multiple lesions, although they differed in size, usually were close together and evolved together. In the DRC, the distribution of lesions was different from that seen in Kenya, with 72% being on the lower limbs, 17% on the upper limbs, 7% on the trunk, and 5% on the head.

Diagnosis

The clinical diagnosis of tanapox is based on the characteristic skin lesions occurring in parts of Africa where tanapox is known or in animal attendants who have had contact with monkeys infected with the virus (151). The slow evolution and lack of pustulation clearly differentiates tanapox from orthopoxvirus infection. Until a PCR test is developed, laboratory confirmation depends on demonstrating a high proportion of enveloped virions in lesion material, characteristic cytopathic effect in primate cell culture, failure to grow the virus on the CAM, and antigenic identification (165).

YMTV in monkeys produces large protuberant virus-containing histiocytic tumors (198). Humans are infected rarely, ordinarily by inadvertant inoculation or contact with infected monkeys. No natural infections have been reported since the original descriptions.

Epidemiology

Tanapox is a rare zoonosis, but neither the reservoir host nor the mode of transmission from wild animals to humans is known. The disease has been seen in Kenya and the DRC but may exist in other parts of tropical Africa. In Kenya, outbreaks in 1957 and 1963 were associated with periods of extensive flooding (58). In the DRC, cases occurred year-long, mostly from November to March, and the majority of cases occurred in the northwestern township of Lisala among people living within 300 meters of the Zaire River (109). Both sexes and all age groups were affected, and cases occurred much more frequently among people who worked or played close to the river than among men who engaged in hunting or worked as plantation farmers. Although clusters of cases occurred both in time and geographically, there was no indication of person-to-person transmission. Tanapox virus may be transferred to humans from monkeys or another reservoir host by biting arthropods, possibly acting as mechanical vectors (142). Mechanical transmission and human-to-human transmission may occur among animal attendants.

Tanapox virus inoculated intradermally produces skin lesions in both African and Asian monkeys (58). Analysis of monkey sera from various parts of the world for tanapox viral antigens revealed that New World monkeys were negative, but sera from several species of African primates contained antibodies (56). Because no studies of tanapox in other African wildlife have been made, it is not clear whether monkeys, like humans, are only incidental and not reservoir hosts. The disease profile in wild monkeys is unknown, but in colonies in which monkeys from various parts of the world are housed together, only Asian monkeys showed symptoms; the initial lesion was a pink, elevated papule that grew to a diameter of about 3 cm 1 week after appearance (91). Lesions regressed within 2 weeks, and usually only one lesion

appeared on an animal; occasionally, there were multiple lesions in some monkeys.

MOLLUSCUM CONTAGIOSUM

History

Molluscum contagiosum is a cosmopolitan human disease; several reviews describe the disease and the virus (13,26,179,183). In 1814, Bateman differentiated the infection from molluscum fibrosum (neurofibromatosis). In 1841, Henderson and Paterson independently described MCV intracytoplasmic inclusions (Henderson-Paterson bodies). In 1905, Juliusberg established the viral etiology, and in 1911, Lipschutz described “elementary bodies” in lesions. In 1931, Goodpasture and Woodruff described the inclusions and elementary bodies of molluscum contagiosum compared with those of fowlpox and concluded that the etiologic agent was a poxvirus. Since 1980, this relatively inconsequential illness at times has occurred in patients with AIDS as a tormenting opportunistic infection, which in Western countries amounts to a 5% to 20% incidence among homosexual men with AIDS (13).

Infectious Agent

Large numbers of MCV particles can be extruded from skin lesions, and large amounts of viral DNA can readily be extracted from virions. MCV has not been grown in established cell cultures, but virus from skin lesions has been propagated in human foreskin xenografts (28,76). The recognition of MCV transcriptional control elements in genetically engineered vaccinia virus indicates that MCV has a replication strategy similar to other poxviruses.

The MCV genome is a covalently closed, linear, double-stranded DNA of 190 kbp and 63% G+C. Restriction enzyme cleavage analysis of the DNAs of several hundred isolates from different parts of the world initially suggested two genome subtypes, subsequently a third, and recently a fourth (164), although the different DNAs cross-hybridize extensively by Southern blotting. The significance between restriction map differences and viral biologic differences is unknown; all DNA subtypes produce the same apparent disease.

Genomic DNA of MCV subtype I has been sequenced (GenBank No. U60315; 190,289 bp). Of 182 potential encoded proteins, 105 have homologs in variola virus DNA that are likely to be essential for virus replication based on correlation with known-function orthopoxvirus proteins; however, MCV generally lacks corresponding sequences for proteins involved in immune surveillance and modulation. Of the 77 predicted MCV proteins without correlates in orthopoxviruses, 36 show potential to be host-interactive homologs. *In vitro* studies indicate these are isologs of cellular glutathione peroxidase, class I MHC protein, two apoptosis inhibitors, two polypeptides that bind IL-18, and a chemokine antagonist (168,201,242).

Pathogenesis and Pathology

The typical molluscum contagiosum lesion consists of a localized mass of hypertrophied and hyperplastic epidermis extending down into the underlying dermis, without breaking the basement membrane and projecting above the adjacent skin as a visible tumor. There are increased mitotic figures in the germinal layer, above which are pathologic changes in the nuclei and cytoplasm. As the surface cells are approached, these lesions become more and more pronounced. Eventually, each cell is many times larger than normal, and the cytoplasm is filled with a large hyaline acidophilic granular mass known as the *molluscum body* (Fig. 12**A**), which pushes the nucleus to the edge of the cell and which may anatomically isolate the virus from the immune system. The core of the lesion consists of degenerating epidermal cells, with inclusion bodies, and keratin, which is produced by uninfected cells. Fully developed lesions are loculated, and there is little inflammatory reaction in the corium unless secondary bacterial infection has occurred. The tumor-like appearance of lesions is from hypertrophy of epidermal keratinocytes because of the presence of virus-packed inclusion bodies and hyperplasia of uninfected basal cells.

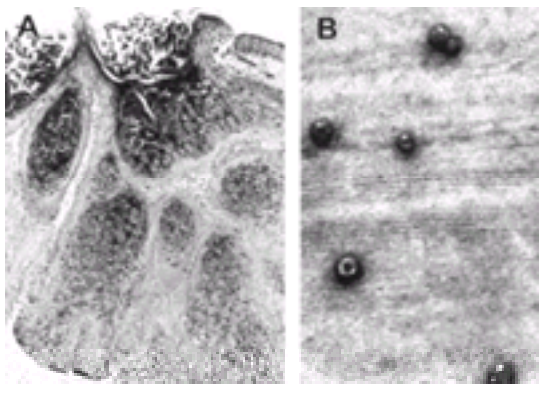

FIG. 12. Molluscum contagiosum. **A:** Section of a skin lesion of molluscum contagiosum. **B**: Lesions of molluscum contagiosum in humans. (Courtesy of D. Lowy.)

Lesions are relatively devoid of cells involved in the immune response, including NK and Langerhans cells, although T cells may be present in the perilesional dermis. Infected keratinocytes no longer display b $_2$-microglobulin (231), possibly because of complexing in the endoplasmic reticulum between an MCV homolog of MHC glycoprotein and cellular b$_2$-microglobulin (202). MCV does not appear to encode an epidermal growth factor homolog (183); however, intense staining of transferrin and EGF receptor has been observed on molluscum bodies, but not on surrounding uninfected keratinocytes (231). MCV appears to provoke little immunity; patients under immunosuppressive therapy, and some AIDS

patients, may have widespread and recurrent lesions. The lesions are noteworthy for the absence of reactive cells, and virus-specific antibodies are demonstrable in about 70% of patients (207); many patients develop antibodies after treatment for MCV (e.g., curettage). Antibodies against MCV do not react with different poxvirus genera. Lesions may persist in some patients for as little as 2 weeks or as long as 2 years, with no sign of inflammation, which may be an effect of an MCV chemokine antagonist (50). Repeated attacks are relatively common in situations in which opportunities exist for reinfection, such as in children's day care centers and among sexually promiscuous adults.

Clinical Features

Molluscum contagiosum is characterized by multiple, small 2- to 5-mm diameter noninflamed skin papules, scattered in a crop, which may arise on various parts of the body, including the torso in children and anogenital area in individuals who engage in anogenital sex. Occasionally, a single localized “giant molluscum” nodule about 10 mm in diameter may occur. Lesions rarely appear on the palms, soles, or mucosa but sometimes occur on the face, where there may be ocular involvement (179). The incubation period, as determined by inoculation of human volunteers, varies from 2 to 7 weeks. Lesions are pearly, flesh-colored, raised, and umbilicated in the epidermal layer of the skin (see Fig. 2**B**). Cropping occurs because of multiple simultaneous infections or localized mechanical spread. The lesions are painless, and at the top of each, there is often an opening through which a small white core can be seen. Infrequently, intrafollicular lesions occur as small, semitranslucent, pearly papules in the epidermis, which are difficult to identify because they lack the central umbilication. All DNA subtypes appear to produce similar lesions (183).

Solitary lesions may resemble pyogenic granuloma, keratocarcanthoma, or epithelioma. The disease is rather chronic, and lesions often persist for months or even years; ultimately, they resolve seemingly spontaneously and sometimes after trauma or bacterial infection of the lesion. Recurrences may be frequent, because of reinfection rather than latency. Lesions may be quite persistent and disfiguring in AIDS patients.

Diagnosis

Diagnosis can be made clinically from the characteristic appearance of the lesions and their chronic nature and can be verified by demonstrating “molluscum bodies” histologically or poxvirions by electron microscopy; diagnostic PCR methods are reported (169,221). Occasionally, solitary lesions on the face or neck may be misdiagnosed clinically as basal cell carcinoma; solitary tumors on the sole of the foot, although rare, also pose a clinical diagnostic problem.

Treatment

Commonly, the umbilicated core can be removed surgically, or the lesions may be treated chemically or by cryotherapy; however, lesions may recur and new ones form, particularly in AIDS patients in the anogenital area and on the head and neck. Lesions in children tend to disappear as they grow older. Topical treatment with DNA polymerase–blocking acyclic nucleoside phosphonates (Cidofovir) is promising (245).

Epidemiology

Infection occurs either by direct skin-to-skin contact or indirectly by means of fomites by virus entry through breaks in the epidermis or in the infundibular portion of the hair follicle. The incidence of disease is 2% to 8% in some populations and is more common among 10- to 12-year-old children in developed countries than in developing countries, such as Fiji and the DRC, where the peak incidence is reported between ages 2 and 3 years and 1 and 4 years, respectively. In New Guinea, a prevalence of 22% with an incidence of 6% in children younger than 10 years of age has been reported (13). The disease occurs sporadically, although it can become endemic, particularly in institutions such as children's day care or boarding schools, or in communities with poor hygiene and overcrowding. Contact transmission has occurred nosocomially, by tattooing, wrestling, or by swim team members sharing towels. Abundant lesions are common in atopic individuals who may acquire a patchy and irritable eczema around sites of infection known as *eczema molluscatum.* Genital molluscum sometimes coincides with other sexually acquired diseases, including AIDS, and may signal sexual abuse of a child; otherwise, children may acquire lesions on the arms, or most often, the upper torso.

The different DNA subtypes do not affect different body locations, as occurs in infections with human herpesviruses type 1 and 2. In one study of 261 patients, MCV subtypes I, II, and III were detected in a ratio of 226:32:3 (183). Usually, specimens from different parts of the body are the same DNA subtype as are isolates among contacts; however, on rare occasions, mixed infections have occurred. Genital MCV infection has recently become much more common based on studies in the United States and Great Britain (13).

POXVIRUS INFECTIONS OF VETERINARY IMPORTANCE

Except for smallpox and molluscum contagiosum, poxvirus infections of humans are zoonoses. Zoonotic poxviruses may cause significant livestock disease and consequent economic losses, and several poxviruses that do not affect humans are important pathogens of livestock. In addition, significant outbreaks in laboratory mice and rabbits, respectively, are caused by ectromelia and rabbitpox viruses. Recent literature is available detailing poxvirus infections of domestic and wild mammals, including ruminants, laboratory and captive animals, and rodents and lagomorphs (53,70,71,74,119,162,171,192).

Orthopoxvirus Infections

Camelpox

Camelpox affects *Camelus dromedarius* and *Camelus bactrianus* as a somewhat benign infection in adult animals but occurs more frequently in young camels as a severe generalized disease with extensive skin lesions (53,234).

Occasionally, there may be lesions in other organs, including the lungs, pharynx, trachea, heart, liver, and small intestine (123). Case-fatality rates may be as high as 25% in some epizootics. Sporadic outbreaks occur in virtually all camel-raising countries, particularly in Africa and southwestern Asia, where the camel is used as a beast of burden and milk animal (53,111). Camelpox virus has a narrow host range and can be differentiated from other orthopoxviruses by biologic characteristics (74), restriction mapping (62,189), and PCR methods (155,181). The camelpox virus genome DNA sequence closely resembles that of variola virus (G. L. Smith, personal communication). However, despite frequent exposure of unvaccinated humans to florid cases of camelpox, unequivocal human infection has not been seen. Camel parapoxvirus (ausdyk) may infect humans, and simultaneous orthopoxvirus and parapoxvirus infections of camels are reported (111,189,234).

Mousepox

Mousepox, also known as *infectious ectromelia* (impairment or loss of a limb), is caused by ectromelia virus and is known to occur only in laboratory mice, which acquire the disease through shipments of infectious laboratory mice and commercial products such as pooled mouse sera (53,70,171). Mousepox has been used as an animal model system for epidemiologic, pathogenesis, and immunologic studies. The infection has been enzootic in several mouse colonies in Europe, China, and Japan and has been imported into the United States, sometimes causing devastating outbreaks. About 40 episodes have been reported since 1950. A large outbreak at the National Institutes of Health in 1979 to 1980 led to U.S. government recommendations for stringent containment for studying mousepox. Ectromelia virus has been claimed to cause various human diseases, but never conclusively, more likely it was a contaminant that was not ruled out during diagnostic testing.

Depending on the mouse genotype, the disease may manifest either as a chronic form, characterized by ulcerating lesions of the feet, tail, and snout, or a quickly fatal illness, with extensive necrosis of the liver and spleen (Fig. 13**B** and Fig. 13**C**). Mice surviving the severe acute disease often develop a generalized pustular rash (see Fig. 13**A**). In this regard, lack of perforin, a component of NK cells, renders asymptomatic carrier C57BL/6 mice susceptible to acute illness (160), as does lack of a locus for active nitrous oxide synthetase II (115). Relevantly, ectromelia virus expresses an avidly binding TNF receptor homolog (134), which possibly modulates TNF-mediated cytolysis, releasing nitrous oxide. Sequencing of 32,318 bp of the right end of ectromelia-strain Moscow DNA showed at least six genes coding for immune modulator proteins, including an abundant chemokine-binding protein (41). Lesions in most organs, except the liver, are characterized by ATIs (Marchal bodies) in infected cells (see Fig. 6**C**).

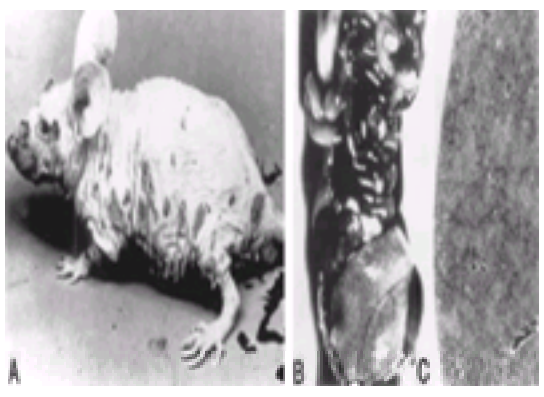

FIG. 13. Lesions of mousepox (ectromelia) in mice. **A:** The generalized rash as seen in a genetically susceptible hairless, nonathymic mouse. **B**: Swelling and necrosis of liver and spleen and hemorrhagic intestine in a susceptible mouse that died before rash appeared. **C:** Histologic appearance of necrotic liver. (**A** courtesy of Zentralinstitut für Versuchstiere, Hanover, Germany; **B** from ref. 7, with permission.)

Demonstration of poxvirus particles in lesion material by electron microscopy is diagnostic because no other poxvirus causes a naturally spreading disease in mice. If a positive result is found in an institution in a country normally free of mousepox, like the United States, other laboratory mice in the institution should be tested for infection, infected colonies should be destroyed, and the husbandry and laboratory areas should be disinfected.

Rabbitpox

At various times, laboratory rabbits in animal houses in Europe and the United States have been observed with a severe infection with rash, which turned out to be caused by the vaccinia virus subspecies rabbitpox virus (162,171). The virus involved was very similar to other strains of vaccinia virus in its restriction map and to so-called neurovaccinia virus in its biologic properties (68,74,236).

Other Species

A few other Old World orthopoxviruses are described (74,158,162,171). Uasin Gishu virus, a rare disease in horses in Kenya and Zambia, causes papular skin lesions, presumably contracted from a wildlife source. Three North American orthopoxviruses are known: volepox virus, isolated from lesions on *Microtus californicus* and *Peromiscus truii* in the Bay area of California; skunk poxvirus, isolated from lung tissue of a striped skunk (*Mephitis mephitis*) shot in Colfax, Washington; and raccoon poxvirus, isolated from lung tissue of North American raccoons (*Procyon lotor*) in Aberdeen, Maryland (125). A recombinant raccoon poxvirus multivalent vaccine candidate for pet cats is described (101); such vaccines appear sufficiently attenuated for vaccination by the intranasal or conjunctival routes (J. Orsorio, personal communication).

Capripoxvirus Infections

The genus *Capripoxvirus* includes lumpyskin disease virus (LSDV), which affects cattle in eastern, central, and mainly southern Africa, and sheeppox and goatpox viruses, which occur endemically in southwest Asia, the Indian subcontinent, and most of Africa, except southern Africa (162). Although the geographic distribution of the diseases may be different, the causative viruses are virtually indistinguishable by conventional serology and hardly distinguishable by DNA restriction assay. Such assays have indicated that African sheeppox virus is more like LSDV than goatpox virus. Although sheeppox and goatpox viruses are often considered host specific, in parts of Africa where sheep and goats are herded together, during an outbreak either virus may produce disease in both animals, indicating that some strains have a dual host range. Attenuated or inactivated vaccines are available in endemic countries; sheeppox vaccine can protect cattle from lumpyskin disease. Recombinant vaccine candidates that use various capripoxviruses to express genes for protective antigens of bluetongue and rinderpest viruses are described for geographic areas where outbreaks by these viruses overlap (14).

Clinical diagnosis presents few problems to veterinary clinicians familiar with capripoxvirus infections. Laboratory confirmation includes demonstration of brick-shaped particles in clinical material, and a PCR test is described for differentiating capripoxviruses from parapoxviruses (105). Capripoxviruses can be isolated in various cell cultures derived from sheep, cattle, or goats; B-type inclusions are formed in infected cells. A gene for a chemokine receptor homolog has been detected in some strains (33).

Sheeppox and Goatpox

Sheeppox and goatpox are clinically similar diseases exotic to the United States that can have mortality rates from 50% to 100%, mainly among young animals. They are the most important of all poxvirus diseases of domesticated animals because of the high transmissibility and significant economic losses (53). Sheeppox was apparently present in Europe as early as the second century A.D., and its infectious nature was recognized in the mid-18th century. Eradication was achieved in the Great Britain in 1866, but in contiguous European countries, it was more difficult to eliminate, probably because of the extensive live animal trade across borders.

After an incubation period of 4 to 8 days, there is a temperature rise, an increase in respiratory rate, edema of the eyelids, a mucous discharge from the nose, and a loss of appetite. One to 2 days later, cutaneous nodules 0.5 to 1.5 cm in diameter develop, which may be widely distributed over the body (Fig. 14**A** and Fig. 14**B**). The nodules usually scab and persist for 3 to 4 weeks, healing to leave a permanent depressed scar. Lesions within the mouth ulcerate and constitute an important source of virus for infection of other animals.

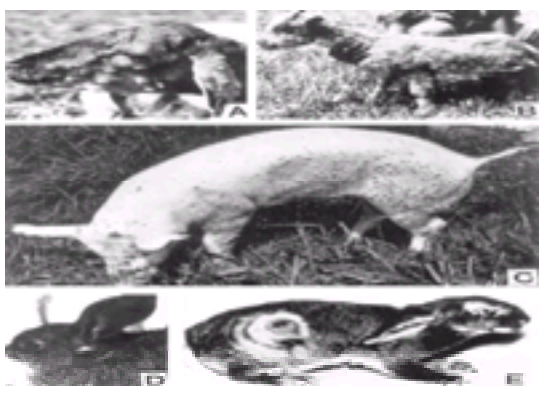

FIG. 14. Infections of domestic animals with poxviruses of other genera. Capripoxvirus infection in native breeds of sheep (sheeppox; **A**) and goats (goatpox; **B**) in Ghana. **C:** Suipoxvirus swinepox infection in pig showing generalized lesions. Leporipoxvirus myxoma virus infection in the native host the Californian rabbit, *Sylvilagus bachmani* (**D**) and the European rabbit, *Oryctolagus cuniculi* (**E**). (**A** to **D** from ref. 162, with permission; **A** and **B** courtesy of M. Bonniwell; **C** courtesy of R. Miller; **D** courtesy of D. C. Regnery.)

Scabs shed by infected animals remain infective for several months; environmental contamination leads to introduction of virus into small abrasions in the skin. The common practice of herding sheep and goats into enclosures at night in affected countries provides adequate exposure to maintain enzootic infection. During an outbreak, the virus is probably transmitted between sheep by aerosol; mechanical transmission of virus by biting arthropods, such as stable flies, may also occur.

Lumpyskin Disease

Lumpyskin disease affects cattle breeds derived from both *Bos taurus* and *Bos indicus* and was first recognized in an extensive epidemic in Zambia in 1929 (53). Since the 1950s, it has continued to spread progressively throughout Africa, first north to the Sudan and subsequently westward, appearing by the mid-1970s in most countries of western Africa. In 1988, the disease was confirmed in Egypt, and in 1989 a single outbreak occurred in Israel, the first report outside the African continent.

The disease is characterized by fever, lacrimation, nasal discharge, loss of appetite, and often generalized lymphadenitis and edema of the limbs followed by the development of nodular skin lesions. The skin nodules involve the dermis and epidermis; they are raised and later ulcerate and may become secondarily infected. Ulcerated lesions may be present in the mouth and nares; postmortem, circumscribed nodules may be found in lungs and alimentary tract. Healing is slow,

and affected cattle often remain debilitated for several months. Morbidity in susceptible herds can be as high as 100%, but mortality is rarely more than 1% to 2%; thus, the economic importance relates to a prolonged convalescence. The virus is probably mechanically transmitted between cattle by biting insects and is perpetuated in a wildlife reservoir host, possibly the African Cape buffalo. LSDV vaccines are used to control the disease.

Suipoxvirus Infections: *Swinepox*

Swinepox (see Fig. 14**C**), caused by the only member of the genus *Suipoxvirus,* is seen sporadically in swine-raising areas throughout the world (140). It is a mild disease with lesions restricted to the skin. When smallpox vaccination was common, some outbreaks of pox disease in swine were caused by vaccinia virus, but swinepox virus is now the only cause. Lesions may occur anywhere but are most obvious on the belly. A transient low-grade fever may precede the development of papules, which, within 1 to 2 days, become vesicles and then umbilicated pustules, 1 to 2 cm in diameter. The lesions crust over and scab by 7 days; healing is usually complete by 3 weeks. The clinical picture is characteristic, and it is seldom necessary to seek laboratory confirmation.

Swinepox is most commonly mechanically transmitted among pigs by the bite of the pig louse, *Hematopinus suis,* which is common in many herds; flies may also be mechanical vectors. Swinepox can be controlled by optimizing hygiene, including elimination of lice from the affected herd; no vaccines are available, or likely are necessary.

Restriction mapping of swinepox virus DNA suggested that it resembles an unclassified Brazilian poxvirus, Cotia virus (228). Sequencing has indicated several potential immune-mediating proteins encoded in the 175-kbp genome DNA of swinepox virus, including a chemokine receptor, but no such activity has been detected in swinepox-infected cell cultures (86). Swinepox virus has been used to develop recombinant vaccine candidates (223).

Leporipoxvirus Infections: *Myxomatosis*

The genus *Leporipoxvirus* contains five species, but only myxoma virus is of veterinary importance because it is a serious risk to breeders of European rabbits in California and Europe, and in the 1950s, myxoma virus was used very successfully to control a vertebrate pest, the feral European rabbit in Australia and Europe (71,119,192). Initially, in the Australian effort to control rabbits, more than 99% of rabbits died within 12 days of infection with a myxoma virus strain derived from a wild rabbit source (*Sylvilagus* species). However, milder virus variants emerged, and surviving rabbits produced resistant progeny, which has enabled the rabbit to continue as a troublesome pest. Myxoma virus recombinants expressing contraceptive proteins are being examined to control rabbits (191).

Myxomatosis was first observed in laboratory rabbits in Uruguay in 1896. The natural hosts of myxoma virus are the tapeti (*Sylvilagus brasiliensis*) in South and Central America and the brush rabbit (*Sylvilagus bachmani*) in California (brush rabbits are resistant the tapeti-derived myxoma virus). Myxoma virus causes a localized benign cutaneous fibroma (see Fig. 14**D**) in wild rabbits (*Sylvilagus* species) in the Americas and a generalized highly lethal disease (see Fig. 14**E**) in the European rabbit (*Oryctolagus cuniculus*).

Early signs of myxomatosis in the European rabbit are blepharoconjunctivitis and swelling of the muzzle and anogenital region, giving the rabbit a leonine appearance. Infected rabbits are listless, febrile, and sometimes, particularly with California myxoma virus, die within 48 hours of disease onset. European rabbits infected with Brazilian strains survive for 10 to 14 days, and subcutaneous gelatinous swellings (hence the name *myxomatosis*) appear all over the body. Virus transmission is usually by mechanical transfer by mosquitoes or rabbit fleas but can occur by droplet infection. Laboratory or hutch rabbits can be protected against myxomatosis by inoculation with the related rabbit fibroma virus or with attenuated myxoma virus vaccines.

Myxomatosis in European rabbits can be diagnosed by the clinical appearance, or by virus isolation in rabbits, on the chick embryo CAM, or in rabbit or chicken cell cultures. Electron microscopy of the exudate or smear preparations of the lesions reveal brick-shaped virions. Genome DNA restriction profiles can be used to differentiate species and strains (119,171). The complete genome sequences, encoding about 168 genes, are reported for the 161,744-bp DNA of Lausanne myxoma virus (GenBank No. AF170726) and the 159,857-bp DNA of Shope fibroma virus (GenBank No. AF170722). Leporipoxviruses express a variety of components for immune modulation in rabbits, many of which have counterparts in other poxviruses (66,166). Expression of certain chemokine receptors on cells markedly influences the growth of myxoma virus and possibly other poxviruses in some cells (129).

Avipoxvirus Infections

Avipoxviruses infect poultry and many species of wild birds, and virus species exhibit extensive DNA and serologic cross-reactivity (224). Viruses are generally recovered from skin lesions and given names related to their hosts (e.g., fowlpox, canarypox, turkeypox, pigeonpox). Mechanical transmission by arthropods, especially mosquitoes, provides a mechanism for transfer of the virus between a variety of different species of birds. There appear be a number of highly diverged avian poxvirus species based on their pathogenicity in various avian hosts and the efficacy of cross-protection afforded by different avipoxviruses in different birds, which varies considerably. Comprehensive restriction digest mapping to classify avipoxviruses has not been done; this may be complicated by the fact that complete or partial avian retrovirus DNAs have been detected within the 300-kbp genome of various fowlpox field strains (95), suggesting that sequencing selected genes might provide a more useful approach to estimate their phylogeny.

Fowlpox

Fowlpox is a serious disease of poultry that occurs worldwide (162,224). Two forms exist that are associated with different modes of infection. The *cutaneous form,* which is the most common, results from infection by biting arthropods and is characterized by small papules on the comb, wattles, and around the beak. Involvement of the skin around the nares may cause nasal discharge, and lesions on the eyelids can cause excessive lacrimation and predispose poultry to

bacterial infection. In uncomplicated cases, healing occurs within 3 weeks, and immunity is solid. The other form of fowlpox is probably due to droplet infection and involves infection of the mucous membranes of the mouth, pharynx, larynx, and sometimes the trachea. This is often referred to as the *diphtheritic form* because the lesions, as they coalesce, result in a necrotic pseudomembrane that can cause death by asphyxiation; the prognosis is poor.

Extensive infection in a flock may cause a slow decline in egg production. Cutaneous infections cause little mortality and seldom present a diagnostic problem. The diphtheritic form is more difficult to diagnose and may be confused with vitamin A deficiency. Electron microscopy, virus isolation in avian cells or on the CAM, and DNA analysis can be used to confirm a clinical diagnosis; the 288,539-bp DNA genome of fowlpox virus APHIS challenge strain has been completely sequenced (GenBank No. AF198100). A 15-second antigen capture assay for fowlpox has been described (114).

Several types of poultry vaccine are available, including attenuated fowlpox virus and a pigeonpox virus vaccine. Vaccines may be applied to the thigh by light scarification, or orally by poultry drinking water. Avipoxviruses engineered to express immunizing antigens of other poultry pathogens are described (19). Several recombinant avipoxvirus vaccine candidates for humans or domestic mammals are reported; such vaccines replicate abortively in mammalian cells, producing no infectious progeny, and thereby providing a margin of safety in being nontransmissible in mammals (133,174).

CHAPTER 86 *Hepadnaviridae:* The Viruses and Their Replication

Donald Ganem and Robert J. Schneider

Of the many viral causes of human hepatitis, few are of greater global importance than hepatitis B virus (HBV). More than 300 million people worldwide are persistently infected with HBV, and of these, a significant fraction develop severe pathologic consequences, including chronic hepatitis, cirrhosis, and hepatocellular carcinoma (22,23,289). The epidemiology, natural history, and therapy of HBV infection are reviewed by Hollinger in Chapter 87. Here, we focus on the cellular and molecular mechanisms of the replication of HBV and its related viruses.

For many years, insight into the fundamentals of the HBV life cycle was impeded by severe experimental obstacles posed by (a) the narrow host range of the virus (resulting in the absence of convenient animal models of infection and disease), and (b) the lack of cell lines that support productive HBV replication. However, the molecular cloning of the viral genome (150,334,392,489,556,558), the development of cell culture–based assays for viral replication (95,151,211,477,516,593), and the discovery of natural animal models of viral infection (335,338,342,514) radically changed this picture. These advances ultimately resulted in the development of recombinant HBV vaccine (344), the first successful recombinant vaccine for a human infectious disease, and the seminal discovery that these viruses replicate their DNA through the reverse transcription of an RNA intermediate (510). The latter finding established HBVs as distant evolutionary relatives of the retroviruses and stimulated the identification of clinically effective drugs based on the inhibition of the viral reverse transcriptase. The more recent development of transgenic mouse models of virus-induced liver injury (86) has led to new ways of thinking about the pathophysiology of viral clearance and persistence, with profound implications for the design of strategies for intervening in the natural history of chronic infection. Virology affords few better examples of the close relationship between research into the molecular aspects of viral replication and advances in clinical diagnosis and therapy.

HEPATITIS B VIRUS BIOLOGY: AN OVERVIEW

Primary HBV infection of susceptible adults results from sexual contact with an infected host or from parenteral exposure to virus-containing blood or blood products (154,217,219,269,289). Primary infection may be asymptomatic or may result in varying degrees of acute liver injury (acute hepatitis). Although such hepatitis can be severe, in most adults, the primary infection resolves (219,233). Host immune responses to viral antigens result in the clearance of infected cells from the liver and the removal of virions from the bloodstream; lasting immunity to clinically evident reinfection typically results (217; but see later section, Viral Pathogenesis and Immunity, for an important caveat). However, in a small proportion of infected adults (generally less than 5%), the primary infection does not resolve (233). These individuals go on to a persistent infection characterized by active viral replication in hepatocytes and variable (but usually substantial) levels of viremia. As in primary infection, the clinical manifestations of the persistent infection vary greatly: many patients are relatively symptom free, whereas others have varying grades of chronic liver injury and inflammation (chronic hepatitis B) (289). Although it is the minority outcome of primary infection, persistence is important for several reasons. First, most of the morbidity and mortality of hepatitis B virus infection results from the persistent infection. Some subsets of symptomatic patients (e.g., those with severe chronic active hepatitis B) have 5-year survival rates of less than 50%, with most deaths resulting from liver failure and its complications (289). Chronic hepatitis B patients who survive 25 to 30 years of viral persistence also have a markedly increased risk for developing heptocellular carcinoma (23), a dreaded malignancy that is usually fatal. Finally, the asymptomatic carriers are the major epidemiologic reservoir of infection: it is principally from them that spread of HBV to susceptible hosts occurs.

The reasons that some individuals resolve HBV infection whereas others do not remain poorly understood. Much correlative clinical evidence suggests that variations in host immune responses are a critical variable. For example, individuals with overt deficits in cell-mediated immunity (e.g., transplant recipients, patients with acquired immunodeficiency syndrome [AIDS]) are more likely to become chronic carriers than are fully immunocompetent hosts. The most biologically important example of this phenomenon is seen in the vertical transmission of HBV from pregnant mother to newborn baby. HBV transmission to babies usually takes place at the time of delivery, when the newborn is exposed to large quantities of viremic maternal blood during passage through the birth canal. The cellular immune

system of the neonate is known to be incompletely developed at birth; in this context, 80% to 90% of HBV exposures result in persistent infections (24,294,381,502). Much has been learned in recent years about the immunologic mechanisms governing viral clearance; these are discussed in more detail later (see Viral Pathogenesis and Immunity).

VIRION STRUCTURE

Particle Types

HBV is unusual among animal viruses in that infected cells produce multiple types of virus-related particles (21,103,444). Electron microscopy of partially purified preparations of HBV shows three types of particles: (a) 42- to 47-nm double-shelled particles (known as *Dane particles,* after their discoverer); (b) 20-nm spheres, usually present in a 10,000- to 1,000,000-fold excess over Dane particles; and (c) smaller quantities of filaments of 20 nm diameter and variable length (Fig. 1). All three forms have a common antigen on their surface, termed *hepatitis B surface antigen* (HBsAg). HBsAg is present in enormous quantity in the serum of infected hosts, with concentrations ranging from 50 to 300 µg/mL; most of the circulating pool of HBsAg is composed of 20-nm spheres, which can reach titers as high as 10^{12}/mL. This unprecedented amount of viral antigen in the circulation allows physicians to use direct viral antigen detection as a sensitive diagnostic test for HBV infection.

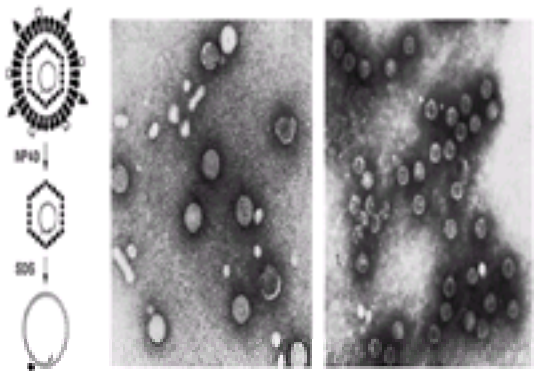

FIG. 1. The structure of hepadnaviral virions and subviral particles. **Left:** Schematic depiction of virion (*top*), core particle (*middle*), and virion DNA (*bottom*). The outer envelope of the virion contains three related surface glycoproteins (*L, M,* and *S*); the inner nucleocapsid contains a single capsid protein (*C*). The viral DNA contains a terminal protein (*oval*) attached to the negative strand and a short RNA (*wavy line*) attached to the positive strand. *Dashes* indicate single-stranded gap region on virion DNA. **Center:** Electron micrograph of hepatitis B virus particles, including virions, 20-nm spheres, and filaments. **Right:** Electron micrograph of virion cores produced by detergent (NP40) treatment of virions. (Experiment by June Almeida, United Medical School, Guy's Hospital, London, U.K.)

The Dane particle is the infectious virion of HBV; titers of Dane particles in the blood can range from less than 10^4/mL to greater than 10^9/mL. Its outer shell is a lipoprotein envelope containing the viral surface glycoproteins, originally detected serologically as HBsAg (35). These are the determinants against which neutralizing antibody (anti-HBs) is directed (217). The envelope can be removed by treatment with nonionic detergents, liberating an inner core particle or nucleocapsid of 25 to 27 nm. The major structural protein of the core is the C protein, a 21-kd basic phosphoprotein that was also originally detected serologically (218) and that is still frequently called *hepatitis B core antigen* (HBcAg) (442,511). Within the core is the viral DNA and a polymerase (P) activity (255,443) now known to be centrally involved in viral genomic replication. Purified cores also contain a protein kinase activity detected by its ability to phosphorylate C protein *in vitro* (2,135,165); because recombinant C and P proteins do not possess kinase activity, it is thought that this enzyme is of host origin. Whether it is truly an internal capsid component or merely tightly associated with cores during extract preparation is still uncertain, as is its biologic role (although there is no doubt that C protein is phosphorylated *in vivo*) (328,421,449,602,609).

The 20-nm spheres and filaments are composed exclusively of HBsAg and host-derived lipid (about 30% by weight); their principal lipids include phospholipids, cholesterol, cholesterol esters, and triglycerides (160,405,406). These particles lack nucleic acid altogether and hence are noninfectious. Nonetheless, in pure form, these particles are highly immunogenic and efficiently induce a neutralizing anti-HBs antibody response. Such 20-nm spheres, as purified from the serum of HBV carriers, in fact served as the initial form of HBV vaccine before the development of recombinant HBsAg preparations (269). Natural infection thus presents the seeming paradox of efficient progression despite the accompanying production of highly immunogenic particles that can elicit neutralizing host responses. How this comes about is not known; one school of thought is that the excess HBsAg particles function to adsorb neutralizing antibody and thus help shield virions from host defenses.

The Viral Genome

HBV virion DNA is a relaxed circular, partially duplex species of 3.2 kb whose circularity is maintained by 5'-cohesive ends (442,458,511) (Fig. 2). This molecule has an unusual structure in that its two DNA strands are not perfectly symmetric. The viral negative strand is unit length and has protein covalently linked to its 5' end (156,166,351). The existence of this terminal protein emerged from the observation that the viral DNA was extracted from the aqueous phase by phenol unless the genome was first treated with proteases. Restriction endonuclease digestion of viral DNA indicated that only terminal DNA fragments bearing the negative strand 5' end displayed this behavior, indicating linkage of the protein to the 5' end of negative-stranded DNA. By contrast, the positive strand is less than unit length and bears a capped oligoribonucleotide at its 5' end (309,472,581). The presence of these terminal structures explains the longstanding observation that neither 5' end of viral DNA can be phosphorylated by polynucleotide kinase. Importantly,

the positions of the 5' ends of both strands map to the regions of short (11 nucleotides) direct repeats (DRs) in viral DNA. The 5' end of negative-stranded DNA maps within the repeat termed DR1, whereas positive-stranded DNA begins within DR2 (309,352,472,581) (see Fig. 2). As detailed later, these repeats are importantly involved in priming the synthesis of their respective DNA strands.

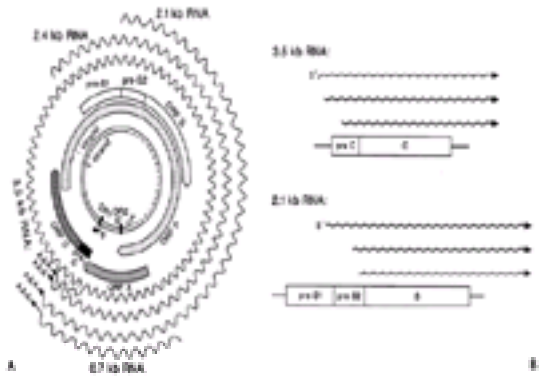

FIG. 2. A: Diagrammatic representation of the hepatitis B virus coding organization. *Inner circle* represents virion DNA, with dashes signifying the single-stranded genomic region; the locations of DR1 and DR2 sequence elements are as indicated. *Boxes* denote viral coding regions, with *arrows* indicating direction of translation. *Outermost wavy lines* depict the viral RNAs identified in infected cells, with arrows indicating direction of transcription. **B:** Fine structure of the 5' ends of the pre-C/C transcripts (*top*) and pre-S2/S transcripts (*bottom*) relative to their respective open reading frames.

Virion DNA thus contains a single-stranded region or gap of fixed polarity but variable length. Early studies showed that cores purified from extracellular virions contain a polymerase activity that can fill in this gap, generating a fully duplex genome (255,443,511). In this so-called endogenous polymerase reaction (EPR), the 3' hydroxyl of positive-stranded DNA serves as the primer, with synthesis extending along negative-stranded DNA templates. The newly synthesized product is therefore entirely of positive-stranded polarity, an asymmetry that is not simply reconciled with a standard semiconservative DNA replication scheme (see later).

Molecular cloning of HBV DNA extracted from Dane particles reveals a coding organization that is highly compact: every nucleotide in the genome is within a coding region, and more than half of the sequence is translated in more than one frame (150,558). As shown in Figure 2, four open reading frames (ORFs) are present in the DNA. The viral polymerase, the central enzymatic activity in genomic replication, is encoded by the *P* gene; ORF *P* also encodes the terminal protein found on negative-stranded DNA (37) (see later). The C (core) region encodes the structural protein of the nucleocapsid (392), whereas ORF *S*/pre-S encodes the viral surface glycoproteins (556).

The DNA sequence of HBV revealed a number of surprises not anticipated from earlier biologic studies. Chief among these was the existence of ORF *X,* a coding region whose product had not previously been detected. The product of ORF *X* is a complex regulatory protein that is required for viral infectivity *in vivo* and modulates the expression of heterologous and homologous genes in trans, at least in transient assays performed in cultured cells (451). How it does so is a matter of considerable debate and is considered in a later section.

Moreover, the coding organization of the genes for the known virion structural components (HBsAg and HBcAg) turned out to be more complex than expected. Early studies had suggested that the major component of HBsAg was a protein of 24 kd (30% to 50% of which is glycosylated, appearing as a second species of 27 kd), but small quantities of larger polypeptides often copurified with this material (164). The coding region for HBsAg was identified by aligning the translated HBV DNA sequence with the known N-terminal amino acid sequence of the 24-kd chain (556). This revealed that the reading frame for this antigen was open for about 400 nucleotides 5' to its AUG (initiation codon) and that this upstream (or pre-S) ORF could be divided into two subregions (pre-S1 and pre-S2) by the presence of two in-frame initiation codons (see Fig. 2). This coding organization provided an explanation for most of the larger polypeptides earlier observed in HBsAg preparations. The largest of these so-called pre-S proteins is the 39-kd L (pre-S1) protein, which is the product of initiation at the first AUG of the ORF (204,585). Initiation at the second AUG generates the 31-kd M (pre-S2) protein (326,327,401,503). Both proteins share the common C-terminal S domain and differ principally by the length and structure of their N-terminal (pre-S) extensions. Classic HBsAg, which contains only the S domain, is now more commonly referred to as the *S protein.*

Both pre-S–encoded polypeptides are quantitatively minor components of the circulating pool of S-related antigens, with the M protein accounting for about 5% to 15% of the total and the L protein typically representing only 1% to 2% or less of the total. Each protein exists in two isomeric forms, differing only by the presence or absence of S-domain glycosylation; in addition, the M protein contains an additional *N*-linked oligosaccharide on its pre-S2–specific domain (204,503). The L protein contains a further posttranslational modification, a myristic acid group in amide linkage to its amino-terminal glycine residue (403). Despite their low abundance, L chains are now thought to play a key role in viral assembly and infectivity (46,235,301,330).

Careful fractionation studies (204) have established that the three envelope glycoproteins are not distributed uniformly among the various HBV particle types. Subviral 20-nm particles are composed predominantly of the S protein, with variable quantities of M polypeptides and few or no L chains. By contrast, Dane particles are substantially enriched for L chains. Because L chains are thought to carry the receptor recognition domain (235,264,411), this enrichment may prevent the more numerous 20-nm particles from competing effectively with virions for cell surface receptors.

The coding organization of the core protein gene revealed a similar surprise: again, two in-frame AUGs were found in the

core ORF, with the classic HBcAg being the product of initiation from the more internal start codon (580). Initiation at the upstream AUG gives rise to a C-related protein that is not incorporated into virions but instead is independently secreted from cells, accumulating in serum as an immunologically distinct antigen known as *HBeAg* (159,345,388,448,498). The function of HBeAg remains enigmatic (see later).

CLASSIFICATION

The *Hepadnaviridae* Family

These unusual structural features clearly set HBV apart from the other families of animal DNA viruses. HBV is the prototype member of a family of related viruses known as hepadnaviruses (for hepatotropic DNA viruses). The first of the nonhuman hepadnaviruses to be discovered was the woodchuck hepatitis virus (WHV). In a colony of captive woodchucks (*Marmota monax*), veterinarians noted the frequent presence of chronic active hepatitis and hepatoma at necropsy (515); these features recalled the histopathology of advanced HBV infection. A search for HBV-like particles in serum from these animals ultimately culminated in the identification of WHV (514), a novel virus that is morphologically indistinguishable from HBV and whose genome shares about 60% nucleotide sequence identity with its human counterpart (149,268). A series of similar viruses have now been recovered from a variety of animal species, including the Beechey ground squirrel, *Spermophilis beecheyi* (ground squirrel hepatitis virus [GSHV]) (156,157,337,338), and the Pekin duck, *Anas domesticus* (duck hepatitis B virus [DHBV]) (336,337,342,497). Less well-characterized viruses have been recovered from arctic ground squirrels, wild herons, several varieties of wild and domestic geese, marsupials, and orangutans (496,527,530). All of these viruses share the following common properties: (a) enveloped virions bearing 3- to 3.3-kb relaxed circular, partially duplex DNA; (b) virion-associated polymerases that can repair the gap in the virion DNA template; (c) the production of excess subviral lipoprotein particles composed of envelope proteins; (d) narrow host range, growing only in species close to the natural host (14,285,336,422,475,542); and (e) production of persistent infections displaying pronounced (but not absolute) hepatotropism.

Table 1 summarizes the biologic properties of the most intensively studied hepadnaviruses. Although the similarities between these viruses outnumber the differences, there are important distinctions to be made among the individual members of this virus family. In general, the avian viruses are the most divergent: their viral genomes are smaller than those of the mammalian viruses and share little primary nucleotide sequence homology with them (334). Most avian viruses encode only two envelope proteins (L and S) rather than three (423,463) and lack the classic X coding region (although a small ORF beginning with a noncanonical initiator is present in this position and can be expressed in transfected cells (H. Will, personal communication). Although they too display a very narrow host range, their hepatotropism is less marked: viral antigens and replicative intermediates can be readily detected in several extrahepatic sites, including the pancreas, kidney, and spleen (193,194,195 and 196,220,247). In animals infected *in ovo,* the yolk sac is a major site of viral replication (520). Extrahepatic infection is also well-documented for HBV (412,447,605) and WHV (274,275 and 276,379), but the titers of their extrahepatic viral DNAs are generally much lower than those observed for DHBV. Nonetheless, even in the avian viruses, the liver remains the predominant site of virus production. Most strikingly, DHBV infection, although it can be associated with mild grades of hepatitis, is not strongly linked to the development of HCC. Although some DHBV-infected flocks in China and Japan have noted the occasional occurrence of hepatoma (234,383,606), infected birds in U.S. and European flocks (and laboratory-held animals) virtually never develop this lesion. It seems likely that the Asian flocks have been exposed to environmental cofactors that may accelerate HCC formation; dietary aflatoxin, a potent hepatic carcinogen, is a leading candidate for this cofactor role (100).

	HBV	WHV	GSHV	DHBV

TABLE 1. *The hepadnaviridae family*

VIRAL REPLICATION

Overview of the Life Cycle

The peculiar asymmetries of virion DNA (and of the endogenous polymerase reaction) provided early clues that a mechanism other than semiconservative DNA synthesis is involved in hepadnaviral genomic replication. Examination of intrahepatic replicative intermediates revealed even more striking asymmetries. Infected liver cells harbor large quantities of negative strands of less than unit length, most of which are not associated with positive strands (340,578). In 1982, Summers and Mason (510) reported seminal experiments establishing that viral DNA replication proceeds not by conventional semiconservative DNA synthesis but by reverse transcription of an RNA intermediate. To do this, they first prepared subviral particles from DHBV-infected liver; these particles, unlike mature virions, incorporate labeled deoxyribonucleoside triphosphates (dNTPs) into both positive and negative strands of viral DNA, exactly as would be anticipated for authentic replication intermediates. Electron microscopy of the particles proved them to be immature (unenveloped) cores that were cytoplasmic in location; thus, most viral replication was occurring outside of the nucleus,

the principal site of host DNA synthesis. Importantly, the synthesis of negative-stranded DNA was resistant to actinomycin D, implying its template was not DNA, whereas positive-stranded synthesis was sensitive to this compound. In addition, a portion of newly made negative-stranded DNA was found in the form of RNA–DNA hybrids. These observations suggested that negative-stranded DNA was made from an RNA template, whereas the positive strand was copied from a DNA template—by inference the negative-stranded DNA whose RNA template had been removed.

These experiments predicted the existence of a full-length, unspliced RNA that would serve as the template for reverse transcription, and such an RNA was indeed identified soon thereafter (55,123,355). This RNA (sometimes called *pregenomic RNA* [pgRNA] to denote its role in genomic replication) has all the hallmarks of a transcript produced by host RNA polymerase II (pol II). But if pol II, a nuclear enzyme, is the enzyme responsible for genomic RNA synthesis, clearly a subpopulation of nuclear viral DNA molecules must exist to serve as its template. This function is provided by a nuclear pool of viral DNA consisting of 10 to 20 molecules/cell of unit-length, covalently closed circular DNA (cccDNA) (340,578). As the presumed viral transcriptional template, these molecules thus play in the hepadnaviral life cycle the role analogous to that of integrated proviral DNA in retroviral replication; however, in hepadnaviral infection, these molecules remain episomal. Presumably, incoming viral DNA is transported to the nucleus and converted to the cccDNA form. Consistent with this, cccDNA is the first novel virus-specific DNA species to appear after DHBV infection, preceding the accumulation of viral RNA (341).

These observations allow formulation of a model for the overall viral replicative cycle (Fig. 3). After receptor binding, virions deliver their nucleocapsids to the cytoplasm. These then translocate to the nucleus, where their genomic DNA is matured to the cccDNA form. This DNA is then transcribed by host RNA pol II, and the resulting RNAs translated to give rise to the P, C, pre-S/S and (in mammalian viruses) X gene products. Viral pregenomic RNAs are selectively encapsidated within core particles in the cytoplasm (124,510), together with the P gene product. Within this structure, viral DNA synthesis is initiated; after negative-stranded synthesis (and concomitant degradation of the RNA template), positive-stranded DNA synthesis occurs. Upon completion of genomic DNA synthesis, progeny cores bud into intracellular membranes, generally the endoplasmic reticulum (ER) or proximal Golgi (252,446), to acquire their glycoprotein envelope. Enveloped virions are then secreted through the constitutive pathway of vesicular transport.

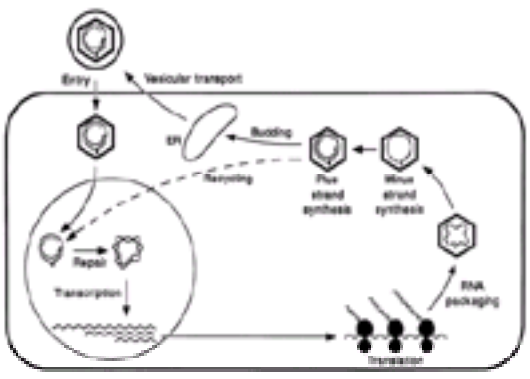

FIG. 3. Schematic depiction of the hepadnaviral life cycle. See text for details.

Many of the events schematized in Figure 3 can now be studied in cell culture. Although there are still no established cell lines that support infection with HBV virions (see later), primary duck hepatocytes freshly explanted directly from liver will support DHBV infection (152,424,546). These are terminally differentiated epithelial cell cultures that engage in little or no cell division and cannot be passaged long-term *in vitro.* Similar preparations of mammalian hepatocytes appear to support mammalian hepadnaviral infections, but much less efficiently (175,176,376). The reasons for this inefficiency are unclear, but HBV infection of primary human hepatocytes can be significantly enhanced by the addition of low concentrations of polyethylene glycol to the medium (175), suggesting that inefficient membrane fusion may be the cause.

Although they will not support virion infection, several well-differentiated and immortalized hepatoma cell lines (e.g., human HepG2 or HuH7, and chick LMH cells) support viral replication and release if cloned viral DNA is delivered by transfection (95,151,425,477,516,593). Presumably, the incoming transfected DNA functionally substitutes for cccDNA upon arrival in the nucleus, allowing the generation of the correct panel of viral transcripts; these can then encode the viral gene products necessary to complete all subsequent stages of the life cycle. Even fibroblasts can support hepadnaviral production after transfection by cloned viral DNA, provided that a heterologous promoter is used to drive expression of pgRNA (470), suggesting that transcription of pgRNA is a major determinant of liver specificity in wild-type hepadnavirus infection. Transfection of hepatocytes can also occur *in vivo* after the direct inoculation of cloned hepadnaviral DNA into the liver of susceptible hosts (471,497,579). In this case, progeny virions elaborated by the transfected cells establish a hepatic and systemic infection exactly as observed after virion inoculation. Similarly, HBV replication can proceed in transgenic mice bearing chromosomal copies of overlength HBV genomes (92,186). In these cases, the integrated transgenes serve the function of transcriptional templates for pgRNA production. Because mouse cells lack the HBV entry pathway, there is no horizontal spread of virus in these animals; however, such spread is not required to maintain viremia because every hepatocyte in the liver harbors a transcriptionally competent integrated viral genome from birth.

The availability of these systems has made possible mutational analysis of virtually all steps in replication. These systems have also revealed an important additional feature of the replication cycle: its noncytocidal nature. Primary cells supporting productive infection generally show no cytopathic effects and are morphologically normal (176,545,546); transfected hepatoma cells bearing viral replicative intermediates display growth rates identical to those of their untransfected parents (516). These facts agree well with clinical observations that many densely infected HBV carriers

have minimal or no hepatocellular injury and support the contention that such injury *in vivo* is largely the result of host immune or inflammatory responses (see later). The phenotype of HBV-positive transgenic mice bears further witness to this model: the livers of these mice (which are immunologically tolerant to the viral antigens) harbor high levels of viral replicative intermediates but remain histologically normal throughout life (185,186,354).

Attachment and Entry

Little is known about the earliest events in the viral life cycle. Enveloped virions must first bind to the cell surface, a reaction that has been best studied for DHBV. Binding occurs at 4°C, but at this temperature, no productive infection takes place. The binding reaction appears to have two components: a low-affinity, nonsaturable one and a high-affinity, saturable component (264). On warming to 37°C, entry and infection take place. After binding, a virus–host membrane fusion event must occur. For some viruses (e.g,. influenza) this occurs after endocytosis and is triggered by a pH-dependent fusion reaction governed by an envelope glycoprotein; in other viruses (e.g. paramyxoviruses, herpes simplex virus [HSV], and human immunodeficiency virus [HIV]), this is mediated by a pH-independent fusion reaction occurring at the cell surface. Experiments using inhibitors of endosomal acidification to examine the pH dependence of DHBV entry have come to divergent conclusions (377,441), but the weight of evidence favors a pH-independent mechanism (266,441).

The kinetics of DHBV uptake are odd: binding and entry appear to be slow, such that for maximal infection to occur, the cells must remain exposed to the inoculum for up to 16 hours (424); the basis of this is not understood. As for several other viruses, entry is blocked by suramin (404) and by some antienvelope monoclonal antibodies (MAbs) (80,81,284,286,612).

Much work has been done on the viral envelope components that may be involved in host cell interactions. For HBV and DHBV, several lines of evidence indicate that pre-S proteins participate in cellular receptor binding. Binding of HBV virions to human liver plasma membrane fractions is blocked by MAbs to the HBV pre-S1 domain; antipeptide antibodies to pre-S1 block adherence of HBV particles to HepG2 cells (370,411). Unfortunately, neither experiment is able to relate binding to productive infection. However, using recombinant DHBV envelope proteins, it has been shown that S proteins do not block DHBV infection of primary duck hepatocytes, whereas recombinant preparations containing both pre-S and S proteins do (264).

Another strong inference that pre-S determinants play a key role in receptor interactions comes from genetic studies of viral host range determinants. Hepadnaviruses typically are restricted to species close to that of their natural host, and DNA transfection experiments show that the block to efficient cross-species infection is at the level of virus entry (151,485). For example, the heron hepatitis B virus (HHBV) grows in herons but not in ducks or chicks, despite its substantial sequence homology with DHBV (496). If the normal entry pathway is bypassed by transfecting HHBV DNA into heterologous cells, replication proceeds normally. Consistent with this, pseudotyping experiments show that HHBV can be enveloped by DHBV envelope proteins and that these pseudotyped virions can efficiently infect duck hepatocytes (235). Examination of HHBV and DHBV chimeric envelope proteins in such pseudotyping assays indicates that pre-S determinants play the dominant role in host range determination (235).

Much less is known of the identities of the cellular receptors for hepadnaviruses. A large variety of proteins have been identified that bind to HBV envelope glycoproteins or to peptides derived from them. Some of these are serum derived, others are found in or on hepatocytes. A major problem has been that none of these molecules has been convincingly tied to infectivity. Mehdi and coworkers (346) have produced excellent evidence that HBV S determinants bind the serum protein apolipoprotein H, but this molecule is not an integral transmembrane protein of the hepatocyte and its role in infection is uncertain. Conceivably, it might play a role in delivery of virus from the periphery to the liver. Similarly, HBV S particles (HBsAg) have been shown to bind the phospholipid-binding protein endonexin 2 (207). The biologic significance of this remains unclear because the observed interaction may simply reflect the known ability of endonexin 2 to bind phospholipids, which are abundant in HBsAg lipoprotein. Because this binding does not involve pre-S determinants, it is unlikely to be the sole important component of attachment; it might, however, play some role in a postbinding membrane fusion event. Other studies have suggested possible roles for yet other molecules in viral entry (51,147,272,273,370,371 and 372,413), but no evidence that these proteins play a role in permissive infection has yet been forthcoming.

Progress in receptor identification has been greater in the DHBV system. In 1994, Kuroki and associates (278) identified a 180-kd surface glycoprotein (gp180) that binds to DHBV virions. Binding is specific to the pre-S region of the viral L protein (237,278,536,555) and is blocked by neutralizing (but not by nonneutralizing) antiviral MAbs. The species distribution of this protein mirrors the known host range of DHBV. All pre-S mutations that block this binding without affecting viral assembly destroy DHBV infectivity (237). Cloning of the cyclic DNA (cDNA) encoding this molecule revealed it to be a novel member of the carboxypeptidase family (279). The protein, also designated *carboxypeptidase D* (CPD), is enzymatically active, but this activity is separable from the virus-binding activity (125). Antibody to gp180 blocks DHBV infection of primary hepatocytes, as does soluble recombinant gp180 (S. Urban and H. Schaller, personal communication), demonstrating a key role for this molecule in viral entry. However, the protein is expressed on a wide variety of cell types in the animal, including many (e.g. fibroblasts) that are not thought to be susceptible to infection, and cDNA transfection into most nonpermissive cell lines (e.g., LMH cells) does not confer DHBV susceptibility (40,278). Thus, CPD is unlikely to be the sole component of the DHBV entry pathway; as in other virus systems, coreceptor proteins are likely to exist, and their identification constitutes one of the great remaining challenges to the field. Although gp180 is found in small quantities on the cell surface, most of it resides on intracellular (Golgi) membranes (40,279), suggesting that recycling of the protein between the cell surface and Golgi may occur. In accord with this, DHBV particles bound to CPD-expressing cells can be internalized (40). It is therefore possible that the accessory components of the viral entry pathway may act not at the cell surface but on intracellular vesicles bearing internalized DHBV.

The subsequent, postreceptor steps in hepadnaviral entry are even less well characterized (267). Cytoplasmic cores must be delivered to the nucleus, where their DNA is converted to the superhelical form. Nothing is known of this delivery process. Conceivably, microtubule-based motor systems might play a role in their transport across the cytoplasm to the nuclear envelope. Consistent with this, microtubule assembly inhibitors profoundly depress viral replication (D. Kedes

and DG, unpublished observations), but the exact mechanism of this inhibition remains uncertain (especially because these drugs display considerable nonspecific toxicity).

Once cores arrive at the nuclear envelope, they or their DNA contents must translocate across this structure. Some believe that core particles themselves are transported to the nucleus because (a) C protein is known to harbor nuclear localization signals in its C-terminus (120,390,601), and (b) the diameter of viral cores (about 25 to 27 nm) is just at the limit of the functional nuclear pore size as determined by experimental measurements in *Xenopus* species oocytes (136). However, the possibility that cores disassemble in the cytosol (perhaps at the nuclear pore) and deliver their DNA to the nucleus in nonparticulate form, as posited for adenovirus, has not been excluded (254). The exclusively cytosolic location of C protein in HBV transgenic mice (184,185) is sometimes cited as evidence in support of this notion. However, because such mice do not support cccDNA accumulation, it is difficult to know whether their phenotype is relevant to authentic viral infection—it may be that it is precisely their failure to transmit cores across their nuclear pore that underlies the absence of cccDNA in their nuclei. Recently, HBV core particle import into the nucleus has been examined in an *in vitro* system (631). Mature capsids purified from infected cells were presented to digitonin-permeablized cells in the presence of a cytoplasmic extract and adenosine triphosphate (ATP), a system in which soluble proteins competent for nuclear import are properly transported. HBV C protein accumulated efficiently in the target nuclei in particulate form. Interestingly, however, these particles appeared to lack viral DNA, suggesting that capsids might have released their genomes during or after import. Alternatively, cores might have disassembled during or after import, then reassembled within the nucleus once separated from their DNA.

Treatment of primary duck hepatocytes with glucagon has been shown to inhibit DHBV replication at a step occurring after receptor binding but before cccDNA formation—compatible with a block involving the cytoplasmic transport or nuclear translocation of cores (or their DNA) (209). Because glucagon modulates the activity of the cyclic adenosine monophosphate (cAMP)-dependent protein kinase A, it is tempting to speculate that at least one step in this process may be regulated by phosphorylation. However, the target of this phosphorylation remains unknown.

Once in the nucleus, the partially duplex viral DNA is repaired to the cccDNA form. This requires repair of the single-stranded gap, removal of the 5'-terminal structures (RNA and P protein), and covalent ligation of the strands. Several lines of evidence suggest that this process can be carried out largely by host machinery. The cloning of Dane particle DNA in *Escherichia coli* results in the recovery of fully duplex, superhelical plasmid clones in which the terminal structures have been correctly processed; thus, there would appear to be no need for viral machinery to effect these steps. Consistent with this notion, DHBV cccDNA formation in primary hepatocytes is not inhibited by phosphonoformate, a known inhibitor of P protein polymerase activity (267); however, the biochemical mechanisms by which the terminal structures are removed remain largely unknown.

Viral Transcription

Overview

Mammalian and avian hepadnaviruses use the circular 3-kb, cccDNA nuclear form of the genome as the template for viral transcription. Figure 2 shows the transcriptional organization of human HBV, which is similar to other mammalian hepadnaviruses. Avian hepadnaviruses differ from the related mammalian viruses in lacking an *X* gene ORF and an X promoter element. There are two classes of transcripts synthesized from cccDNA, known as the *genomic* and *subgenomic* classes, that have been identified in transfected cells in culture and in virus-infected liver. Both classes contain several transcripts, all are capped, and all are polyadenylated at a common polyadenylation sequence located within the core gene. The subgenomic transcripts function exclusively as messenger RNAs (mRNAs) for translation of the envelope pre-S1, pre-S2, S (also known as L, M, and S proteins) and X protein. The two genomic mRNAs encode the pre-C, C, and P ORFs. The C/P genomic mRNA is bifunctional, serving as the template for reverse transcription of the viral DNA negative strand (therefore known as *pregenomic RNA*), in addition to its role in translation of C and P protein products. The pre-C mRNA is not used for reverse transcription and functions only in translation of pre-C protein. Functional transcripts of the hepadnavirus genome are synthesized from the negative strand of the viral cccDNA template. RNAs transcribed from positive-stranded DNA, although detected in cells transfected in culture with viral genomic DNA, have not been found in infected cells or have not been found to encode viral polypeptides. None of the major hepadnavirus mRNAs contain classic introns. However, spliced viral transcripts have been detected for both avian and mammalian hepadnavirus mRNAs in cells transfected with genomic DNAs and in infected liver (74,508,517,529,586). Moreover, a spliced transcript encoding an alternately transcribed form of the S protein has been identified for the avian DHBV hepadnavirus in cultured hepatocytes and infected liver (375). Elimination of the spliced transcript by site-directed mutagenesis demonstrated that it is essential for viral replication in culture and in ducks. All of the hepadnavirus transcription elements, including promoters, enhancers, and the single polyadenylation signal, reside within viral genes that are actively transcribed and translated. This unusual arrangement reflects the compact organization of the hepadnavirus genome.

cis-Acting Transcription Elements

In HBV, the four overlapping ORFs are controlled by two enhancer elements and four (possibly five) promoters, corresponding to independent transcription from *pre-S1* (L protein), *pre-S2/S* (M and S proteins), *C* (core protein), *X* (X protein), and possibly *pre-C* (precore protein) genes (5,58,190,191,216,333,435,436,448,487,488,540,553,591,600,619). The fine structure and function of the individual HBV promoters have been very well characterized and shown in Figure 4. Most studies have investigated the activity of individual DNA fragments and used site-directed mutagenesis to then map transcriptional promoters that direct transcription of reporter genes. Several studies have also examined the transcriptional activity of DNA regions in the context of the virus genome. From these studies, it can be concluded that the *pre-C/C, pre-S1, pre-S2/S,* and *X* genes are controlled by independent promoters. Transcription from the pre-C/C promoter (5,216,448,592) is highly restricted to liver (216,431). Studies in transfected cultured cells suggest that transcription of pre-C and C RNAs is controlled by two physically overlapping, but functionally distinct, promoters that are differentially regulated (72,305,610,611). Studies have not yet verified the dual disposition of the pre-C and C promoters in infected cells. However, a frequently arising mutation in the presumptive pre-C promoter region has been documented

in HBV-infected individuals, which results in selective down-regulation of pre-C mRNA and protein (50,305,459). These results are fully consistent with the separate regulation of transcription by pre-C and C promoters. The liver-specific expression of *C* gene transcription is thought to result from the combined requirement for multiple liver-enriched transcription factors in the pre-C/C promoter. These include factors c/EBP, HBF1, HNF3, and HNF4 (64,73,112,158,189,249,321,322,430,437). The C promoter is thought to be controlled by both positive and negative regulation (431,611). Binding by the factor COUP-TF suppresses transcription from both promoters, HNF4 suppresses the presumptive pre-C promoter, and RXRa specifically enhances C promoter activity. Thus, part of the hepatotropism of HBV is likely attributable to liver-specific transcription of the C promoter, which is required for synthesis of pregenomic RNA.

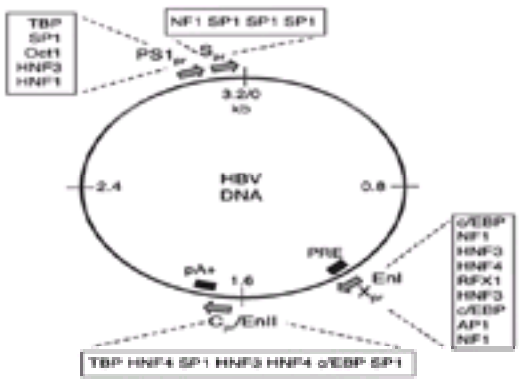

FIG. 4. Fine structure of hepatitis B virus promoter regions.

The HBV pre-S1 promoter directs transcription of the 2.4-kb large envelope (pre-S1 or L [large] HBsAg mRNA). It is located immediately upstream of the pre-S1 protein AUG initiation codon (64,65,434,436). The pre-S1 promoter functions weakly within the context of the virus genome, and when tested independently of other viral transcription elements, is consistent with the low level of pre-S1 protein observed during infection (5,434,436). The liver specificity of the pre-S1 promoter is derived from its dependence on liver-enriched transcription factor HNF1 (98). The S promoter directs transcription of several mRNAs of about 2.1 kb, which are translated to produce the pre-S2 (middle) and the S (small) HBsAg polypeptides (54,64,105,128,432,435,436,482,487,622). The S promoter is located within the coding region of the *pre-S1* gene and lacks a classic TATA sequence (5,64), likely accounting for the transcriptional stuttering that gives rise to mRNAs that either contain or lack the pre-S2 translation AUG initiation codon. The S promoter is constitutively active in a wide range of cell types, although it is more active in hepatocyte-related cell lines and in the liver of transgenic mice (7,11,64,91,105,128,132,133,499,501). The increased liver-specific transcription of the S promoter is probably related to the greater activity of enhancer II in hepatocytes (discussed later) (622).

The mammalian virus *X* gene mRNA is generally of low abundance *in vivo,* consistent with the low levels of X protein observed (101,102). When studied in transfected hepatoma cells independently of other viral elements, a region identified as the X promoter is considerably more active than in the context of the virus genome (5,190,434,488,540,543,592). In HBV, the X promoter is located adjacent to and downstream of enhancer I (EnI), which is within the ORF *P.* Based on transfection of cells with subgenomic HBV DNA fragments, the 5' end of the X mRNA appears to initiate at heterogeneous sites (488,540,543), consistent with the absence of canonical TATA and CAAT elements. X-promoter activity involves binding of both liver-enriched transcription factors (e.g., c/EBP) and ubiquitous factors (e.g., AP-1, ATF/CREB) and is strongly augmented by EnI (5,27,111,112,127,148,189,190,192,241,321,393,448,483,543).

Two genomic regions identified as EnI and EnII have been shown in HBV to fulfill the classic definition of transcriptional enhancer elements. These DNA fragments provide position- and orientation-independent stimulation of transcription when examined independently of viral genes in transient reporter assays (73,75,483,531,572,600,614). Regions corresponding to HBV EnI and EnII were also found to display DNase hypersensitivity patterns consistent with transcriptional activity when examined as integrants in transgenic mice (1), consistent with their identification as enhancer elements. Although both EnI and EnII can increase transcription from a variety of heterologous promoters, the activity of EnII is largely restricted to hepatic cells (600,615). HBV EnI functions in both hepatic and nonhepatic cells, although it more strongly activates transcription in hepatocytes (5,148,241,483,559,613,615). Accordingly, EnI has been shown to be activated by the binding of both ubiquitous and liver-enriched transcription factors, including c/EBP, HBF4, and HBLF (27,127,148,158,189,384,386,490,543). Although EnI is located adjacent to and upstream of the X promoter (and within the ORF *P*), it strongly up-regulates all of the major HBV promoters, both in heterologous reporter constructs and in the native context of the viral genome (5,225). WHV probably does not contain a region equivalent to HBV EnI (108). EnII is located within the ORF *X* and is adjacent to the pre-C/C promoter that directs transcription of pregenomic RNAs (600,615). EnII is a bipartite element that contains binding sites for, and is activated by, a constellation of liver-enriched transcription factors, including the c/EBP family of proteins, HBF1, HNF3, HNF4, and possibly a novel factor known as hB1F (189,249,283,307,308,321,322,431,433,625). One factor (E4BP4) has also been identified as a negative regulator of EnII, based on studies using artificial reporter constructs (283). In a similar manner, a negative regulatory element was identified within EnII that suppresses its activity (314). EnII strongly promotes liver-specific transcription of the pregenomic C promoter, and possibly X and S promoters, but not the pre-S1 promoter, for unknown reasons (108,216,308,322,506,572,614,624). It was also shown by mutagenesis of EnII that within the context of the viral genome, transcription of the viral genome is significantly (more than 10-fold) reduced with EnII impairment (576).

In addition to its role in activating viral transcription in a liver-specific manner, EnII plays an important role in oncogenesis by WHV. Unlike HBV, which integrates apparently at random, woodchuck hepatocellular carcinoma (HCC) tumors usually contain WHV sequences integrated from 2 to 200 kb away from the two *N-myc* gene loci (141,144,222). The genetic arrangement of WHV–cellular gene junctions of genomic integrants implicated WHV EnII in up-regulation of *N-myc*

genes (126,574). This is supported by studies using artificial constructs in which EnII was shown to be capable of directly activating *N-myc* genes (553,574).

Transcriptional Regulation of the Hepadnavirus Genome

The congested architecture of hepadnaviral transcriptional elements, with promoter and enhancer elements embedded within coding regions and physically adjacent or overlapping, necessitates complex regulatory controls. Studies have begun to examine transcriptional regulation of the hepadnavirus genome. The ratio of pre-S1 to pre-S2/S transcription appears to be one such form of regulation and is an important control point in the viral life cycle. The pre-S1 L protein product acts as an inhibitor of virus secretion (described later), and therefore its level must be tightly controlled. When assayed in reporter constructs independent of other viral genes, the pre-S1 and pre-S2/S promoters display similar activities, whereas in the context of the viral genome, the pre-S1 promoter is much less active (5). The S promoter down-regulates the pre-S1 promoter in the context of the HBV genome (54,323). Down-regulation is attributed to interference in pre-S1 transcriptional elongation, possibly by a CCAAT/NF-Y–binding element (323,324). Other complex regulatory circuits are emerging as well. In DHBV, an active C promoter appears to impair the usage of downstream pre-S and S promoters (228). The mechanism of promoter occlusion is thought to be involved, in which elongating transcription complexes originating from the C promoter impair pre-S1 and S promoters by passing through. Despite the fact that the pre-S1 promoter is located immediately upstream of the S promoter, there is no evidence for promoter occlusion in this complex arrangement.

Hepadnavirus Posttranscriptional Regulatory Element

RNA splicing in eukaryotes is tightly coupled to 3' end formation and export of the RNA from the nucleus to the cytoplasm (373). Consequently, intronless RNAs are poorly exported to the cytoplasm. A number of animal viruses encode intronless mRNAs that nevertheless efficiently accumulate in the cytoplasm. To overcome the export restriction to intronless RNAs, hepadnaviruses use a large RNA element known as the *posttranscriptional regulatory element* (PRE) (reviewed in 604). The PRE is located partially within the X promoter and ORF and downstream of the ORF *S,* indicating that it is contained in all viral transcripts (227,230,231,560). The PRE was shown to promote directly the export of unspliced transcripts. The HBV PRE and the HIV Rev response element (RRE), which performs a similar function, are largely but not completely interchangeable (113,231). However, the HBV PRE is not dependent on HBV proteins for export activity, whereas the HIV RRE requires binding by HIV Rev protein (227,230,231). The HBV PRE is conserved in mammalian hepadnaviruses, and a similar element has been described in WHV (114,630). The mechanism by which the PRE functions is not well understood. In contrast to the HIV RRE–Rev complex, the HBV PRE is not inhibited by the antibiotic leptomycin B, which poisons the nuclear export signal (NES) receptor CRM1/exportin-1 (387).

Processing of Viral RNA

The co-terminal nature of the viral transcripts (see Fig. 2) poses an interesting problem in the control of RNA processing. The subgenomic mRNAs are efficiently polyadenylated at a signal within ORF *C.* The genomic RNAs, being terminally redundant, contain two copies of this signal: one at the 5' end of the transcript and one at the 3' end. Thus, the transcriptional apparatus, which efficiently polyadenylates at this signal in subgenomic RNAs, must bypass this signal on its first pass in genomic RNA synthesis but use it efficiently on its second pass. (This problem is formally analogous to that encountered in retroviral genomic RNA synthesis, in which polyadenylation signals embedded in the 5'-LTR are ignored, but identical signals in the 3'-LTR are used).

Exactly how this problem is solved is still somewhat unclear, but the elements of the solution have at least been identified. Canonical eukaryotic poly(A) signals include the hexanucleotide AAUAAA, a cleavage site about 30 nucleotides downstream, and a U- or GU-rich element 3' to the cleavage site. Mammalian hepadnaviruses have polyadenylation signals that resemble these canonical signals, with one exception: the hexanucleotide is UAUAAA, which is known to function inefficiently. To bolster the efficiency of hepadnaviral RNA processing, the virus has evolved additional elements upstream of the hexanucleotide that enhance its use (455). Some of these elements are 5' to the genomic RNA cap site, such that full processing efficiency is possible only at the 3' end of the RNA. However, beyond this, it appears the the proximity of the 5' processing site to the 5' end of the RNA somehow drastically curtails its use (78,79). The mechanism by which cap-site proximity exerts this effect is unknown, but similar effects have been observed in cellular and retroviral transcripts (238).

X Protein and Its Role in the Virus Life Cycle

X Protein Is Required for Mammalian Hepadnavirus Infection in Animals

The small ORF located between EnI and the single polyadenylation signal of the HBV, WHV, and GSHV genome is referred to as the *X* gene, *HBx* or *pX,* originally reflecting a lack of evidence for gene expression. Subsequently, several groups showed that some infected individuals develop antibodies to X protein during natural infection (208,257,304), and X protein was detected by radioimmunoassay in some infected patients (407). The ORF *X* is contained within all of the mammalian hepadnavirus mRNAs, given its location just upstream of the single polyadenylation signal. However, a 0.7- to 1-kb RNA, corresponding solely to the ORF *X,* has been detected in hepatoma cells transfected with the entire HBV genome (191), and a specific *X* gene promoter was identified in transfected cells (190,509). It is assumed, but not proven, that the X protein is translated from the 0.7- to 1-kb transcript rather than from the core, pre-S1, or S antigen mRNAs through internal ribosome entry. An *X* gene–specific transcript was also detected in the livers of woodchucks chronically infected with WHV (102,253). In HBV-infected human liver tissue, a putative *X* gene mRNA was indirectly detected by reverse transcription–polymerase chain reaction amplification of X region–specific RNA (109,394). Although X protein has been detected in infected liver tissue (304,407,618), it is often difficult to do so because the protein is poorly immunogenic and has a short half-life (101,460). Consequently, it has been shown that immunohistochemical detection of X protein in infected liver tissue with certain antibodies can represent cross-reaction to cellular polypeptides (416,507). Nevertheless, it has been possible to unambiguously detect X protein in acute and chronically infected

woodchuck livers using high-affinity, multiple X protein–specific antibodies (102,240), where it is estimated to accumulate at 10,000 to 50,000 copies per cell (102). HBV X protein has been detected by a similar approach in infected human liver (416,507).

Seminal studies from Zoulim and colleagues (628) and Chen and associates (70) demonstrated that X protein performs an essential (but still unknown) function in WHV infection of woodchucks. Wild-type WHV genomic DNA, which expresses X protein, establishes an infection and an easily detectable viremia when directly injected into the liver of young woodchucks. Mutation of the *X* gene in a manner that does not disrupt the overlying Pol reading frame, either by elimination of the ORF *X* AUG codon or by severely truncating the COOH-terminus of the X protein, fully blocks establishment of infection. It was concluded that X protein performs an essential function in the infectious cycle of the virus, possibly to initiate or maintain viral replication, because there was no detectable level of WHV in serum or in liver tissue (628). This is consistent with a report that X protein expression strongly co-localized with active centers of WHV replication in the liver of chronically infected woodchucks (102). Consequently, HBV X protein is also thought to be essential for human infection. Although a replication function for X protein in viral infection still remains to be described in animal models, the first standard by which to consider various X protein activities is the requirement for viral infection in animals.

X Protein Is a Weak Transcriptional Activator

By comparing the location of the ORF *X* in the HBV genome to the genetic organization of complex retroviruses, it was proposed that the 154–amino acid (17-kd) X protein might possess transcriptional transactivating activity similar to the regulatory proteins Tat of HIV and Tax of human T-cell lymphotropic virus type I (HTLV-I) (350). HBV X protein was subsequently shown to possess a moderate ability (3- to 10-fold) to stimulate transcription of reporter genes (495,549). Subsequently, many reports demonstrated that HBV, WHV, and GSHV X proteins display a weak to moderate ability to stimulate transcription of a wide variety of enhancers and promoters (reviewed in 450 and 603). These include viral elements, such as the SV40 early promoter, the HIV LTR, the HSV tyrosine kinase promoter, and HBV EnI (303,480,486,488,495,549,584,616). Cellular promoter elements stimulated by X protein include those for interleukin-8, c-fos, c-myc, class I major histocompatibility complex, and tumor necrosis factor-a (TNF-a), among others (9,10,12,171,288,332,623; an extensive list can be found in 450). X protein also stimulates RNA pol I– and pol III–dependent promoters (adenovirus virion associated (VA) RNA, cellular transfer RNA [tRNA], and U6 elements) (6,8,282,563,564 and 565). RNA pol II transcriptional elements activated by the X protein usually contain a DNA-binding site for either NF-kB, AP-1, AP-2, c-EBP, ATF/CREB, or the calcium-activated factor NF-AT, among others (129,258,287,303,325,331,332,478,547,548,583). Biochemical evidence for activation of DNA-binding activity of NF-kB, AP-1, ATF/CREB, and NF-AT was also obtained (15,29,83,287,331,367,504,577,583).

The effect of X protein on HBV, WHV, and GSHV transcription elements is consistent with the weak transactivation observed for non-HBV transcriptional elements. When studied within the context of the whole viral genome in transfected hepatoma cells, most studies found that expression of X protein stimulates a modest increase (threefold to eightfold) in accumulation of viral mRNAs (94,263,295,362,594,628), although no effect on transcription was also observed in certain cell lines (34). These results imply that stimulation of transcription may not be a critical function of X protein during infection. Weak up-regulation of viral transcription is also not consistent with the absolute requirement for X protein in WHV infection (628). If the major function of X protein is to stimulate viral transcription slightly, then in its absence, there should be only a concomitant decrease in viremia. In contrast, serum and tissue levels of virus are actually undetectable in the absence of X protein expression (628).

Although it is possible during whole animal infection that X protein might stimulate viral transcription much more strongly than in cultured cells, there is presently no evidence to support this contention. Transgenic mice have been developed to express the HBV X protein specifically in the liver. When crossed with mice that express a reporter gene controlled by the HIV LTR, liver-specific expression of the reporter was increased by only three to six times (13). Therefore, X protein only modestly stimulates transcription of a wide variety of different elements, whether expressed in the context of the whole viral genome, independently in transfected cells, or in the liver of experimental animals. The importance of this weak transactivation activity in establishment of infection and virus replication remains to be determined in relevant animal models.

Mechanism of X Protein Action

Overview

A considerable amount of effort has been directed toward understanding the fundamental molecular activity of X protein. Although there has traditionally been little consensus regarding a common mechanism of action of X protein, several patterns have emerged, which are summarized here and reviewed later.

1. X protein is found largely in the cytoplasm and in small amounts in the nucleus of cells, whether expressed independently of other viral genes in transfected cells, in the context of HBV or WHV genomes, or in infected livers of humans and woodchucks (101,102,115,206,240,287,380,416,492,507,577). A few studies have described X protein as a predominantly nuclear protein in cell lines (202,214,488). In two of these instances (214,488), the nuclear location of X protein can be explained by the coexpression of SV40 large T antigen, which mediates nuclear accumulation of certain proteins, including X protein (115,479). Cytoplasmic X protein has not been found in association with organelles (115), although there is the possibility of an association with proteasomes (226,492).

2. X protein probably functions by several distinct mechanisms, which include direct interaction with components of the transcriptional machinery and stimulation of cytoplasmic signal transduction pathways.

3. The molecular actions of X protein are not restricted to transcriptional activation. Several studies concur that a fraction of X protein interacts with a probable DNA repair protein, known as UVDDB, which might affect viral replication,

pathogenesis, and carcinoma (26,30; for an extensive review, see 56,296, and 493). Whether X protein interaction with UVDDB alters nucleotide excision repair is presently unresolved. Using essentially similar assay systems to measure excision repair fidelity and frequency, several groups observed a slight to moderate decrease on expression of X protein (26,177,245,420), whereas another report did not (30). X protein has also been widely reported either to induce or sensitize cells to induction of apoptosis by pro-apoptotic cytokines and chemical agents in experimental cell systems and transgenic mice (30,84,261,505,528). However, in some systems, X protein is found to inhibit induction of cellular apoptosis (122,172,571), and the relationship of these observations to viral pathogenesis in animals and humans has not been investigated.

4. X protein is probably only weakly oncogenic at best, perhaps contributing indirectly to development of HCC (for an extensive review, see 4). Although X protein expressed in the liver of transgenic mice was originally reported to strongly promote tumorigenesis (259), this has not been found in subsequent studies, except perhaps at supraphysiologic levels of X protein expression (53,271,297). Moreover, studies implicating X protein interaction with, and impairment of, cellular p53 protein (134,541,570) have not been substantiated in more recent investigations (426, reviewed in 603). However, X protein was found to moderately promote development of HCC in the liver of transgenic mice coexpressing the *c-myc* gene (528) or when animals were exposed to hepatocarcinogens at levels that do not independently promote tumor development (102,494). Thus, it is probably correct to conclude that X protein expression is slightly pro-oncogenic.

X Protein Interacts with Several Components of the Transcriptional Apparatus

Most studies agree that X protein does not act by directly binding DNA (evidence reviewed in 603). Through interaction-cloning techniques using overexpressed proteins, it was shown that X protein associates with several components of the basal transcription machinery, including factors TFIIB and TFIIH, the RPB5 subunit of RNA polymerases, and TATA-binding protein (77,201,203,311,358,427,428). In these studies, coassociation of X protein and components of the basal transcription apparatus was observed in mammalian cells upon overexpression of both X and target proteins. Nevertheless, it is still possible that low levels of X-interacting complexes are sufficient to stimulate transcription but cannot be readily detected. X protein also directly interacts, *in vitro* and in cells upon overexpression, with the cyclic adenosine monophosphate (cAMP) response element–binding protein (CREB), a b-Zip family transcription factor (331,583). Evidence that X protein possesses a nuclear function in transcription, possibly by interaction with transcription components, is derived from three sets of observations:

1. X protein can stimulate transcription if tethered to a DNA-binding domain (202,478), which is consistent with, but does not prove, a direct mode of transcriptional activation.
2. X protein directly interacts with the basic leucine zipper region of CREB (583), which is involved in DNA-binding activity, and increases CREB affinity for its DNA-binding site by an order of magnitude (15,391,583). Occupation of the HBV EnI ATF/CREB-binding site is strongly enhanced *in vitro* by X protein interaction with CREB and correlates with CREB-dependent transcriptional activation of this element *in vivo* by X protein expression (4,15,399,583). A similar mechanism of action was described for X protein interaction with another b-Zip transcription factor, cEBPa (90).
3. X protein engineered to contain a nuclear localization signal, and shown to accumulate exclusively in the nucleus, strongly stimulates transcription from an EnI reporter construct in transfected cells, but no longer activates transcription dependent on factors NF-kB and AP-1 (115).

It should now be possible, using experimental approaches such as nuclear-targeted X protein, to determine whether nuclear activation of transcription occurs in the context of viral replication and whether it plays a role in the viral life cycle, pathogenesis, or transformation.

X Protein Stimulates Cytoplasmic Signal Transduction Pathways

Evidence from a number of groups indicates that X protein in the cytoplasm activates several related signal transduction pathways. It was first shown that dominant-inhibiting forms of the kinase Raf, an effector of the Ras-Raf-MAP kinase signal transduction pathway, could block X protein–induced activation of transcription factor AP-1–dependent transcription, as shown in transient transfection studies (99). It was then shown that a dominant-inhibiting form of Ras also blocks X protein activation of AP-1–dependent transcription (28,367,368). X protein increased Ras activity by increasing guanosine triphosphate (GTP) loading onto Ras, not by altering Ras-GAP activity (29). Importantly, the magnitude of Ras activation by X protein is not like that of growth factor stimulation, which strongly but transiently stimulates Ras. Rather, X protein only modestly stimulates Ras, but the activation is sustained or at least periodic (29,206). X protein stimulation of the Ras-Raf-MAP kinase pathway is critical for activation of transcription factor AP-1 in transiently transfected cells (28,29,97,99,115,262,367,368,504). More recently, X protein was found to stimulate Ras-Raf-MAP kinase signal transduction when expressed in the context of replicating HBV or WHV in hepatoma cells in culture (262,263). X protein stimulation of Ras was also found to be essential for its activation of RNA pol I– and pol III–dependent transcription in stably transfected insect cells (563,564 and 565). Thus, the ability of X protein to stimulate Ras is observed in a variety of cell types under different conditions. Retargeting X protein to the nucleus, by fusion to a nuclear localization signal, abolished activation of the Ras pathway (115). The activation of cytoplasmic signaling pathways by X protein is consistent with its predominant cytoplasmic location.

X protein was also shown to stimulate the stress-activated protein kinase (SAPK)-NH2-terminal-Jun kinase (JNK) pathway (29). This pathway is primarily activated by the Ras-related G protein Rac (107). Activation of the SAPK-JNK pathway by X protein was shown by several groups working with a variety of different cell lines, under different conditions (29,206,522; O. Andrisani, personal communication). Thus, there is good evidence that X protein stimulates Ras-Raf-MAP kinase and SAPK-JNK signal transduction pathways in the cytoplasm of a variety of different cells, whether expressed independently of other viral genes or from viral genomes during viral replication. It is not known whether these signal transduction pathways are activated by X protein in natural infection of animals and humans.

Although studies uniformly concur that X protein activates transcription factor NF-kB, whether activation of Ras or other

signaling pathways is involved is not resolved. One report found an essential requirement for X protein stimulation of protein kinase C in activation of NF-kB (258), whereas others did not (99,325,358,368,504). Two studies found that Ras signaling is necessary for NF-kB activation (115,504), whereas another did not (83). These discrepancies may result from the fact that NF-kB consists of multiple related proteins that may be activated to different extents in different ways (343,617). Related NF-kB proteins include p65/RelA, c-rel, and p105 (617). In most cells, NF-kB is sequestered in the cytoplasm, bound to inhibiting IkB proteins, which release NF-kB when phosphorylated by the IkB kinase (617). It has been reported that X protein directly binds to the cytoplasmic IkBa protein when both are overexpressed, mediating direct release of NF-kB and becoming transported to the nucleus (577). However, two previous studies did not detect direct interaction of X protein with endogenous NF-kB or IkB (83,504).

Activation of Ras by X protein is indirect because it has not been found in association with Ras, Ras-GAP, the GTP exchange factor Sos, or Ras adapter proteins Grb2 or Shc (29,262). More recent studies demonstrated that X protein activates Ras by activating the nonreceptor tyrosine kinases of the Src family, which are upstream activators of Ras GTPases (262). X protein constitutively activated Src kinases when expressed from WHV or HBV genomes during viral replication in cultured hepatoma cells and when expressed independently of the viral genome. Activation of Src kinases was modest (twofold to fourfold), as observed for X activation of Ras-signaling pathways. Additional evidence consistent with X protein activation of Src kinases includes X protein activation of the JAK-STAT signaling pathway (299), which is directly activated by Src kinases (544,607).

It is possible that some of the complications and contrasting results in the field of X protein research may be related to the finding that expression of the *X* gene in transfected cells can give rise to several related X proteins by alternate ribosome initiation at several in-frame AUG codons by leaky ribosome scanning (256,282,362,369,621). Although multiple X protein products have not been detected during replication of WHV in cultured cells (101,102), in transfected cells, they can apparently be synthesized from certain constructs and display somewhat different activities (282,362). Thus, expression of different related X proteins (whether biologically relevant or not) could influence different mechanisms of activation.

Possible Function of X Protein in Virus Infection and Replication

The molecular function of X protein in infection of animals and humans has not been investigated. However, studies have examined the function of X protein in WHV and HBV replication in cultured cells. Using cell culture systems, the activation of Src kinases by X protein, but not Ras, was found to stimulate HBV and WHV replication in hepatoma cell lines (263). In this system, ablation of X protein expression by mutation of the *X* gene impairs HBV and WHV replication 5- to 20-fold (94,263,295,347,362,594,628). Accordingly, inhibition of Src kinases impaired HBV and WHV replication 10- to 15-fold at the levels of reverse transcription of pregenomic core-associated RNA, and second-stranded DNA synthesis (263). Viral-specific transcription and translation were reduced only twofold to fourfold. However, it is not known whether X protein stimulates Src kinases during natural infection, nor whether the molecular function of Src kinases in viral replication is the same as in hepatoma cells. Importantly, activation of Src kinases cannot account for the entire function of X protein in viral replication in cultured cells because a constitutively activated form of Src only partially replaced X protein function (263). The mechanism by which X protein activates Src kinases has not been established, but it appears to involve calcium-dependent activation of the tyrosine kinase Pyk2 (M. Bouchard and R. Schneider, unpublished results), which is an upstream, calcium-dependent entry point into the Src pathway (110,302). Given X protein stimulation of calcium-dependent transcription factor NF-AT (287), it is possible that a fundamental activity of X protein is to release intracellular calcium, which could account for many of the reported activities of X protein.

Translation of Viral Gene Products

Hepadnaviruses have evolved multiple transcriptional and translational strategies to maximize the use of the limited coding capacity of their DNA. As previously noted, they make extensive use of overlapping reading frames (see Fig. 2), and within reading frames, they often employ multiple initiation codons to generate structurally related but functionally distinct proteins. Because of their 5'-scanning mechanism, host ribosomes tend not to initiate internally with high efficiency (277). Thus, to guarantee host ribosomes access to these internal AUG codons, the viral transcriptional program has deployed separate mRNA 5' ends just 5' to each AUG. In the case of the envelope proteins, it does this by (a) employing a dedicated promoter for the pre-S1 mRNAs, and (b) having the TATA-less S promoter display microheterogeneity of its start sites, such that some begin 5' to the pre-S2 AUG and others just 3' to it (58,499). In this way, both M and S proteins can be translated as the first ORF of a transcript (see Fig. 2).

Heterogeneous start sites also characterize the genomic promoter, whose RNA 5' ends bracket the pre-C AUG. Those initiating 3' to this AUG encode the C protein, the structural protein of the nucleocapsid (123,355,581). Those initiating 5' to this AUG encode the pre-C protein, which enjoys an altogether different biosynthetic fate. The pre-C region encodes a signal sequence that targets this protein to the secretory pathway (159,388,498). After cleavage of the signal in the ER lumen, the protein is transported through the vesicular transport system, undergoing cleavage of its basic C-terminal region in the process (242,243,462,498,569). Ultimately, it is secreted from the cell, accumulating in the extracellular medium (or serum) as the 17-kd protein known serologically as *e antigen* (HBeAg). In a minority of chains, ER translocation is aborted after signal peptide cleavage, and the resulting products are returned to the cytosol (159) or even the nucleus (390). The significance of these unusual events is uncertain. HBeAg immunoreactivity can also be found on the plasma membrane (462,466), although the mechanism of this cell surface localization is not well defined.

The function of HBeAg is still unknown. Clearly, it is dispensable for replication *in vitro* because nonsense or frameshift mutations within pre-C grow relatively well in cultured cells or in experimental animals (62,71,465,467). However, clinical studies of human HBV carriers show that during persistent infection, mutant viruses with pre-C lesions spontaneously and regularly arise, often coming to prevail over the wild-type virus after years of carriage (41,42,188,382,456,457,538). Transmission of these mutants confirms that they are infectious (198). This implies that there is some selection against HBeAg expression. Such a selection has also been seen in some experimental infections with mixtures of wild-type and pre-C–mutant DHBV isolates, although it is not a uniform occurrence in that setting (620). Because deliberate overexpression of pre-C can interfere with wild-type replication (186), it is conceivable that normal levels of pre-C

expression may confer a subtle growth disadvantage on the wild-type genome. Alternatively, host immunologic attack on HBeAg-bearing cells may select against cells infected by viruses expressing pre-C polypeptides. Whatever the mechanism of selection, all this raises a deeper paradox that is as yet unresolved: if there is a selection against pre-C products at the level of the individual host, how has the *pre-C* gene been maintained in the population? No entirely satisfactory answer to this question has yet been forthcoming. One proposal is that HBeAg may serve as a neonatal tolerogen (348); if so, transmission of pre-C–positive viruses could be selected for during vertical transmission because the induction of neonatal immune tolerance to HBV would promote the development of chronic infection in the infected baby. However, experimental studies do not show an important effect of pre-C proteins on immune function (440). Thus, the forces selecting for or against pre-C expression remain deeply enigmatic at present.

The genomic RNA species that initiates downstream of the pre-C AUG is the mRNA not only for C protein but also for P protein. Evidence that this is so comes from several sources: (a) it is the only identified viral transcript bearing the entire P coding region; (b) no viral transcripts have been identified with 5' ends just upstream of the P AUG, despite vigorous and sensitive searches; and (c) the fact that DHBV pregenomic RNAs are infectious (229) implies that P protein must have been translated from the input RNA. Examination of the coding organization of pgRNA shows that ORF *P* overlaps the 3' end of the upstream *C* gene; the P frame is +1 relative to the C frame. This organization recalls that of most retroviruses, whose upstream core gene (*gag*) overlaps the downstream polymerase gene (*pol*); there, however, the *pol* reading frame is –1 relative to that of *gag.* In those cases, the retroviral polymerase is expressed as a gag-pol polyprotein by ribosomal frameshifting in the overlap region (239). Early assumptions that this would prove true for hepadnaviruses seemed to be supported by the finding of proteins with both C and P immunoreactivity in HBV-infected liver samples (582). However, genetic studies with DHBV soon established that polymerase is made by *de novo* initiation at the P initiator rather than by C-P frameshifting. These studies showed that (a) mutation of the first P AUG to an ACU codon inactivates DNA synthesis; (b) stop codons in ORF *P* located 3' but not 5' to this AUG inactivate polymerase activity; and (c) *C* gene frameshift mutations do not impair the production of P protein (66,68,464). Subsequent experiments in HBV confirmed these findings and indicated that missense mutations in the P AUG could be reverted by construction of a new, in-frame AUG either upstream or downstream of the original mutation (244,454).

The mechanism by which ribosomes gain access to this internal AUG remains incompletely understood. Attempts to identify internal ribosome entry sequences of the type that function in picornavirus translation have failed, and *P* gene translation appears fully sensitive to poliovirus superinfection (66), suggesting that, like most translational events, it is cap dependent. Elaborate genetic studies have led to a model that invokes modified ribosomal scanning from the 5' end of genomic RNA. In this model, ribosomes scan from the cap site until they reach a small ORF overlapping the *C* gene; translation of this ORF allows bypass of a strong out-of-frame AUG that would otherwise occlude scanning further downstream, thereby allowing ribosomes that originated at the 5' end of the transcript access to the internal P AUG (140).

Genomic Replication

The Viral Polymerase

Early inferences that ORF *P* encoded the viral polymerase were strongly supported by the recognition of homology between this coding region and those of retroviral reverse transcriptases (532). Since then, many other reverse transcriptases have been identified from numerous sources, and all of them share sequence relatedness to the hepadnaviral enzyme. Sequence alignments between these coding regions reveal the existence of subregions with obvious homology to either other polymerases (including RNA-directed RNA and DNA polymerases) or to *E. coli* RNaseH (67,212,429,468). Mutational analysis of retroviral *pol* genes has confirmed that these regions indeed represent functional domains that control the polymerase and RNaseH activities of the retroviral enzyme (521). In hepadnaviruses, the polymerase homology domain is centrally located, whereas the RNaseH homology region is located near the C-terminus of the chain (Fig. 5).

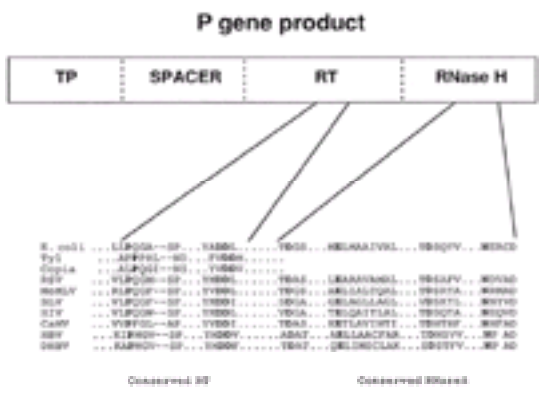

FIG. 5. Domain structure of the hepadnaviral P protein. **Top:** Schematic depiction of the functional domains of P protein. TP, terminal protein; RT, reverse transcriptase; RNaseH, ribonuclease H. **Bottom:** Amino acid sequence alignments with other RNA-dependent DNA polymerases; these homologies form the basis of the assignment of the RT and RNaseH domains.

In retroviruses and many retrotransposons, polymerase genes also encode protease and endonuclease activities, and recognizable homologies also characterize each of these activities. As might have been anticipated from the absence of a known role for integration in the growth of hepadnaviruses, no homology exists between ORF *P* and the integrases of other reverse-transcribing elements. Similarly, no functional protease homologies have been located within ORF *P* (or ORF *C*) (364), consistent with the fact that P protein is not processed from a C-P polyprotein.

The functional significance of these homology-based domain assignments has been validated *in vivo* through the study of mutant viral genomes bearing lesions in these regions. HBV and DHBV mutants bearing point mutations in highly conserved residues within the polymerase homology region are defective for viral DNA synthesis, whereas certain mutations within the RNaseH homology region allow negative-stranded but not positive-stranded DNA synthesis (67,130,429). Just upstream of the polymerase homology region, overlapping the pre-S coding domain, is a region of the *P* gene that is apparently unrelated to other polymerases and displays high sequence divergence between different hepadnaviral *P* genes. This region appears to define an unessential portion of the P protein because it tolerates a wide variety of substitution, deletion, and insertion mutations (18,67,306); 5' to it is the region implicated in the covalent linkage of the P protein to the viral DNA (see later). For this reason, the unessential region is often referred to as a "spacer" or "tether" region connecting the terminal protein (TP) domain to the polymerase and RNaseH domains (see Fig. 5).

Owing to the low abundance of P protein *in vivo,* it has been difficult to visualize P chains in virions. Attempts to do so by immunoblotting (329) or activity gel analysis (20,374) have often revealed species of less than full length, raising the question of posttranslational proteolytic processing. However, by engineering a protein kinase recognition site into the P chain (17), investigators were able to visualize directly encapsidated P chains after their phosphorylation *in vitro;* these studies strongly suggest that cores bear full-length P chains.

RNA Encapsidation

The classic experiments of Summers and Mason (510) indicated that virtually all reverse transcription takes place within subviral core particles, thereby implying that encapsidation of the genomic RNA template must represent the initial step in the genomic replication pathway. As noted previously, hepadnaviral genomic RNAs display microheterogeneities at their 5' ends (see Fig. 2), with the longer ones encoding pre-C proteins and the smallest one encoding the C and P gene products. Importantly, only the smallest genomic mRNA is encapsidated into the core particle (124), indicating that only this transcript (pgRNA) can serve as a template for reverse transcription; host RNAs, subgenomic RNAs, and even the closely similar longer genomic transcripts are excluded. (The basis of this fine discrimination among such closely related RNAs will be discussed later).

The viral proteins required for encapsidation have been identified by examining the impact of mutations in individual genes on pgRNA packaging. As expected, C protein is required to form the structure into which the RNA is packaged (212,293). Capsid formation is independent of pgRNA packaging: isolated *C* gene expression in heterologous hosts results in the accumulation of morphologically normal capsids devoid of pgRNA (33,93,388,448,580,626,627). However, such recombinant capsids do contain host and viral RNAs, which are encapsidated by virtue of the sequence-nonspecific nucleic acid–binding properties of the arginine-rich C-terminal domain of the molecule (33,153,199,363). (Deletion of this region still allows capsid formation, but not RNA encapsidation.) Assembly of capsids proceeds through C protein dimer intermediates (627); these dimers form very rapidly, perhaps even while the chains are still nascent (63). Once the dimers have reached a threshold concentration (estimated at 1 µmol), a sharply cooperative assembly reaction takes place to yield intact capsids (476). In general, no higher-order assembly intermediates can be detected *in vivo* between dimers and capsids. As a result, it is not yet known exactly where in this sequence the addition of RNA occurs.

The fine structure of recombinant HBV core particles produced by C protein expression in *E. coli* has been examined by cryoelectron microscopy (38) and x-ray crystallography (588). The individual C monomers have a unique folding pattern, unrelated to the b-barrel structure so often seen in capsid proteins in other viruses. Dimerization of these monomers occurs through association of two amphipathic a-helical hairpins, generating a four-helix bundle that protrudes from the capsid surface as a spike. Surprisingly, two different particle structures form in *E. coli*: T=3 capsids containing 180 C subunits, and T=4 structures containing 240 such subunits (38). Both particle types seem likely to exist *in vivo,* but it is unclear which can support formation of an infectious virion in the presence of pgRNA and the remaining viral proteins (or if both can do so). It is equally unclear what forces govern the assembly of C into these distinct structures.

In addition to the expected requirement for C protein, P gene products are also necessary for RNA packaging (16,212). Null mutations in ORF *P* result in cores with reduced or undetectable levels of pregenomic RNA. The P protein function required for packaging can be dissociated from those involved in DNA synthesis: many missense mutations that ablate polymerase or RNaseH activity are still competent for RNA encapsidation (212,429,453). This requirement for polymerase gene products in packaging of viral RNA is strikingly different from the retroviral case, in which only gag proteins are required.

How does the encapsidation machinery select the proper RNA? First, a cis-acting packaging signal is present on the encapsidated message. The location of this packaging signal was determined by assaying for the ability of hepadnaviral sequences to confer encapsidation upon heterologous transcripts to which they were fused. In HBV, a small (about 100 nucleotides) region from the 5' end of pgRNA (termed e) suffices to allow packaging (82,250,409). In DHBV, the corresponding e region is necessary but not sufficient; a second, noncontiguous region downstream of e is also required (57,213). Because of the terminal redundancy in pgRNA, the e element is present at both ends of the RNA. Interestingly, however, only the 5' copy is functional for RNA packaging; deletion of the 3' element has no impact on viral replication (213). How this position dependence comes about is unknown, but it helps to explain the exclusion of subgenomic RNAs from encapsidation (124). Although all viral transcripts harbor e sequences at their 3' ends, only the genomic RNAs harbor them in the 5' (functional) position (see Fig. 2); thus, subgenomic RNAs cannot be encapsidated.

Examination of the nucleotide sequence within e reveals a series of inverted repeats that can be predicted to fold into an RNA stem-loop structure (Fig. 6). This predicted stem-loop is phylogenetically conserved among all hepadnaviruses despite significant primary sequence variation in this region among the avian viruses (250). Consistent with this finding, direct biochemical analyses confirm that such a structure actually exists in HBV RNA (265,409). Mutational analyses have probed the regions of this structure that are functionally important for encapsidation (265,409,537). The lower stem (but only limited portions of the upper stem) must be base-paired, but primary sequence in this region is not critical; the

6-nucleotide bulge must be present, but again, primary sequence within the bulge can be radically altered without impairment of encapsidation. By contrast, the specific nucleotide sequence in the loop is critical, and base changes there are poorly tolerated by the packaging machinery.

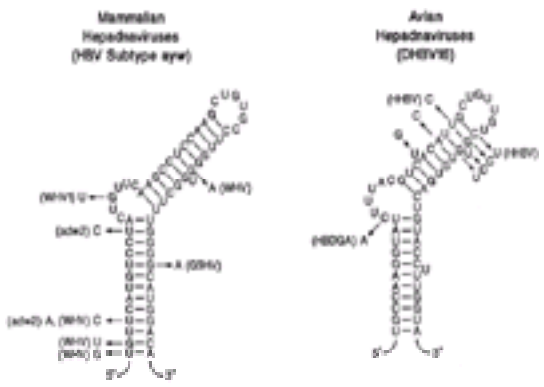

FIG. 6. Phylogenetic conservation of the e stem-loop structure in mammalian (*left*) and avian (*right*) hepadnaviruses. The positions of base changes in naturally occurring isolates are indicated.

What is the e recognition apparatus? The simplest model compatible with the genetic analysis of encapsidation is that P protein directly recognizes this element, and *in vitro* evidence for P protein–RNA interactions have been obtained by several groups (223,410). That this binding relates importantly to RNA encapsidation is supported by analysis of e mutations; all such mutations that block the P-e interaction *in vitro* block RNA encapsidation *in vivo.* However, there is one important discordance: loop mutations, known to strongly impair packaging *in vivo,* do not abolish P-e binding (410). This might mean that additional factors, possibly of host origin, may be binding to the loop region; alternatively (or additionally), lesions in the loop may subtly affect e structure. Searches for host proteins that bind to the apical loop have been unrevealing (400), but evidence for structural changes in e after P binding has recently been presented (25). Loop mutations that block encapsidation do not display these changes, suggesting that they are functionally significant (25).

The assembly of the P-e ribonucleoprotein (RNP) has recently been found to require host molecular chaperones and ATP (223,224). Addition of monoclonal antibodies to heat shock protein 90 (hsp90) blocks the ability of P synthesized *in vitro* to bind to e RNA, as does geldanomycin, a drug that blocks the association of hsp90 with its essential cofactor p23. (Interestingly, p23 also appears to bind directly to DHBV P protein, in a geldanomycin-resistant fashion.) The proteins p23 (and presumably hsp90) remain associated with the polymerase after encapsidation; this is unlike many other chaperone-assisted reactions, in which the association of chaperone and target is transient. However, clever temperature-shift experiments with a temperature-sensitive DHBV polymerase reveal that, after encapsidation and DNA priming, geldanomycin has no impact on subsequent reverse transcription (224). Thus, hsp90–p23 complexes act primarily to assist in the formation of an RNP competent for encapsidation and DNA priming (see later).

The next step in RNA encapsidation is presumably the association of the P-e complex with assembling core subunits. Detailed understanding of these events is lacking, but recent evidence indicates that HBV P protein produced in baculovirus-infected cells can interact noncovalently with C protein (R. Lanford, personal communication). Additional information has emerged from the study of structure–function relations within the DHBV P protein. By examining truncation mutants of DHBV P produced by *in vitro* translation, it has been shown that the C-terminus of P protein is dispensable for e binding; however, this same region is important for RNA encapsidation *in vivo* (212,410). This is compatible with a model in which the N-terminal two thirds of P protein binds pgRNA, leaving the C-terminus free to interact (directly or indirectly) with assembling C polypeptides. A full accounting of the mechanism of the encapsidation reaction will likely require development of an *in vitro* system in which the entire process is faithfully reproduced. The first step in this direction has been achieved: the assembly of “empty” HBV cores from C proteins produced in cell-free translation systems (312). However, no group has yet succeeded in observing P-dependent RNA encapsidation into such structures *in vitro.*

Thus, in hepadnaviruses, the encapsidation of polymerase occurs by a fundamentally different mechanism from that employed by retroviruses. The latter produce pol as a gag-pol polyprotein, which is assembled into capsids by interactions of its gag domain with assembling gag polypeptides. In hepadnaviruses, P protein is bound to the RNA that is destined for encapsidation, and noncovalent interactions, direct or indirect, between C and the P-containing RNP must exist to package the pregenome. Such interactions, however, must depend on a unique property of the P-e complex not shared by free P because DHBV genomes bearing e deletions produce cores that lack P protein as well as RNA (19). Perhaps one function of the stably complexed chaperones in the RNP is to maintain P protein in a conformation that is competent for interactions with assembling C subunits; evidence that P undergoes conformational changes after e binding has in fact been presented (525).

An interesting feature of the encapsidation reaction is the marked preference of the P gene product for its own mRNA during the packaging process. This is most easily demonstrated by cotransfecting a wild-type and P-negative mutant genome (which is differentially marked with a new restriction enzyme site). Examination of either the encapsidated RNA or the subsequently reverse-transcribed viral DNA reveals that the mRNA encoding the wild-type (functional) P gene product is preferentially encapsidated (90% to 95% of the encapsidated genomes are of wild-type origin) (212,293). The mechanistic basis of this cis-preference is unclear. One possibility is that the nascent P polypeptide co-translationally binds to its own mRNA. Alternatively, the levels of functional P gene product might be limiting, so that concentrations of P sufficient for encapsidation are found only in the vicinity of its own mRNA. In the case of HBV, the inefficiency in trans complementation can be at least partially overcome by deleting the encapsidation signal (16).

As noted earlier, the 5' ends of the genomic RNAs are heterogeneous, but only the shortest of these RNAs is encapsidated (124). Because all these transcripts contain an intact 5' copy of e, how is packaging of all but the shortest pregenomic RNA suppressed? Examination of the 5' termini of these RNAs indicates that all but the shortest transcript (i.e., pgRNA) include the upstream, in-frame pre-C AUG (see Fig. 2). Mutations that inactivate this AUG allow these longer messages to be encapsidated (365). These and other data suggest that translation through this region suppresses recognition of e. Because the shortest genomic RNA (pgRNA) lacks the pre-C AUG, such ribosome-mediated suppression cannot operate on this RNA.

Viral DNA Synthesis

The complex mechanism by which single-stranded pregenomic RNA is converted to partially duplex virion DNA is now understood in considerable detail. The current view of this reaction is summarized schematically in Figure 7. Pregenomic RNA is terminally redundant; its about 200-nucleotide redundancies (termed R) include the e stem-loop and a short sequence of 11 to 12 nucleotides termed *DR1.* Another copy of this same sequence is present near the 3' portion of the unique region of the RNA and is termed *DR2.* The potential importance of the DR sequences in viral DNA synthesis was recognized when the 5' termini of the viral DNA strands were precisely mapped. This showed that the 5' end of negative-stranded DNA mapped within DR1, whereas the 5' end of positive-stranded DNA mapped to DR2 (96,309,352,472,581). The exact roles of these sequences are discussed later.

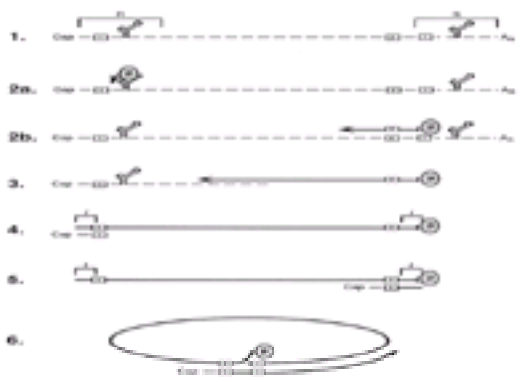

FIG. 7. The hepadnaviral reverse transcription pathway. Pregenomic RNA (*dashed line,* step 1) is capped and polyadenylated and has a large terminal redundancy (*R*). The locations of direct repeats 1 and 2 (DR1 and DR2) are shown as correspondingly numbered boxes, and the e stem-loops are indicated. Pregenomic RNA packaging into cores is initiated by the interaction of P protein with the 5' copy of e. P initiates reverse transcription at the 5' stem-loop and extends negative-stranded DNA (*solid line*) for 3 to 4 nucleotides (step 2a). P and the covalently attached nascent DNA are then transferred to the 3' copy of DR1 (step 2b), and the DNA is extended. During negative-stranded elongation, pgRNA is degraded by the RNaseH activity of P (step 3). When P reaches the 5' end of the template, its RNaseH activity leaves an RNA oligomer consisting of r plus DR1 sequences (step 4). This RNA oligomer is translocated and annealed to DR2, where it primes positive-stranded DNA synthesis (*lower solid line,* step 5). Positive-stranded elongation proceeds to the 5' end of the negative-stranded DNA template, including the sequences denoted as r. Because complementary r sequences are found at the 3' end of negative-strandeds DNA, a second homology-mediated template transfer can now circularize the genome. The positive strand is then extended for a variable length (step 6) to yield mature viral DNA.

Negative-Stranded Synthesis

Negative-stranded DNA has protein covalently linked to its 5' end (156,166,351). This so-called terminal protein was identified as the viral P protein by showing that viral DNA could be immunoprecipitated by anti–P protein antibodies (37). Limited proteolysis suggested that the N-terminal portion of the P polypeptide contained the site of covalent attachment to the DNA (18); this has now been directly confirmed for DHBV, in which the DNA protein joint has been precisely mapped to tyrosine 96 of the P protein (573,629).

Because of the fact that all nascent chains of viral DNA are found linked to P protein (351), virologists have for years suspected that the protein serves as the primer for DNA synthesis, in a fashion formally analogous to that established for the terminal protein of adenovirus DNA (61). This inference has now been directly sustained by a seminal experiment of Wang and Seeger (561). When DHBV P protein was translated *in vitro* (from a mRNA that also contains DR1 and e sequences) in the presence of ^{32}P- dNTPs, P protein chains become labeled by covalent attachment of nucleotides. Most product consists of P chains bearing bout 4 nucleotides; longer products (up to several hundred nucleotides) are present at a very low level. That this reaction reflects authentic viral DNA synthesis is indicated by the following: it is inhibited by mutations in the reverse transcription active site, and the sequence of bases at the DNA protein joint corresponds exactly to the authentic 5' end of viral DNA. In this reaction, the priming hydroxyl group is supplied not by a 3'OH of DNA or RNA but by the side chain of a tyrosine residue on P protein (573,629).

If P protein is the primer, what is the template for initiation? Because the 5' ends of viral DNA map to DR1, it was long assumed that the priming of negative-stranded DNA was templated by DR1 sequences. However, analyses of the DHBV priming reaction both *in vitro* (562,629) and in recombinant yeast expressing functional P protein (523,526) indicate that this is not the case. Rather, negative-stranded initiation is templated by sequences within the bulge of the e stem-loop. The involvement of e sequences in the reverse transcription reaction had previously gone unrecognized because *in vivo* e is required for the RNA packaging step that is a necessary precondition for DNA synthesis. Thus, defects in DNA synthesis due to e mutations could be accounted for entirely by their RNA packaging defect. However, both of the recombinant P protein expression systems mentioned previously were designed to be independent of DHBV packaging

functions. Under these conditions, the involvement of e in reverse transcription rapidly became apparent: deletions of e (or even of the e bulge alone) completely ablated all viral reverse transcription. Analysis of large numbers of more subtle e mutations reveals a close correlation between lesions affecting RNA packaging and those affecting DNA priming, suggesting that the same RNA protein recognition reaction underlies both processes (410). In accord with this, blockade of P-e RNP formation with anti-hsp90 or geldanomycin also blocks DNA priming (223,224). Taken together, these data all indicate that initiation of viral DNA synthesis occurs within e, not DR1 as initially supposed.

There is growing evidence that this critical step results in structural changes in both the RNA template and the enzyme that may be required to facilitate the subsequent events in the replication cycle. Beck and Nassal (25) have shown that the fine structure of e is subtly altered by P protein binding, and analysis of e mutants indicates that this change is correlated with competence for DNA synthesis. Similarly, the P protein may also undergo conformational changes following binding. This was initially revealed by an altered susceptibility of P to proteolytic digestion after contact with e RNA. All e mutations that allow DNA priming induce this change, whereas those that do not (including apical loop mutations that can still bind P but do not allow DNA synthesis) fail to induce the change (525). Thus, the e RNA might serve not only as the template for the polymerase but also as its allosteric effector.

The next events in replication are depicted schematically in Figure 7. After P-e binding, initiation occurs within the e bulge, generating an initial P-linked oligonucleotide of about 4 nucleotides. Because the sequences of the e bulge and DR1 share 4 nucleotides of identity, this DNA product can be transferred and annealed to DR1 sequences; from this position, the DNA can be extended by traditional elongation mechanisms (524,526,562). This strand transfer reaction has been studied in great detail but remains incompletely understood. It is clear that sequence homology between donor and acceptor sites is required for the reaction because disruption of the homology strongly impairs transfer (246,315,524). However, second-site mutations in DR1 that restore complementarity to a mutant e region do not always restore efficient transfer, indicating that homology, although necessary, is not sufficient for the reaction. Many other factors appear to be involved, including local sequence or structure surrounding the acceptor site, the position of the acceptor site relative to the donor, and the length of the transferred strand (317,524).

Both DR1 and e are represented twice in the pgRNA template. The fact that the 3' copy of e can be deleted from pgRNA without blocking viral replication (473,474) suggests that it is the 5' copy of e that is functional in initiation. This inference has been directly validated by genetically marking the 5' e with a sequence polymorphism and showing that this sequence marker appears at the 5' end of negative-stranded DNA after one round of reverse transcription (526,562). Analogous genetic tagging experiments indicate that it is the 3' copy of DR1 to which the nascent P-linked primer is transferred (473). Once this transfer reaction is complete, elongation can continue to the end of the RNA template. As negative-stranded elongation proceeds, degradation of the newly copied pregenomic RNA template occurs concomitantly (349,510); this is necessary to make negative-stranded DNA available to template positive-stranded synthesis. As in other reverse transcription reactions, this function is attributed to the RNaseH activity of the viral polymerase itself (429). Consistent with this notion, lesions in the RnaseH domain of P inhibit positive-stranded synthesis (67,429). The final product of this elongation reaction is a negative-stranded DNA that is actually terminally redundant by about 8 nucleotides (this shorter redundancy is known as r) (309,472,581).

Positive-Stranded Synthesis

After negative-stranded DNA synthesis is complete, positive-stranded DNA synthesis can begin. Positive strands are initiated at DR2 (309,472,581) (see Fig. 7), in a reaction primed by short (about 15 to 18 nucleotides), capped oligoribonucleotides derived from the 5' of pregenomic RNA; these include DR1 sequences and the 6-nucleotide 5' end of DR1. The viral RnaseH activity is also presumed to be responsible for the cleavages that generate these primers. The reaction does not proceed by sequence-specific endonucleolytic cleavage at the border of DR1 because nucleotide changes around the cleavage sites do not perturb either the specificity or efficiency of cleavage (500). However, when insertions or deletions are placed between the 5' end of pregenome and the 3' end of DR1 (316), the sites of cleavage remain a constant distance (15 to 18 nucleotides) from the 5' end of the pregenome. This indicates that the cleavages are somehow positioned by measurement from the end of the template and that the actual scission event is independent of the sequence at the cleavage site. A model for how this distance might be measured has been proposed (316).

The site of primer generation is many hundreds of bases away from the actual site of positive-stranded DNA synthesis at DR2. Thus, the newly cleaved RNA primer must be translocated to the 5' end of negative-stranded DNA to base-pair with DR2 for positive-stranded DNA synthesis to begin. Because the primer is being moved from a region (including r and DR1), where it is base-paired for 18 nt to a region (DR2) where it is base-paired for only 12 nt (see Fig. 7); this primer translocation is not thought to occur passively. Most likely, it is actively facilitated by proteins, but how this is accomplished remains a matter of conjecture. It is known that positive-stranded synthesis is very sensitive to mutations not only within the primer but also to lesions in several other regions of the template, including a region in the middle of the genome and others near DR2 and DR1 (200,315,318,319,357). The two terminal regions have the potential to base-pair with the central region (D. Loeb, personal communication), suggesting that these regions may be important in maintaining a structure in the template that facilitates the transfer, perhaps by juxtaposing the donor and acceptor sites.

Occasionally, primers that are cleaved fail to be translocated. This occurs at a low rate with wild-type virus genomes (about 1% to 5% of primers) but can be greatly increased by cis-acting mutations in and around DR1. Typically, primers that are cleaved but not translocated are instead extended from their original position, a process referred to as *in situ* priming. The result is fully duplex linear viral DNA (500). Such molecules are found in all stocks of hepadnaviral particles. Many of these duplex linear DNAs are dead-end products. However, recent work has shown that some of these species can participate in a variety of illegitimate recombination reactions, with interesting consequences. Although the viral life cycle is maintained by episomal DNA, integration of the genome into host DNA is known to occur at low frequency, an event that in some systems plays a role in hepatocellular carcinogenesis (see later). Analysis of these integrants suggests that a substantial fraction of them likely derive from double-stranded linear DNAs produced by *in situ* priming (168,169 and 170; W. Yang and J. Summers, personal communication). Illegitimate recombination can also circularize such linear DNAs, generating cccDNA forms with abnormal circle junctions. Some of these are competent to undergo additional rounds of transcription and reverse transcription, a process that has been termed *illegitimate replication*

(597,598 and 599).

Once the RNA primer is translocated, synthesis of positive-stranded DNA can begin. Elongation proceeds to the 5' end of negative-stranded DNA, at which point the template is exhausted and an intramolecular strand transfer is required to complete positive-stranded synthesis (see Fig. 7). This transfer is facilitated by the short redundancy (r) in the negative-stranded DNA template: annealing of the nascent positive strand DNA (by its r homology) to the 3' end of the negative strand circularizes the genome and allows continuation of positive-stranded synthesis. As for other hepadnaviral strand transfers, sequence complementarity is necessary but not sufficient for this process. Circularization can be affected by other variables, including the sequence and length of the transferred strand and the sequences adjacent to DR1 at the 3' end of negative-stranded DNA (200,315,318,319). Once accomplished, the strand transfer allows positive-stranded synthesis access to the rest of the negative-stranded DNA template. However, in most cases, synthesis does not proceed to completion (the exception is DHBV, in which 80% of the positive strands complete elongation) (310,352). The result is the characteristic single-stranded gap that is a hallmark of hepadnaviral DNA.

Why positive-stranded synthesis terminates prematurely is not entirely clear but might be related to the process of viral budding. The DNA of cytoplasmic core particles is substantially more immature than that of extracellular virions, suggesting that maturation of viral DNA synthesis is somehow coupled with envelopment and secretion of the Dane particle. In keeping with this, *P* gene mutations affecting viral DNA synthesis can strongly influence envelopment and release (162,576). Presumably, a structural change or posttranslational modification of the core particle occurs concomitant with reaching a certain stage in genome maturation (608), creating a signal for core envelopment. Once budded into the ER, the core particle would presumably no longer have access to cytoplasmic dNTP pools, and further DNA synthesis would be expected to arrest.

Viral Assembly and Release

20-nm Subviral Particle Assembly

As noted previously, 20-nm particles contain predominantly the S protein with variable amounts of M and only trace quantities of L subunits. With the advent of cloned HBV DNA, it became possible to express the surface protein coding regions in heterologous cells, leading to the discovery that cells expressing only the S polypeptide can assemble and secrete morphologically normal 20-nm particles. Thus, all of the viral information necessary for this assembly process resides in the S domain (290,313,401). Because the cellular machinery for particle assembly is present in virtually all vertebrate cells, expression of 20-nm particles is possible in a wide variety of expression systems (116,353,501). This has made possible the development of recombinant HBV vaccine, the first recombinant DNA-based vaccine licensed for any human infectious disease. Interestingly, yeast cells (the source of one widely used recombinant vaccine) do not secrete HBsAg and may not form intracellular particles at all. However, subparticulate lipoprotein aggregates of S subunits likely do form intracellularly and may rearrange during extraction to yield immunogenic particulate antigen (557,560).

How do 20-nm particles form in mammalian cells? Early electron microscopic studies of infected liver revealed that particles accumulated within cisternae of the ER (161), an observation also confirmed by later electron microscopic studies of transfected, HBsAg-positive cells in culture (395). Consistent with this is the fact that intracellular particles contain asparagine-linked high-mannose oligosaccharide chains, a modification specific to the ER (396). Subsequent biochemical studies have more precisely localized the major site of particle assembly to the so-called intermediate compartment between the ER and Golgi (232). Assembled complexes are then transported through the constitutive secretory pathway, traversing the Golgi complex, where their carbohydrates are processed to the complex, endoglycosidase H-resistant form (396). Transport of the complexes through the Golgi appears to be the rate-limiting step in export because all intracellular glycosylated S protein is found in the endoH-sensitive form, whereas all extracellular glycosylated HBsAg is endoH resistant.

S proteins are synthesized in the ER as integral membrane proteins. Their transmembrane topology has been determined in cell-free translation systems supplemented with ER-derived microsomal vesicles (117,119). In these experiments, nascent S protein chains were found to be oriented in the bilayer such that both N- and C-termini are in the vesicle lumen. To do so, the polypeptide must span the bilayer at least twice; many current models, based largely on theoretical considerations, envision up to four transmembrane passages (Fig. 8). (The S coding region contains three hydrophobic domains, encompassing residues 4 to 28, 80 to 100, and 164 to 221. Hydrophobicity and other considerations lead most to assume that all of these regions are located within the bilayer, generating the model of Figure 8. However, the disposition of the C-terminal hydrophobic domain has not been experimentally assessed.) This topology is achieved through the conjoint action of two topogenic signal sequences. Signal I corresponds to the first hydophobic domain and initiates chain translocation across the bilayer. It resembles conventional N-terminal signal sequences except for the fact that it remains uncleaved during translocation. Signal II (corresponding to the second hydrophobic domain) is a complex topogenic element that serves both as a stop-transfer sequence (anchoring the protein in the bilayer with residue 80 facing the cytoplasm and residue 100 facing the ER lumen) and a signal sequence directing the translocation of the distal region of the molecule. Thus, the region between signals I and II is a cytoplasmic loop; downstream of signal II is the major glycosylation site of S as well as its immunodominant surface epitope.

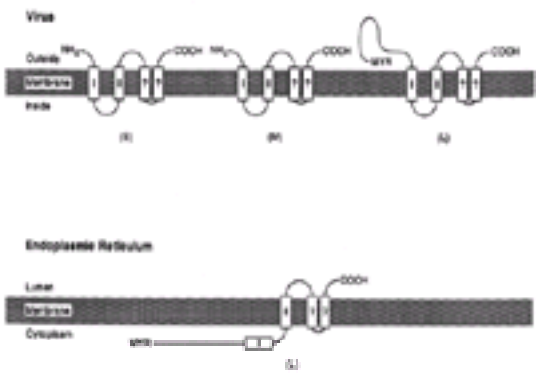

FIG. 8. Top: Proposed transmembrane topologies for the HBV L, M, and S glycoproteins in the virion envelope. *Rectangles* denote S-protein hydrophobic domains. [The transmembrane orientation of domains I and II have been addressed experimentally (87), whereas the disposition of the remaining hydrophobic regions remains speculative.] The *psi* symbol denotes *N*-linked carbohydrate. *Myr* is the myristate group in amide linkage to glycine at the N-terminus of L protein (292). **Bottom:** Transmembrane structure of L protein in endoplasmic reticulum membranes. Virtually all pre-S sequences reside on the cytoplasmic face of the membrane. (The disposition of S hydrophobic region I is here drawn as cytoplasmic, but this has not been directly validated.)

This transmembrane form of S is only a transient intermediate in particle formation; *in vivo,* this form is rapidly converted to a series of defined assembly intermediates (232,491), and *S* gene mutations affecting one or more of these steps have been examined (44,418). After membrane insertion, the transmembrane monomers aggregate and in the process exclude host proteins from the complex. (With one exception, in DHBV, subviral particles also harbor large quantities of the host chaperone hsp70, a known participant in many protein-folding reactions. Because hsp70 is a cytosolic protein, it must be interacting with cytoplasmically disposed regions of the viral envelope proteins. It is not clear, however, why so much hsp70 remains in the final particle because in most other folding reactions, the chaperone is released from its targets once folding is accomplished.) The aggregate then buds or extrudes into the lumen. It is likely that this extrusion event differs from more conventional viral budding reactions in that the “budded” product lacks a typical unit membrane structure. In addition, its lipid content is much lower than that of most cellular membranes, suggesting that that the host lipids may be substantially reorganized in the process.

This pathway shares many features with morphogenetic events postulated for the envelope proteins of other animal viruses: transmembrane insertion, aggregation, and budding. However, in other viruses, envelope glycoproteins remain anchored in the bilayer until interactions with other viral components (e.g., nucleocapsid or matrix proteins) trigger the budding step, thus ensuring that envelope proteins can exit the cell only by enveloping the nucleocapsid. The distinctive feature of the S protein is that it can carry out the entire assembly sequence without the involvement of other viral proteins. The result is the release of the subviral particles containing only envelope proteins—the distinctive signature of hepadnaviral infection.

In authentic viral infection, 20-nm particles frequently contain M as well as S subunits (204,503). In such particles, the pre-S2–encoded domain of the M protein is exposed on the particle surface, as demonstrated by (a) its reactivity with antisera specific for the pre-S2 domain of M, and (b) its ability to bind polymers of human albumin, an activity of uncertain biologic importance that is mediated uniquely by this domain (326,327,401). Given its surface location on the particle, in the transmembrane form of the M protein, this domain would be predicted to be translocated into the ER lumen (Fig. 9); this prediction has been experimentally confirmed (118). Because the pre-S2–encoded domain lacks a definable signal sequence, its transmembrane transport must be mediated by the downstream signals in the S domain.

Natural history of experimental HBV infection of two chimpanzees. **Left:** Chimpanzee, 1558. **Right:** Chimpanzee, 1564. **Top:** serum hepatitis B virus DNA levels and HBsAg levels as a function of time post inoculation. **Center:** Liver HBV DNA levels and the percentage of HBcAg-positive hepatocytes as a function of time after inoculation. **Bottom:** Serum transaminase levels and the percentage of hepatocytes undergoing mitosis (*black bars*) or apoptosis (*gray bars*) as a function of time after inoculation. (From ref. 187, with permission.)

As noted previously, natural 20-nm particles often lack detectable L protein (204). The reason for the low abundance of L chains on 20-nm particles became clear in experiments in which L chains were deliberately overexpressed in cultured cells. In cells infected with vaccinia vectors that express only the L protein, the L chains themselves are not secreted, despite the presence of an intact S domain that contains all the information required for the export process (76). This

suggests that the pre-S1–specific domain of L contains signals that promote intracellular retention of the chain and that can override the secretory elements in the S domain. When L chains are overexpressed in the presence of M and S chains, the ability of the M and S chains to be secreted is inhibited in a dose-dependent fashion (76,88,389,402); all three chains accumulate intracellularly (87). Presumably, this reflects the formation of mixed arrays of L, M, and S subunits, with the inhibitory influence of the pre-S1 domain now being conferred upon the entire aggregate. The inhibitory effect of L overexpression on S particle secretion explains the underrepresentation of L chains on 20-nm spherical particles.

The region of the pre-S1 domain that specifies the intracellular retention of HBsAg has been mapped by deletion mutagenesis to the extreme N-terminus of the molecule (281). The observation that this region of the L protein is myristoylated (403) raised the possibility that ER retention might be mediated by the affinity of this hydrophobic fatty acid for the ER membrane. However, point mutations that ablate myristylation have either no (281) or only incomplete (417) effects on secretion-inhibition, indicating that primary sequences in this region of the chain are important for this activity. The mechanism of the secretion-inhibition by L remains uncertain. Early models proposed that L chains might not be mobilized from their transmembrane state. However, subsequent studies (589) suggest that, when expressed in the absence of M and S proteins, L chains form intraluminal aggregates that remain trapped within the secretory system, where they can be found associated with the chaperone calnexin. This suggests that the block to release is distal to the budding step. Interestingly, in electron microscopic studies of the hepatocytes of transgenic mice overexpressing L chains (relative to M and S), 20-nm filamentous forms were frequently observed in the ER (87). This accords well with earlier observations that filaments are relatively enriched in L subunits (204) and suggests that filaments may arise in regions of the ER where local concentrations of L are high relative to S.

The overaccumulation of retained L-M-S aggregates can be injurious to the host cell. Hepatocytes of transgenic mice bearing such aggregates develop characteristic cytopathic effects (in the relative absence of inflammation) and are very sensitive to killing induced by interferon-a (IFN-a) and TNF (361). Morphologically similar cells, termed *ground-glass hepatocytes* by pathologists, are sometimes seen in biopsy specimens from acute hepatitis B, indicating that deregulation of envelope protein expression may make some contribution to the process of liver cell injury. The magnitude of this contribution, however, is uncertain, and is likely to be modest.

Dane Particle Assembly

Conceptual views of Dane particle assembly have been heavily influenced by the emerging understanding of the morphogenesis of subviral particles. Because all three HBV envelope proteins are expressed primarily on intracellular membranes rather than on the cell surface (389), virion formation almost certainly proceeds on intracellular membranes; EM studies consistent with this have been reported (252,446). However, an important distinguishing feature of virions is that they contain relatively large quantities of L proteins; in the best preparations, the ratio of L to M to S subunits was about 1:1:4 (204). Because these preparations are often contaminated to some extent with 20-nm particles, it is possible that the ratio of L to S chains in authentic virions is still higher. It is unlikely that subviral particles bearing this much L protein could be efficiently released; this suggests that distinctive mechanisms are involved in virion assembly and export.

To define the components required for Dane particle production, permissive HepG2 cells have been transfected with missense or nonsense mutants selectively affecting the HBV L, M, or S proteins and the ability of these mutants to support virion release assayed (45). Several conclusions have emerged from these studies: (a) unlike retroviruses, whose nucleocapsids can still bud out of cells in the absence of envelope proteins, no HBV cores are exported if the synthesis of all envelope proteins is aborted by nonsense mutations in S; and (b) both L and S proteins are required for virion formation and release. Although one report to the contrary has appeared (552), the weight of evidence is that M proteins are not required for assembly (45,137,457). Missense mutants affecting L myristylation also remain competent for virion assembly and secretion, although the unmyristylated virions are noninfectious (45,46,330,513). Myristylation may thus play its most important role in the adsorption, entry, or uncoating of virions on the next cycle of infection.

How the L protein contributes to viral assembly remains incompletely understood, but recent studies of its transmembrane topology have suggested new possibilities. Studies of HBV virion architecture reveal that the L protein–specific, pre-S1–encoded domain is exposed on the virion surface. For example, it is accessible to exogenous proteases as well as to pre-S1–specific MAbs (204,280,385). This would suggest that, like pre-S2, the pre-S1 domain in the transmembrane form of L should reside in the ER lumen. However, biochemical studies of HBV L chains synthesized *in vitro* in the presence of microsomal membranes indicated that this is not the case; rather, most pre-S–encoded L protein sequences are on the cytoplasmic surface (385). This result was subsequently confirmed by similar analysis of nascent HBV L chains *in vivo* (47,419) and is supported by other findings that indicate that pre-S1 regions are at least transiently cytosolic (see Fig. 8). For example, DHBV and HBV L chains can associate with cytosolic hsp70, through sites mapped to the pre-S region (320,518). Moreover, HBV and DHBV pre-S can undergo phosphorylation by cytosolic kinases (173,174,452). This phosphorylation has no impact on viral replication or assembly but is required for yet another known activity of L protein—its ability to up-regulate reporter genes in co-transfection assays (210).

This topology helps to explain how L might make a distinctive contribution to virion morphogenesis because it now can present unique determinants to nucleocapsids on the cytoplasmic face of the ER membrane. In one attractive model, capsid–L protein interactions trigger the budding event that incorporates the mature core into the viral envelope. This notion is supported by mutational studies examining the impact of pre-S topology on virion assembly. If the pre-S region of L is delivered to the ER lumen by an engineered N-terminal signal sequence, no virions can be formed, despite the fact that subviral particles can still be assembled and released (47). Examination of deletions and linker scanning mutations within pre-S confirms that only those mutations whose pre-S domain is cytosolically disposed are competent for virion assembly, and point to a region at the pre-S1–pre-S2 border as critical for virus production (43,48,49). The simplest model is that this region is directly involved in contacting the nucleocapsid.

We are left, however, with an important remaining problem: how does the pre-S1 domain wind up on the surface of the budded virion? One possibility is that nascent L chains exist in two orientations in the ER: one with luminal pre-S sequences and another with cytoplasmic pre-S domains. However, virtually all detected nascent chains have only

cytoplasmic pre-S determinants. A more likely scenario is that during or after budding, the components of the envelope undergo a dramatic rearrangement, resulting in delivery of the pre-S1 domain across the bilayer. How such a process would occur remains mysterious, but it happens with surprising efficiency; biochemical analysis of mature virions indicates that more than half of their constituent L chains bear pre-S1 regions that have been transposed to the virion surface (47).

Nuclear Delivery of Progeny Core DNA: cccDNA Amplification

Consideration of the overall replication cycle schematized in Figure 3 indicates that the central genomic species involved in viral persistence is nuclear cccDNA. Only cells that harbor this form of the genome can continue to produce virus. Because hepadnavirus-infected cells are not killed by viral replication, they may continue to grow and divide. (Admittedly, under normal circumstances, hepatocytes divide infrequently, but proliferation is often greatly enhanced during chronic infection as a result of inflammation and regeneration.) Thus, a mechanism must exist to ensure the inheritance of this molecule by both daughter cells after mitosis. In principle, this problem could be solved by equipping cccDNA with an origin for semiconservative DNA replication because all the machinery for this process exists in the nucleus; this would be analogous to the solution adopted by Epstein-Barr virus or papillomaviruses, for example. However, density labeling studies (545) indicate that this is not the case: all nuclear cccDNA is derived instead from the reverse transcription pathway. Because reverse transcription is a cytoplasmic process, this implies that mechanisms exist to deliver cytoplasmic reverse transcription products into the nucleus. For DHBV, such mechanisms operate efficiently early in the establishment of infection in primary duck hepatocytes, leading to the rapid accumulation of 10 to 20 or more copies of cccDNA per nucleus.

One possible way to account for the maintenance of a pool of cccDNA would be to imagine that it was replenished by reinfection of cells by extracellular virus. However, it was soon shown that cccDNA amplification could be observed in the presence of inhibitors of viral entry like suramin or neutralizing antibody; it also can occur after transfection of viral DNA into cells that lack the surface receptor, thereby eliminating the possibility of reinfection by released progeny virus (587). Thus, cytoplasmic cores bearing virion DNA can be shunted to the nucleus by an intracellular pathway. A key step forward was made with the recognition that DHBV mutants lacking the L envelope protein (or bearing certain point mutations in pre-S) (301) displayed greatly enhanced amplification, resulting in the nuclear accumulation of very high levels of cccDNA (512,513). This implies that the subcellular trafficking of cores is regulated: early in infection, when envelope proteins are at low levels, nuclear delivery is favored, allowing accumulation of cccDNA. This ensures that this infected cell will be stably colonized. Late in infection, with rising levels of envelope proteins, export of cores as virions is favored, allowing horizontal spread of infection to surrounding cells. Thus, in this view, nuclear transit is the default pathway; as envelope proteins accumulate, cores are shunted from this pathway to the export pathway.

Examination of DHBV pre-S mutants that up-regulate cccDNA accumulation reveals that these variants are often cytotoxic; presumably, cells do not tolerate high levels of cccDNA or the resulting elevated levels of viral gene products. The mechanisms of this toxicity are unknown but are not immune mediated because this phenomenon is also observed in cultured cells. Infection of animals with DHBV pre-S point mutants that display deregulated cccDNA gives rise to an early phase of liver injury, which subsequently resolves; this resolution is accompanied by the outgrowth of noncytopathic second-site revertants that restore normal cccDNA regulation (300).

VIRAL PATHOGENESIS AND IMMUNITY

Save for the rare pre-S mutants just described, hepadnaviruses are generally agreed to be noncytopathic. If the viral replication cycle is not itself injurious to hepatocytes, how does clinical hepatitis arise? And why do some individuals develop serious liver disease, whereas others escape with only minor pathologic changes? Correlative clinical data suggested early on that host immune attack on infected hepatocytes, a response normally designed for clearance of infection, might also be the prime source of the injury (and that variations in the magnitude or nature of this response might account for the variety of clinical outcomes in different hosts). Here we summarize the growing body of experimental evidence that supports this inference and outline the mechanisms now thought to be involved.

The study of immune responses to HBV has long been bedeviled by a number of experimental obstacles that have only recently been overcome. HBV grows only in humans and higher primates, a fact that has severely constrained immunologic investigation. Apart from the evident ethical constraints involved in human experimentation, all primate hosts are genetically outbred, making many experimental manipulations of immunity (e.g., adoptive transfer of sensitized lymphocytes) impossible. Similar difficulties apply to the study of the other animal hepadnaviruses (e.g., WHV and DHBV), all of which grow poorly or not at all outside of their outbred native hosts. Thus, efforts to understand immune responses to hepadnaviruses in their native hosts have been limited largely to descriptive studies. Nonetheless, such studies have provided a useful starting point for hepadnaviral immunology because any model for immune-mediated liver injury must account for their observations.

As noted at the outset of this chapter, most primary infections of immunocompetent adults result in variable degrees of acute hepatitis, following which viral infection is cleared. Figure 9 depicts the virologic, serologic, and pathologic events seen in a primary HBV infection, here studied in two experimentally inoculated chimpanzees (187). After an incubation period of 4 to 6 weeks, HBsAg and viral DNA become evident in the serum, peaking at about postinoculation week 8, at which time more than 75% of hepatocytes in the liver display HBcAg by immunohistochemical analysis. In DHBV and WHV, virtually 100% of hepatocytes are infected in a typical primary infection (247,248,251). Importantly, at the peak of virus production, there is little evidence of liver injury, either histologically or by measurement of serum transaminases—in keeping with the noncytocidal nature of the viral replicative cycle. However, beginning 1 to 3 weeks thereafter, serum markers of liver injury become dramatically abnormal, along with histologic evidence of inflammatory cell infiltrates and cell destruction—markers of cell-mediated immunity. A particularly important point is that a 10-fold decrease in intrahepatic (and serum) viral DNA is evident even before the onset of liver injury (see Fig. 9; more about this anon). Ultimately, viral DNA and antigens are cleared from liver and blood, inflammatory infiltrates resolve, and serum

antibody to HBsAg provides immunity to reinfection.

Given the enormous size of the liver and the huge burden of infection achieved, clearance of HBV and other hepadnaviruses during acute hepatitis is remarkably efficient. However, although this clearance process achieves eradication of clinically detectable infection, there is evidence that a few infected cells may persist in the hosts after successful resolution of acute disease. For example, very sensitive nested polymerase chain reaction assays can detect low quantities of viral DNA in liver and serum of some such hosts years after primary infection (438,439). Virus-specific cytotoxic T lymphocytes (CTLs) are also detectable at high frequency in most such cases many years later (438,439). In fact, such CTLs may display activation markers, suggesting that a few persistently infected cells remain in the body and serve as ongoing stimuli of such responses. Rare reports that organ donors with serologic profiles compatible with resolved infection can occasionally transmit HBV after liver transplantation are compatible with this notion (69).

What are the determinants of successful clearance? Efforts to answer this question have focused on comparison of HBV-specific immune responses in patients who clear primary infection with those who fail to do so. Particular emphasis has been placed on the role of CTLs in this process (86). In those in whom primary infection resolves, the CTL response to HBV is vigorous, polyclonal, and directed against most or all of the viral gene products (31,85,181,236,397,398). The breadth of these responses may be important in preventing the emergence of CTL escape mutants, although rare escape or antagonist mutations have been observed (32). By contrast, in chronic HBV carriers, CTL responses to viral antigens are weak or undetectable. Such carriers often display weak responses of helper (CD4+) T cells to viral antigens as well. The latter may not be due to deletion of such cells because successful reduction of viral loads with lamivudine can restore significant CD4+ cell proliferative responses to viral antigen (36), although this does not result in clearance of infection.

These correlative clinical data have focused attention on T-cell responses (especially CTL responses) to HBV as the key to understanding viral clearance and immunity. However, meaningful analysis of the biologic roles of antiviral CTLs had to await development of tractable experimental systems for the study of HBV immunity. This became possible with the development by Chisari and coworkers (86) and Moriyama and associates (354) of transgenic mouse models of HBV infection and disease. The models involve inbred mice bearing one of two classes of HBV transgenes: those bearing subgenomic fragments expressing one or more viral antigen, and those bearing intact, replication-competent viral DNA. The latter mice have the full complement of viral replicative intermediates in the liver and release infectious virus into the bloodstream. These mice display two important virologic differences from natural infection: (a) because they lack HBV receptors, there is no horizontal spread of virus between cells; and (b) for unknown reasons, they do not support cccDNA formation. However, their integrated HBV transgenes serve to replace the transcriptional template function of cccDNA. Most HBV transgenic mice do not experience liver disease because replication is noncytopathic and they are immunologically tolerant to the transgene products, which are viewed as self because their genes are present from conception. One exception to this is the case of transgenic mice that overexpress the viral L protein relative to S and M. These mice accumulate viral glycoproteins to pathologic levels in their ER and display cytotoxicity on this basis (87,88 and 89).

Although these mice experience no liver disease in the ground state, when sensitized T cells from an immunized syngeneic mouse are adoptively transferred into them, dramatic liver injury results (354). CTLs account for the bulk of this injury, which can be reproduced with individual CTL clones; CD4+ cells can also mediate liver injury, but do so with much lower efficiency and intensity (146,398). CTL-mediated injury is dependent on viral antigen expression in the recipient and is class I major histocompatibility complex restricted. These studies provided the first experimental proof that CTLs could mediate liver injury as well as participate in viral clearance and put notions of HBV immunopathogenesis on a firm experimental footing.

They also permitted a major insight into the role of these cells in viral clearance. In addition to producing liver cell injury, transfer of CTLs to mice bearing replicating HBV resulted in a dramatic decrease in viral replication (178,183). Careful quantitation of direct CTL-mediated killing in the livers of these animals revealed that the reduction in viral load achieved after CTL transfer was much greater than could be accounted for by the number of infected hepatocytes directly killed by CTL contact. In fact, large fields of viable hepatocytes surrounding isolated CTL infiltrates could be shown to have lost HBcAg and viral DNA. This suggested that paracrine, noncytopathic mechanisms might be operating to effect much of the observed viral clearance, an inference sustained by the discovery that this clearance could be blocked by administration of antibodies to TNF-a and IFN-g. It is now thought that these cytokines, which are released from CTLs after contact with their targets, are major effectors of the antiviral response seen to accompany CTL administration. The molecular basis of this response is now under active study; the cytokines appear able to reduce the accumulation of viral RNA (perhaps by engagement of the 2',5'oligo(A) synthase–RnaseL pathway) and also, in some settings, to destabilize viral capsid components (59,167,182,205).

If intrahepatic cytokine release is in fact an important determinant of HBV clearance, other stimuli to their release should also produce a similar result. This is supported by the finding that many other infectious agents that replicate in the liver of HBV transgenic mice can suppress HBV replication. For example, LCMV strains that replicate in hepatic macrophages (but not in hepatocytes) dramatically suppressed HBV replication in hepatocytes—a suppression that could be reversed with antibodies to TNF-a and IFN (in this case, IFN-a and -b) (179,180). Induction of the same cytokines was shown to mediate a similar suppression of HBV replication by hepatocyte superinfection with adenovirus or cytomegalovirus (60). Apart from their intrinsic interest, these reports may have direct clinical relevance because it has been observed that superinfection of human HBV carriers with hepatitis A virus or hepatitis C virus has occasionally resulted in the resolution of the underlying HBV infection (60).

Does this form of noncytocidal antiviral mechanism operate during normal viral clearance? The best evidence that it might comes from consideration of the experimental study of acute HBV infection of chimpanzees (see Fig. 9). Recall that a significant decrement in virus production was achieved in the period before histologic evidence of massive cellular infiltration or hepatocyte destruction. Local production of IFN-g and TNF is demonstrable during this interval, although the source of these cytokines is not yet clear. Recent experimental evidence indicates that cells from the innate immune system, possibly derived from the natural killer T-cell population normally resident in the liver, may be important sources

of these cytokines early in the infectious process, before the development of adaptive CTL responses (J. Baron and D. Ganem, unpublished results).

Could this understanding of clearance during acute hepatitis be parlayed into a strategy for the immunotherapy of chronic hepatitis B? The answer to this is presently unclear because the basis of the absence of HBV-specific CTLs from chronic carriers is not understood. However, if the burden of infected cells could be reduced by long-term administration of antiviral drugs, up-regulation of CTL responses by therapeutic vaccination—or modulation of cytokine production by other means (e.g., gene therapy)—might provide a way to eliminate the remaining reservoir of HBV-positive cells.

HEPADNAVIRUSES AND HEPATOCELLULAR CARCINOMA

Biology and Epidemiology

The first indication that chronic HBV infection might predispose to the development of hepatocellular carcinoma emerged from studies of the global epidemiology of HBV carriage (519). These studies revealed that HBV is not uniformly distributed among human populations. In Western Europe and North America, only about 0.1% to 0.5% of individuals are HBsAg carriers; however, in Southeast Asia and Subsaharan Africa, fully 5% to 15% of all humans are chronically infected with HBV. (The remaining areas of the globe have an intermediate prevalence of HBV carriage.) This pattern of HBV infection strikingly reproduces the known global epidemiology of HCC, a rare tumor in the West but long known as a leading malignancy in Africa and Asia. This remarkable finding prompted deeper investigation of this linkage.

In HBV-endemic countries, most HCCs arise in patients who are HBV carriers (22,154,514); even though carriers may represent 5% to 10% of the population, they represent 50% to 80% of HCC patients in those societies. However, the strongest evidence for an association comes from careful prospective studies done in Taiwan, in which large numbers of carriers and noncarriers were followed prospectively and deaths due to HCC recorded. These classic studies demonstrated that chronic HBV carriage is associated with a 100-fold increase in risk for HCC relative to noncarriers (22,23). This massive increment in cancer risk makes HBV one of the most important environmental risk factors in human cancer epidemiology.

In Taiwan (as in all HBV-endemic areas), most infections are acquired in the first decade of life (154). Thus, in these studies, most of the individuals being followed had been carrying HBV for many decades. From the age distribution of Taiwanese hepatoma cases, it can be inferred that most tumors arise after 30 or more years of persistent infection; relatively few cases occur in children and adolescents. Extrapolation of this estimate of relative cancer risk to Western societies should be done with caution. In the West, most infections are acquired in young adulthood, as a result of sexual transmission or parenteral drug abuse. Although few doubt that such infections present an increase in cancer risk, it is unclear if the magnitude of this risk is as large as in the HBV-endemic zones, if only because those infected as adults have fewer years at risk. Nonetheless, even in the West, the interval between acquisition of infection and HCC development remains at least 30 years (154).

Further support for the oncogenic potential of hepadnavirus infection came with the discovery of the animal hepadnaviruses. Studies of WHV infection showed that this virus is even more potent than HBV as a hepatic carcinogen: nearly 100% of woodchucks infected from birth with WHV develop HCC, starting at about 18 to 24 months of age (163,414,415,469). Uninfected woodchucks housed in similar circumstances do not develop HCC at all. The oncogenic drive accompanying this infection is so strong that many animals develop multiple independent hepatic tumors; even animals who experienced only a transient WHV infection (as judged by the presence of antisurface and anticore antibodies in the absence of surface antigenemia) display an increased prevalence of HCC (163). Ground squirrels infected with GSHV also display an increased prevalence of HCC, although the tumors are less frequent and arise much later in life (339,539). Because WHV and GSHV can both be grown in woodchucks (3,475), it has been possible to compare the oncogenic potential of both infections in a common host. These studies (469) showed that the biology just described is determined largely by the viral genome and not by the host: GSHV-infected woodchucks display HCC later in life and at a lower frequency than WHV-infected woodchucks. As noted earlier, studies of the oncogenic potential of DHBV have not clearly established it as a tumor virus. Although some DHBV-infected flocks in Asia have shown HCC, most laboratory-raised animals or commercial flocks in America and Europe have not exhibited HCC (100), suggesting that environmental factors (or cofactors) may account for a large portion of the oncogenesis in Asia. There is no evidence that Asian DHBV isolates (550) differ from Western isolates in their oncogenicity.

Viral DNA and Hepatocellular Carcinoma

When the tumors themselves are examined, some can be shown to produce one or more viral antigens, but many have extinguished all HBV gene expression. Nonetheless, most (85% or more) of such tumors harbor integrated viral DNA, often multiple copies per cell (39,481,484). The HBV integrants are usually highly rearranged, with deletions, inversions, and sequence reiterations all commonly observed (121,359); as expected, most of these rearrangements ablate viral gene expression. WHV insertions in woodchuck HCC in general display similar features (378). In addition, alterations of host DNA often accompany these integrations. Described alterations include deletions or repeats at the host–virus junctions (445,484,534,535,590) as well as (more rarely) large chromosomal translocations, some of which harbor HBV sequences at the interchomosomal junctions (533); the latter might have arisen by homologous recombination between viral integrants on two different chromosomes. Importantly, tumors are clonal with respect to these integrants; that is, every cell in the tumor harbors an identical complement of HBV insertions. This implies that the integration events accompanied or preceded the clonal expansion of the cells. Although much has been made of this fact, by itself, it puts HBV DNA at the scene of the crime but does not establish criminality.

How HBV integration is achieved is poorly understood. As opposed to its role in retroviral replication, integration is not an obligatory part of the hepadnaviral replication cycle; it is therefore not surprising that hepadnaviruses have no virus-encoded integration machinery. Presumably, HBV DNA is assimilated into the nucleus by host mechanisms; it is reasonable to suppose that this event proceeds by pathways akin to those operating in the integration of exogenous DNA

in transfected mammalian cells in culture. Such mechanisms likely involve topoisomerase I (461,566) and other host enzymes involved in DNA recombination and repair. A major problem that has confounded study of the integration process has been that the integrants characterized in HCC specimens are many years removed from the primary insertion event. During this (about 30-year) interval, there has presumably been strong immunologic selection against viral antigen expression; this is the likely force that has selected the genomic rearrangements described previously. Recently, it has become possible to examine the structure of integrants newly generated in cultured cells permissive for DHBV replication. In acute infection of primary duck hepatocytes, integrated DHBV DNA can be detected as early as six days after infection, although such integration is a rare event (estimated at 1 insertion per 1000 to 10,000 hepatocytes; W. Yang and J. Summers, personal communication). LMH cells stably transfected with overlength DHBV clones similarly accumulate new DHBV insertions during serial passage (168,169 and 170). In both systems, many of the resulting integrants have structures compatible with a derivation from the double-stranded liner genomes produced by *in situ* priming; in accord with this, mutant DHBV genomes that display enhanced *in situ* priming display an increased frequency of integration.

Models for Hepatitis B Virus Oncogenesis

The molecular mechanisms by which hepadnaviruses predispose to malignancy remain much debated. Models for how they might act fall into two broad categories, direct and indirect, according to the roles they envision for the viral genome and its products (155).

Direct Models

Direct models posit that viral DNA makes a direct genetic contribution to the lesion, either by providing cis-acting sequences that activate or suppress host growth-regulating genes or by elaborating trans-acting factors that alter the program of cellular growth control. The most straightforward version of such a model is that a viral protein might act as a dominant oncogene, much as src does in Rous sarcoma virus infection. However, hepadnaviruses carry no gene directly transduced from the host cell genome; in addition, hepadnaviral infection does not lead to growth transformation or immortalization of primary cells *in vitro,* although there is one report (215) of further growth deregulation induced by HBV X expression in a cell line already immortalized by SV40 T antigen. These facts, together with the prolonged incubation period between infection and tumor development, make it extremely unlikely that the direct action of a single viral gene product can itself transform a hepatocyte. However, they by no means exclude more subtle roles for viral proteins that might help initiate the loss of growth control, even if they cannot by themselves complete this process.

In this connection, two viral proteins are frequently mentioned. Primary attention has centered on the X protein, for two reasons: (a) it is highly divergent or absent in the avian viruses, the only hepadnaviruses not reliably associated with HCC; and (b) as a known regulator of signal transduction, it is easy to envision models for how such a molecule might affect cellular growth. The debate about X protein's role in oncogenesis has been powerfully influenced by reports that transgenic mice bearing X sequences under the control of the X promoter and EnI develop HCC (260,270). However, this effect has not been observed by other groups using X vectors driven by heterologous promoters (298), nor has comparable oncogenesis been seen in transgenic mice bearing other subgenomic or genomic HBV DNAs containing the X region (11,92,131,133). The reasons for these divergent results are obscure; possibilities include differing levels of X expression or the different genetic backgrounds of the mice used in different laboratories. One thing is certain: if X protein plays a role in oncogenesis, it cannot be necessary for the entire life of the transformed cell because most advanced tumors have extinguished all HBV gene expression. Thus, if X is required early in oncogenesis to promote cell proliferation, this requirement must be obviated at later stages of transformation.

The second viral gene product for which a role in oncogenesis has been postulated is the truncated M protein generated by occasional viral integration events (291,292,366). The roles ascribed to such factors are formally identical to those outlined previously for X protein, but experimental evidence supporting such roles is scant at present: many tumors cannot encode such M variants, and expression of these proteins in cultured cells does not lead to loss of growth control. Finally, rare viral integration events might be able to generate other novel proteins by fusion of viral coding sequences with adjacent cellular genes, analogous to the generation of novel oncogenic proteins by chromosomal translocations in other settings. One potential example of this surfaced in a human HCC, in which integration fused the HBV pre-S region to a retinoic acid receptor locus (104,106). However, such events have been documented extremely rarely and are unlikely to represent a major pathway of oncogenesis.

Most advocates of direct models favor the notion that viral sequences act primarily by contributing cis-acting sequences rather than coding regions. There is unequivocal evidence for this mode of oncogenesis in WHV infection. In this system, about 40% of all HCCs contain an integrated WHV genome within several kilobases of one of two *N-myc* loci; these *N-myc* rearrangements are readily detected by Southern blotting (145,197). *N-myc* genes are normally silent in adult liver but are transcriptionally activated by enhancer elements within WHV DNA (575); recent studies implicate EnII (and, less frequently, EnI) in this effect (138,139,143,551,554). Interestingly, *N-myc* transcription is elevated very early in the oncogenic process, even in premalignant nodules (595), and is observed in virtually 100% of cases. Moreover, among many tumors that lack *N-myc* rearrangements by conventional Southern blotting, integrated WHV DNA can be found in cis to *N-myc2* by pulse-field gel analysis, at distances up to 150 to 180 kb away from the activated locus (142). This raises the possibility that all WHV-associated HCC may be initiated by insertional activation of *N-myc,* with many cases resulting from previously unsuspected long-range activation events. Consistent with this, antisense inhibition of *N-myc* expression in a woodchuck hepatoma cell line reverts its growth phenotype (567), and overexpression of *myc* in the livers of transgenic mice gives rise to HCC (52,221,356). Tumors in such mice require many months to develop, consistent with a requirement for multiple additional genetic hits in the pathogenesis of full malignancy.

N-myc expression may also explain other known features of the biology of woodchuck HCC. For example, it has long been known that such tumors overexpress insulin-like growth factor-2 (IGF-2) (595). Recent studies show that *N-myc2* overexpression often triggers apoptosis, and this effect can be suppressed by exogenous IGF-2 (551,596). It is likely that the up-regulation of IGF-2 naturally observed in HCC is the result of selective pressure exerted by the insertional

activation of *N-myc* alleles by WHV.

Efforts to make a similar case for insertional activation by HBV have been largely unsuccessful. Dozens of human hepatomas have been screened for common sites of HBV integration (359,534). This is done by cloning HBV integrants and using the flanking host DNA as a probe to screen Southern blots of DNA from other HCCs for rearrangements of the corresponding host sequences. (This is the same strategy that was employed productively for WHV.) To date, no rearrangements common to many human HCCs have been detected; although a few isolated examples of insertions near interesting loci have been reported (104,106,568), these insertions appear to be unique to the tumors in which they were discovered. Similarly, deliberate screens of human HCCs for rearrangements of known host oncogenes have likewise been largely unrevealing. It should be emphasized, however, that all of these methods can only detect rearrangements within a few kilobases of the locus being probed; if long-range activation events of the type identified for WHV (142) operate in HBV infection, insertional activation might still contribute to the biology of HBV-induced HCC.

Indirect Models

The relative paucity of experimental support for direct models of HBV-induced oncogenesis has led to the growing popularity of indirect models. Here, the term *indirect* means that HBV genes and their products make no direct genetic contribution to the transforming event. Rather, HBV-induced liver injury (itself largely the result of host immune or inflammatory responses to infection) triggers a series of stereotypic host responses that lead to liver cell regeneration. Vertebrate hosts are known to respond to liver cell injury of many types with a brisk regenerative response (although the mechanism of this response is poorly understood). Under conditions of chronic regeneration, the increase in the number of cells undergoing DNA synthesis results in an increased probability of mutation; this in turn increases the probability that one or more of the resulting mutant cells will have a proliferative advantage. As this cell is preferentially expanded, the same logic predicts an increased opportunity for additional mutational lesions in its progeny (and so on, until full growth transformation is achieved). Thus, in indirect models, the role of HBV is to act as an agent of liver injury; everything else—in particular, the growth-deregulating mutations directly responsible for tumorigenesis—is contributed by the host. (The identification of host mutations in HCC is now an active area of inquiry that has turned up numerous candidate loci. Readers interested in this aspect of HCC research are referred to references 52 and 408 for recent review.)

Supporters of indirect models point to several compelling facts, chief among which is that most conditions in human medicine that lead to chronic liver injury are associated to one degree or another with a risk for HCC: alcoholic cirrhosis, a_1-antitrypsin deficiency, Wilson's disease, and so forth. Even hepatitis C virus, an RNA virus with no known DNA intermediate, can predispose to HCC during chronic infection. However, none of these precedents can fully explain why the magnitude of the HCC risk appears to be so much larger in chronic HBV infection. Strong experimental support for this hypothesis is derived from influential experiments in transgenic mice (89). These mice were engineered to overexpress the HBV L protein relative to the M and S proteins. As noted previously, when L is overexpressed, it leads to retention of all the viral envelope glycoproteins in the ER (87,88); this retention is toxic to cells, although the mechanism of this toxicity is unknown. Initially, the mice display only hepatocellular necrosis and accompanying regeneration. Over time, however, malignant HCC arises with great regularity.

Confusion has arisen over the proper interpretation of this experiment, in part because it uses HBV gene products to drive the liver injury. Strictly speaking, the experiment demonstrates that chronic liver injury promotes regeneration and HCC. Although it raises the possibility that viral envelope glycoproteins might contribute to this injury, it does not establish that this form of injury is relevant to clinical hepatitis B. Indeed, it appears unlikely that this would be so; most evidence favors the notion that the bulk of the injury is produced by immune attack on infected hepatocytes (86), and the relative levels of L protein in natural infection are nowhere near those achieved in the HCC-prone transgenic mice. Although hepatocytes with the histologic appearance of cells undergoing damage from deregulated envelope expression can be seen in hepatitis B, in most cases, they are not numerous enough to explain the regenerative drive that accompanies this infection.

A more recent transgenic mouse experiment has affirmed that immune-mediated injury mechanisms can drive hepatic oncogenesis. This study employed mice expressing HBV envelope components at nontoxic levels (akin to those encountered in natural infection) (360). The tolerized immune systems of such animals were ablated by lethal irradiation and replaced with bone marrow and splenocytes from syngeneic mice immunized with a vaccina virus expressing HBsAg. As expected, the recipients developed a chronic hepatitis due to immune attack of the sensitized donor cells on their antigen-expressing hepatocytes. By 17 months after transfer, nearly all such animals had developed HCC, whereas control recipients that received immunocytes from a tolerized (HBV-transgenic) donor developed only minimal liver injury and had a low incidence of HCC. Thus, immune-mediated injury is sufficient to drive hepatic oncogenesis; direct cytotoxicity from deregulated L protein expression is not required.

CHAPTER 87 Hepatitis B Virus

F. Blaine Hollinger and T. Jake Liang

HISTORY

Viral hepatitis is a term that is reserved for infections of the liver caused by one of at least five distinct hepatitis viruses. The most notable sign of this disease is jaundice, an orange-yellow discoloration of the scleroproteins of the skin and conjunctivae seen with an increased plasma bilirubin resulting from faulty excretion of bile pigment by damaged hepatocytes.

The existence of a parenterally transmitted form of hepatitis was documented by Lurman (473) in 1885. He reported the development of jaundice in 15% of 1,289 shipyard workers in Bremen, 2 to 8 months after they had received smallpox vaccine prepared from human “lymph.” Subsequent outbreaks of hepatitis were eventually traced to the use of improperly sterilized syringes and needles among patients who required parenteral inoculations and among those receiving tattoos (224,283).

It was not until the late 1930s that the existence of hepatitis transmitted by parenteral inoculation of human serum was firmly established. In 1937, it was reported from England (522) that approximately 40% of 109 individuals receiving inoculations of a single batch of human measles convalescent serum developed jaundice after incubation periods of up to 114 days. This was followed by an outbreak in British troops given filtered human mumps convalescent plasma (62). These clinical entities were grouped together as “homologous serum jaundice” (504). In 1937, Findlay and MacCallum (222) described cases of jaundice occurring 2 to 7 months after inoculation of volunteers with an attenuated strain of yellow fever vaccine prepared with the addition of human serum to stabilize the product. Fox et al. (227) subsequently implicated human serum as the vehicle of transmission. They also observed that the incubation period of parenterally transmitted hepatitis was much longer than that described for infectious hepatitis. It is assumed that these outbreaks were caused by hepatitis B virus (HBV) infection, but a hepatitis C virus (HCV) etiology also cannot be excluded.

Before a serum-free yellow fever vaccine product was generally used, a widespread epidemic of hepatitis occurred in U.S. military troops early in 1942, resulting in 28,000 cases with 62 (0.2%) deaths (660). Studies conducted more than 40 years later clearly established that this epidemic was caused by HBV (677). As a result of these investigations, the risk of hepatitis associated with the use of pooled and dried human plasma or the administration of whole blood became well recognized (61,528,841).

Based on the epidemiologic differences observed between infectious hepatitis and homologous serum jaundice, the groundwork was laid for the definition of a second major form of viral hepatitis. The terms *hepatitis A* and *hepatitis B* were introduced by MacCallum (475) in 1947 to categorize infectious (epidemic) and serum hepatitis (homologous serum jaundice). These terms have been adopted by the World Health Organization (WHO) Committee on Viral Hepatitis to replace the myriad descriptions previously applied to these disorders (816).

Between the late 1950s and early 1970s, the studies of Murray (536) and Krugman et al. (411) were instrumental in further defining the seroepidemiologic relationships between hepatitis A and B, which eventually led to the evaluation of new methods for the diagnosis and immunoprophylaxis of these diseases (412). Two distinct types of hepatitis with different incubation periods and lack of cross-immunity were differentiated at the Willowbrook State School for the Mentally Handicapped (see also Chapter 26).

The chain of events that culminated in the discovery of HBV and an effective vaccine for the prevention of hepatitis B was a tortuous one. It began in 1963 when Baruch Blumberg, of the National Institutes of Health, began examining thousands of blood samples from diverse populations in a study designed to look for inherited polymorphic traits in different geographic areas of the world (91). To detect novel antigens, sera from multiply transfused hemophilia patients were used because it was postulated that such sera might contain antibodies against these unique proteins. In the course of the investigation, Blumberg discovered that a serum sample from an Australian aborigine contained an antigen that reacted specifically with an antibody in the serum of an American hemophilia patient. Subsequent studies showed that this Australia (Au) antigen was relatively rare in North American and western European populations but was prevalent in some African and Asian populations and among patients with leukemia, lepromatous leprosy, and Down syndrome (90). The additional association of the Au antigen (now designated the hepatitis B surface antigen, or HBsAg) with what was then known as serum hepatitis was not recognized fully until 1967. By 1968, other investigators, notably Prince (624) and Okochi and Murakami (578), had established that the Au antigen was found specifically in the serum of hepatitis B patients.

The discovery and characterization of HBsAg was a major breakthrough in hepatitis research because it permitted intensive study of the disease and of the nature of the infectious agent even though the virus itself had not yet been identified conclusively (17,103). In 1970, Dane et al. (168) detected the complete hepatitis B virion, a 42-nm double-shelled particle that consisted of an outer envelope composed of HBsAg and an inner core or nucleocapsid containing its own distinct antigen, the hepatitis B core antigen (HBcAg), in addition to a small, circular, partially double-stranded DNA molecule and an endogenous DNA polymerase enzyme (384,649). A third antigen, designated hepatitis B e antigen (HBeAg), was described subsequently by Magnius and Espmark (479). This antigen is a reliable marker for the presence of intact virions and thus for enhanced infectivity.

INFECTIOUS AGENT

Biologic Characteristics

HBV is the prototype virus for a family of DNA viruses called the *Hepadnaviridae.* Related viruses are found in woodchucks, ground squirrels, Pekin ducks, and tree squirrels. These viruses share certain features such as virion size and ultrastructure; a distinctive polypeptide and antigenic composition; a comparable DNA size, structure, and genetic organization; and a unique mechanism of viral DNA replication. Separate genera have been proposed for the mammalian and avian hepadnaviruses because of differences that exist in their molecular biology. A detailed review of the *Hepadnaviridae* and their replication that includes virion structure and the life cycle of HBV can be found in Chapter 86.

The stability of HBV does not always coincide with that of its envelope protein, HBsAg. Immunogenicity and antigenicity are retained after exposure to ether, acid (pH 2.4 for at least 6 hours), and heat (98°C for 1 minute, 60°C for 10 hours); however, inactivation may be incomplete under these conditions if the concentration of virus is excessively high. Exposure of HBsAg to 0.25% sodium hypochlorite for 3 minutes destroys antigenicity (and probably infectivity). Infectivity in serum is lost after direct boiling for 2 minutes, autoclaving at 121°C for 20 minutes, or dry heat at 160°C for 1 hour. More recent studies have shown that HBV is inactivated by exposure to sodium hypochlorite (500 mg of free chlorine per liter) for 10 minutes, 0.1% to 2% aqueous glutaraldehyde, Sporicidin (Ash Dentsply, York, PA) (pH 7.9), 70% isopropyl alcohol, 80% ethyl alcohol at 11°C for 2 minutes, Wescodyne (American Sterilizer, Medical Products Division, Erie, PA) diluted 1:213, or combined b-propiolactone and ultraviolet irradiation (95,394,625). HBV has been shown to retain infectivity when stored at 30° to 32°C for at least 6 months and when frozen at –20°C for 15 years.

Propagation and Assay of HBV in Cell Culture

Although HBV has been successfully grown in primary cultures of normal adult or fetal human hepatocytes (234,259,564), susceptibility wanes as the cells differentiate, and serial propagation over a prolonged period of time is limited by availability of human liver tissue. Nevertheless, these susceptible cell cultures remain important for the propagation of HBV *in vitro* and for the study of early events in the life cycle of the virus such as attachment, adsorption, penetration, and uncoating. In 1982, Will et al. (809) reported that cloned HBV DNA could infect chimpanzees after direct inoculation into the liver. Since then, a number of investigators have reported the successful transfection of established cell lines with cloned HBV DNA leading to the expression of HBV proteins and the sustained production of HBV DNA (683,731,780,824). The particles produced by the stably infected human hepatoma cell lines were infectious to chimpanzees (3,730). Although these established cell lines are not directly susceptible to HBV, they provide a model

whereby intracellular events of HBV replication and release of virions can be studied. Transfected cell lines also are useful for the evaluation of potential antiviral compounds (405).

Nonhuman HBV Infections

Chimpanzees and other high-order primates are highly susceptible to experimental induction of hepatitis B (42). The immunobiology of infection is similar to that observed in humans except that the disease is generally less severe. Although the chimpanzee model has played an important role in studies of viral inactivation, vaccine safety and efficacy, disinfection kinetics, infectivity determinants, immunopathology, and seroepidemiology, its role as a model for studying viral replication or for the evaluation of antiviral agents has been limited. In many instances, the chimpanzee is being replaced by other animal systems such as the woodchuck, Pekin duck, ground squirrel, and transgenic mouse (485) (see Chapter 86). By introducing HBV genomic and subgenomic fragments into the germline of transgenic mice, the viral expression of HBV proteins in tissue, viral replication, regulatory functions, evaluation of antiviral compounds, and the immunopathogenesis of disease, including carcinogenesis, can be studied (33,147,398,481,530,542).

PATHOGENESIS

HBV is a noncytopathic virus that causes a spectrum of liver diseases ranging from acute hepatitis (including fulminant hepatic failure) to chronic hepatitis, cirrhosis, and hepatocellular carcinoma. The majority of patients recover from their infection. Of those who become persistently infected, many have mild liver disease with little or no long-term morbidity or mortality.

The eventual outcome, extent, and severity of HBV infection depend on a variety of viral and host factors. Although host responses play a major role in disease pathogenesis and viral clearance, the natural history of HBV infection is often predicated on a variety of viral adaptive mechanisms. Frequently, viral mutations in critical regions of the viral genome are the result of these adaptive mechanisms.

Although the early events of primary HBV infection remain largely unknown, hepatocellular injury most likely begins with antigen recognition by HBV-specific cytotoxic T lymphocytes (CTLs) with the induction of apoptosis in HBV-positive hepatocytes. Recruitment by the CTLs of host-derived, antigen-nonspecific inflammatory cells—including macrophages, neutrophils, and other lymphocytes—leads to formation of necroinflammatory foci. Infiltrates of these inflammatory cells are primarily responsible for hepatocellular death. At this stage, clinical evidence of hepatitis becomes apparent with elevation of aminotransferases. During acute self-limited infection, the pathology is mild to moderate, and viral replication is effectively controlled by host immune responses with resolution of hepatitis. In some cases, these virus-nonspecific inflammatory responses are markedly augmented by yet-unknown host determinants or viral factors, resulting in massive hepatocellular injury and fulminant hepatitis. On the other hand, chronic hepatitis results from continuous hepatic injury as a consequence of ineffective viral clearance. In asymptomatic carriers, tolerance to HBV antigens confers little or no immune-mediated injury in the infected liver.

Primary Infection

Animal models have been used to elucidate many stages of infection in the pathogenesis of HBV. The virus gains entry into a susceptible host through parenteral or percutaneous routes. Once inside the host, HBV is transported through the bloodstream to the liver, which is the primary site of infection. Since hepadnaviruses can infect nonhepatocytes, the existence of an intermediate compartment of replication before infection of the liver has been proposed (404), but this remains controversial (71,366). Viral spread within the liver appears to be a rather efficient process, with potential infection of virtually all hepatocytes (71,367). The onset of viremia is inversely related to the dose of virus administered, and one virion may be sufficient to cause infection (365). Viremia can reach very high levels (>10^9 virions/mL) and may result in dissemination to other sites of potential viral tropism that include kidney, pancreas, testis/ovary, spleen, and lymph nodes (402). Whether immune activation occurs in the resident liver or other distant sites during primary HBV infection remains a subject of debate. Irrespective of the mechanism, a vigorous antiviral immune response is directed to the infected liver. In most situations, this activated immune response can rapidly and effectively control the viral infection despite extensive infection of hepatocytes (71,368,379). The molecular and cellular spectrums of these virus–host interactions are discussed later.

Host Responses

Although virus-specific immune responses are thought to be protective in many viral infections, these same responses also are the mediators of tissue pathology (838). They frequently trigger a variety of nonspecific inflammatory reactions in the host, augmenting the potential for cellular injury. Consequently, both virus-specific and virus-nonspecific mechanisms invariably lead to injury at the sites of viral replication, the extent of which depends on the vigor and character of the inflammatory response. From a simplistic point of view, successful clearance of virus requires a timely deployment of effective antiviral regimens, but at the same time the target and duration of attack has to be orchestrated with great precision and care to avoid excessive pathology. Detailed knowledge of these factors and their relationships is pivotal to our understanding of how HBV infection leads to hepatocellular injury. Figure 1 summarizes the multiple pathways of HBV immunopathogenesis, which are described in detail later.

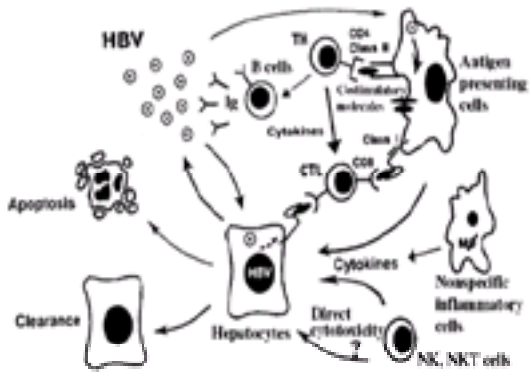

FIG. 1. Immunopathogenesis of HBV infection. See text for details. (Modified from Fig. 3 of ref. 148, with permission.)

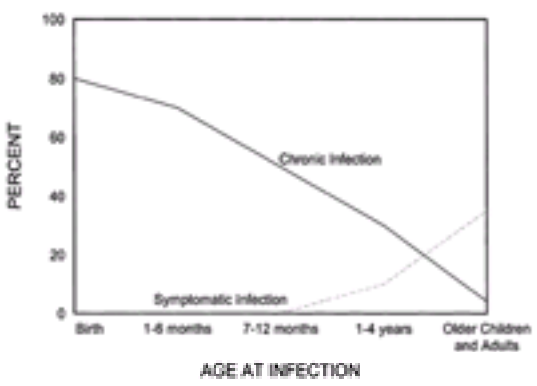

FIG. 3. Relationship between age and outcome after acute HBV infection. (Modified from M. Kane, personal communication, 1999.)

Innate Cellular Mechanisms

Following viral infection, higher eukaryotic cells have the innate ability to undergo programmed cell death (apoptosis) to terminate viral replication. Many viruses encode antiapoptotic gene products that function to oppose the cell death program triggered by viral infection and allow the virus to complete its replication within the infected cells (757). This mechanism is particularly relevant for viruses whose replication induces cytopathic changes. For noncytopathic viruses like HBV, the utility of such a mechanism is less obvious. In HBV DNA-transfected or HBV-infected cells, there is no evidence of apoptosis or cytopathic effect. However, in certain situations, as discussed later, direct hepatotoxicity can result from atypical patterns of viral replication and gene expression.

Certain HBV gene products, including HBX and pre-S1, have been implicated in activation of the NF-kB pathway (126), which is known to exert a potent antiapoptotic effect, particularly in hepatocytes (63). Further evidence suggests that HBX also may directly regulate cytokine-induced apoptosis (728). Induction of interferons is part of the innate antiviral responses generated by infected cells. Although HBV-infected cells may be more sensitive to interferon-induced cytotoxic effects (148), the predominant antiviral mechanism is most likely a noncytopathic one. Interferon-a has been shown to directly downregulate HBV transcription *in vitro* (652), whereas interferon-g may exert a potent inhibitory effect on various aspects of HBV replication (see later section, Cytokine Induction). Conversely, the HBV polymerase, possibly the terminal protein region, and the C-terminal region of the core protein have been shown to inhibit the cellular response to interferon-a/g and to suppress interferon-b gene transcription, respectively (225,807). Another cellular response to viral infection is the induction of heat-shock proteins including ubiquitin and other proteins involved in proteolysis; this response enhances the host cell's capacity to degrade proteins with abnormal conformations, such as viral proteins (657). Recent findings suggest that the proteasome complex, the predominant nonlysosomal pathway for intracellular protein degradation, may play an active antiviral role in degrading viral proteins following viral infection (673). Such a mechanism may be counteracted by HBV X protein during HBV infection (344).

Humoral Response

Activation of the humoral immune response with production of neutralizing antibodies prevents further viral spread and leads to subsequent elimination of circulating virus (591). This mechanism is particularly relevant for HBV infection because of the high level of HBV replication and viremia, which can reach more than 10^9 virions per milliliter in circulation. The antibody response to HBV envelope proteins is a T-cell-dependent process (514). In the majority of infected persons, antienvelope antibodies are readily induced and lead to viral clearance and protection from subsequent infection. This constitutes the basis for the successful formulation of an HBV vaccine based on the envelope proteins. However, a minority of infected persons fail to produce antienvelope antibodies, and this can contribute to the establishment of persistent infection. This deficiency resides at the level of T-cell nonresponsiveness, probably as a result of tolerance or anergy induction toward the HBV proteins (148,838). The molecular mechanisms underlying this deficiency, however, are largely undefined. On the other hand, the antibody response to HBV core protein is both T-cell-dependent and -independent (514). The anti-HBc response is the first serologic evidence of host immune response and often persists for years after viral clearance in infected individuals, even for life. Although chronically infected patients may be nonreactive to HBV core protein at the T-cell level (148), the alternative T-cell-independent mechanism appears to sustain the presence of an anticore response in these individuals. In contrast, antibody response to HBeAg, the other core gene product, is strictly T-cell dependent (514). Presence of antibodies to HBeAg is often associated with

recovery from active disease and is clinically used as the hallmark of response to treatment. However, this association does not imply a causal role for this antibody response in viral clearance. The seroconversion from HBeAg to anti-HBe merely indicates reduction of HBV replication and suggests a transition from an active to a quiescent disease state. In HBeAg-positive patients, antibodies to HBeAg frequently exist in immune complexes. Therefore, the status of HBeAg/anti-HBe is usually determined by a dynamic equilibrium between the titers of HBeAg (a marker of viral replication) and anti-HBe (a marker of host immune response). The role of anti-HBc/anti-HBe antibodies in HBV pathogenesis has not been defined. Cell surface forms of HBcAg/HBeAg on infected hepatocytes could be potential targets for antibody-directed cell cytotoxicity (510,669). However, this mechanism has not been shown to be operative in hepatocellular injury associated with HBV infection. In contrast, immune complex diseases with complement fixation, including glomerulonephritis, vasculitis, and cryoglobulinemia, which are major extrahepatic manifestations of HBV infection, can result from abnormally activated antibody responses to HBV antigens (e.g., HBsAg). Antibodies to viral polymerase and HBX proteins have been described in patients with HBV-associated chronic hepatitis and hepatocellular carcinoma, but their pathologic implications are unknown (793,800).

Cell-Mediated Immunity

The cellular immune responses directed against HBV have been studied in detail in both infected humans and transgenic mice expressing HBV gene products. Nonprimate animal models that are susceptible to hepadnavirus infection (woodchucks, ground squirrels, ducks) have provided limited utility in this venue of research, mostly because of a lack of immunologic reagents and inbred strains. Recent efforts to develop such reagents should lead to important insights into this complex process (505,508,544). In human infection, individuals acutely infected with HBV can mount a vigorous, multispecific, and polyclonal cellular immune response to HBV. In contrast, chronically infected patients have a weak or barely detectable anti-HBV response (148). This is true for both CD4 and CD8 responses. During acute hepatitis B, a vigorous human leukocyte antigen (HLA) class II–restricted, CD4+, helper-T-cell response to multiple epitopes of HBcAg/HBeAg predominates in virtually all patients. Such a response to HBV envelope antigens, however, is much less evident. It is not clear why this disparity exists, because individuals vaccinated with recombinant HBsAg are capable of mounting a strong class II–restricted, CD4+ response to the HBV envelope proteins (128,372). Possibly, an antienvelope T-cell response occurs early during the primary phase of infection but becomes exhausted or tolerant to the antigen because of exposure to high levels of virus or to inappropriate antigen presentation to the immune system (148,838). The relative absence of antienvelope T-cell response notwithstanding, the class II–restricted, CD4+ T cells specific for nucleocapsid probably play an important immunoregulatory role in the control of viral infection (148,218). By helping B cells produce neutralizing antienvelope antibodies and activating HBV-specific CTLs, this CD4+ T-helper population may direct the initial antiviral response. During chronic HBV infection, the once-strong nucleocapsid-specific CD4+ T-cell response becomes barely detectable, presumably because of a switch to T-cell exhaustion or nonresponsiveness. Again, the molecular mechanism of this switch is unknown. It is interesting to note that during reactivation or successful treatment of chronic hepatitis B, this nucleocapsid-specific T-cell response could reappear (97,484).

CTLs are believed to evolve teleologically in response to intracellular pathogens, particularly viruses. They possess the unique ability to detect and eliminate virus-infected cells through recognition of viral peptides in the context of HLA class I molecules. Using short synthetic peptides mimicking processed viral antigens and cells genetically engineered to express viral proteins, CTL responses to HBV in humans have been studied extensively (73,598,599,644,645 and 646). These studies indicate that patients acutely infected with HBV develop a strong, polyclonal, HLA class I–restricted CTL response that is directed against multiple epitopes in all viral proteins (547,599,645). Unlike the class II–restricted antienvelope response, the CTL responses to HBV envelope and pol are vigorous and multispecific. Similar to the class II–restricted CD4 responses, the class I–restricted CTL responses also are barely detectable during the chronic phase of HBV infection (218,643). Although these observations suggest that CTLs probably play a vital role in viral clearance, the critical factors determining the CTL responsiveness during HBV infection have not been defined. Since detailed studies on prospectively followed individuals acutely infected with HBV are lacking, the potential echanisms underlying the immunologic differences between patients who recover and those who progress to persistent infection cannot be delineated. Furthermore, the detection of HBV-specific CTLs in the peripheral blood and liver of chronically infected individuals, albeit with low frequency, suggests a pathogenic relationship between the indolent CTL activities and necroinflammatory liver disease associated with chronic hepatitis B (45,219,643). Therefore, the CTL response is a double-edged sword in HBV infection: A vigorous CTL response leads to viral clearance, whereas an ineffective CTL response results in chronic hepatocellular injury.

Although studies in humans have provided important correlative information, the molecular and cellular consequences of the immune response can be elucidated only in appropriate animal models. Transgenic mice have been used extensively to address these issues. Adoptive transfer of murine CD8+, class I–restricted HBsAg-specific CTLs into syngeneic transgenic mice expressing HBV envelope protein in the liver leads to acute hepatitis (27,148,530). Interactions between the HBV-specific T-cell receptors and the antigen-presenting HLA class I molecules on the hepatocytes cause scattered apoptosis of hepatocytes. By secreting cytokines, including interferons, the CTLs recruit a variety of antigen-nonspecific inflammatory cells into the liver, resulting in more extensive necroinflammatory injury of the liver that resembles acute hepatitis B in humans. The predominant infiltrating effector cells are the macrophages, which probably mediate the majority of hepatocellular injury in this model (28). A major consequence of these immunologic events is the marked inhibition of hepatocellular HBV gene expression and viral replication (148,262). Although the CTLs may contribute to this effect by direct cytolysis of HBV-expressing hepatocytes, a noncytolytic mechanism very likely plays a more substantial role. This concept also is supported by observations in the duck hepatitis B virus (DHBV) and woodchuck hepatitis virus (WHV) models, in which viral clearance is not accompanied by massive hepatocellular death (368,379). Interferon-g and tumor necrosis factor (TNF)-a produced by activated CTLs and other effector cells are the key cytokines involved in this mechanism (262). The effects of cytokines are discussed later.

These observations delineate a logical progression of immunologic events for HBV infection. However, transgenic models are not an infectious model. In the transgenic models, the complex virus–host interactions during the early stage of infection, which are critical in determining the manifestations of immune response and the outcome of infection, cannot be studied. Furthermore, the transgenic model does not offer the opportunity to study the events during a “curative response.” However, a recent study in chimpanzees (265) provided key insights into some of the unanswered questions

encountered in the transgenic models. This study, while supporting the noncytopathic mechanism as the major antiviral response responsible for viral clearance during acute hepatitis B, demonstrates that CTLs are probably not the primary mediator of this response. Instead, these results reveal that natural killer cells or other nonstandard T cells (g/d or NKT cells), which normally reside in the liver in relative abundance (65,167,270), may play an important role in this early phase of infection (127,265, and J. Baron and D. Ganem, personal communication, 1999). Furthermore, studies in the duck and woodchuck models suggest that accelerated hepatocyte turnover in infected liver may partially explain viral clearance during the recovery phase (379). However, these observations do not necessarily imply that CTLs are not important in controlling viral infection. The infiltration of CTLs, which occurred later in the chimpanzee study, probably mediates the control of the residual HBV infection. This is consistent with the observation that patients who have recovered from acute HBV infection harbor HBV-specific CTLs many years after viral clearance (644). It is believed that the CTLs persist as a result of continuous stimulation by low-level viral replication and in the meantime keep the infection in check. It is well established that low-level HBV virus can be detected in patients with serologic evidence of recovery (452,453,593,598,644,825,831,835). Furthermore, active HBV infection can be reactivated in these patients upon immunosuppressive therapy, and their sera or livers are capable of transmitting HBV infection (84,188,469,759).

Cytokine Induction

CTLs have been thought to be the principal effector in the clearance of viruses. However, studies in a variety of viral model systems point to the importance of cytokines in containing and eliminating the virus, in addition to their immunoregulatory functions (82). Upon antigen recognition, CTLs secrete a multitude of cytokines to activate other inflammatory cells, such as macrophages, that constitute a potent source of additional cytokines. The interferons are known to elicit a variety of direct antiviral factors in infected cells, such as protein kinase R, 2'-5'-oligoadenylate-activated RNase L, Mx protein, and inducible nitric oxide synthase (429). Recent studies in HBV animal models have provided compelling evidence that inflammatory cytokines, especially interferon-g and TNF-a, are the principal mediators of viral clearance during primary viral infection (262,263,266). These cytokines inhibit viral replication at several levels in infected hepatocytes. First, the cytoplasmic nucleocapsid particles that contain replicating viral genomes are rapidly eliminated (262). The kinetics of the elimination suggests that an activated degradative process may be the mode of action (266). Second, the cytokines induce a profound decrease in viral RNA level, most likely by a posttranscriptional mechanism (779). Third, the HBV covalently closed circular DNA (cccDNA) is susceptible to a similar noncytopathic control by the cytokines (265). Because the cccDNA appears to have a relatively long half-life in infected hepatocytes (152,379), an active mechanism of elimination may need to be evoked. Recent studies suggest that these cytokines may induce certain cellular nucleases and RNA binding proteins as a potential explanation for these noncytopathic actions (296,297). Finally, whether interferon-g and TNF-a mediate these effects directly or indirectly through a yet-unknown paracrine or autocrine mechanism on the infected hepatocytes is not known. Nitric oxide, a potent inflammatory mediator, has recently been implicated in this process (L. Guidotti and F. Chisari, personal communication, 1999).

Viral Pathogenic Determinants

Immune Escape

RNA viruses, retroviruses, and hepadnaviruses have high mutational rates because their polymerases do not have a proofreading capacity. This infidelity is beneficial to these viruses in terms of their ability to mutate their genomes in response to an active immune response. Many of them can mutate the binding sites of neutralizing antibodies on the viral surface proteins, as well as the viral sequences that are presented to the immune cells in the context of class I molecules, thus leading to the emergence of immune escape mutants. Immune escape mutants have been described to occur in both arms of the host immune response in HBV infection. Vaccine escape mutants have been detected in vaccinated infants born to HBV-infected mothers despite protective levels of anti-HBs (124), and in liver allograft recipients who were HBsAg carriers and who received hepatitis B immune globulin (HBIG) for prophylaxis (501). These strains contained mutations in the immunodominant region of HBV envelope protein, leading to poor reactivity with HBIG. Naturally occurring mutations in dominant CTL epitopes of HBV have been found to antagonize recognition of infected cells by HBV-specific CTLs (74). Many viruses, such as herpes simplex viruses, cytomegalovirus (CMV), and adenoviruses, encode gene products capable of preventing recognition of viral-infected cells by CTLs through inhibition of class I antigen presentation (582). Whether this mechanism is operative in HBV persistence is not clear.

Viral Strains

HBV has been classified into various serotypes/genotypes, which exhibit distinct geographic distributions (390,561,576). Whether they impart variable pathogenic potentials is not clear. The A genotype of HBV has been associated with better disease outcome and long-term survival, the C genotype with more severe disease, and the B genotype with development of hepatocellular carcinoma (383); however, the clinical significance of these relationships has yet to be firmly established. The precore stop codon mutation associated with fulminant hepatitis is much more prevalent in specific genotypes (such as D) than in others (such as A) because a genotype-specific nucleotide difference upstream of the stop codon mutation is involved in critical base-pairing with the mutation in the secondary structure of the HBV encapsidation signal (451). In addition, genotypes A and D have different replication efficiencies in tissue culture (47). Whether this difference can be equated to a pathogenic difference *in vivo* is not clear. This strain difference in pathogenicity also has been borne out by a study in which two naturally isolated WHV strains (WHV7 and 8) have different replication efficiency and pathogenicity in woodchucks (J. Gerin and B. Tennant, personal communication, 1999). Therefore, viral divergence may be linked directly to variant biologic behaviors.

Recent studies have identified and characterized viral mutations associated with fulminant hepatitis B. Two types of mutations—precore mutations leading to the HBeAg-negative phenotype (122,285,408,455,583) and core-promoter mutations resulting in enhanced replication (48,117,529,575,658)—have been described. Most reported precore mutations occur in codon 28 of the precore open reading frame, resulting in a stop codon that leads to absence of HBeAg synthesis (46). Other precore mutations, such as precore start codon mutations or deletions/insertions in the precore sequence resulting in HBeAg-negative phenotype, also have been reported. The described core promoter mutations cluster in a region of the promoter elements that contain binding sites to various transcriptional factors (117,636,832).

Some studies have suggested that two of the mutations confer diminished precore transcription leading to diminished HBeAg synthesis (117,661). Other studies have demonstrated that many of the core promoter mutations lead to a high replication phenotype (48,117,268). In addition, mutations in the core protein have been linked to severe or fulminant hepatitis B (198). However, these core mutations may reflect selection by a vigorous immune response during fulminant hepatitis, because they affect important T-cell epitopes (148). They also have been described during viral clearance and the active phase of liver disease in chronic hepatitis B (34,198).

Because all the mutations just described affect the core gene, it is worthwhile to briefly review the known and putative functions of the two core gene products (HBcAg/HBeAg). The HBcAg forms the nucleocapsid and is essential for viral replication and assembly. The HBeAg is synthesized as an alternative processing of the core gene and is a secreted circulating antigen. The gene product is not essential for replication nor for productive infection *in vivo* (143). HBeAg has been used clinically as an index of viral replication, infectivity, severity of disease, and response to treatment. Because HBeAg is evolutionarily conserved among all hepadnaviruses, it probably plays an important role in the life cycle of HBV.

The concept of HBeAg as an immunoregulatory protein has emerged from several lines of evidence (511). First, HBeAg may play a role in perpetuating viral infection during perinatal transmission (513). Perinatal infection from mother to infant is the most common form of HBV transmission in the world. Infants born to anti-HBe-positive, HBsAg carrier mothers are likely to develop acute hepatitis but less frequently to progress to chronicity (758). Studies in transgenic mice expressing HBeAg have demonstrated induction of immunologic tolerance to HBcAg/HBeAg *in utero* (513), although this phenomenon may be strain specific (647). Because HBeAg is synthesized as a soluble small protein, it may traverse the placenta, exposing the fetus to the antigen. Such an exposure may result in a partial tolerance of the infant's immune system to the virus. Following perinatal infection, the newborn infant, with the additional problem of a relatively immature immune system, may have limited ability to eliminate the virus. Although this is an attractive hypothesis, the role of HBeAg as a neonatal immunologic toleragen remains controversial (647).

Second, despite extensive sequence overlap with the core protein and sharing of the identified CD4 and CD8 epitopes (148), HBeAg has properties that are distinct from those of the core protein in terms of interactions with the host. HBeAg has been shown to induce a T_H2 immune response in mice, whereas HBcAg induces a T_H1 response (512,516). The T_H2 response to the HBeAg is dominant over the T_H1 response to the core antigen, resulting in depletion of the HBcAg-specific T_H1 cells *in vivo* (512). This event may have a profound effect on viral persistence. Experiments in mice have shown that circulating HBeAg is capable of abrogating the nucleocapsid-specific T_H1 response, which includes production of interferon-g and other cytokines essential for viral clearance. This concept is supported by studies in the woodchuck model in which WHV mutants negative for HBeAg are less likely to result in chronicity (143). In addition, HBeAg differs from HBcAg with respect to the antigen-processing pathway. Endogenously synthesized HBeAg can be presented through both the class I and II pathways (192), thereby inducing both CD8+ and CD4+ effector cells. This also may provide a plausible explanation for the emergence of HBeAg-negative mutants in chronic HBV infection. It is possible that CD4+ cytotoxic T cells exist that recognize only the HBeAg-expressing cells, not the HBcAg-expressing cells. Furthermore, despite extensive sequence overlap between HBeAg and HBcAg, HBeAg contains additional amino acids in the N-terminus, where a CD4 epitope has been mapped (192). Therefore, HBV mutants lacking HBeAg expression may have a selection advantage *in vivo*. Because overexpression of precore may inhibit HBV replication, HBeAg-negative mutants could be selected on the basis of a more efficient replication phenotype (264,425,662). However, studies of naturally occurring HBeAg-negative mutants *in vitro* and in animal models do not support this concept (47,143,769,832,836).

Although many questions remain unanswered, the HBeAg-negative mutants represent a true biologic variant of HBV with a distinct phenotype. If the HBeAg-negative mutants do have a biologic advantage over the wild-type virus, one would expect that these strains should be evolutionarily selected. However, wild-type strains still prevail over the mutants in the general population. For viral dominance, both intrapopulation and intrahost factors must be considered. Whereas the mutants may exhibit a selection advantage within an infected host during chronic infection, they may be disadvantaged in terms of transmission to the other hosts because they may be less efficient in inducing neonatal tolerance or causing chronicity. Therefore, the overall impact is probably more favorable to the wild-type strain.

Finally, the question remains as to whether the HBeAg-negative mutants are indeed responsible for more severe or fulminant hepatitis. The strongest evidence comes from studies of outbreaks of fulminant hepatitis B, in which transmission of a unique HBV strain to several unrelated individuals resulted in fulminant hepatitis (207,455,610,727,755,758). A compilation of all studies on fulminant hepatitis B revealed that the HBeAg-negative mutants were not universally present in all cases of fulminant hepatitis, nor were they completely absent in individuals with acute self-limited hepatitis, although the prevalence rate of these mutants was significantly higher in the former group (32,34,121,230,431,454,715). Therefore, these mutations may contribute to the development of fulminant hepatitis, but they are neither necessary nor sufficient for this outcome. On the other hand, a combination of viral mutations or host factors are probably involved in the pathogenesis of fulminant hepatitis. Recent studies also have demonstrated that core promoter mutations are commonly present in patients with severe or fulminant hepatitis B (268,432,575,658), and some of the mutations confer enhanced replication (48,117,529,630,716). During acute infection, enhanced replication may lead to a more widespread HBV infection in the liver. Because the core and pol are major targets of the host immune response, an increase in their expression resulting from enhanced replication also may render hepatocytes more vulnerable to immune-mediated injury. In addition, the absence of HBeAg production may be associated with a more T_H1-like, proinflammatory response. Taken together with the secondary nonspecific necroinflammatory infiltrate, this event may be more detrimental during the acute phase of HBV infection.

A vigorous and extensive immune response with enhanced viral replication may lead to massive liver injury and ultimately to fulminant hepatic failure. In addition, other unidentified viral pathogenetic factors also may contribute to the development of fulminant hepatitis. Therefore, viral factors, in concert with various host determinants directing the vigor and character of the antiviral inflammatory response, underpin the complicated interplay of virus–host interaction in the pathogenesis of fulminant hepatitis B.

Seronegative Infection

Other atypical infections include seronegative occult HBV infections. This heterogeneous group consists of HBsAg-negative patients who are either seronegative for all HBV markers or positive for anti-HBc and/or anti-HBs (452,593,598,644,825,831,835). Many of these patients also are positive for HBV DNA by polymerase chain reaction (PCR) in the liver or serum or both. Some of these patients have underlying liver disease, suggestive of ongoing hepatocellular injury from persistent HBV infection. Studies in the animal models have demonstrated long-term persistence of viral genomes in the serum and/or liver of animals who have biochemical and serologic evidence of viral clearance and recovery from infection (404,406,453). The important question is whether this represents ongoing viral replication, and therefore clinically significant infection, in terms of liver disease and transmission. Existing evidence supports the notion that this indeed indicates low-level viral replication, capable of transmission (453,759). A recent report on the WHV model demonstrated several well-documented examples of maternal–fetal transmission of occult WHV infection (157). Studies on liver transplantation revealed transmission of HBV infection to the recipients if the donors carried the anti-HBc marker (188). In addition, reactivation of HBV infection has been reported in patients with serologic evidence of recovery who were undergoing immunosuppression or chemotherapy (84,188,469,759). These observations, together with the immunologic studies previously described, provide compelling evidence that one may not be able to completely eliminate HBV infection. Patients with serologic evidence of recovery probably have low-level viral replication that is effectively controlled by an active immune response.

The possibility that these seronegative infections are caused by HBV mutants has been proposed. Although mutations have been reported in various regions of the viral genome (86,339,386,825), definitive evidence in support of a pathogenic role of these mutants is lacking. Furthermore, whether liver disease can result from these occult HBV infections is controversial. At present, there are no convincing studies in support of a causal relationship. Therefore, these occult HBV infections may not be clinically important except in the special situations described.

Abnormal Viral Gene Expression

There is accumulating evidence that abnormal expression of certain HBV gene products can result in cytotoxicity. First, “ground-glass” hepatocytes seen variably on histology of HBV-infected liver have been shown to contain high levels of HBsAg within the amorphous content of the ground glass (240,356). This intriguing histologic observation may provide a clue that abnormal expression or accumulation of HBV envelope gene products can lead to cellular injury. Second, overexpression of HBV large envelope protein (pre-S1-S2-S) in both tissue culture (93,821) and the transgenic mouse model (149) can result in a massive accumulation of the protein within the endoplasmic reticulum, accompanied by evidence of cytotoxicity with the appearance of ground-glass cells, and the eventual development of hepatocellular carcinoma (150). Third, liver pathology with minimal inflammation (fibrosing cholestatic hepatitis) can be seen in HBV-reinfected liver allograft recipients (436). Although the pathogenesis of this entity is unknown, it is possible that abnormal HBV replication in the transplantation setting may be partially responsible. Fourth, *in vitro*–generated pre-S1 mutants in the DHBV model have exhibited enhanced replication and cytopathicity in infected animals (446). Although there has been no direct proof that such a mutation or genotype exists in naturally occurring HBV strains, it is tempting to speculate that some HBV strains with this type of mutation may exist and cause more severe disease. Finally, high-level expression of HBX in tissue culture appears to sensitize cells to TNF-a-induced apoptosis, and possibly to induce other mechanisms of cellular injury (146,728).

Mechanisms of Viral Persistence

The outcome of a viral infection is determined by several opposing forces. On the one hand, the infected host commands a powerful armamentarium of antiviral defenses that target the virus for destruction and elimination. On the other hand, viruses have evolved sophisticated mechanisms to counteract, elude, and in some cases forestall these host defenses. If immune responses are more dominant, the infected host will clear the viral infection, whereas if viral mechanisms prevail, persistent and chronic infection will ensue. The balance of these competing forces underlies the molecular mechanisms of persistent viral infection. In HBV infection, establishment of persistent infection has been attributed to multiple viral and host factors. Although several *in vitro* studies have suggested that HBV gene products may potentially interfere with pathways of the immune response (225,344,807), there is no direct evidence that these mechanisms are operative *in vivo*. Many potential mechanisms of viral persistence have been discussed in the previous sections and are summarized in Table 1.

Host factors
Hepatotropism: tolerance or anergy induction
Infection of immunologically privileged sites: viral reservoir
Infection of lymphocytes: HBV-specific immunosuppression
Genetic modifiers: HLA or other genetic associations
Viral determinants
High-level replication: immune exhaustion
High rate of mutations: immune escape in antibody and cell-mediated immunity, antagonism
HBeAg: transplacental tolerance induction and dominance of T_h2 response
Miscellaneous: HBcAg and *pol* (interfere with interferon actions?), HBX (modify immune responses?)

TABLE 1. *Mechanisms of HBV persistence*

As the primary site of HBV tropism, the liver may be a key predisposing factor for viral persistence. Hepatocytes are poor

antigen-presenting cells because they do not express HLA class I and II and co-stimulatory molecules except during inflammation (467,524). Because of the lack of co-stimulation, presentation of viral antigens to T cells is more likely to induce anergy than activation (141). In addition, the liver is a principal site of death for circulating activated T lymphocytes (345). Once arriving in the liver, activated T cells may be short-lived and relatively ineffective as an anti-HBV effector mechanism.

As discussed previously, perinatal infection induces neonatal tolerance, probably because of the transplacental passage of soluble HBeAg. This tolerance is mostly toward the HBeAg–HBcAg complex, because infants born to HBV carrier mothers respond well to HBsAg immunization. During adult infection, several mechanisms may be operative. First, HBeAg may play a role in directing an immune response that is less favorable to viral clearance. Second, high viral load, typical of acute HBV infection, may induce immunologic anergy or tolerance by inappropriate antigen presentation to the immune system or by exhaustion of the antiviral CTLs. In support of this hypothesis, high doses of inoculum virus in the DHBV model are more likely to cause chronic infection (365).

Hepadnaviruses may infect lymphocytes, monocytes, and other nonhepatocytes (402,403,559,644). This has a twofold implication in viral persistence. First, as has been shown for other lymphotropic viruses, selected alterations of the immune response against HBV may result from infection of lymphocytes or antigen-presenting cells by HBV (838), although this has not been demonstrated experimentally. Second, infection in immunologically privileged sites that are protected from an anti-HBV response may function as a reservoir of persistent HBV infection (26,829). Finally, once a chronic infection is established, several mechanisms are potentially operative to perpetuate viral persistence. High mutational rates associated with hepadnaviral replication can lead to selection of immune escape mutants at both the antibody and cell-mediated levels. In addition, selection of antagonistic T-cell receptor epitopes could result in active suppression of CTL recognition of infected hepatocytes (74). However, this mechanism may be operative only when the CTL response is strong and focused predominantly on one epitope. Because the anti-HBV CTL response is typically polyclonal and multispecific, T-cell receptor antagonism may not play a substantial role in the overall mechanism of viral persistence.

Finally, certain HLA class II haplotypes have been associated with viral clearance and a favorable outcome of HBV infection (766). Other genetic modifiers of hepatitis B also have been reported (64). Because host response to infection is a complex process that is likely to be controlled by polygenic loci, these genetic associations may contribute to the overall outcome of infection and disease. However, whether these linkages imply a direct pathogenetic relationship or represent surrogate markers for other genetic loci of importance is unknown at present.

PATHOLOGY

HBV causes both acute and chronic liver disease. The pattern of liver injury is characterized by hepatocellular destruction, regeneration, and inflammatory infiltrates. Although these pathologic changes typically resolve completely after viral clearance, chronic infection is often accompanied by progressive fibrosis and architectural disarray that culminates in cirrhosis. The pattern of injury accompanying chronic viral hepatitis has distinct features and may be distinguished from other forms of liver disease, such as cholestatic liver disease, autoimmune hepatitis, metabolic liver disease, drug-induced hepatitis, and steatohepatitis. However, the pattern of injury seen with acute hepatitis B overlaps significantly with other causes of viral hepatitis. Because chronic hepatitis B takes decades to progress to end-stage liver disease, it is important to assess not only the pattern of injury but also the histologic severity and stage of hepatitis B.

Acute Hepatitis

The histologic features associated with acute hepatitis B are similar to those of hepatitis A (see Chapter 26), but hepatitis B is characterized by more extensive parenchymal abnormalities and less cholestasis and portal inflammation (356). Hepatocellular injury is marked by either ballooning degeneration or acidophilic bodies, which probably reflects two distinct mechanisms of hepatocyte damage. The former is characterized by swollen hepatocytes with fragmenting cell membranes, pale granular cytoplasm, and disintegrating nuclei. The latter alteration represents the histologic manifestation of apoptosis and is marked by a progressively shrinking cell, eosinophilic cytoplasm, and pyknotic nuclei. Focal hepatocellular necrosis, the histologic hallmark of acute viral hepatitis, is characterized by intralobular foci of necrotic or apoptotic hepatocytes surrounded by inflammatory cells including lymphocytes, macrophages, and, rarely, plasma cells. These necroinflammatory changes are distributed throughout the lobules with more extensive pericentral involvement (zone 3). Regenerative changes consisting of double-cell-thick hepatic cords, binucleated hepatocytes, and nuclear hyperchromasia often accompany necroinflammatory foci. Other histologic features include lobular inflammatory cell infiltrate, Kupffer cell hypertrophy, and sinusoidal reaction. Bile duct lesions such as ductular proliferation or cholestatic obstruction are rare events.

About 1% of patients with acute hepatitis B develop severe or fulminant hepatitis (441). Histologically, necrosis of a large area of liver cells (confluent necrosis) is evident. In more severe cases, the necrotic zones extend from zone 3 to adjacent vascular structures of the hepatic acini, forming bridging necrosis, which can be seen between central veins or between central veins and portal tracts. Submassive necrosis, in which bridging necrosis and parenchymal collapse are present extensively throughout the liver, often characterizes the fulminant form of acute hepatitis. Although most cases of acute hepatitis B resolve without histologic sequelae, the fulminant form often results in nodular regeneration, architectural distortion, and scar formation. This has been designated postnecrotic scarring, which is a nonprogressive lesion different from the cirrhosis of chronic hepatitis. It rarely leads to long-term morbidity or mortality.

Chronic Hepatitis

The histologic hallmark of chronic hepatitis B is inflammatory destruction of hepatocytes, accompanied by progressive fibrosis. The histologic classification of chronic hepatitis has undergone extensive modification to provide a more quantitative and clinically relevant description of the disease. The classical terms of chronic persistent, chronic lobular, and chronic active hepatitis are being replaced by revised grading and staging systems that consider the degree and

extent of necroinflammation and fibrosis (60,183,355,472). These histologic systems describe a continual spectrum of liver injury and disease activity and provide a more accurate assessment of prognosis and therapeutic effect.

The most widely used system is based on the modified Knodell scores (355). This system has two scores: one based on inflammatory activities (grade) and the other on fibrosis (stage). The grade is indicative of ongoing disease activity, whereas the stage represents the cumulative effect of the disease. The inflammatory component is divided into three compartments: the interface zone between the hepatocytes and the portal area (limiting plate), the portal area, and the hepatocellular parenchyma. Piecemeal necrosis or interface hepatitis describes the destruction of hepatocytes at the limiting plate, which forms a well-defined structure demarcating the hepatic parenchyma and the portal area. On microscopy, the smooth edge of the limiting plate becomes eroded and indistinct as the junctional surfaces of periportal hepatocytes are invaded by lymphocytes or macrophages (peripolesis) (Fig. 2A). Occasionally, lymphocytes are seen to actively penetrate the hepatocytes (emperipolesis) (see Fig. 2A). Piecemeal necrosis may be focal, involving only one or two hepatocytes with little destruction of the limiting plate, or it may be extensive, involving the entire circumference of the portal area with penetration of the inflammatory cells to a depth of several hepatocytes. In more severe cases, the necroinflammatory process extends into the parenchyma, reaching to the terminal hepatic veins or to other portal areas (bridging necrosis).

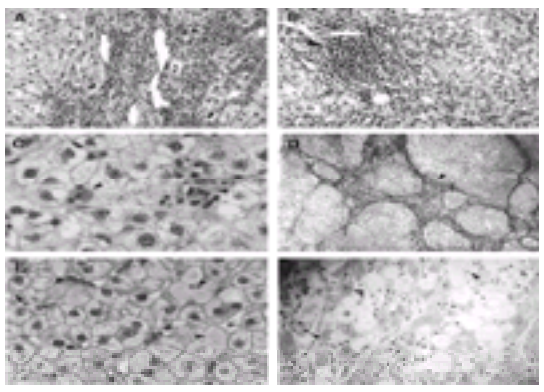

FIG. 2. Pathology of chronic hepatitis B. **A:** Piecemeal necrosis (interface hepatitis). *Arrowheads* indicate lymphocytic infiltrates disrupting the limiting plate of the portal area and invading the parenchyma (×200). **B:** Lymphoid aggregates. *Arrowhead* shows a dense lymphoid aggregate in the portal area surrounding the bile duct (×200). **C:** Lobular inflammation. Scattered apoptotic hepatocytes (*arrowheads*) with surrounding lymphocytes are shown in the hepatic lobule (×600). **D:** Cirrhosis. Thick bands of fibrotic tissues (*arrowhead*) encircling regenerative nodules (×100). **E:** Ground-glass hepatocytes (*arrowheads*) (×600). **F:** Fibrosing cholestatic hepatitis. Diffuse ballooning degeneration of hepatocytes and marked cholestasis with bile plugs (*arrowheads*) are shown (×200).

The portal area, while contiguous with the periportal compartment, is being considered separately because it delineates a distinct pathologic feature. When bound by the limiting plate, lymphoid infiltrates can fill and expand the portal areas, occasionally forming aggregates of variable density (see Fig. 2B). Like the primary follicles of lymph nodes, the lymphoid aggregates are composed of a mixture of B and T cells with small numbers of macrophages and dendritic cells. Rarely, the lymphoid aggregates resemble reactive germinal centers with a core of B and plasma cells and a mantle of B and T cells. Bile duct lesions (Poulsen lesions) also can be seen accompanying the lymphoid aggregates; they are characterized by reactive epithelial changes and lymphocytic infiltration without true cholestatic features. These histologic changes are more commonly observed in chronic hepatitis C infections, as is steatosis.

Parenchymal inflammation in chronic hepatitis B generally consists of small foci of lymphocytes and macrophages surrounding apoptotic bodies or necrotic (“drop-out”) hepatocytes (see Fig. 2C). Plasma cells and eosinophils can sometimes be seen in these foci. The relative abundance of plasma cells serves to distinguish chronic hepatitis from acute hepatitis. The parenchyma often shows areas of ballooning degeneration and focal collapse. There also may be features of regenerative activity such as hepatocellular mitotic figures, binucleated cells and widened liver cell plates. When these foci of lobular necrosis are the dominant features of the inflammatory pattern, it often is difficult to distinguish chronic from acute hepatitis. Regardless, this pathologic feature can be seen in many patients with chronic hepatitis B, particularly those with HBeAg-negative-mutant infection who experience periodic flares of symptoms and biochemical abnormalities (113). Occasionally, more extensive lobular necroinflammation with confluent, bridging, or panlobular necrosis can be seen. Often, these exacerbations resolve spontaneously with a return of the histologic features to minimal-to-mild inflammation. However, frequent and severe attacks can lead to more rapid progression to cirrhosis.

Although the pattern of inflammation characterizes the pathologic process of chronic hepatitis, it is the extent of fibrosis that determines the severity and prognosis of the disease. The earliest change is an expansion of the portal area by new collagen formation. Single hepatocytes or groups of hepatocytes are surrounded by newly formed connective tissue, forming active fibrous septa. When arranged in a tubular fashion around a central lumen, the liver cell groups form rosettes. Periportal fibrosis separates the hepatocytes from the limiting plate and disrupts the smooth edge of the limiting plate. These fibrous septations gradually extend from portal areas to other portal areas or to the terminal hepatic veins (bridging fibrosis). With continued inflammation, diffuse bridging fibrosis of varying width develops and, together with regenerative changes and acinar destruction, results in the distorted architectural pattern that we recognize as cirrhosis. Cirrhosis is defined as a diffuse change of the liver in which the normal architecture is replaced by regenerative nodules surrounded by bands of fibrosis (see Fig. 2D). Once patients reach this stage, end-stage (decompensated) liver disease ensues with high morbidity and mortality.

One unique feature of chronic hepatitis B is the presence of ground-glass hepatocytes (see Fig. 2E), which are rarely detected in acute hepatitis B patients. They are irregularly distributed and often appear in clusters. The hepatocytes are

slightly larger than normal and the cytoplasm contains a pale, eosinophilic, sharply circumscribed, finely granular, homogeneous inclusion that often displaces the nucleus to one side. Immunoperoxidase staining with HBsAg-specific antibodies demonstrates a high level of HBsAg immunoreactivity within the ground-glass material. By electron microscopy, large quantities of HBsAg-containing tubular and spherical structures are observed within the smooth endoplasmic reticulum. The pathogenesis of these cells is unknown but is thought to arise from impaired HBsAg secretion of the large envelope protein. An additional feature, often seen in the transplanted liver, is the entity of fibrosing cholestatic hepatitis (see Fig. 2F), which represents injured hepatocytes laden with HBV antigens, accompanied by excessive parenchymal fibrosis in the setting of little or no inflammation (436). Similar lesions also have been seen in the transplanted liver of HCV-infected individuals (843). Again the underlying mechanism is unknown. HBV mutants have been proposed to be associated with these two pathologic entities, but a direct causal relationship has not been established (93,98).

CLINICAL FEATURES

The course of hepatitis B can be extremely variable (Table 2). In addition to the inapparent or subclinical cases, patients may develop anicteric or icteric hepatitis. The terms *inapparent hepatitis* and *anicteric hepatitis* are often used interchangeably. However, the latter term should be reserved for those patients who develop clinical symptoms but who are not jaundiced. Patients with inapparent (subclinical) hepatitis have neither symptoms nor jaundice. These asymptomatic cases previously went unrecognized but can now be identified by detecting biochemical or virus-specific serologic alterations in their blood. Symptoms ranging from mild and transient to severe and prolonged may accompany clinical hepatitis. Patients may recover completely, progress to chronic hepatitis, or develop fulminant hepatitis and die. In general, the frequency of clinical disease increases with age (499), whereas the percentage of carriers decreases (Fig. 3).

Predicted parameter	Outcome (%)
Inapparent (subclinical) or anicteric disease	65–80
Icteric disease	20–35
Complete recovery	95–98
Chronic disease (% of total number infected)	2–10[a]
Mortality rate	
Based on infection	0.2–0.5
Based on icteric cases	0.5–1.5

[a]Data compiled for immunocompetent adults; rate in immunocompromised patients may be higher. Infection in the perinatal period leads to chronic disease in 70% to 90% of infants born to HBeAg-positive carrier mothers.

TABLE 2. *Predicted outcome after an infection with hepatitis B virus*

Clinical Phases of Acute Infection

Regardless of etiology, the course of acute viral hepatitis is similar and can be divided into four clinical phases: (a) the incubation period (time between exposure and the first day of symptoms or jaundice); (b) a prodromal or preicteric stage; (c) the icteric phase; and (d) the convalescent period (395). Thus, the clinician faces a formidable task in determining which type of hepatitis a patient has acquired, unless appropriate serologic assays are requested.

The incubation period for viral hepatitis type B ranges from 45 to 120 days (14,43,227,287,409,548,660). Incubation periods of less than 35 days or more than 150 days are unusual. Factors that might account for these extremes in HBV disease include (a) the size of the inoculum, (b) the route of infection, (c) co-infection with another hepatitis agent, (d) alteration of viral pathogenicity by chemical or physical means, (e) unusual virus–host interactions, and (f) the concurrent administration of specific antibody.

The influence of virus dose on the incubation period is suggested by several studies in which increasing the quantity of virus administered shortened the time of onset of hepatitis (13,43,410,625). The shorter incubation periods sometimes recorded for HBV in earlier studies may have reflected the presence of previously unrecognized non-A, non-B hepatitis agents in the inocula or, in rare circumstances, may have represented contamination of blood with hepatitis A virus (323). Occasionally, patients from high-risk groups enter studies already infected with HBV, and this can result in a spuriously shortened incubation interval.

Krugman and Giles (409) showed that the portal of entry may affect the incubation time. Volunteers who received an oral dose of HBV that was 50 times greater than that administered by the intramuscular route had an average incubation time that was approximately 1 month longer. Prolongation of the incubation period for HBV also has been observed after ultraviolet irradiation of infected plasma (43,549), after storage of pooled plasma at room temperature (537), and after heating (318), presumably because of a reduction of virus dose. It is noteworthy that the severity of clinical illness in these delayed cases is usually not affected, although progression to chronicity may be curtailed.

Variations in host response may affect the incubation period. Groups of children (409) or adults (334) who receive the same dose of HBV can have onsets of their disease that differ by as much as 1 to 2 months within each group. Among chimpanzees experimentally infected with HBV, the incubation period is found to be significantly shorter in the older animals (625). Finally, the late administration of high-titer HBIG or monoclonal antibody to HBV-exposed persons or chimpanzees during the incubation period may lead to a significant delay in the onset of hepatitis, sometimes exceeding 6 months (253,410,567).

A short prodromal or preicteric phase, varying from several days to more than a week, precedes the onset of jaundice. In over half of the patients, the prodromal state typically is characterized by mild fever, easy fatigability, malaise, anorexia, myalgia, nausea, and vomiting. It is felt that many of these symptoms may be mediated by interferon induction (see the section, Pathogenesis). In hepatitis A, the transition from well-being to acutely ill occurs abruptly (within a period of 24 hours) in over 60% of patients, whereas the onset is more insidious in hepatitis B. Weight loss of 2 to 10 pounds is common as a result of anorexia from disordered taste and smell (299,707). Older children and adults may complain of right upper quadrant pain or discomfort as a consequence of hepatomegaly, which usually precedes jaundice by 1 to 2 weeks. Severe abdominal pain and protracted vomiting are unusual manifestations of the disease and should lead the clinician to either question the diagnosis or suspect a more severe variant of the disease.

The icteric phase of acute viral hepatitis is ushered in by the appearance of dark, golden-brown urine (bilirubinuria) followed one to several days later by pale stools and yellowish discoloration of the mucous membranes, conjunctivae, sclerae, and skin. This icteric phase begins within 10 days of the initial symptoms in over 85% of the HBV cases (525,840). Fever, if present, usually subsides after the first few days of jaundice.

Physical examination of the patient with acute disease shows tenderness to palpation or percussion of the liver. Percussion often shows an enlarged liver, with a span of 16 cm or more. Measurement is essential because a reduction in size in a deteriorating patient often heralds massive necrosis. The edge is firm but not irregular. Approximately 5% to 15% of patients have splenomegaly. Generalized adenopathy is not a component of viral hepatitis A, B, or C. Palmar erythema and spider angiomata may be observed.

Occasionally, during acute viral hepatitis, more extensive necrosis of the liver occurs that leads to severe impairment of hepatic synthetic processes, excretory functions, and detoxifying mechanisms. This entity, designated fulminant hepatitis if it occurs during the first 8 weeks of illness, is characterized by the sudden onset of high fever, marked abdominal pain, vomiting, and jaundice, followed by the development of hepatic encephalopathy associated with deep coma and seizures (67,659,774). Although fulminant hepatitis B is uncommon when compared with infection, it is observed in up to 4% of the hospitalized cases (589). Ascites, a bleeding diathesis, renal dysfunction, and decerebrate rigidity lead to death in 70% to 90% of the patients. Overall survival rates for hepatitis B are lower than those observed for hepatitis A (33% versus 50%), but more than those of non-A, non-B hepatitis (19%) (68). However, within each of these populations careful evaluation of the patients can often differentiate those who will have a poor outcome from those who will survive. For example, mortality is highly correlated with age, survival being uncommon over the age of 40 years or under the age of 11 (66,532,563,774). Other clinical signs associated with a poor prognosis include a rapid decrease in liver size, prolongation of the prothrombin time to greater than 50 seconds, an elevated bilirubin level of greater than 17.5 mg/dL, often in the presence of a rapidly declining alanine aminotransferase (ALT) value, and encephalopathy developing within 7 days of the onset of jaundice (563). Factor V levels also may serve as a prognostic indicator (69).

Clinical Features of Chronic Viral Hepatitis

In the United States, chronic liver disease is among the 10 leading causes of death in men. Nearly 50% of these deaths are in individuals under 60 years of age. However, the vast majority of patients with chronic hepatitis B remain asymptomatic for many years even though there may be biochemical and histologic evidence of liver disease. Thus, clinicians are seeing only a part of the spectrum of pathology that is present in the community at any given time.

Some of the chronically infected patients may have no clinical or biochemical evidence of liver disease. To distinguish this group from patients with chronic hepatitis, they are often categorized as asymptomatic hepatitis B carriers or simply HBsAg carriers. De Franchis et al. (173) recently studied the natural history of chronic hepatitis B in a cohort of these carriers. At baseline, 96% of 92 patients were anti-HBe positive, and histologic abnormalities were normal or minimal in all but five who had only mild chronic hepatitis. During a mean follow-up of 130 months, liver enzymes remained normal in 85% of 68 patients who were extensively followed; 13% of these patients cleared their HBsAg. Among 21 HBsAg carriers who showed no biochemical changes during 10 years of follow-up, no histologic changes were detected. Spontaneous reactivation was a rare event (4% of 68 patients), and no hepatocellular carcinoma (HCC) was detected. Other investigators have reviewed the outcome of patients who have been histologically classified as having mild chronic hepatitis. Fewer than 10% of these patients progress to cirrhosis (637,679).

Patients with moderate to severe chronic hepatitis may have no symptoms, or they may be significantly incapacitated. Easy fatigability, anxiety, anorexia, and malaise are prominent complaints. At the time of the initial diagnosis, jaundice is uncommon. Ascites and pedal edema are seen in approximately 20% of patients, whereas fewer than 5% present with endogenous encephalopathy or variceal bleeding. Transaminases, bilirubin, and gammaglobulin levels are mild to markedly elevated. During follow-up, there may be a series of remissions and relapses. Remissions may last a few months to several years. During a relapse, aminotransferases may be markedly elevated and jaundice may be present. Predictors of progression to cirrhosis include hepatic decompensation, repeated episodes of severe acute exacerbation with bridging hepatic necrosis and/or high alpha-fetoprotein levels (greater than 100 ng/mL), acute exacerbations without HBeAg clearance, and HBV reactivation with the reappearance of HBeAg (163,459).

In one study (802), the estimated overall survival rates at 5 years were 97% for patients with mild chronic hepatitis (n = 121), 86% for those with moderate chronic hepatitis (n = 128), and 55% for severe chronic hepatitis patients with cirrhosis (n = 130). However, 54% of the original cohort were not contacted for this analysis. In another series (459), the overall annual incidence for developing cirrhosis among a group of 684 HBsAg-positive patients with chronic hepatitis was 2.4% among the HBeAg-positive group and 1.3% among anti-HBe–positive subjects. In a third study (174), the 5-year survival rate for compensated cirrhosis was 84% (97% for patients with HBeAg-negative cirrhosis and 72% for HBeAg-positive patients). No deaths occurred in any of the patients followed for an additional 5 years. On the other hand, a dismal 14% 5-year survival rate was observed in decompensated cirrhotic patients with ascites, jaundice, encephalopathy, and/or a history of variceal bleeding at entry into the study. Predictors of death included older age,

elevated bilirubin, ascites, and HBeAg positivity.

A number of hepatitis B patients will develop HCC (see the section, HBV and Hepatocellular Carcinoma). Clinical features include weight loss (77%), right upper quadrant pain (61%), fever (47%), and gastrointestinal bleeding (30% overall, and 65% among cirrhotics). On physical examination, ascites and hepatomegaly are common, whereas jaundice and a palpable mass are uncommon. The mean duration of symptoms before diagnosis is 6 months (range, 0.5 to 30 months). The tumor is relatively slow growing, with a median doubling time of 4 months (range, 1 to 14 months) (691,692). Metastatic spread is uncommon, the most frequent sites being the lung (36%), direct extension through the hepatic or portal venous systems (12%), adrenal glands (10%), skeletal tissue (10%), and brain (6%) (350). Persons at high risk of developing HCC include adult male, chronic hepatitis B patients with cirrhosis who contracted their disease in early childhood and who display serologic or histologic evidence of active HBV replication (HBV DNA, HBeAg, IgM anti-HBc, cytoplasmic HBcAg) (186,703). From 55% to 85% of patients with HCC have cirrhosis at the time of diagnosis (389,580). Conversely, only about 5% of patients with cirrhosis develop HCC. Other studies have shown incidence rates from 0.1% to 1.1% per year for male HBsAg carriers based on increasing age (51,498) unless cirrhosis is present, in which case the annual incidence of HCC ranges from 2% to 7% (460,579). Rates in female patients are almost six times lower.

Figure 4 illustrates the natural history and growth of HCC in an HBsAg-positive carrier (186). Acquisition of HBV in infancy often leads to a persistent infection, prolonged active viral replication, HBV DNA integration, and eventually cirrhosis. Malignant transformation occurs with clonal expansion of hepatocytes until HCC becomes detectable serologically, radiologically, and/or clinically. The mean 5-year survival rate of 25% to 60% varies depending on the size of the tumor, resectability, symptoms, and the presence or absence of alpha-fetoprotein (AFP). Patients with unresectable tumors have an overall median survival of 5 months for AFP-positive tumors and 10.5 months for AFP-negative tumors, depending on which treatment modality is selected (725).

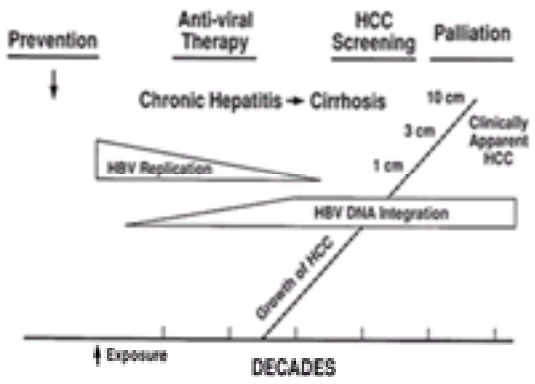

FIG. 4. Natural history and growth of HCC in an HBsAg-positive carrier. (From ref. 186, with permission.)

Extrahepatic Manifestations of Hepatitis B

Extrahepatic manifestations of viral hepatitis B are seen in 10% to 20% of patients. The nonhepatic disorders include (a) transient serum sickness–like syndrome, (b) acute necrotizing vasculitis (polyarteritis nodosa), (c) membranous glomerulonephritis, and (d) papular acrodermatitis of childhood (Gianotti-Crosti syndrome). Essential mixed cryoglobulinemia, although previously thought to be associated with HBV infection, is an uncommon clinical manifestation of this disease. Indeed, most patients with this disorder are found to be infected with HCV (235,498). Although the pathogenesis in several of these entities is unclear, most are believed to be mediated by virus-specific immune complex injury.

The major clinical features of the serum sickness–like syndrome are fever, skin rash, and polyarthritis (18,195,797). These disease traits usually precede the onset of jaundice by a few days to 4 weeks and may be the primary or only manifestation of anicteric HBV infection (195,724). Fever is generally more than 100°F and may exceed 102°F. Skin rashes typically consist of erythematous, macular, maculopapular, urticarial, nodular, or petechial lesions (672,801). The acute articular inflammation that develops is easily distinguished from the generalized arthralgia/myalgia that occurs in HBV infection. Joint involvement is usually symmetrical and is more commonly observed in female patients. It often involves multiple joints simultaneously but sometimes exhibits a migratory or additive pattern. Joint fluid examination is not diagnostic (195). Symptoms subside rapidly after the onset of jaundice but may persist throughout the course of illness. Neither recurrent nor chronic arthritis has occurred after recovery. This disorder resembles experimental serum sickness in which immune complexes activate the classic and alternative pathways of complement (797). Supporting this hypothesis are the following: the depression of complement levels in serum and synovial fluid of HBsAg-positive patients with arthritis (18); the detection of cryoprotein-immune complexes containing HBsAg, anti-HBs, and complement components; and the identification of complement, HBsAg, and IgM in cutaneous vascular walls of patients with urticaria.

One third to over one half of the patients with acute necrotizing vasculitis (polyarteritis nodosa) have HBsAg in their serum (250,507,773). The disease is uncommon in long-term carriers and thus appears to be a complication of a recent infection (267,498). Profound constitutional symptoms, high fever, anemia, and leukocytosis are prominent early manifestations of illness. Patients often have arthralgia, arthritis, renal disease (proteinuria and hematuria), hypertension, heart disease (pericarditis and congestive heart failure), gastrointestinal disease (acute abdominal pain), skin manifestations, and neurologic disorders [mononeuritis multiplex and central nervous system (CNS) abnormalities]. The disease is highly variable and has a mortality rate of approximately 40% within 3 years unless treated. Decreased levels of complement and circulating HBsAg–anti-HBs complexes have been demonstrated in addition to the presence of HBsAg and immunoglobulins in involved tissue (104,250,507,773). The diagnosis depends on finding the characteristic

arterial lesions on tissue biopsy. Angiography represents a simple and direct procedure for establishing the diagnosis (223).

HBV-associated nephropathy, especially membranous glomerulonephritis, has been described by several investigators in both adults and children (115,199,359,393,540,753,754). Liver disease may be minimal or absent in many of the patients, especially children. Although the incidence of HBV infection in cases of glomerulonephritis has not been established, it is frequently observed in countries with a high prevalence of HBV. Both HBeAg and HBsAg have been detected in glomeruli. Subepithelial electron-dense deposits are usually associated with HBeAg-immune complexes, presumably because of the low molecular weight of HBeAg, whereas the relatively large size of HBsAg (3.5 to 4.4 × 10^6 daltons) (see Chapter 86) results in the formation of larger immune complexes having a mesangial distribution (309,359,422,753). A good correlation has been found between nephropathy and serum HBeAg, but the same correlation is not seen with HBsAg. Remission of the nephropathy occurs in 85% to 90% over a 9-year interval and is associated with clearance of HBeAg from the serum (248,341,787).

A distinctive disease of childhood, papular acrodermatitis (Gianotti-Crosti syndrome) is irregularly, but not invariably, associated with hepatitis B infection and is believed to be mediated by circulating HBsAg–anti-HBs complexes (161,246,358). The skin lesion lasts 15 to 20 days and consists of lentil-sized, flat, erythematous, and papular eruptions localized to the face and extremities. It is accompanied by generalized lymphadenopathy, hepatomegaly, and acute anicteric hepatitis B with a predilection for the *ayw* subtype (246,358).

Laboratory Findings in Acute and Chronic Viral Hepatitis

The clinical diagnosis of acute hepatitis is made by biochemical assessment of liver function. The initial laboratory evaluation of a jaundiced patient should include the following tests: total and direct bilirubin, ALT, aspartate aminotransferase (AST), alkaline phosphatase, gamma-glutamyl transpeptidase, lactic dehydrogenase, albumin and total protein, complete blood count, and coagulation studies (prothrombin time, partial thromboplastin time). The aminotransferases are highly sensitive indicators of hepatocellular damage. They provide a quantitative assessment of the degree of damage sustained by the liver. Because the ALT is localized primarily to the liver, it is the most meaningful of the aminotransferases. The ALT level is significantly higher than the AST level in uncomplicated viral hepatitis. Bilirubin, albumin, prothrombin time, and partial thromboplastin time assess the synthetic function of the liver and are important predictors of survival. The prothrombin time accurately reflects early and potentially serious derangement in liver function, as does the factor V level (68,563). Ultrasonography can help exclude biliary tract disease.

The biochemical and hematologic tests that are useful for evaluating patients with chronic hepatitis are similar to those chosen for acute hepatitis. Evidence of portal hypertension associated with hypersplenism can be suspected in a patient with thrombocytopenia and/or leukopenia. Anemia may be present as a late manifestation of liver disease, but it also may signal evidence of a gastrointestinal bleed from esophageal varices. Hypoalbuminemia, hypergammaglobulinemia, elevation of the prothrombin time, hyperbilirubinemia, and creatinine are harbingers of more serious chronic liver disease and presumably cirrhosis, often confirmed by a percutaneous or laparoscopic liver biopsy. By determining the Child-Pugh classification of a chronic hepatitis B patient with cirrhosis (based on the presence or absence of clinical ascites, encephalopathy, prothrombin time, albumin level, and bilirubin), an excellent prognostic assessment of the patient can be made (353).

DIAGNOSIS

The terms used in identifying the various serologic markers of viral hepatitis B are shown in Table 3. An understanding of this nomenclature is essential for interpreting the results of the various serologic tests (Table 4).

Term	Abbreviation	Description
Hepatitis B virus	HBV	The 42-nm, double-shelled particle, originally called the Dane particle, that consists of a 7-nm outer shell and a 27-nm inner core. The core contains a small, circular, partially double-stranded DNA molecule and an endogenous DNA polymerase. This is the prototype agent for the family Hepadnaviridae.
Hepatitis B surface antigen	HBsAg	The complex of antigenic determinants found on the surface of HBV and on the 22-nm particles and tubular forms. It was formerly designated Australia (Au) antigen or hepatitis-associated antigen (HAA).
Hepatitis B core antigen	HBcAg	The antigenic specificity associated with the 27-nm core of HBV.
Hepatitis B e antigen	HBeAg	The antigenic determinant that is closely associated with the nucleocapsid of HBV. It also circulates as a soluble protein in serum.
Antibody to HBsAg, HBcAg, and HBeAg	Anti-HBs, anti-HBc, and anti-HBe	Specific antibodies that are produced in response to their respective antigenic determinants.

TABLE 3. *Nomenclature for viral hepatitis B*

Assay results			
HBsAg	Anti-HBs	Anti-HBc	Interpretation
Positive	Negative	Negative	Early acute HBV infection. Confirmation is required to exclude nonspecific or nonspecific reactivity (see text).
Positive	±	Positive	HBV infection, either acute or chronic. Differentiate with IgM anti-HBc (see text for exceptions). Determine level of replicative activity (infectivity) with HBeAg or HBV DNA.
Negative	Positive	Positive	Indicates previous HBV infection and immunity to hepatitis B.
Negative	Negative	Positive	Possibilities include HBV infection in remote past; "low-level" HBV carrier; "window" between disappearance of HBsAg and appearance of anti-HBs; or false-positive or nonspecific reaction. Investigate with IgM anti-HBc, and/or challenge with HBsAg vaccine (see text). Where present, anti-HBe helps validate the anti-HBc reactivity.
Negative	Negative	Negative	Another infectious agent, toxic injury to the liver, disorder of immunity, hereditary disease of the liver, or disease of the biliary tract
Negative	Positive	Negative	Vaccine-type response

TABLE 4. *Interpretation of HBV serologic markers in patients with hepatitis*

Course of HBV Infection

The clinical course and serologic changes that follow exposure to HBV represent a complex interaction between host, virus, and specific antigen. In a typical case of acute transfusion-associated HBV infection, HBsAg is first detected 7 to 9 weeks after transfusion (520), which is 1 to 3 weeks before the ALT level becomes abnormal and 3 to 5 weeks before the onset of symptoms or jaundice. It reaches a peak concentration during the acute stage of the illness, then slowly declines to undetectable levels within 4 to 6 months (Fig. 5). HBV DNA is detected 3 to 5 weeks after infection and up to 40 days before the appearance of HBsAg (average, 6 to 15 days), although newer, more sensitive HBsAg assays are closing this gap (118,419). The HBV DNA rises slowly and circulates at relatively low levels (10^2 to 10^4 genomic equivalents/mL) during the early HBsAg seronegative window period. In contrast, viral concentrations exceeding 10^9 HBV DNA genomic equivalents per milliliter are often present during the prodromal, acute, or chronic phase of the infection (118,168). As anticipated, communicability is highest when concentrations of infectious virus attain their highest levels in the blood.

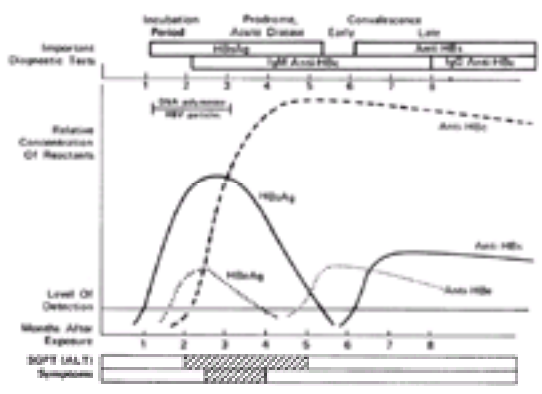

FIG. 5. Serologic and clinical patterns observed during acute HBV infection. (From ref. 317, with permission.)

HBeAg and IgM-specific anti-HBc are usually detected subsequent to the appearance of HBsAg (23,538) and concurrent with the onset of ALT abnormalities (116,158,243,417,650). Because the IgM-specific anti-HBc is produced in high titer (>1:1,000) in response to the synthesis of the nucleocapsid protein of the virion, its appearance in the serum is indicative of ongoing viral replication. These elevated titers decline to undetectable levels regardless of whether the disease resolves or becomes chronic, but the antibody may reappear during reactivation of HBV (see the section, Differentiating Acute Hepatitis from Chronic or Remote Infection). On the other hand, IgG-specific anti-HBc generally remains detectable for a lifetime.

During the early stages of convalescence and before HBsAg disappears, anti-HBe replaces HBeAg and signals (a) a reduction in viral replication and (b) the beginning of the resolution of the disease (329). Within 6 months, anti-HBe levels are no longer detectable in approximately one third of the patients. In 5% to 10% of the acute cases of hepatitis B, usually in life-threatening episodes such as fulminant hepatitis, HBsAg may not be detectable. Examination of the serum may show HBV DNA or IgM-specific anti-HBc (with or without anti-HBe) as the only indicators of active viral replication in this situation.

Termination of acute HBV infection occurs with the disappearance of HBsAg and the appearance of anti-HBs. It is believed that anti-HBs production may be initiated much earlier, but the antibody is not observed as a result of immune complex formation and removal in the presence of excess HBsAg. Anti-HBs generally persists for a lifetime in over 80% of the patients.

Those patients with acute hepatitis who maintain high levels of HBsAg concentration throughout the infection (317,319), or those whose serum HBeAg persists 8 to 10 weeks after symptoms begin to resolve, are most likely to become healthy carriers or to develop chronic liver disease. By convention, HBV carriers are identified by the persistence of HBsAg for at least 6 months. In approximately 5% to 10% of chronic carriers, anti-HBs also can be detected in low concentrations. Many of these patients have more serious liver disease.

In reviewing the natural history of chronic hepatitis B, loss of HBV DNA (as determined by relatively insensitive hybridization techniques) is followed by seroconversion from HBeAg to anti-HBe (38,458). This stage of disease is often accompanied by normalization of liver enzymes and remission of the disease (210,457). HBsAg may persist for years after the loss of HBeAg and its seroconversion to anti-HBe (100). Using the more sensitive PCR assay, HBV DNA usually remains detectable as long as HBsAg is present in the serum (407).

Diagnostic Assays

A number of assays are available to differentiate acute from chronic or remote HBV infection, to evaluate relative infectivity and prognosis, and to assess the immune status of the patient (319). Readers interested in details of the procedures listed later are referred to a recent review by Hollinger and Dienstag (317).

Among the many commercially licensed assays offered, the radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA) are the most sensitive and specific. These assays can detect HBsAg in the 0.2 to 0.7 ng/mL range, and anti-HBs at a level of 1 mIU/mL. Within limits, the level of reactivity represents an approximation of the concentration of antigen or antibody present in a specimen. However, comparisons of results from one sample to another are usually meaningless unless paired samples are tested concurrently. Dilutions are often required because the capacity of commercial solid-phase systems is easily exceeded at relatively low concentrations (319). For example, most patients with acute HBV have HBsAg concentrations of 200 µg/mL or more, but the HBsAg assays reach saturation above 1 µg/mL. Similarly, anti-HBs assays reach a plateau at concentrations that approach values of 300 to 500 mIU/mL. Reactivities that are close to the cutoff values of the assay may signify a false-positive result.

Nucleic acid hybridization procedures (418,463,676,784,829) and the PCR assay (418,708) for the detection of HBV DNA in serum and tissue have been important in unraveling some of the intricate immunopathogenetic mechanisms of HBV disease and for evaluating the response to antiviral therapy. Filter or liquid-phase hybridization assays can detect quantities of HBV DNA sequences from 0.1 to 1.0 pg (33,000 to 330,000 genomic equivalents) within 24 hours, with a two- to tenfold increase after 5 days of autoradiography. A branched DNA signal amplification assay has a cutoff level of about 700,000 genomic equivalents per milliliter. In contrast, the PCR assay can detect less than 100 HBV DNA genomes per milliliter, a level that is over 300 to 7,000 times more sensitive than the hybridization techniques. Using this technique, virus has been detected 2 to 3 weeks before the appearance of HBsAg in experimentally infected chimpanzees and has continued to be detectable for 1 to 3 weeks after anti-HBs seroconversion (382). All HBsAg/HBeAg-positive patients have detectable HBV DNA in their serum, whereas only 70% to 90% of the HBsAg/anti-HBe-reactive patients are positive. All patients who recover from acute HBV are negative for HBV DNA. On the other hand, some chronically infected patients who have lost their HBsAg remain HBV DNA positive (see the section, Seronegative Infection).

Because the agents of viral hepatitis often cannot be distinguished clinically, and superinfection with HAV, HCV, or hepatitis delta virus (HDV) in an HBV carrier can occur—especially in groups at high risk of acquiring viral hepatitis—serologic means are required for their identification (313,317,319). To accomplish this, a variety of diagnostic profiles are available to the clinician to ensure that a misdiagnosis does not occur, because this may impinge on recommendations for prevention, prophylaxis, or therapy. Figure 6 is an algorithm that is designed to assist clinicians and diagnosticians in arriving at a correct diagnosis of (a) acute viral hepatitis A, B, C, or D; (b) chronic hepatitis B, C, or D; (c) past infection with HAV, HBV, or HCV; (d) the relative infectivity of the hepatitis B patient; and (e) the determination of hepatitis A or B vaccine status. Detailed interpretations of the serologic markers observed during infection with HAV, HCV, and HDV can be found in the appropriate chapters of this book.

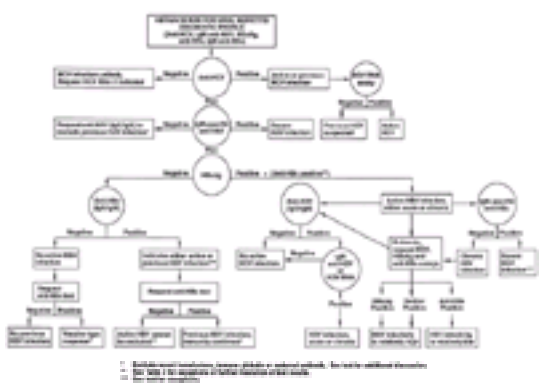

FIG. 6. Algorithm for the serologic diagnosis of HAV, HBV, HCV, and HDV.

Differentiating Acute Hepatitis from Chronic or Remote Infection

As summarized in Table 4 and illustrated in Figure 5 and Figure 6, detection of HBsAg in serum indicates that an active HBV infection, either acute or chronic, is present. Almost all HBsAg-positive sera from acute and chronic hepatitis B patients will be anti-HBc positive because it is only during the incubation period of acute hepatitis B, before liver abnormalities or clinical symptoms, that anti-HBc–positive reactions do not accompany the HBsAg response (see Fig. 5).

Patients with acute hepatitis B develop high titers of IgM-specific anti-HBc antibody commencing with the onset of aminotransferase abnormalities (158,415,417,443,602,650). These titers gradually decline over a 6- to 8-month period regardless of whether the disease is resolved or becomes chronic. By means of special research procedures, low concentrations of IgM-specific anti-HBc have been detected for up to 2 years in patients whose disease has resolved successfully, and in many chronic carriers (243,444,702,778). Among HBsAg carriers, the predominant component is a 7S IgM fraction, as opposed to a 19S component in acute disease (702,778). However, only a few chronic hepatitis B patients have an IgM-specific anti-HBc titer that is high enough to be detected in the conventional IgM anti-HBc dilutional assay. Even then, reactivity is relatively low when compared with that observed in acute disease. However, one event that can lead to a detectable IgM anti-HBc reaction in chronic disease is reactivation of HBV, especially after steroid withdrawal. Regardless, from a practical standpoint, the presence of IgM-specific anti-HBc at a dilution of 1:1,000 or higher (which is stipulated for that assay) is presumptive evidence of a recent acute infection (see Table 4).

Detection of anti-HBs and anti-HBc in an HBsAg-negative specimen normally indicates a previous infection with hepatitis B and confirms immunity against reinfection with HBV. However, in some hepatitis B–infected patients, especially in acutely ill neonates and in those with fulminant disease in which HBsAg expression by necrotic liver tissue is severely restricted, similar serologic results may be observed. In these situations, IgM-specific anti-HBc will distinguish between

acute disease or prior immunity.

The IgM-specific anti-HBc test also may provide assistance in evaluating HBsAg-negative sera from patients with hepatitis who are positive only for total anti-HBc (which measures both IgG and IgM anti-HBc) as shown in Table 4. Assuming that the solitary anti-HBc test result is not a false-positive reaction, the diagnostic alternatives include (a) chronic hepatitis B in which the HBsAg concentration is too low to be detected by conventional assays; (b) passively acquired anti-HBc [maternal–neonatal transmission, blood derivative therapy, immune globulin (IG) administration]; (c) previous hepatitis B infection with loss of detectable anti-HBs; and (d) acute HBV infection in which the sample was collected in the early convalescent stage of the illness when HBsAg has declined to undetectable levels (see Fig. 5). In this latter situation, the presence of a strongly positive IgM-specific anti-HBc result is definitive evidence for a recent (acute) hepatitis B infection. These sera also are likely to contain anti-HBe or, rarely, HBeAg. It is assumed that these patients are still infectious, although the degree of infectivity is muted by the low level of circulating virus present in the blood. Fortunately, fewer than 5% of acute clinical cases present with this serologic profile. Results can be verified and immunity documented by demonstrating anti-HBs seroconversion in 2 to 8 weeks.

In the absence of anti-HBs and high-titered IgM-specific anti-HBc, a serologic distinction between a chronic infection with undetectable HBsAg (an unusual event), or a past infection in which the anti-HBs level has declined to below the range of detectability, often is not feasible. Some of these patients could be co-infected or superinfected with HCV, which may interfere with the replication of HBV and result in a low-level HBV carrier (519). Testing these samples for HBV DNA by PCR may help resolve this issue, as would detection of HBV DNA in tissue from a liver biopsy. Another diagnostic approach is to challenge these patients with HBsAg vaccine and examine their blood for anti-HBs seroconversion 2 weeks later. Fewer than 3% of HBV-susceptible patients or chronic low-level carriers will generate anti-HBs levels of greater than 10 mIU/mL within this time interval. In contrast, the covert immune patient will generally develop an anamnestic response. Theoretically, completing the basic three-injection HBsAg immunization series in the initial nonresponders might separate the susceptibles from the low-grade carriers, because over 90% of the susceptibles should develop anti-HBs. The absence of anti-HBc in a specimen almost always excludes past or present hepatitis B, except in highly unusual situations (see the section, Seronegative Infection).

Relative Infectivity of Blood in HBV-Infected Patients

To determine whether the blood or body fluids of an HBsAg-positive patient are highly infectious or contain a relatively small concentration of infectious virions, the clinician can have the sample tested for HBeAg, anti-HBe, or HBV DNA. Because virtually all patients with acute hepatitis B are initially HBeAg positive (415,538), this diagnostic test should be reserved for chronically infected patients. HBeAg-positive specimens usually contain high concentrations of HBV DNA and infectious virions (>10^8 per milliliter of blood) (414,415,785), in contrast to anti-HBe–positive samples, in which the number of hepatitis B virions may be fewer than 100 per milliliter except in those individuals infected with precore mutants. As anticipated, HBeAg-positive patients are more likely to transmit hepatitis B sexually, percutaneously, or perinatally. In contrast, the HBV infectivity of persons who are HBsAg and anti-HBe positive is generally very limited. HBeAg is almost never detected in sera nonreactive for HBsAg.

As previously discussed (see the section, Pathogenesis), anti-HBe-positive carriers with precore mutations may have moderately high levels of HBV DNA. These patients can alternate between periods of apparent health and acute reactivation of their illness, or their clinical course may be very aggressive. When confronted with such a clinical picture, a specific evaluation for HBV DNA seems justified, especially if treatment with an antiviral agent is being contemplated.

Between 70% and 90% of infants born to HBV-infected mothers who are HBeAg positive are likely to become chronically infected, compared with fewer than 10% of infants whose mothers are HBsAg and anti-HBe positive. Fortunately, screening of mothers and immunization of at-risk neonates has reduced this concern (see the section, Prevention and Control). HBeAg, anti-HBe, and HBV DNA determinations also may be used to assess risk after an accidental needle-stick exposure or to judge the potential for sexual transmission.

Hepatitis B Immune Status

The conventional anti-HBs and anti-HBc assays are essential for determining the immune status of an individual to HBV, for evaluating risk factors associated with the transmission of HBV, and for assessing recovery or the progress of infected patients. Their presence confirms immunity to HBV, whereas their absence serves to identify those persons who are susceptible to HBV and who may benefit from being vaccinated. Both anti-HBs and anti-HBc results are necessary to render an appropriate interpretation concerning natural immunity to HBV. In a small percentage of patients, the concentration of anti-HBs may decline over time to undetectable levels, leaving the patient with an isolated anti-HBc result. As indicated previously, an anamnestic response to vaccination may serve to identify this group of individuals.

Anti-HBs is the principal neutralizing antibody of hepatitis B, and its appearance usually signifies recovery from infection (415). It has been detected in the IgG and IgM fractions of sera (427) and as an IgA antibody in secretions (569). Patients with preexisting anti-HBs are protected against acquiring HBV (44,314,327,427). Although this antibody is usually not detectable until the convalescent period (see Fig. 5), the occurrence of immune complexes leading to a serum sickness–like disorder during the prodromal phase of acute hepatitis B suggests that anti-HBs may be synthesized much earlier (16,195,320). When evaluating a response to the hepatitis B vaccine, only the anti-HBs test is required because the immunogen is HBsAg. Anti-HBc, a marker of viral replication (past or recent), remains nonreactive in this situation.

Depending on the circumstances, passive transfer of anti-HBs or anti-HBc may be observed after IG administration, or in neonates of mothers with recent or past hepatitis B infection. Because blood donations are pretested for total anti-HBc, passive transfer of anti-HBc and anti-HBs after transfusion of blood is unlikely. However, if a blood donor has been given the HBsAg vaccine, anti-HBs (but not anti-HBc) can be passively acquired by the recipient. Recognition of these possibilities can avoid an erroneous interpretation of serologic results.

Discordant or Unusual Hepatitis B Test Results

Profiles that yield discordant or unusual results require further evaluation (313). Factors leading to an isolated HBsAg, anti-HBs, or anti-HBc response already have been discussed. The most obvious isolated response encountered today is the presence of anti-HBs in HBsAg vaccine recipients, although solitary anti-HBc responses are becoming more evident, especially in patients infected with HCV. In general, an isolated antibody or antigen response should remain suspect until verified by repeat testing of the same sample or, preferably, by testing an additional sample.

Although a number of technical determinants may account for erroneous results, the testing of partially heparinized or severely hemolyzed blood, or the examination of sera from patients with coagulation disorders (258), still figures prominently in the occurrence of false-positive results, especially when testing for HBsAg. Most of the responses are low-positive reactions—near the cutoff value for the test—which is very uncommon among hepatitis B patients.

Anti-HBs reactivity in an HBsAg-positive patient is uncommon. It is most likely to occur (a) during resolution of acute hepatitis B, (b) in chronic carriers who have more serious liver disease, or (c) in carriers exposed to heterologous subtypes of HBsAg. Leading candidates for this type of response are parenteral drug abusers or individuals who receive multiple transfusions.

TREATMENT

Management of Acute Hepatitis B

There is no specific treatment for benign acute viral hepatitis. Thus, therapy should be supportive and aimed at maintaining comfort and adequate nutritional balance (for a complete discussion of this topic, see Management of Acute Viral Hepatitis in Chapter 26). It should be emphasized that there is no indication for the use of corticosteroids in the treatment of acute, uncomplicated hepatitis B, because they have no effect on the rate of resolution of the underlying disease process and may increase the rate of relapse (204,205). Furthermore, evidence has been presented that early treatment of acute hepatitis B with steroids may result in the development of persistent infection in a significant proportion of patients (208,667). Finally, the administration of HBIG to patients with fulminant hepatitis B is of no apparent benefit (4), and the therapeutic effectiveness of interferon or lamivudine on the course and prognosis of acute hepatitis B remains unknown.

Management of Chronic Hepatitis B

The goal of therapy for chronic hepatitis B is to suppress HBV replication to reduce symptoms, minimize chronic inflammation, and prevent progression to cirrhosis and HCC. Because the complete eradication of HBV infection often is not possible, the treatment is aimed at achieving a quiescent state of viral replication and remission of liver disease. Although the ultimate benefits on survival have not been demonstrated, several long-term follow-up studies on patients successfully treated with interferon have indicated a reduction in the complications that accompany end-stage liver disease (209,433,556).

Treatment is recommended for patients with persistently elevated serum aminotransferase values, active viral replication, and histologic evidence of moderate-to-severe inflammation or fibrosis. HBV carriers with normal aminotransferases should not be treated. Indications for other patient populations, including patients with severe extrahepatic manifestations, with human immunodeficiency virus (HIV) co-infection, with active alcohol or substance abuse, with renal disease, or with solid-organ transplantation, and patients on cancer chemotherapy or immunosuppressive agents, are less defined. Because serum biochemical tests and clinical evaluations often do not accurately reflect the extent of liver injury, a liver biopsy is recommended prior to initiation of treatment to confirm the diagnosis, to establish the grade and stage of liver disease, and to assess prognosis. Patients with contraindications for liver biopsy, such as coagulopathy, could be treated without a biopsy. The therapeutic end points employed in most clinical trials to define a complete response following the treatment of hepatitis B include HBeAg seroconversion to anti-HBe, clearance of HBV DNA from the serum (by a non-PCR assay), normalization of aminotransferases, and/or improvement observed in the liver biopsy. Because the first three parameters usually predict the last one, it is not necessary to perform a posttreatment liver biopsy unless in a protocol setting.

A number of agents have been used in the treatment of chronic hepatitis B. In general, corticosteroids, adenine arabinoside (and its water-soluble derivative), acyclovir, and dideoxyinosine have not been found to be beneficial and may even be deleterious (12,236). Several studies have shown that the administration of steroids to patients with chronic hepatitis B causes an increase in the serum concentration of HBsAg and HBV DNA and increases the expression of HBcAg in hepatocytes (424,634,655,783,819). Regulation of this response is via a glucocorticoid responsive element present in the HBV genome, which leads to the augmentation of an HBV enhancer element that presumably influences expression of specific HBV genes (782). In conjunction with this enhanced expression of virus and viral antigens during treatment with steroids, T-lymphocyte function is suppressed (280). The abrupt withdrawal of steroids elicits an intense, cell-mediated immune response that leads to the destruction of hepatocytes expressing these viral antigens. This event coincides with an increase in the serum ALT level, a decline in HBV DNA, and the development of symptoms of hepatitis. A similar response occurs after the discontinuation of cytotoxic chemotherapeutic agents. Either of these events has been associated with recurrence of disease and fulminant hepatic failure (81,233,331,437,765). In contrast, physicians must recognize that naturally occurring reactivation often culminates in substantial improvement of liver function, especially in HBeAg-positive carriers who are undergoing spontaneous remission of their disease (468). To administer steroids in this situation might abort this process and prevent clinical remission from occurring. Most of these individuals will eventually seroconvert to anti-HBe, a process that may take several months to develop. Currently, the only agents shown to have beneficial effects, and which are approved for the treatment of chronic hepatitis B, are alpha-interferon and lamivudine. Other agents under investigation are listed in Table 5.

Immunomodulatory agents
Nonspecific: interferons, thymosin, levamisole, IL-2, IL-12, etc.
Viral specific: therapeutic vaccines (pre-S/S vaccine, CTL epitope vaccine, and DNA immunization)
Cell based: adoptive immune transfer
Antivirals
Nucleoside analogs: lamivudine, famciclovir, adefovir, lobucavir, BMS-200475, L-FMAU, β-L-Fd4C, etc.
Glycosylation inhibitors: inhibit viral assembly
Gene therapy: antisense, ribozyme, targeted drug delivery, etc.

IL, interleukin; CTL, cytotoxic T lymphocyte.

TABLE 5. *Therapeutic approaches for hepatitis B infection*

Immunomodulatory Agents

Interferons are a class of molecules produced by higher eukaryotic organisms that have potent antiviral and cell regulatory (immunomodulatory) functions (605). Among the interferons, alpha interferon has been used successfully in the treatment of chronic hepatitis B (330). The recommended regimen is either 5 million units daily or 10 million units three times a week (or every other day) for 4 to 6 months. Side effects of interferon treatment are frequent and include constitutional symptoms, bone marrow suppression, neuropsychiatric effects, and the occurrence of autoimmune disease, especially of the thyroid.

During therapy, patients should be monitored frequently with hematologic and biochemical tests. Serologic assays for HBsAg, HBeAg, and HBV DNA level can be reserved for the end of treatment. Because seroconversion from HBeAg to anti-HBe can occur months after treatment (209,433,556), HBV markers should be followed at 3- to 6-month intervals. Transient increases in serum aminotransferase levels are common during therapy, particularly preceding HBeAg to anti-HBe seroconversion. This probably reflects the immune-mediated clearance of HBV-infected hepatocytes induced by alpha interferon. Typical patterns of treatment response to interferon are shown in Figure 7A and Figure 7B.

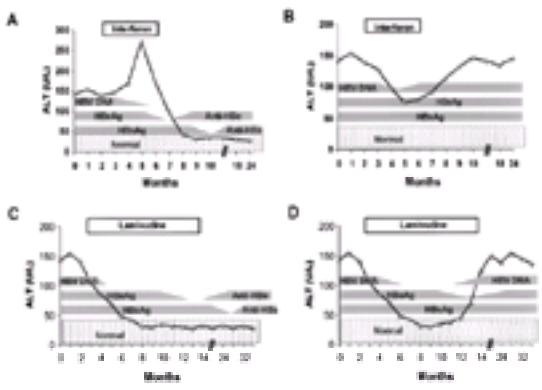

FIG. 7. Patterns of treatment response to interferon or lamivudine. **A:** Response to interferon. HBV viral levels gradually decline: Exacerbation of hepatitis with further elevation of ALT often precedes HBeAg seroconversion to anti-HBe. Many responding patients may experience late HBeAg seroconversion (after interferon treatment). Some patients also may experience HBsAg seroconversion to anti-HBs after treatment. **B:** Nonresponse to interferon. Transient ALT improvement and decline in HBV levels may occur, but no sustained response is noted. **C:** Response to lamivudine. HBV titers decline rapidly, usually to undetectable level (by a non-PCR assay) within 4 weeks. This is accompanied by improvement in ALT. HBeAg usually disappears gradually with or without anti-HBe development. HBsAg seroconversion occurs rarely. **D:** Development of lamivudine resistance. As in the responders, HBV titers decrease rapidly with ALT improvement but reappear late in the course of lamivudine treatment. The reemerging virus often carries lamivudine-resistant mutations, and relapse of hepatitis often accompanies viral resistance.

Several clinical, biochemical, and serologic factors are associated with a more favorable response to interferon treatment. They include low serum HBV DNA level, high serum aminotransferase concentration, active liver histology (inflammation and fibrosis on biopsy, but not cirrhosis), a short duration of infection, female sex, and absence of comorbid illnesses (330,814). The first two factors are the best predictors and probably reflect an underlying active anti-HBV immune response.

Based on a meta-analysis of 15 studies (Table 6) (814), a standard course of therapy resulted in the loss of HBsAg 6% more often in interferon-treated patients when compared to the natural loss of antigen seen in controls. Similarly, when compared to untreated controls, 21% of the treated patients more often lost HBeAg following treatment and 20% lost HBV DNA as determined by the relatively insensitive hybridization assay, which has a lower limit of detection of 1.5 to 3.0 pg/mL (500,000 to 1 million copies/mL). When tested by the more sensitive PCR methodology, most of these patients still have low levels of HBV DNA in their blood. Regardless, patients responding to therapy have a survival advantage over nonresponders.

Therapeutic intervention	Loss of HBsAG	Loss of HBeAg	Loss of HBV DNA
Alpha-interferon	7.8%	33%	37%
No treatment	1.8%	12%	17%
Difference	6%	21%	20%

Source: From ref. 814, with permission.

TABLE 6. *Meta-analysis of 15 studies on the efficacy of interferon in patients with HBeAg-positive chronic hepatitis B*

Children with active chronic hepatitis B (high serum aminotransferase concentrations) respond as well as adults to treatment with alpha interferon (654,712). Children with normal aminotransferase concentrations should not be treated, because they have a poor response rate (421). The standard regimen is 6 million units per square meter of body-surface area daily for 4 to 6 months.

Some patients with chronic hepatitis B have an atypical serologic pattern: elevated aminotransferase levels with a positive serum HBV DNA but no HBeAg. These patients are probably infected by a variant strain of HBV that has a mutation (or mutations) that inhibits the synthesis of HBeAg (see Viral Strains). Interferon therapy is effective in these patients, but the response rate is low and the relapse rate high (11).

Stimulators of HBV-Specific Immune Response

Patients with chronic hepatitis B have impaired anti-HBV cell-mediated immunity. Initial therapeutic approaches targeted at activating anti-HBV cellular responses have been attempted, but the antiviral effect has been weak (291). An alternative approach to overcome the tolerance and anergy of HBV antigens in chronically infected patients has been to use either the standard HBsAg vaccine or new pre-S–containing vaccines with or without novel potent adjuvants. Preliminary trials have shown some promise, but larger studies are required for confirmation and overall efficacy (164) (see also the later section, Immunization of HBsAg Carriers). Immunization with plasmid DNA-expressing HBV antigens has been shown to induce an immune response sufficiently robust to suppress viral replication in chronically infected animals (651). However, the duration and benefits of this response remain to be determined, and safety issues are a major concern. Finally, bone marrow transplantation from HBV-immune donors to HBV-infected recipients has been shown to lead to viral clearance in the recipients (435,697). Although this approach is not practical for therapy of chronic hepatitis B, a more viable option based on *in vitro* stimulation of autologous lymphocytes may be applicable. The anti-HBV immune response can be stimulated by *ex vivo* activation and reinfusion of immunocytes harvested from HBV-infected individuals. The *ex vivo* activation can be accomplished by either nonspecific [interleukin 2 (IL-2)] or specific (HBV antigens) stimulation. A preliminary trial using this approach showed some benefit (185).

Nucleoside Analogs

Most of the newer anti-HBV agents are nucleoside or nucleotide analogs that target the viral-encoded reverse transcriptase, inhibiting its activity and terminating DNA chain extension. Because the reverse transcriptases between the human immunodeficiency virus and HBV share structural and sequence homologies, many of the agents are effective for both viral infections.

Lamivudine is a cytosine nucleoside analog. It is phosphorylated by intracellular kinases to the active compound. The drug is rapidly absorbed, not altered by food, and has an *in vitro* intracellular half-life of 17 to 19 hours, making once-daily dosage possible. Hepatic impairment does not affect the pharmacokinetics of this product, but renal insufficiency may require dose adjustments. The dose used for HBV is 100 mg daily, which is lower than that for HIV (300 mg daily). Treatment of HBV patients with lamivudine is associated with a rapid and profound reduction of serum HBV DNA (median, five-log decrease) and an accompanying decrease in aminotransferase levels (189,239,420). Seroconversion from HBeAg to anti-HBe can be seen in 17% to 20% of patients (versus 6% to 7% of controls) after 1 year of lamivudine treatment. Biochemical and histologic improvements also are evident in those who respond to lamivudine. As with interferon, higher pretherapy levels of ALT influence HBeAg seroconversion (145,600). Reduction of HBV DNA to less than 10,000 genomes per milliliter by 20 weeks is also associated with HBeAg seroconversion (239). In those who seroconvert, remission is durable in most, histologic progression is slowed, and rates of HCC and liver-related deaths are reduced.

Lamivudine is well tolerated with few side effects. Therefore, long-term treatment has been proposed, as longer duration of therapy appears to result in increased rates of response. Because of an absence of bone marrow suppression, induction of autoimmune disease, and flares of aminotransferase values, lamivudine can be used in situations where interferon is not appropriate, such as decompensated cirrhosis, liver transplantation, and other immunosuppressed states (37,600). HBV carriers—even those with minimal liver damage—who are undergoing chemotherapy for malignancies should be prophylactically treated with lamivudine because of possible exacerbations of liver disease (19).

The major drawback of lamivudine is the emergence of drug-resistant mutants. In recent clinical trials, 14% to 39% of immunocompetent patients developed evidence of drug-resistant viruses (15,328,420,557). The emergence of the lamivudine-resistant mutants, usually occurring after 8 to 10 months of treatment, can be associated with increased serum HBV DNA and aminotransferase levels. Cessation of treatment is frequently associated with rapid emergence of the wild-type strain and can occasionally be accompanied by a marked flare of liver disease and even liver failure (456).

In addition, lamivudine-resistant mutants reemerge rapidly with retreatment, even at a higher dose of lamivudine (434). Lamivudine-resistant HBV strains contain mutations in the YMDD motif (Tyr, Met, Asp, Asp), which is part of the catalytic site (C domain) of the reverse transcriptase, and/or in the B domain (15). Mutation from methionine to valine or isoleucine at aa552 diminishes the binding affinity to lamivudine. Two other amino acid mutations in the B domain (V521L and L528M) occur primarily in combination with the YMDD mutation. However, despite these mutations, continual treatment is advocated to prevent relapse of the wild-type virus and to partially suppress HBV replication. Furthermore, this approach can lead to late anti-HBe seroconversion in some patients, which often is accompanied by an acute flare of hepatitis (456). Typical responses to treatment with lamivudine are shown in Figure 7C and Figure 7D.

Other nucleoside analogs, including famciclovir, ganciclovir, acyclovir, adenine arabinoside 5'-monophosphate (ARA-AMP), zidovudine, didanosine, and fialuridine have been tested clinically in patients with chronic hepatitis B (330). None of them have been shown to induce lasting beneficial effects on HBV DNA level and disease activity, and many of them are poorly tolerated or have significant toxicity.

Adefovir dipivoxil is an adenosine monophosphate analog that is a potent inhibitor of HBV reverse transcriptase *in vitro.* In recent clinical trials, adefovir has been shown to reduce serum HBV DNA by several logs with improvement of liver disease (290), and it appears to be clinically active against drug-resistant mutants of lamivudine (584,820). Therefore, lamivudine and adefovir may be promising as combination therapy to reduce the occurrence of drug resistance. Although adefovir is well tolerated, renal toxicity at higher doses may become a limiting factor. The effect is cumulative, with crystal formation injuring the proximal tubules and resulting in a Fanconi-like syndrome. However, this appears to be reversible with discontinuation of the drug. Other promising nucleoside analogs are 1-(2-fluoro-5-methyl-beta- L-arabinofuranosyl) uracil (L-FMAU), 2',3'-dideoxy-2',3'-didehydro-b- L-5-fluorocytidine (b-L-Fd4C), 5-fluorothiacytidine (FTC), and dioxolane guanosine (DXG), all of which have been shown to be potent inhibitors of HBV replication *in vitro* and in animal models (813,837). Unlike the fluorinated nucleoside analog fialuridine (496), the L forms appear to have no or little mitochondrial toxicity.

Novel Antiviral Approaches

Targeted delivery of antivirals to the liver has been developed to minimize side effects and reduce the dosages of the drugs. Preliminary studies have supported the utility of this approach (401,770). Development of antisense molecules, ribozymes, dominant negative mutants, or other gene therapy approaches to specifically inhibit HBV transcription or replication is theoretically possible and has shown some promises *in vitro* and in limited animal studies (80,565,805,818,839). However, these approaches are limited by a variety of obstacles including the foremost problem of efficiency and specificity of the delivery technology.

Combination Therapy

Interferon in combination with other immunomodulatory agents has been tested in various clinical trials but does not appear to be more effective than treatment with interferon alone. Results from a pilot study and a multicenter placebo-controlled trial showed that the combination of lamivudine and interferon may confer a marginally better response than lamivudine alone (539,665). Therefore, the more promising approach of combination therapy is probably in the use of direct antivirals such as nucleoside analogs.

EPIDEMIOLOGY

Prevalence and Risk Factors

HBV is a ubiquitous organism that is globally distributed. Although HBsAg has been found in the serum of certain species of nonhuman primates, humans remain the principal reservoir for HBV. In the United States in 1998, the number of cases of hepatitis B reported to the National Notifiable Diseases Surveillance System operated by the Centers for Disease Control (CDC) was 10,258, a rate of 3.8 cases per 100,000 population (140). This represented 28% of the total number of viral hepatitis cases reported. Approximately half of the hepatitis B cases occur in persons 25 to 39 years old. It is estimated that the true incidence of hepatitis B is 15 to 30 times the reported rate, of which about half are symptomatic. Since 1987, the number of reported cases of acute hepatitis B has declined by over 60%. This presumably has occurred as a direct result of universal immunization of neonates, vaccination of at-risk populations, life-style or behavioral changes in high-risk groups, refinements in the screening of blood donors, and the use of virally inactivated or genetically engineered products in patients with bleeding disorders.

To understand and appreciate the various epidemiologic patterns found in hepatitis B requires that the source of infectious virus be known. This is usually the blood, but the virus also has been detected in a variety of other bodily secretions and excretions, including semen (22,172,363,385,675), saliva or nasopharyngeal fluids (22,40,172,363,385,675,792), and menstrual fluid (169,352). Intravenous inoculation of chimpanzees with semen from HBV carriers (22), as well as the intravaginal instillation of semen in gibbons (675), has resulted in the transmission of hepatitis B. On the other hand, oral ingestion of semen failed to infect these animals. There is no convincing evidence that airborne infections occur (322). Feces have not been incriminated as a source of infection (287,474,503,548,549). Virus is sometimes present in urine (172,385,705), but this is probably of limited epidemiologic importance. Exceptions may occur when persons are exposed to chronically infected, diapered infants or to the urine of HBsAg-positive uremic patients undergoing hemodialysis (179). Gastric juice is not a source of HBV (684), but HBsAg has been detected in both bile and pancreatic juice (310,684). Pleural fluid, ascitic fluid, cerebrospinal fluid, tears, and breast milk also have been positive for HBsAg (120,176,668,750). From these reports, it should be assumed that all biologic fluids from HBV-infected patients may be infectious and capable of transmitting HBV. This is especially relevant when percutaneous or mucous membrane exposure has occurred, because this is the most efficient route for introducing the virus into the susceptible host. When you consider the high concentration of virus that may be present in the blood of an HBeAg-positive carrier and the stability of HBV (96), the possibilities for transmission are abundant.

Serologic surveys have documented the existence of hepatitis B throughout the world, including the most isolated and remote areas. The true prevalence of the disease can only be estimated because the collection of accurate data has been hampered by inadequate reporting, lack of laboratory confirmation, insensitive assays, and selection bias. Nevertheless, it is clear that the HBsAg carrier rate varies from country to country, with higher rates being reported from developing countries with primitive or limited medical facilities (Fig. 8) (35,83,89,260,711,733). Even within apparently homogeneous groups in the same country or area and among different ethnic groups, the HBsAg carrier rate may vary substantially (269,364,711,733,744,816).

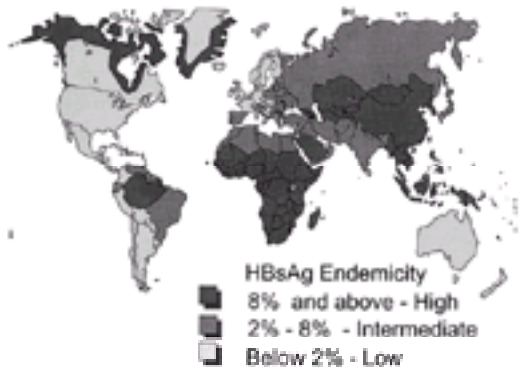

FIG. 8. Prevalence of HBsAg in the world. (From M. Kane, personal communication, 1999.)

There is no seasonal trend for HBV infection, and epidemics are unusual. Cumulative infection rates in the United States increase with age, with an overall age-adjusted prevalence of 4.9%, based on the presence of anti-HBc. Among the major racial groups, the rates were 2.6% in non-Hispanic whites, 4.4% in Mexican-Americans, and 11.9% in non-Hispanic black participants (502). The male-to-female ratio was 1.5:1. From these data, an estimated 1 to 1.25 million Americans are believed to have contracted chronic hepatitis B. Those with an enhanced likelihood of having acquired this infection include residents and staff of penal institutions and residential facilities for the developmentally disabled; multiply transfused patients (pre-1988); patients and staff of oncology or hemodialysis units and organ transplantation patients; male homosexuals and sexually promiscuous groups; users of illicit injectable drugs who share needles; close contacts of chronic carriers; sexual partners of patients with acute hepatitis; neonates born to women who have acute or chronic hepatitis B; and health care workers (particularly dentists, surgeons, and clinical laboratory staff). However, the availability of an effective vaccine, optimized blood donor screening, and better sterilization procedures for blood derivatives have dramatically altered the risk in many of these groups.

Based on data obtained from the Sentinel County Program sponsored by the Hepatitis Branch of the CDC (M. J. Alter, personal communication, 2000), acute hepatitis B cases resulting from illicit injecting drug use have decreased by 90% since 1988 (to 21%), whereas cases in heterosexuals who had sexual contact with a hepatitis B patient, with an HBV carrier, or with multiple partners declined by more than 40%. Homosexual activity is currently associated with 15% of the cases, whereas hepatitis B in health care workers declined from a range of 3% to 6% down to 1%, perhaps due, in part, to vaccination. Thus, heterosexual activity remains the single largest risk factor, accounting for 45% of the acute HBV cases seen between 1991 and 1997.

In endemic areas of Asia and Africa, the epidemiologic patterns of infection are different from those seen in North America and western Europe (735). Serologic surveys indicate that most infections in these geographic regions occur in infants and children as a result of maternal–neonatal transmission or early childhood contact, although percutaneous exposure with contaminated needles or following unsafe injections is always a possibility in these countries. An annual incidence of infection among children of 3% to 5% has been projected.

Modes of Spread

Percutaneous or Parenteral Transmission

Percutaneous or parenteral transmission is one of the principal modes of spread of hepatitis B in communities. The risk of acquiring infection following the administration of blood or blood components has undergone a dramatic reduction in recent years as a result of (a) the addition of sensitive and specific anti-HBc testing in 1986 to complement incremental improvements in HBsAg testing, (b) the use of an all-volunteer blood donor population, (c) improvements in assessing the qualification of donors and the implementation of donor self-deferral, and (d) the development of viral inactivation procedures in conjunction with the use of recombinant products to render blood components and derivatives safe. The current residual risk of receiving a unit of HBV-infected blood from a screened donor during the seronegative window period is estimated to be 1 in 63,000 [95% confidence interval (CI): 31,000 to 147,000] (118,671). New screening tests such as nucleic acid testing for HBV DNA and /or enhanced sensitivity of the HBsAg assay should reduce the risks even further.

Although the situation has changed dramatically, prevalence rates of hepatitis B are highest in hemodialysis patients and in adult hemophilic patients who, prior to 1988, received blood components and derivatives that had not been purified or virally inactivated. Up to 75% of HIV-positive and 33% of HIV-negative adult hemophilic patients have serologic evidence of hepatitis B infection as a result of exposure to contaminated blood derivatives (777), with active HBV disease being demonstrated in 12% and 4%, respectively.

In contrast to the current reduced risk of hepatitis B found among recipients of blood products, the hazards of

percutaneous exposure associated with repeated or one-time sharing of contaminated syringes and needles by users of illicit drugs continue to be responsible for many of the hepatitis B cases seen today in the United States (24,132). If followed long enough, most members of this group will develop clinical and/or serologic evidence of hepatitis B (238,252,679).

HBV infection is common in some, but not all, hemodialysis units and in unimmunized household contacts of hemodialysis patients (611,740,767). In 1997, a CDC survey of 3,077 hemodialysis centers in the United States, representing 253,001 patients and 63,054 staff members, revealed that the incidence of HBV infection had decreased from 3.0% in 1976 to 0.05% among patients, and from 2.6% to 0.05% among staff members, with the greatest decline occurring between 1976 and 1980 (767). Similarly, during the same period, the prevalence of HBsAg positivity among patients and staff declined from 7.8% to 0.9% and from 0.9% to 0.4%, respectively. The higher rate of chronic disease in patients can be attributed to a disease-related immunologic deficiency in many hemodialysis patients that prevents them from clearing HBsAg from the blood (or responding to vaccine). In 1997, 3.3% of the centers reported one or more newly acquired HBV infections, whereas 24.1% reported having one or more patients with chronic HBV infection. The virus generally spreads from patient to patient, or from patient to staff member, via contaminated equipment or the environment (169,214,709). Not only is the antigen stable on various surfaces for extended periods (211) but infectivity is retained (96). Reuse of dialyzers is not associated with any increased risk of HBV infection in either patients or staff. The use of hepatitis B vaccine was approximately 70% effective in preventing newly acquired HBV infection (518). By 1997, 47% of patients and 87% of staff members had received at least three doses of hepatitis B vaccine.

Health care personnel have a higher prevalence of HBsAg or anti-HBc than do those who have no occupational exposure to patients or blood products (450,595,666). In contrast, the recent incidence of clinical hepatitis is very low because of requirements for vaccination by the Occupational Safety and Health Administration (OSHA). The prevalence of hepatitis B markers increases with age and years of occupation (177,190,666) and is a function of the frequency of percutaneous and permucosal exposures to blood or body fluids containing blood (139,190,491). The unrecognized reservoir of HBV infection that is present in about 1% of the patients admitted to urban hospitals (216,464,480,492) represents the principal hazard to hospital personnel who handle blood or bodily fluids (438,449). In 1993, an estimated 1,450 health care workers became infected with HBV through exposure to blood and serum-derived body fluids, a 90% decrease from 1985 (139,685). An estimated 100 to 200 health care workers have died annually during the past 15 years because of the chronic sequelae of HBV infection.

Transmission of HBV by the percutaneous route also may occur as a result of inadvertent (or inapparent) inoculation after the use of shared razors, toothbrushes (531), and communal bath houses (105) or towels, and by tattooing (462,535,663,706), acupuncture (555), or ear piercing (374). In addition, transmission of hepatitis B has been documented after a human bite by an HBV-infected person (279,477). Engorged mosquitoes, bedbugs, and ticks, particularly if collected in homes or areas where HBsAg carriers reside, may be positive for virus or HBsAg (108,187,376,554,570). Under suitable circumstances, viral dissemination by mechanical transfer may occur, although the epidemiologic importance of this transmission pattern is still being debated (490). However, in one study, inoculation of HBsAg-containing mosquito tissue or the feeding of HBsAg-positive mosquitoes or ticks to susceptible chimpanzees failed to transmit HBV (70,377).

Contact-Associated Transmission

The hypothesis that contact-associated transmission of hepatitis B may exist comes from several disciplines. Between the late 1930s and mid 1970s, the traditional premise that hepatitis B is communicable only by a percutaneous route was altered when uninoculated contacts of icteric patients and familial clusters of hepatitis B cases were observed (252,277,303,354,741). Currently, one of the most important routes of transmission of HBV in the United States is by sexual contact with an infected person, either heterosexual or homosexual.

The successful experimental transmission of hepatitis B to children by the oral route using human serum containing high-titered virus, although with apparently minor clinical consequences, has been cited as supporting the possibility that oral transmission may occur under natural conditions (249,411). The subsequent detection of HBV in saliva (22,40,172,287,363,385,477,675,792), albeit at concentrations that were 100 to 10,000 times less than that found in serum (172,363), intensified interest in saliva as a mechanism for transmitting HBV. It has been postulated that saliva is contaminated by virus entering the mouth through the crevicular fluid at the gingival surface following rinsing of the mouth with water or after mastication (322). Alternatively, peripheral blood lymphocytes may be another source of HBV DNA in saliva (172,830). In three separate animal studies (22,40,675), five anthropoid apes were found to be susceptible to HBsAg-positive saliva, but only by parenteral routes (subcutaneous and intravenous). No hepatitis B occurred in the 13 primates that received HBV-contaminated saliva by the oral route. It is concluded that unless the inoculum is large or the concentration of virus is high, oral transmission by saliva or by objects contaminated with saliva is probably rare in nature, although percutaneous transmission via a human bite has been reported (119,279,477).

Hepatitis B has long been recognized as endemic in residential facilities for the mentally handicapped, no doubt reflecting problems of crowding and poor hygiene (409,411,416). A matched-pair susceptibility study evaluating equally exposed clients demonstrated that those with Down syndrome—like hemodialysis patients—frequently fail to develop specific antibody and are more likely to become chronic HBsAg carriers, whereas other mentally handicapped clients appear to resolve their infection successfully with the production of anti-HBs (321). The advent of immunization has rectified this situation so that clients are no longer acquiring HBV infection.

HBV transmission is a relatively common event among individuals residing in the same household with an HBsAg-positive carrier (277,289,603,604,741,791). In these situations, the occurrence of clinically overt infections is relatively uncommon. The actual mechanism of transmission is not always known, but sexual transmission or inapparent exposure through shared razors, towels, toothbrushes, oozing skin lesions, or fomite contamination of surfaces is frequently suspected.

Although all household contacts of a chronically infected individual are at high risk of infection, not all are equally likely to become carriers once infected (see also Fig. 3) (72,260,736). Siblings of carriers are found to be HBsAg positive more frequently than are parents (736). Transmission from HBsAg-positive carrier fathers to their offspring is relatively limited, in contradistinction to spread from carrier mothers to their children. Spouses of carriers also are infected frequently, but they are less likely to become persistently infected (72,260,736). Transmission of HBV from men to women appears to be more efficient than the corollary (590). Risk factors favoring transmission from HBsAg carriers to another household contact include the presence of high concentrations of HBV DNA or HBeAg in the serum of the carrier (603). Serologic evidence of intrafamilial spread is greatest in nonwhite families and increases with family size (736). The risk of infection also is increased in those families who adopt or care for HBsAg-positive children who come from high-risk areas of the world, such as India, Korea, Southeast Asia, Rumania, or Russia (560,790), because infants and children are more likely to be HBeAg-positive and thus are potentially more infectious.

In contrast to the rather pervasive transmission pattern seen in families exposed to chronically infected individuals, spread of hepatitis B among household contacts after acute disease appears to be a more limited process. At greatest risk is the spouse or sexual partner, with parents, siblings, or other domestic contacts having a much lower probability of acquiring hepatitis B (Table 7) (303,396,531,604).

		% Infected	
Investigators (ref.)	Number of susceptibles	Spouses or sexual partners	Nonsexual contacts
Mosley (531)	170	17.6	1.5
Peters et al. (604)	101	20.0	5.5
Koff et al. (396)	81	23.1	0.0

TABLE 7. *Secondary attack rates in household contacts of persons with acute hepatitis B*

Increasing promiscuity and the early age at which many teenagers now begin sexual activity have increased the incidence of venereal diseases, and thus probably hepatitis B as well, in these younger age groups. Rates of infection are especially significant among young homosexual men and prostitutes (232,292,362). Previously, about 7% of homosexual men were HBsAg positive, and nearly 60% of these also were HBeAg positive (159,201,734,737). The main reason for the high rate of infection among men having sex with other men is exposure to large numbers of sexual partners, coupled with the promiscuity of these partners. Men with monogamous relationships are at lower risk. Receptive rectal intercourse, especially when associated with rectal bleeding, increases the risk of transmission, implying that trauma to the rectal mucosa may facilitate entry of HBV (670). The frequency of disease in this group has decreased dramatically in recent years (132), as homosexuals have modified their high-risk behavior in an attempt to prevent HIV infection and have availed themselves of the hepatitis B vaccine.

Maternal–Neonatal Transmission

Perinatal and, uncommonly, transplacental transmission of viral hepatitis type B from an infected mother to her offspring have been documented often enough to suggest that this may represent the most important mechanism for maintenance of an HBV carrier population in certain areas of the world (493,506,571,674). It is estimated that at least 23% of the carriers in Asia and 8% of the carriers in Africa occur as a result of perinatal transmission (381). For the United States, 20% to 30% of the carrier pool is believed to result from perinatal and preschool transmission, even though only 1% to 3% of reported cases of HBV occur in children under 5 years of age (483).

Women with acute hepatitis B late in pregnancy or during the neonatal period readily infect their infants (506,674,768). On the other hand, neonatal transmission is infrequent when the acute infection occurs in the first or second trimester of pregnancy (674,704). From these data, it is concluded that the virus apparently does not cross the placenta easily. Women who are chronic HBsAg carriers also transmit the virus; however, the rate of infection varies among ethnic groups and in different parts of the world (180,588,718). For example, transmission from carrier mothers is unusual in most white populations (fewer than 10% transmit the virus) but is common among Asians (40% to 50%). In Senegal and other parts of Africa, infection of children more often occurs during the first few years of life, in contrast to Asia, where perinatal transmission is more common (59,430,718). This reflects differences in the prevalence of the HBeAg (e.g., virus burden) in these populations.

The most important feature of HBV infection in the newborn is its chronicity. From 70% to 90% of HBeAg-positive carrier women transmit the virus to their newborn infants (59,440,572,695,719), 80% to 85% of whom become chronic carriers. Among HBeAg- and anti-HBe–negative carrier mothers, most of whom are low-level HBV DNA positive, 10% to 12% of their infants will become chronically infected. On the other hand, babies born to mothers who are anti-HBe positive, especially if they are HBV DNA negative, seldom become infected, or the HBV infection is usually transient. The majority of infants who become carriers are asymptomatic and have variable elevations of their aminotransferase levels (718). The liver biopsy usually shows mild chronic hepatitis (674). However, some develop acute hepatitis (215,674), and severe icteric hepatitis has been reported in infants born to anti-HBe–positive carrier mothers (699). An estimated 25% of the carrier infants eventually succumb during adult life to the more serious complications of HBV infection, such as

cirrhosis or HCC (88,430,571).

Infants born to hepatitis B carriers and to women with acute hepatitis B late in pregnancy are usually HBsAg-negative at birth and develop antigenemia at 1 to 3 months of age. This coincides with the known incubation period for HBV if infection had occurred at the time of delivery and indicates that perinatal transmission from mother to infant probably occurs during labor or delivery in most cases. How the perinatal infection occurs is not known, but HBsAg has been detected in maternal blood, amniotic fluid, cord blood, breast milk, and vaginal secretions (101,180,440,588,674,718). The fetus swallows amniotic fluid *in utero* and frequently swallows maternal blood during passage through the birth canal. Gastric aspirates taken shortly after birth are often HBsAg positive (440). In contrast, several studies have failed to show a correlation between the presence or absence of HBsAg in cord blood and the eventual development of hepatitis B (440,588,674). Transmission also might occur through fetal monitoring sites, minor abrasions, or even across mucous membranes. Finally, it is suspected that 5% to 10% of infants born to HBsAg-positive mothers may be infected late *in utero* (52,375,720,751). Maternal red blood cells are known to cross the placenta during labor, and it is assumed that HBV also could cross the placental barrier at that time or even earlier.

Theoretically, the virus could be transmitted after birth through breast-feeding because HBsAg (and presumably HBV) can be detected in breast milk and could be present in maternal blood or serum that oozes from cracks or fissures around the nipple. However, in high-risk infants (i.e., those born to HBeAg-positive carrier women), breast-feeding has been shown to pose no added risk to the infant (58,180).

Nosocomial Transmission

In hospital settings, contamination of mucous membranes with infectious material may follow mouth pipetting accidents, incidental eye contamination, or direct contact with the eye or mouth by infected fingers. It also is not uncommon for members of the health care profession to acquire hepatitis B from patients following a needle stick or other sharp-instrument injury. Vaccination essentially eliminates this risk. On the other hand, transmission in the opposite direction—from hospital staff to patients—is infrequent. Nevertheless, health care providers who are acutely or chronically infected with HBV are potential sources of infection to their patients. In many situations, performance of exposure-prone procedures have been implicated. The largest published provider-related outbreak of hepatitis B (55 cases) was traced to an asymptomatic oral surgeon who was an HBsAg/HBeAg-positive carrier (648). Frequent hand cuts were suspected to be responsible for spread of the infection. At least six nosocomially related outbreaks (30 patients) were associated with obstetric–gynecologic surgeons (447,804). Clusters of cases in Britain from 1980 to 1983 involving 22 patients were traced to cardiac surgery units, a surgical registrar, and a perfusion technician (617). Other outbreaks (17 cases) involved an HBsAg-positive dentist who returned to practice after developing postnecrotic cirrhosis following acute hepatitis B (448) and an inhalation therapist with acute hepatitis B (710). The inhalation therapist was responsible for obtaining blood samples from indwelling arterial cannulas during open-heart surgery. She had a severe exudative dermatitis on both hands for which she was receiving topical and systemic steroids during the incubation phase of her illness, and she never wore gloves while collecting samples.

In contrast to these studies, prospective serologic surveys involving three chronic HBsAg-positive health care workers (an endocrinologist, a medical consultant, and a practical nurse) and a physician, food handler, and two dentists with acute hepatitis B have provided evidence that transmission from such personnel to their patients is highly unusual (20,810). Clearly, the real risk has not been established. However, in most instances, a number of interacting, fortuitous events seem to be necessary for transmission to occur. For example, the subjects are usually HBeAg positive and often unaware of their infection. In the limited number of studies in which transmission has occurred following exposure to an HBeAg-negative surgeon, a precore mutation was present (301,729). In these situations, measurable quantities of HBV DNA exceeding 250,000 copies per milliliter have been detected. In some studies, a medical condition that favors transmission was sometimes present. Finally, gloves often were not worn despite the fact that a traumatic-type procedure was being performed. For dentists and oral surgeons, the opportunities for blood droplet transmission after puncture wounds sustained in the oral cavity is well recognized (322). Potential control measures (e.g., use of gloves) should reduce the risk in most cases.

HBV and Hepatocellular Carcinoma

The incidence of HCC varies with geography, race, age, sex, and cirrhosis (581). HCC constitutes 90% of the primary malignant tumors of the liver observed in adults. Worldwide, liver cancer ranks eighth in frequency. It is the sixth most frequent cancer in men and eleventh most common in women. From 4% to 5% of the global cancer burden is attributed to this condition, and in developing countries it is the third most common cancer in males after the stomach and lungs (592,614). It is estimated that liver cancer may be responsible for more than 500,000 deaths annually throughout the world, with a male-to-female ratio of 3:1. In the industrialized nations of the world it is rare to relatively uncommon, yielding an age-adjusted incidence rate of less than 10 per 100,000 population per year in men from northern Europe, North America (except in migrants from high-risk countries such as China and Korea), Central and South America, and Australia. In the United States, HCC accounts for 2% to 3% of new cancer cases of the digestive organs, or approximately 4,000 to 6,000 cases per year (99,698,749). In contrast, in many areas of sub-Saharan Africa, Melanesia, Southeast Asia, China, and Japan, annual age-adjusted incidence rates from 23 to 48 per 100,000 among men have been recorded. The mortality-to-incidence ratio is close to or greater than 1, which indicates that most patients do not survive for more than 1 year.

A number of epidemiologic studies have shown a strong relationship between persistent or past infection with HBV and the eventual development of HCC. It is noteworthy that the frequency of HCC follows the same general geographic pattern of distribution as that of persistent HBV infection (see Fig. 8) (489). In cohort studies in developing countries, the incidence of HCC ranged from 240 to 281 per 100,000 HBsAg carrier-years (144,430).

Perhaps the most conclusive study designed to support the hypothesis that HBV plays a primary role in the pathogenesis of HCC was the prospective study of Beasley et al. (53; and R. P. Beasley, personal communication) in which 22,707

Chinese men in Taiwan were followed for a mean of 11.25 years. In this study, all but three of 194 men who subsequently died of HCC were in the original group of 3,454 men who were HBsAg positive. Nine of the 10 HCC patients who had seroconverted and had become HBsAg negative at the time of death were still anti-HBc positive (with or without anti-HBs). The annual incidence of HCC remained essentially constant over 10 years, implying that new liver cancers were continuously developing. There was an excess risk of dying from HCC among HBsAg carriers compared to noncarriers (relative risk of 217). A high carrier rate among the mothers of HCC infants supports the contention that HBV infection antedates the development of HCC and not the reverse. It also implies that offspring who are infected at birth are more susceptible to developing HCC in the future (50,430).

Although most HCCs occur in patients with cirrhosis, 15.7% to 45% appear to develop in the absence of cirrhosis (144,389,460,580,696), which is in contrast to HCV-associated HCC, in which over 90% occur in a background of cirrhosis. In patients without cirrhosis, the annual incidence of HCC is about 0.3%; this increases to 2% to 7% in male patients with cirrhosis (460,570) Rates in females are much lower. Factors accelerating this transition include hepatic decompensation, intermittent episodes of reactivation, duration of disease, alcohol intake, age, and, as indicated, male sex. Of the various types of cirrhosis, macronodular or mixed macro- and micronodular cirrhosis is more frequently associated with HCC than is micronodular cirrhosis. In this regard, it is noteworthy that HBV is more often associated with macronodular cirrhosis, whereas mixed macro- and micronodular cirrhosis is more often found in HCV-infected patients, with a predominance for the mixed type of cirrhosis (400).

HCC is common among Asian-Americans, in whom the prevalence of HBV markers is 10 to 40 times higher than in other ethnic groups living in the same area (744,749). Nearly all of the HBV infections are of the subtypes most prevalent in Asia (*adw* and *adr*). The age-standardized mortality rate from HCC of 131 per 100,000 among Chinese men in New York City was four times higher than that among black men (33.5 per 100,000), and 10 times higher than that among white men (12.5 per 100,000) (744). The excess mortality was observed at all age groups. These data indicate that Chinese-Americans are at high risk for both HBV infection and HCC, and they provide support for the hypothesis that the two conditions are causally related.

The incidence of HCC (and death from HCC) increases progressively with increasing age (53,388). However, the peak incidence of the disease may vary in different countries, especially in Mozambique, which has one of the highest incidence rates of HCC in the world, accounting for 65% of all malignant tumors in men and for 31% of the tumors in women (623). The shift toward a younger age group among Mozambicans compared with Chinese who are infected with HBV at a similar age (Fig. 9) suggests that exposure to environmental carcinogens, such as aflatoxin in Mozambique, may be an important determinant in these differences.

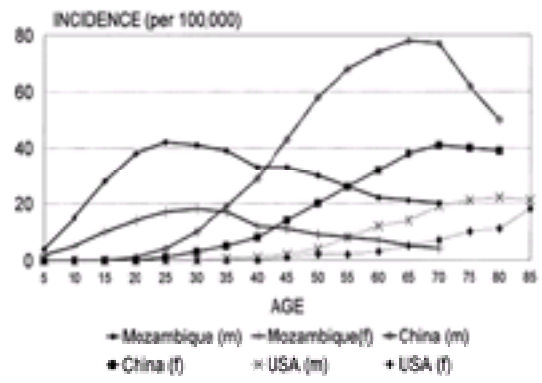

FIG. 9. Age-specific incidence rates of HCC for males (m) and females (f) in Mozambique, China, and the United States. (From F. D. Chen, personal communication, 1995.)

The emerging concept of the pathogenesis of HCC is that HBV infection in early life proceeds from chronic antigenemia to chronic hepatitis, then to cirrhosis, and finally to HCC, usually after a delay of 30 to 50 years (see Fig. 4) (92,690). Although both sexes may be equally infected at birth, men are more apt to develop chronic hepatitis (by a ratio of approximately 1.5:1). More men than women develop cirrhosis of the liver (by a ratio of 3:1), and an even greater proportion develops liver cancer (by a ratio of 6:1). Thus, at each progressive stage of liver disease, the ratio of men to women appears to double so that HCC becomes predominantly a disease of men (92,342,768). Additional factors accounting for the higher incidence rates in men might be their greater exposure to chemical carcinogens. Details concerning the cellular and molecular mechanisms of hepatocarcinogenesis of HBV and the role of environmental carcinogens can be found in Chapter 86.

PREVENTION AND CONTROL

HBV is a ubiquitous organism that is globally distributed. Over 75% of the world's population lives in areas where there are high levels of infection. It is estimated that more than 2 billion people have been, or are currently, infected with HBV, resulting in over 350 million carriers worldwide. Approximately 25% of these will eventually die from chronic liver disease or HCC, with as many as 1 million deaths per year being attributed to the ravages of this virus. Depending on the estimates, 2.5 to 4 times more people will perish from chronic HBV than from HIV. Since 85% to 95% of hepatitis B infections are vaccine preventable, emphasis should be placed on vaccination in resource-poor countries to limit the spread of this disease. Indeed, the greatest impact is being experienced in Asia, where over 75% of the world's chronic infections exist (estimated at 287 million, compared to 1.9 million infections in North America).

Prevention and control of hepatitis B depends on the proper selection and screening of blood donors, education of the populace regarding patterns of transmission, use of environmental procedures to limit the risk of infection, employment of

universal blood and body fluid precautions, and appropriate immunoprophylaxis (212,213). The latter includes a comprehensive vaccination strategy that focuses on prenatal testing of mothers, with vaccination of at-risk newborns and identified household contacts, universal immunization of all infants, and vaccination of adolescents and adults at high risk of infection.

The establishment of an all-volunteer blood donor population who donate periodically, combined with a stringent health screening process and mandatory testing of blood donors for HBsAg and anti-HBc, has led to a substantial reduction in transfusion-associated hepatitis B. Between 1981 and 1988, the number of posttransfusion hepatitis B cases reported to the American Red Cross declined by approximately 50% (194). This corresponded with the addition of anti-HBc testing of blood donors in 1986 that presumably identified low-level HBV infected individuals whose blood contained only anti-HBc (534). Currently, the residual risk of detecting an HBV infection in a donor sample is estimated to be 1 out of 63,000 units of blood processed (95% CI: 31,000 to 147,000) (118,671).

Acquiring hepatitis B is a well-recognized risk among health care personnel who work in blood-contaminated environments, such as surgical suites, hemodialysis units, obstetric services, gastrointestinal endoscopy suites, hematology and oncology wards, and blood-processing facilities (252,594,710,767). However, between 1985 and 1993, reported infections with HBV declined 90% among healthcare workers (133,137,139,685). The risk depends on the frequency of percutaneous and permucosal exposure and the concentration of the inoculum (190,247,274,686,762). The highest concentration of virus is found in blood and liver; thus, the most efficient route of transmission is percutaneous. Infection also can occur after direct mucous membrane contact, after oral ingestion of blood, or through contamination of skin lesions, open cuts, or abrasions. The risk of infection following a needle stick from an HBsAg-positive patient ranges from 19% in recipients of sera positive for HBeAg, to 2.5% among recipients of anti-HBe positive sera, a risk ratio of about 8:1 (806). Even risk following accidental inoculations with HBeAg-positive samples is variable and often associated with the concentration of virus in the sera (487). Larger doses of virus are apparently necessary to initiate infection via the oral route (see the section, Modes of Spread). Infections after fecal contamination have not been reported. Thus, enteric precautions are not necessary once the diagnosis of hepatitis B has been made. Other modes of transmission that have not been associated with HBV outbreaks include food-borne, waterborne, or airborne routes, or via casual contact.

Universal Blood and Body Fluid Precautions

Universal precautions represent an approach to infection control that should be used when handling human blood and body fluids (586). All body fluids are treated as if they are infectious, and methods should be devised to prevent contact with such material. Although the first line of defense is immunization, experience has taught us that not everyone will avail themselves of this proven method. Specific precautions include the use of gloves when handling potentially infectious materials contaminated with blood, when performing autopsies, or when dermatitis, cuts, or abrasions are present on the hand. Most inadvertent self-injections are the result of carelessness (e.g., recapping needles by a two-handed technique). Because many needle sticks occur while resheathing the needle, it is recommended that needles be discarded directly into puncture-resistant containers specifically constructed for this purpose, or that one-handed shielding and disposal equipment be used. Laboratory personnel should be prohibited from mouth-pipetting, and from smoking, eating, or drinking in their work area. Work surfaces can be decontaminated effectively with intermediate- to high-level disinfectants, such as 0.05% to 0.5% sodium hypochlorite or 2% aqueous alkalinized glutaraldehyde (95,682), or low-level disinfectants such as quaternary ammonium germicides and phenol-based disinfectants (629). Because of the known risk of transmission of hepatitis B by contaminated sharp instruments, only sterile disposable needles and stylets for finger puncture should be used. Plastic should be substituted for breakable glass whenever feasible. Protective garments should be worn when working with potentially infectious material and should be removed before leaving the work area. Masks in combination with eye protection should be worn whenever splashes, spray, splatter, or droplets of potentially infectious material may be generated and eye, nose, or mouth contamination can be reasonably anticipated. Autoclaving and the use of ethylene oxide gas are both acceptable methods for disinfecting metal objects, instruments, or heat-sensitive equipment (131,134,546).

Immune Globulin Immunoprophylaxis

Early Studies

After the remarkable success of human IG in the immunoprophylaxis of hepatitis A, it was only natural that similar studies would be instituted to determine if IG also could reduce the incidence of hepatitis B and the frequency of its complications. Data have clearly established that protection against reinfection with HBV resides with the anti-HBs fraction (21,314,327,426).

The development of sensitive and specific assays for the detection of the various hepatitis B antigens and antibodies has provided an opportunity to review the results of the early clinical trials on the protective efficacy of IG and to resolve some of the discrepancies (678). Before 1970, the preenrollment immune status of study participants could not be determined, nor could subclinical cases adequately be detected. Thus, attack rates could not be accurately evaluated. In addition, the important role of non-A, non-B hepatitis agents in causing posttransfusion hepatitis was not appreciated. However, perhaps the most significant unknown variable found in every study before 1970 was the concentration of anti-HBs present in the IG preparation. Retrospective analysis has shown that 50% to 80% of the commercial lots of IG manufactured before 1972 were devoid of detectable anti-HBs and that the titer of anti-HBs detected in the remaining lots was relatively low. In addition, as many as 0.8% of the IG preparations contained detectable amounts of HBsAg (332). These anomalies resulted from the pooling of plasma from HBsAg-positive carriers with plasma from immune individuals before the preparation of IG. It also has been argued that the efficacy demonstrated with IG in some of the earlier clinical trials may have been due to primary immunization with HBsAg that was present in some of the IG lots, rather than the result of neutralization of HBV by anti-HBs (680).

In 1972, routine screening of plasma donors for HBsAg was introduced, resulting in a sharp decline in the concentration

of HBsAg inadvertently added to donor pools destined for IG production. Concomitantly, the anti-HBs level increased from a mean titer of 1:4 in pre-1970 IG lots to a mean of 1:128 by 1978 (337). Since 1977, all tested lots of commercial IG contain anti-HBs at a titer of at least 1:100 by RIA (241). Human HBIG is similar to conventional IG except that it is prepared from plasma preselected for a high titer of anti-HBs. In the United States, HBIG has an anti-HBs titer of 1:100,000 or greater.

Side effects associated with the administration of IG are rare. However, the inadvertent administration of conventional IG by the intravenous route may lead to anaphylactic shock (41), and, rarely, single or repeated intramuscular injections can result in allergic reactions (49), especially in immunoglobulin-deficient children (794). Transmission of HBV, HAV, HCV, or HIV by intramuscular IG isolated from plasma by the cold ethanol fractionation technique has not been documented since screened plasma was introduced over 25 years ago. However, production lots prepared outside the United States by zinc or ammonium sulfate precipitation techniques have been implicated in outbreaks of hepatitis B (373,609).

Preexposure Immunoprophylaxis with Immune Globulin

In 1974, Szmuness et al. (739) reported that a conventional IG preparation with a low concentration of anti-HBs (1:16) and a special lot of high-titered HBIG, significantly reduced the frequency of hepatitis B infections among institutionalized children when compared with an untreated group. The HBIG appeared to protect by passive immunization, whereas passive–active immunization was more frequently observed in those who received the conventional IG. Regardless, persistent antigenemia was not observed in either the HBIG group or the conventional IG group, but it occurred in 14% of those for whom no treatment was provided.

Several preexposure immunoprophylaxis studies have been conducted in dialysis units among patients and staff (184,361,392,626). When HBIG was compared with no treatment (or a placebo), significant protection was inevitably observed. Concentrations of anti-HBs similar to that found in conventional IG were nearly as effective in preventing hepatitis B when compared concurrently with HBIG. Despite this success, the availability of a vaccine for hepatitis B and mandatory screening of blood donors for HBsAg and anti-HBc eliminates the need for HBIG in preexposure prophylaxis.

Postexposure Immunoprophylaxis with Immune Globulin

There are some situations in which postexposure prophylaxis with HBIG, usually in conjunction with vaccination, is essential or desirable. These include (a) exposure of an individual to hepatitis B–containing material by percutaneous inoculation, oral ingestion, or direct mucous membrane contact; (b) transient HBV contact through sexual exposure by the partner(s) of an acutely infected patient; and (c) fetal/neonatal exposure to mothers with hepatitis B. Several double-blind, randomized trials have addressed these issues, as shown in Table 8 (57,254,601,639,681). The conclusion reached from these studies is that HBIG administration (or conventional IG containing a lower dose of anti-HBs), used alone, is statistically and epidemiologically superior to a placebo or to no treatment in preventing hepatitis B following exposure. However, in some clinical trials, the conventional IG contained a small quantity of HBsAg, which may have resulted in active immunization. Timing of the initial dose of HBIG or IG after exposure and the concentration of HBV present in the source material are important factors in determining how successful prophylaxis will be after the administration of anti-HBs. For isolated episodes, effectiveness appears to diminish rapidly if administration is delayed for more than 3 days (254,533). Most of the regimens used today combine passive immunization with active immunization induced by vaccine, thereby providing immediate protection with more durable immunity.

Type of exposure	Investigators (ref.)	Summary of results
Needle stick	VA/NIAID, Seeff et al. (681)	HBIG > IG placebo[b]
	NHLBI, Grady et al. (254)	HBIG = IG[c]
Sexual contact	Redeker et al. (539)	HBIG > IG placebo[b]
	Perrillo et al. (601)	HBIG = IG[c]
Perinatal	Beasley et al. (57)	HBIG > placebo[b]

[a]Double-blind, randomized trials
[b]No detectable anti-HBs
[c]No placebo or untreated groups were evaluated. Instead, a comparison was made with IG containing low-dose anti-HBs. In these situations, it is difficult to determine protective efficacy, as results were comparable.

TABLE 8. *Efficacy of IG and HBIG in the prevention of hepatitis B: postexposure prophylaxis studies*[a]

Maternal–neonatal transmission of HBV presents special problems in prophylaxis. Prevention of chronic liver disease and HCC during adult life are the ultimate goals of infant immunoprophylaxis, because most acutely infected infants are not overtly ill. A randomized, double-blind, placebo-controlled trial in Taiwan, in which 185 infants were followed for 15 months, clearly established the effectiveness of HBIG in preventing chronic infection in neonates of HBsAg-positive mothers (see Table 8) (57). This study indicated that repeated doses of HBIG (0.5 mL usually given within 1 hour of birth and repeated at 3 and 6 months) had a higher protective efficacy rate (PER) of 71% than a single, larger dose (1.0 mL) given at birth (PER of 42%). In two subsequent studies (642,827), large doses of HBIG given in multiple doses to neonates of HBeAg-positive mothers also were protective.

The urgent need to prevent HBV infection in the newborn has emphasized the importance of identifying mothers who are most likely to transmit HBV to their offspring. Women with symptomatic hepatitis B near the time of delivery are easily recognizable. Chronic carriers, on the other hand, are usually asymptomatic and can be detected only through testing of serum for HBsAg. Initially, an attempt was made in the United States to identify and test only those women who were likely to be carriers of HBV. This voluntary program was not successful and, in 1988, the CDC recommended that (a) all

pregnant women should be tested for HBsAg during pregnancy and (b) neonates born to HBsAg-positive mothers should receive HBIG and hepatitis B vaccine immediately after delivery (7). In 1991, this policy was formally revised by the Advisory Committee on Immunization Practices (ACIP) of the U.S. Public Health Service to include universal immunization of all infants, with the stipulation that infants born to HBsAg-positive mothers continue to receive HBIG as well.

Once treated, infants of HBV-infected mothers need not be isolated from their mothers. Whether to avoid breast-feeding is a complex issue. Where safe, alternative feeding methods are available, the potential extra risk of breast-feeding should be avoided. However, under conditions of poor sanitation in developing countries, bottle-feeding may greatly increase the risk of potentially fatal gastroenteritis. Here, breast-feeding should be strongly encouraged, even if there is a small additional risk of HBV infection. Conversely, no additional precautions are necessary once the infant receives prophylaxis.

Table 9 summarizes the salient features extracted from the various controlled and uncontrolled IG clinical trials described here.

Immune globulin containing anti-HBs (HBIG or conventional IG) is superior to placebo or no treatment in preventing hepatitis B.
Larger doses of HBIG or more frequent dosing intervals in HBV-exposed infants are associated with higher efficacy rates in preventing chronicity.
Persistent antigenemia after HBV infection is unusual after anti-HBs administration with HBIG or conventional IG.
A prolonged incubation period often occurs in persons who receive HBIG and who subsequently develop hepatitis B.

IG, immune globulin; HBIG, hepatitis B immune globulin.

TABLE 9. *Summary data from hepatitis B passive immunoprophylaxis trials*

Development and Safety of Established Hepatitis B Vaccines

Plasma-Derived Vaccines

Active immunization against hepatitis B in humans was initially investigated by Krugman and colleagues between 1971 and 1973 using a crude immunogenic preparation of HBV-containing serum (MS-2 strain; subtype *ayw*; titer of $10^{7.5}$ chimpanzee infectious doses per milliliter) (410,412,413). The serum was diluted 1:10 and heat-inactivated at 98°C for 1 minute. The heat-treated inoculum did not result in clinical or biochemical evidence of hepatitis in 29 vaccinated children, although anti-HBc seroconversion occurred in a few children. Between 4 and 8 months after receiving one to three inoculations, the group was challenged with the unheated HBV-containing serum. This was followed by complete protection in 17 (59%) and a transient, subclinical infection in three (10%).

These studies led to the development of more sophisticated hepatitis B vaccines harvested from the plasma of asymptomatic, apparently healthy human carriers of HBV by a series of steps that may include precipitation, ultracentrifugation, gel filtration, and/or affinity chromatography (5,110,200,308,627). These vaccines consisted of highly purified, formalin-inactivated (5,200,308,693) and/or heat-inactivated (641), alum-adsorbed, hepatitis B subvirion particles of HBsAg that were free of detectable nucleic acid. (The production processes and quality control measures used by various manufacturers for the plasma-derived vaccines can be found in ref. 200.)

The only plasma-derived hepatitis B vaccine manufactured in the United States was licensed in 1981 (Heptavax-B, Merck & Co., West Point, PA). It used a series of purification and inactivation steps designed to remove or inactivate not only infectious hepatitis B virions but also representatives of other groups of animal viruses known to cause human disease (130,307). It is noteworthy that each of the final purification steps (pepsin, urea, and formalin) will inactivate at least 10^{5} chimpanzee infectious doses of HBV per milliliter and all other classes of animal viruses, including the retroviruses (130,307,748).

In the late 1980s, Heptavax-B was replaced by recombinant yeast-derived vaccines and is no longer manufactured in the United States. However, plasma-derived vaccines are still being manufactured in North and South Korea, China, and Indonesia and are in development in Myanmar and Vietnam (701). Most of these vaccines are produced for local or regional consumption. Regardless, more than 30 million doses of plasma-derived vaccine have been distributed globally, and the safety and efficacy record for this product is impressive (see later). Immunogenicity is generally thought to be superior to the genetically engineered products and is increased in those plasma-derived products that use less stringent inactivation procedures such as formalin only (315,494), compared to heat alone (110,815), or heat and formalin (693,822).

Recombinant Yeast-Derived Vaccines

Yeast-derived recombinant vaccines were developed initially to counterbalance some of the perceived, but unfounded, concerns regarding the safety of plasma-derived vaccine. However, from the manufacturers' viewpoint, the fact that the production cycle could be decreased from 65 weeks to 12 weeks, batch-to-batch consistency could be more easily attained, and a continuous supply of material could be generated made the new technology very attractive. Thus, the licensure of a recombinant DNA–derived vaccine in 1986 eventually rendered the plasma-derived vaccine obsolete in the

United States (306).

Today several mammalian cell–derived [Chinese hamster ovary (CHO) cells] and yeast cell–derived recombinant vaccines are commercially available. Except for one of the mammalian expression systems (Genehevac-B, Pasteur-Merieux, Lyons, France), which consists of a pre-S2/S gene product, all other licensed vaccines consist of the major (S gene) product.

Current United States–licensed, yeast-derived vaccines of HBsAg are produced in large fermentation cultures of *Saccharomyces cerevisiae* cells, which carry a recombinant yeast expression vector (plasmid) consisting of specific promoter sequences from a yeast gene specifying a glycolytic enzyme, the S gene, and plasmid DNA from *Escherichia coli* (202,281,597,608). HBsAg is released from the cells by homogenization or disruption with glass beads, it is purified by clarification, ultrafiltration, chromatography, and ultracentrifugation, and it is then adsorbed onto aluminum hydroxide, after which thimerosal is added as a preservative (see discussion later on the thimerosal controversy). For a more complete description of the various production processes and quality control procedures for recombinant DNA hepatitis B vaccines, the reader is referred to the book by Ellis (200).

The two major yeast-derived hepatitis B vaccines that are licensed in most countries are Engerix-B [Smith Kline Beecham (SKB), Rixensart, Belgium, and Philadelphia, PA] and Recombivax HB [Merck (MSD), West Point, PA]. Other structurally and chemically similar commercial recombinant products are being produced in France, Japan, Cuba, South Korea, and India or are in various stages of development in several other countries. Before its adsorption with alum, Recombivax HB, but not Engerix-B, is treated with formaldehyde. Physicochemical characterization of the particles that are formed confirm the purity of these vaccines and their similarity with plasma-derived HBsAg based on molecular weight (24 kd), amino acid composition, peptide mapping by fast-atom bombardment mass spectrometry, electron microscopy, density in cesium chloride, and lysed composition. These vaccines contain less than 2% yeast protein and no detectable yeast DNA. Unlike the plasma product, the yeast-derived vaccine is not glycosylated. Nevertheless, immunologic analysis with monoclonal antibodies that have virus-neutralizing properties against two different serotypes of HBV indicates that the yeast- and plasma-derived vaccines contain epitopes known to be important in inducing protection after vaccination (286).

Safety Issues and Concerns

More than 500 million people have received the plasma-derived or genetically engineered hepatitis B vaccines. Local and systemic reactogenicities of the recombinant vaccines are comparable to those observed after an injection with plasma-derived vaccine (200,834). Andre (29) reviewed 122 clinical trials representing 40,140 vaccine doses of Engerix-B and found no clinically adverse effects. Soreness at the injection site was observed in 23% and induration in 8%. Fewer symptoms were seen in children than in adults. Clinical hypersensitivity to residual yeast antigens that might be present in the inocula has been cited rarely, even though most people harbor antibodies to the bakers' yeast, *S. cerevisiae* (107). In addition, new anti-yeast IgG specificities have not been elicited, nor has there been an increase in IgG-type antibodies (30,608). Thus, the risk of inducing an allergic reaction is negligible. However, anaphylaxis and life-threatening, immediate hypersensitivity reactions or an apparent hypersensitivity reaction of delayed onset that includes arthritis/arthralgia, fever, and dermatologic reactions (serum sickness–like) have been reported rarely (<1 event per 600,000 doses) (138; and package inserts of pharmaceutical companies). An association between hepatitis B vaccination and erythema nodosum or alopecia also may exist (812).

To date, there has been no confirmed scientific evidence that these vaccines cause chronic illnesses such as CNS demyelinating disorders (including multiple sclerosis), chronic fatigue syndrome, rheumatoid arthritis, or autoimmune disorders. Nor is there any clear causal association between administration of these vaccines and Guillain-Barré syndrome, sudden infant death syndrome (SIDS), transverse myelitis, optic neuritis, or seizures (6,278,558,687; J. E. Maynard et al., unpublished observations; H. S. Margolis, testimony before a subcommittee of the U.S. House of Representatives Committee on Government Reform, May 18, 1999). Two case-control reports from France (hospital based) and the United Kingdom (population based) failed to document a statistically significant association between hepatitis B vaccine and CNS demyelination disorders at the 5% level (226,726). However, both lacked sufficient power to definitively conclude that there are no risks, and vigilance to the possibility of a rare association should be maintained.

Recently, concerns have been raised about the administration of vaccines containing thimerosal to newborn babies. Thimerosal is an organic mercurial compound that has been added to many vaccines since the 1930s to prevent contamination with pathogens, which might occur during production or from imperfect aseptic handling. Adverse events, such as rashes, are rare, but exposure to much larger concentrations of mercury than are present in vaccines can cause neurotoxicity with learning disabilities. Unborn babies and newborn babies are at greatest risk, and high levels in pregnant mothers may result in brain damage to the unborn baby. However, there has been no evidence of harm from vaccines that contain 0.003% or 0.01% thimerosal. The risk, therefore, is theoretical, uncertain and extremely small. Regardless, because infant immunizations utilizing a number of vaccines containing thimerosal could theoretically raise mercury levels above some established regulatory agency limits, thimerosal has been eliminated from hepatitis B vaccines in the United States and Europe. In contrast, the WHO, because of cost and cold-chain considerations, is currently not recommending removing thimerosal from vaccines being used in developing countries.

Protective Efficacy Studies in Chimpanzees

Preexposure protective efficacy of plasma-derived and recombinant-derived hepatitis B vaccines has been established in susceptible chimpanzees, which have successfully withstood challenge with HBV after receiving the vaccine (200,300,494,627,631,632,664). Cross-protection by different serotype vaccines against opposing HBV subtypes has been observed; thus subtypes are not of major concern in formulating the vaccines because of the shared group *a* antigenic determinant. Postexposure immunization after an HBV challenge also has been found to be efficacious in chimpanzees.

Factors Influencing the Immune Response

Because the peak geometric mean antibody levels that are achieved after the basic immunization series determine how long antibody will persist at detectable levels, factors that influence immunogenicity must be considered. These can be separated into immunization factors and host factors (775). However, durability of immunity, based on the presence of circulating antibody, is only one aspect of protection. Retention of immunologic memory by partially differentiated antigen-specific B cells and specific helper T cells is necessary for rapid recall even when no antibody can be detected (307). How immunization or host factors influence this aspect of the immune system is less certain.

Immunization Factors

Dosage and Immunization Schedules

Several studies using age- and weight-matched subjects have shown unequivocally that the dose of vaccine administered to a subject is of considerable importance in determining the peak immune response achieved by that person (Fig. 10) (326,775,828,833). Not only is the immune response enhanced as the dose increases, but a more rapid response occurs, factors that could be important in postexposure prophylaxis.

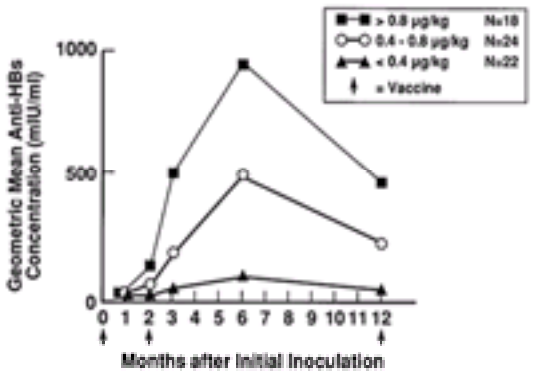

FIG. 10. Geometric mean anti-HBs concentration (mIU/mL) over time as a function of vaccine dose per kilogram of body weight. (Adapted from ref. 833, with permission.)

A number of vaccine schedules have been evaluated (316,369,833), but none has supplanted the current regimens. Using weight-matched subjects and a single lot of plasma-derived vaccine, Hollinger et al. (316) evaluated seven different schedules (Table 10). After three injections, 98% to 100% of the vaccinees developed anti-HBs, confirming the observation that seroconversion data have limited usefulness in comparing responses except during the first 3 months of a vaccine trial. The highest responses occurred when vaccine was given at 0, 1, and 6 months, and at 0, 2, and 4 months. In another study, injections at months 0, 1, and 12 achieved significantly higher anti-HBs responses when compared to a 0-, 1-, and 6-month schedule (370). It is important to recognize that although adherence to an optimal schedule is recommended, deviations will not lead to an adverse outcome if the primary series of three (or four) injections is completed within a reasonable period of time (273). A good response to the 0-, 2-, and 4-, or to the 0-, 2-, and 6-month schedule is encouraging because these regimens are similar to what has been proposed for the universal immunization of infants.

TABLE 10. *Maximum geometric mean anti-HBs levels attained during follow-up and at the conclusion of the study based on vaccine schedule*

Currently, two primary immunization regimens have been instituted. The usual schedule, consisting of three doses of vaccine given at 0, 1, and 6 months, is recommended for preexposure prophylaxis. An alternate four-dose schedule, with dosing at 0, 1, 2, and 12 months, was designed for immunocompromised persons, for infants born to infected mothers, and to hasten the immune response in travelers planning to go to high-risk areas. However, the addition of HBIG to the regimen for infants or travelers may neutralize this advantage. Although delaying the final injection for 12 to 18 months may eventually lead to high-peak anti-HBs responses, a potentially undesirable “window of vulnerability” occurring during the interval between months 1 and 12 (or 18) may restrict its use to groups who have a low immediate risk of acquiring

hepatitis B infection (370,833). Compliance and attrition also become issues when such delays are instituted.

Storage of Vaccine

Inadvertent freezing of alum-adsorbed, plasma-derived vaccine indicated that such a practice may be deleterious to immunogenicity (587). Although no additional clinical trials have been designed to verify this observation with recombinant vaccines, animal studies have confirmed that freezing reduces the immune response (193), presumably by altering the physical properties of the adjuvant and its relationship to the immunogen. Conversely, storage of a recombinant-derived vaccine at temperatures of 37°C for up to 4 weeks did not reduce the immunogenicity of the product in a significant manner (378). Potency is optimally preserved when vaccine is stored at 2° to 8°C.

Site and Route of Inoculation

Based on careful comparative studies, the site of inoculation has proven to be a critical factor. Persons administered vaccine into the adipose tissue of the gluteal region have lower seroconversion rates and geometric mean anti-HBs levels when compared with those who receive all of their injections intramuscularly in the deltoid region (72% and 85 mIU/mL versus 93% and 1,454 mIU/mL, respectively) (156,497,688). Such tissue is apparently a poor repository for vaccine (445).

Intradermal inoculation, which is safe and uses one-tenth the dose, has proponents throughout the world because of its potential for substantial reductions in cost. Whereas seroconversion rates are comparable to full-dose, intramuscular injections, the peak antibody levels are substandard (114,153,596,640). Horowitz et al. (338) concluded that the intradermal route was quite satisfactory as a mechanism for boostering individuals who had completed their basic intramuscular immunization series, but it does not improve response rates in non- or hyporesponders (220). Heijtink et al. (293) found that protective immunity and geometric mean concentrations were comparable when groups were given the same low-dose vaccine either intramuscularly or intradermally.

Methods to Enhance Immunogenicity

Adjuvanted vaccines can favorably influence the immune response. Alum (aluminum phosphate or hydroxide), the most common adjuvant, is clearly superior to aqueous or saline suspensions of vaccine (494,656). The use of other adjuvants and biologic response modifiers has been explored to enhance immunogenicity in nonresponders and hyporesponders and to reduce the number of injections from three to two, thereby improving compliance and providing earlier protection. The three new adjuvants that may fulfill these goals, at least partially, are (a) MF59, an oil-in-water emulsion consisting of the metabolizable oil, squaline, together with surfactants (295), (b) SBAS4, a combination of aluminum salt and monophosphoryl lipid A (761), and (c) DC-Chol, a cationic lipid (111). The MF59 adjuvant was combined with a new recombinant HBV subunit vaccine containing the pre-S2 and S antigens (295). The combination was up to 100-fold more immunogenic than Recombivax HB with a similar local and safety profile. It achieved levels after two doses (given 2 months apart) that were comparable to the 0-, 1-, and 6-month schedule used for the alum-adjuvanted licensed vaccine. Whether the enhanced response was secondary to the MF59 adjuvant alone or to the subunit vaccine containing Pre-S2 and S antigens (or a combination of the two) was not evaluated.

Several recombinant vaccines have been developed for human use that contain antigens from the pre-S and S regions of the S gene expressed in yeast or mammalian (CHO) cells (8,295,298,340,495,732,842). Immune responses to the S and pre-S regions are under major histocompatibility complex (MHC) control but are regulated independently. In animals, nonresponsiveness to the S region may be circumvented by the addition of pre-S antigens to the vaccine (515,517). Finally, antibodies to pre-S2 synthetic peptides neutralize HBV *in vitro* and *in vivo* in the absence of anti-HBs (360,550,764). Two genetically engineered vaccines containing the S antigen, pre-S1, and pre-S2 epitopes appear to have induced antibodies in S vaccine nonresponders, even in elderly patients or immunosuppressed patients (298,495,842). Whether these additions to HBsAg vaccines will be important for long-term protection from HBV infection remains to be determined in controlled clinical trials.

Host Factors

Age and Weight of the Subject

Increasing age, especially above 30 years, has been shown to correlate independently with a decreasing response to the vaccine (Table 11) (338,688,743,776). In one study, anti-HBs seroconversion rates declined from a relatively low frequency of 69% in persons 61 to 70 years of age to less than 39% in those more than 80 years of age (178).

TABLE 11. *Multiple linear regression of age, weight, sex, and dose on anti-HBs response to three doses of HEPTAVAX B at 8 months postinoculation*

Suboptimal responses occur in obese persons (156,775). Correspondingly, the immune response is inversely related to weight (Fig. 11) or, more precisely, the Quetelet index of body mass (weight/height ^{2}), especially in those subjects who are under 30 years of age (see Table 11). In this regard, it is noteworthy that one of the most important criteria for determining the intensity of the immune response in young adults and children is the dosage administered per kilogram of body weight (see Fig. 10). As indicated previously, a higher dose of vaccine per kilogram administered to any given individual will result in a more rapid immune response and lead to higher levels of anti-HBs (315,338,775,808,833).

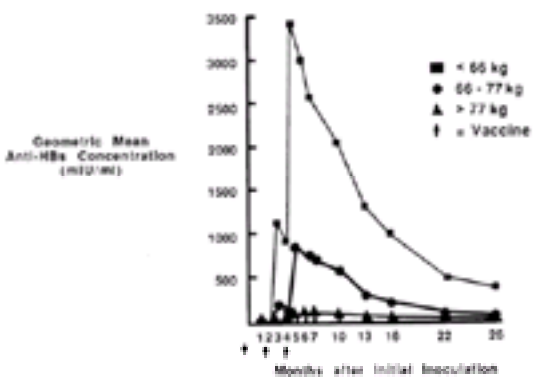

FIG. 11. Geometric mean anti-HBs concentration (mIU/mL) as a function of body weight observed in subjects receiving the same dose of HBsAg vaccine. (From ref. 316, with permission.)

Genetics, Immunosuppression, Smoking, and Gender

Genetics also may play a role in determining the strength of the immune response in individuals vaccinated under identical circumstances. Several studies have demonstrated an association between nonresponsiveness to the hepatitis B vaccine and certain HLA specificities, with accumulating evidence of an association between different HLA-DR alleles such as the HLA-DRB1 0701; DQB1 0202 genotype (495). This genotype not only was associated with a more rapid decline of anti-HBs following immunization with a vaccine containing S, Pre-S1, and Pre-S2 antigens, but also it was frequent among those individuals who remained nonresponders following booster inoculations. Other extended haplotypes (B44; DR7; FC31 and B8; DR3; SC01) also have been associated with nonresponders (166,616,786,798). The same histocompatibility antigens have been associated with the HBsAg carrier state and chronic active hepatitis, suggesting that these antigens may predispose individuals to detrimental cell-mediated immune reactions during an HBV infection in addition to modulating the immune response to HBsAg during vaccination.

Immunosuppressed groups, such as hemodialysis patients (109,261,397,488) and those on chemotherapy or infected with HIV (125,160,244,470), respond poorly to vaccination when compared with healthy individuals. About one third of hemodialysis patients who initially respond revert to being seronegative within 12 months of the initial vaccine dose. Smoking also appears to have an adverse affect on the immunologic response to HBsAg, presumably because of elevated levels of suppressor T cells that occur in smokers (94,338,688). Another study also found higher populations of suppressor T cells among nonresponders but failed to determine whether smoking was a factor (562).

Sex does not seem to play an important role in the immune response to hepatitis B vaccination. Although initial studies found that women often responded to the vaccine with higher peak antibody levels than did men (294,742), the key factor in this response may have been the weight of the vaccinee and not the gender, as discussed previously (i.e., no difference in immune response is observed when men and women are weight-matched) (see Table 11) (776).

Immunization of HBsAg Carriers

Vaccination of HBV carriers rarely generates an anti-HBs response. Indeed, nonresponders should be tested for HBsAg because anti-HBs is unlikely to develop in these individuals unless subtype differences exist between the immunogen and the HBV subtype infecting the host. In one of the earliest studies (191), 16 male carriers received two to six monthly injections of a 40-µg dose of plasma-derived vaccine (mean number of doses was 4.1). Some of the carriers received HBsAg having the same subtype as their chronic infection; others received a heterologous subtype vaccine. Circulating immune complexes were detected in six of the 16 vaccinees before immunization, and these levels did not increase subsequently. The 10 subjects who did not have prior evidence of immune complexes did not develop any complexes after inoculation. None of the individuals developed anti-HBs. Five carriers normalized their enzymes and three others showed a decline toward normal levels. However, evaluation of these changes was confounded by the fact that a downward trend was already occurring before vaccination in four of these subjects.

To determine whether other hepatitis B vaccines could ameliorate infection in HBV carriers, Pol et al. (615) vaccinated 46 chronic hepatitis B patients, who were HBsAg and HBV DNA positive, with three monthly injections of a pre-S2/S vaccine. Six months after the first injection, HBV DNA disappeared in 26% and an additional 17% showed a significant decrease (of more than 50%) in their HBV concentration. In another controlled trial by the same investigator (615), response to a pre-S2/S vaccine with HBV DNA disappearance was superior to that observed with an S vaccine (20% versus 4.8%) or with no vaccine (3.1%). No side effects or vaccine-induced escape mutants occurred.

Induction of Escape Mutants

HBV variants that have amino acid substitutions within the S gene involving the major antigenic “a” determinant have been detected in recipients of both plasma-derived and recombinant HBsAg vaccines (123,282,343,585). Vaccinated children contract these variants primarily through vertical transmission, although horizontal transmission can occur. These vaccination-associated escape mutants display a predominance of the G145R mutation and appear to circumvent neutralization by anti-HBs, raising a concern that they may be resistant to immunoprophylaxis. Although detected before the implementation of vaccination programs, universal immunization has hastened the accumulation of these mutants, which replicate independently of anti-HBs and remain stable over time. The G145R variant was recently found to be infectious and pathogenic in seronegative chimpanzees. The virus was used to challenge four chimpanzees that had been immunized with either the MSD or SKB recombinant vaccine (566). All chimpanzees were protected against infection, implying that the HBV variant was not a true neutralization-escape mutant. Thus, *a* domain–defective mutants presumably induced by vaccine may not pose a threat to vaccine responders as previously feared. Recently, vaccine escape mutants have been identified in patients with HCC. Mutations outside the “ *a*” determinant also have been detected.

Combined Vaccines

The availability of safe, efficacious HBsAg vaccines provides public health officials with an opportunity to reduce the incidence of HBV through mass immunization programs. To achieve this goal, more than 100 countries have integrated hepatitis B vaccine into their Expanded Program on Immunization (EPI), as recommended by the WHO (817). One approach was to physically combine the hepatitis B vaccine with other childhood vaccines, which would substantially reduce the number of injections that a child would require at each visit and lead to economic benefits (165). It was concluded that concurrent vaccination of neonates or infants with HBsAg and BCG or DTP–poliovirus vaccines yielded equivalent responses when compared with the results observed when the vaccines were given separately. However, lower measles and yellow fever antibody titers were detected when either of these vaccines was injected simultaneously with the hepatitis B vaccine. Recently, SKB has produced a tetravalent diphtheria–tetanus–pertussis and hepatitis B vaccine substituting acellular pertussis vaccine for whole-cell vaccine (245). The vaccine was safe, well tolerated, and highly immunogenic. In six pivotal vaccine trials, hepatitis A was combined with hepatitis B and administered to 843 healthy 17- to 60-year-old adults employing a 0-, 1-, and 6-month schedule (760). The combined vaccine appeared to be safe, well tolerated, and highly immunogenic, with responses that compared favorably with monovalent vaccines. Follow-up of 129 vaccinees at 48 months showed that all were still positive for anti-HAV and more than 95% were protected against hepatitis B.

Alternative Hepatitis B Vaccines

Although the current HBsAg vaccines have been shown to be safe and efficacious, a number of manufacturers continue to search for alternative vaccines that may be less expensive to produce and will provide greater immunogenicity, especially in immunocompromised hosts (see ref. 312 for a historical perspective on these vaccines). Except for the polypeptide preparations of HBsAg (325), and the DNA genetic vaccines or the pre-S gene products described previously, none of the other products appear likely to replace or supplement the current vaccines at this time. In this context, the rapid anti-HBs response that occurred in humans after an initial inoculation of an HBsAg polypeptide vaccine packaged in a micellar configuration and alum-adsorbed (75% seroconversion rate in 2 weeks), and the superior anti-HBs levels achieved (325), suggest that such an immunogen might be beneficial in postexposure prophylaxis when the early development of immunity is advantageous, or as a therapeutic vaccine against HBV in chronically infected carriers.

Early Clinical Trials

Homosexual Men

The first large-scale hepatitis B vaccine study in the United States in a high-risk group was initiated in 1978 by Szmuness et al. (746,747). Plasma-derived HBsAg (40 µg) was administered at 0, 1, and 6 months to 549 HBV-susceptible male homosexuals. An additional 534 homosexual men received a placebo containing alum, diluent, and formalin but not HBsAg. Fully 96% to 98% of the vaccinees developed an anti-HBs response at 9 months (3 months after the third injection). The protective efficacy rate (PER), computed by dividing the differences in attack rates between placebo and vaccine recipients by the rate in placebo recipients, was 92% with respect to clinical hepatitis B and 81% for all HBV events (including those with anti-HBc seroconversion alone). When recipients who had received their third dose of vaccine (and responded with adequate anti-HBs levels) were compared with the placebo group, the PER increased to 100%. Most important, no clinical or biochemical cases of hepatitis B occurred in anti-HBs responders who achieved anti-HBs levels above 10 mIU/mL. Of the 21 nonresponders, seven (33%) acquired hepatitis B, a rate similar to that of the placebo group. When hepatitis B occurred in these vaccine nonresponders, a typical course was observed. It is noteworthy that of the 14 vaccine recipients who became HBsAg-positive, one (7.1%) developed chronic antigenemia, which is comparable to the 10.4% rate observed in the 96 placebo recipients who became HBsAg positive.

During the first 60 days after randomization to the placebo or vaccine group (747), the number of HBV events was similar. It is presumed that many of these events resulted from exposure that occurred before or shortly after entry into the study. However, 77% of the placebo recipients developed clinical hepatitis B during this interval, whereas such events occurred in only 18% of the vaccine subjects. Thus, one might conclude that vaccination with HBsAg may abort hepatitis B or modify its course when given just before exposure or very early in the incubation period. These results of apparent benefit after postexposure prophylaxis are consistent with similar efficacy studies reported in chimpanzees (494,632).

A second study of similar design in homosexual men using 20 µg of a plasma-derived HBsAg vaccine yielded similar results regarding vaccine-induced immunity and efficacy (98%) (228). A similar PER of 77% has been recorded for

homosexual men followed for 3 years after being inoculated with 20 µg of a yeast-derived recombinant vaccine (251).

The wide spectrum of immunologic abnormalities that accompanies HIV infection, especially during the later stages of disease, has a profound effect on the anti-HBs seroconversion rate after vaccination with plasma- or yeast-derived HBsAg. Both the frequency of responders (33% to 56% for HIV-positive subjects versus 89% to 91% for HIV-negative controls) and the concentration of anti-HBs are decreased (160,244,470). It is recommended that active immunization should be performed at the earliest stages of the disease, before severe depression in cell-mediated immunity and defects in B-lymphocyte dysfunction occur.

Hemodialysis Patients and Staff

Clinical trials in hemodialysis patients and staff were initiated in France in 1975 by Maupas et al. (488). Table 12 summarizes the immunogenicity results from several of these hepatitis B vaccination studies (106,109,261,397,488). Seroconversion rates in uremic patients (and peak geometric mean anti-HBs concentrations) were substantially less (median of 60%) than those observed in staff members (median of 92% to 94%). Indeed, the anti-HBs response rate was inversely related to the degree of uremia present at the time of vaccination. Thus, vaccination should be considered before patients require dialysis. The PER ranged from 71% to 85% for the staff but was only 53% for the patients enrolled in large clinical trials (261,742). As was observed in the clinical trials that involved homosexual men, many of the HBV infections in the vaccine group occurred before the second month, indicating that viral infection probably existed before vaccination commenced (261). In one trial, the *ay* subtype of HBV accounted for 81% of the infections. Because an *ad* monovalent vaccine was used in this clinical trial, and the PER for the *ay* hepatitis B events was 85%, this study was the first to demonstrate subtype cross-protection in humans, thus confirming earlier results in chimpanzees. Results with a yeast-derived product suggest that doubling (or quadrupling) the dosage of vaccine that is routinely administered to adults and using a four-dose schedule may be optimal for hemodialysis patients (see the section, Guidelines for Preexposure Immunoprophylaxis and Booster Doses).

TABLE 12. *Seroconversion rates to hepatitis B vaccine in hemodialysis staff and patients*

Alaska Natives

Two vaccine studies were conducted in Alaska (305,500). In the first study, 1,581 susceptible Alaska natives were immunized with three doses of plasma-derived vaccine. Ten years after the first dose of vaccine, the annual incidence of HBV decreased from 50 to 0.93 HBV infections per 1,000 residents (795). None developed clinical illness or a sustained HBsAg response.

In a second study, 90% of an area's susceptible population (9,840 residents) were immunized, and all newborn infants were offered the vaccine at birth (500). The annual incidence declined from 215 cases per 100,000 population before immunization to 7 to 14 cases per 100,000 after vaccination (Fig. 12), primarily manifested as anti-HBc seroconversions. No carriers have been detected in recent years among infants immunized with vaccine only.

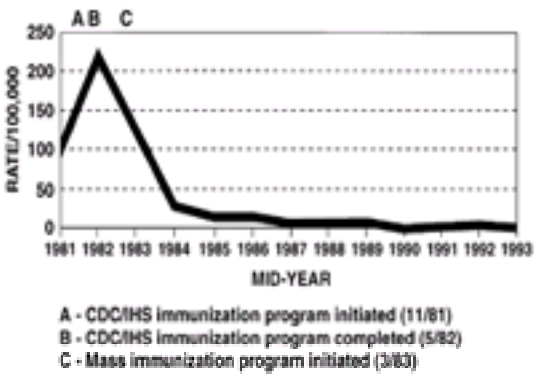

FIG. 12. Incidence of acute symptomatic hepatitis B observed in Alaska natives residing in southwest Alaska, 1981 to 1993. *Points A and B* represent the initiation and completion, respectively, of an immunization demonstration project in 17 villages. Mass immunization began in all villages at *point C.* (Adapted from refs. 500 and 795, with permission.)

Neonates

In contradistinction to the preexposure vaccination trials in homosexual men, hemodialysis patients, and Alaska Natives, early studies conducted in neonates were postexposure in principle. Current practice is to use a combination of passive and active immunization in these situations to provide prompt protection with HBIG, followed by long-term immunity with the vaccine, although this viewpoint is changing, especially in developing countries where cost is a factor. Concerns that HBIG might interfere with the active immune response of the vaccine have not materialized at the currently recommended doses. In one study in adults, doses of HBIG up to 3.0 mL failed to depress the active immune response to 20 µg of plasma-derived HBsAg given simultaneously at a different site (745). The usual dose of HBIG given to neonates is 0.5 mL. When concurrent administration of HBIG and vaccine are contemplated, different sites should be used.

A number of randomized, double-blind trials and open-label studies have been conducted in neonates of HBeAg-positive mothers to evaluate the effectiveness of HBIG alone, HBsAg vaccine alone (plasma-derived or genetically engineered), and HBIG plus HBsAg vaccine administered in close proximity to each other (Fig. 13) (31,57,312). The overall results of these studies indicate that the combination of HBIG and vaccine, or yeast-derived vaccine alone, is highly effective in reducing the incidence of chronic antigenemia in neonates born to mothers who are HBeAg positive. In 36 studies, PERs have ranged from 70% to 100%, with the median PER being 95% for the yeast-derived vaccine with HBIG compared to 91% for the plasma-derived vaccine with HBIG. Even better results should be obtained in infants of anti-HBe–positive mothers who are at a lower risk of acquiring an infection. In all of these studies, HBIG was administered after delivery, usually in the first 6 hours but certainly by 24 hours. Significantly delaying the time when vaccine is administered appears to lower the PER unless an additional dose of HBIG is given 1 to 3 months later. Except for this, the schedule chosen for vaccination is less critical. Interestingly, one of the better PERs was observed in a group of neonates receiving HBIG at 0 and 3 months, at which time vaccination was initiated with an “adult” HBsAg dose of 20 µg administered at 3, 4, and 9 months (52).

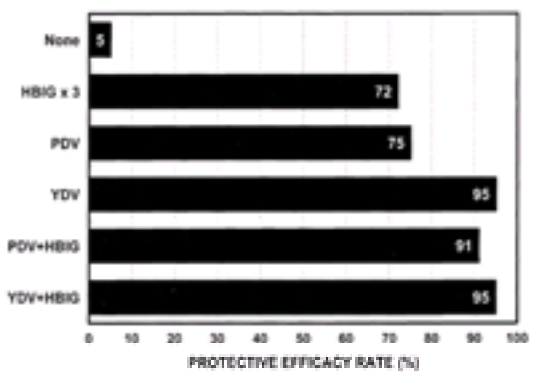

FIG. 13. Protective efficacy rates in neonates born to HBeAg-positive mothers after immunization with hepatitis B immune globulin alone, HBsAg vaccine alone, and a combination. HBIG, hepatitis B immune globulin; PDV, plasma-derived vaccine; YDV, yeast-derived vaccine. (Adapted from refs. 31,57, and 312, with permission.)

Because of the cost engendered in using combination therapy, a number of investigators in developing countries have opted to evaluate the PER of vaccine alone, including the use of the four-dose schedule. A wide range of responses has been generated with PERs that range from 90% to 95% for the yeast-derived products (three studies; median PER of 95%), to a range of 65% to 100% for the plasma-derived vaccine (11 studies; median PER of 75%) (see Fig. 13). The wide disparity that exists between the yeast-derived and the plasma-derived vaccines is perplexing, especially because the plasma-derived product is considered to be a superior immunogen in adults (311). Indeed, the suboptimal results obtained with plasma-derived vaccine are comparable only to that observed with HBIG alone, given as a series of three 0.5-mL doses at birth, 3 months, and 6 months of age (57). However, when interpreting these data, it must be recognized that the level of viremia present in a mother's serum can be approximated only with the HBeAg assay. Recent quantitative evaluation of sera for HBV DNA using molecular hybridization technology has shown that wide fluctuations in the concentration of virus exist in HBeAg-positive carriers (418). Because virus burden can significantly affect the outcome in an infected neonate, any comparisons between groups or vaccine regimens in the same or different communities must consider this important variable.

Guidelines for Preexposure Immunoprophylaxis and Booster Doses

Table 13 lists those individuals or groups for whom preexposure vaccination is recommended. If all members of these groups were immunized, the incidence of hepatitis B would rapidly decrease. However, except for infants and health care personnel, for whom governmental regulations mandate immunization of those exposed to blood-borne pathogens, attempts to recruit many of these individuals have been unrewarding. Therefore, control of this disease will require vaccination of all newborn infants regardless of the HBsAg status of their mothers (324). Universal screening of pregnant women for HBsAg will identify neonates at risk who would be given HBIG, in addition to vaccine, at delivery (see the section, Guidelines for Postexposure Immunoprophylaxis). The remainder of the infants could be vaccinated beginning at birth or in conjunction with the routine immunization program already established. Options for adding hepatitis B vaccine to the EPI schedule are in a state of flux because of the introduction of new formulations of childhood vaccines that are often combined with other vaccines. Regardless, protective levels of anti-HBs (³10 mIU/mL) are achieved when the hepatitis B vaccine is administered in a variety of regimens, including those begun soon after birth (620,720,822).

1. Infants (universal immunization)
2. Adolescents at high risk of infection
3. Persons with occupational risk (exposure to blood or blood-contaminated environments) and students of health-care professions before they have blood contact
4. Clients and staff of institutions for the developmentally disabled and susceptible contacts in day-care programs who are at increased risk from HBV carrier clients with aggressive behavior or special medical problems that increase the risk of exposure
5. Hemodialysis patients; vaccination before dialysis treatment is recommended
6. Recipients of frequent and/or large volumes of blood or blood components
7. Susceptible injecting drug abusers
8. Sexually active men and women (homosexual and bisexual men; persons with recently acquired sexually transmitted disease; prostitutes; promiscuous heterosexuals)
9. Susceptible inmates of long-term correctional facilities who have a history of high-risk behavior
10. Household contacts and sex partners of HBV carriers. Screen adoptees from countries with high HBV endemicity for HBsAg. If positive, vaccinate family members.
11. Populations with a high incidence of disease (refugees; Alaska natives; Asian-Americans)
12. International travelers to areas of high HBV endemicity if specific at-risk circumstances exist (includes military personnel identified as being at increased risk)
13. Transplant candidates preferably before transplantation

[a]Prevaccination screening is recommended to determine susceptibility where stipulated. Anti-HBc is the preferred serologic test for this purpose.
ACIP, Advisory Committee on Immunization Practices.

TABLE 13. *ACIP recommendations for preexposure immunization with hepatitis B vaccine*[a]

Table 14 summarizes the recommended doses and schedules to be used for preexposure prophylaxis with the two hepatitis B vaccines currently licensed in the United States. Vaccine is to be administered by intramuscular injection in the anterolateral thigh of infants, or the deltoid muscle of children and adults, to achieve optimal protection. Longer intervals between the last two doses result in higher final titers of anti-HBs (273,370). If vaccination is interrupted after the first dose, the second dose should be given as soon as possible, with the third dose separated by an interval of at least 2 months. If the third dose is delayed, administration can proceed whenever convenient. For hemodialysis or immunocompromised patients, larger doses or an increased number of doses given either by the intramuscular or the intradermal route may result in a higher frequency of responders (206,371,717).

Group	Recombivax HB (0, 1, 6 months)	Engerix-B (0, 1, 6 months[a])
Infants and children (≤10 years)	5.0 μg	10 μg
Adolescents (11–19 years)	5.0 μg	10 or 20 μg
Adults (≥20 years)	10 μg	20 μg
Immunocompromised patients	40 μg[b]	40 μg[b,c]

[a]Alternate schedule with injections at 0, 1, and 2 months is designed for neonates born to HBsAg-positive mothers, for persons recently exposed to HBV, for immunocompromised patients, and for travelers to high-risk areas where a rapid response is desirable. A booster at 12 months is recommended.
[b]Dialysis formulation.
[c]Dosing schedule at 0, 1, 2, and 6 months is recommended.

TABLE 14. *Recommended dosages and schedules for preexposure prophylaxis with hepatitis B vaccines licensed in the United States*

To ensure that protective levels of antibody have been generated, blood should ideally be examined for anti-HBs concentration 2 to 6 months after the basic immunization series has been completed, although tests performed at a later time also can provide meaningful information (317). This is especially desirable for persons at high risk of contracting HBV, such as surgeons. A report from the laboratory that a test result is positive is not satisfactory because the level of protection may be inadequate. Based on quantitative anti-HBs results, vaccinees can be divided into four groups: (a) nonresponder, no detectable anti-HBs; (b) inadequate responder or hyporesponder, positive for anti-HBs, but with a concentration of less than 10 mIU/mL; (c) low responder, with a concentration of 10 to 100 mIU/mL; and (d) normal or adequate responder, with a concentration of greater than 100 mIU/mL. A fifth category, high responder, can be used for anti-HBs responses of greater than 1,000 mIU/mL. These designations have clinical relevance in that nonresponders or inadequate responders continue to be at risk of acquiring HBV, whereas risk of infection is low to absent in the other categories (Fig. 14) (275).

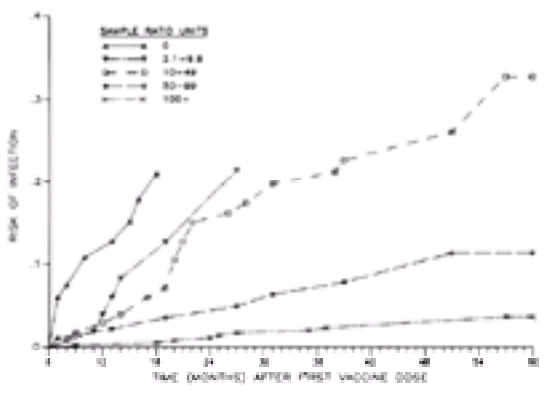

FIG. 14. Life-table analysis of risk of HBV infection according to the maximal anti-HBs level after three doses of vaccine. (From ref. 275, with permission.)

Although genetic factors may play a role in nonresponsiveness to hepatitis B vaccination, nonresponders or inadequate responders should be examined for evidence of HBV infection (HBsAg, anti-HBc, and/or HBV DNA) as another reason for

their inability to generate an adequate anti-HBs response (752). In the absence of this discovery, booster doses—consisting of one to three additional injections of vaccine in which the standard dose, or two to four times the standard dose (e.g., dialysis formulation; see Table 14), is administered—are recommended. In general, the anti-HBs concentrations remain low in these subjects. There is no evidence that nonresponders to plasma-derived vaccine will respond any differently to genetically engineered vaccines (803), but the use of hepatitis B vaccines that incorporate additional components of the envelope gene, and/or employ novel adjuvants, may be warranted (295,340,761,842).

Most experts will agree that low responders also should be encouraged to receive a booster inoculation 1 to 2 years after their last injection because breakthrough disease seems to occur earlier and more frequently in this group (see Fig. 14) (25,272). In the CDC study of homosexual men (272), 26% of 139 non- or hyporesponders had serologic and/or clinical evidence of HBV infection, with 44% of these subjects displaying HBsAg in the sampled specimen. Six of these subjects (4.3% of the total group) became persistently infected. In contrast to these data, long-term protection observed in persons who develop an adequate anti-HBs response after vaccination with the plasma-derived vaccine (greater than 100 mIU/mL) has been encouraging, as shown in Table 15 (482). In the CDC study cited earlier (272), only 11% of the 634 responders acquired HBV during follow-up, and none of these had clinical symptoms or became persistently infected. Only two (0.3%) had detectable HBsAg at the time they were sampled, and both of these individuals were positive for HIV. Most of the HBV events observed in vaccine responders were delayed for 4 to 9 years, and 72% occurred in those whose anti-HBs levels had declined to less than 10 mIU/mL. Similar results were found in another clinical trial in homosexual men (722), in the Yupik Eskimo trial in Alaska (795), in health care workers (482), in 104 infants of HBeAg-positive mothers (722), and in 654 infants of HBeAg-positive mothers in Taiwan (723).

TABLE 15. *Long-term protection from HBV infection among responders (anti–HBs>100 mIU/mL) to plasma-derived hepatitis B vaccine*

Whether to recommend a booster dose for vaccinees who have an adequate response to the vaccine remains controversial (25,275,300). One group of experts has gone on record as favoring at least one booster inoculation approximately 5 or more years after the basic series of immunizations (300). Another group of experts recommends that no booster dose is necessary for at least 10 years (135). However, for the moment it is comforting to know that few, if any, relevant clinical infections have been recorded among vaccine responders who have been followed for up to 10 years, even if they have lost detectable antibody (275,349,465,722,795). Unfortunately, in most of these studies, only limited numbers of vaccinees have been evaluated at these late time intervals, and most of these were administered the antigenically more potent plasma-derived product. In addition, the subjects being surveyed often come from high-risk groups that may be receiving sporadic natural boosters. Thus, whether the vaccine will confer lifelong immunity against chronic infection among all vaccine responders is not known. In the interim, at least one booster dose 5 to 10 years after completing the basic immunization series seems prudent, especially if the recently discontinued low-dose (2.5 µg) yeast-derived vaccine was previously administered.

It is the consensus of hepatitis experts that neither HBIG nor conventional IG should be used for preexposure prophylaxis, because active immunization with HBsAg is more effective and leads to long-term protection. In addition, there is no substitute for good personal hygiene, strict surveillance, and appropriate environmental control measures to limit transmission (129), not only of HBV but also of HCV and HIV.

Guidelines for Postexposure Immunoprophylaxis

Appropriate immunoprophylaxis can effectively prevent HBV infection following perinatal, sexual, household, or inadvertent exposure to the virus. HBIG is the mainstay of postexposure prophylaxis, although vaccine can provide an additional degree of protection in some settings, especially following perinatal exposure. Table 16 is a general guide to the recommended treatment that should be initiated following exposure to HBV, whereas Table 17 provides detailed current ACIP recommendations for postexposure immunoprophylaxis of infants born to HBsAg-positive mothers or of individuals having sexual contact with an HBsAg-positive person. When it becomes advisable to determine susceptibility prior to initiating postexposure prophylaxis, anti-HBc is the preferred serologic test for this purpose. In general, no postexposure prophylaxis is indicated for contamination of unbroken skin, for staff members who are providing routine care of patients with hepatitis B, for immune individuals, or for those who inadvertently share food or utensils with a person who subsequently develops hepatitis B, unless there are extenuating circumstances. It is hoped that all at-risk individuals should already have been immunized.

Type of exposure	Immunoprophylaxis
Perinatal	HBIG + vaccination
Sexual	
Acute infection	HBIG ± vaccination
Chronic infection	Vaccination ± HBIG
Household contact	
Acute case, no known exposure	None
Acute case, known exposure	HBIG ± vaccination
Chronic carrier	Vaccination
Inadvertent	
Percutaneous/permucosal	HBIG + vaccination

HBIG, hepatitis B immune globulin.

TABLE 17. *ACIP recommendations for postexposure prophylaxis for perinatal or sexual exposure to HBV*

An algorithm has been devised for determining a particular course of action to take after exposure of health care workers or other individuals to a potential source of HBV (Fig. 15). If a puncture wound has been sustained, the person should be instructed to wash the affected area immediately with copious amounts of water and soap or 0.5% sodium hypochlorite, and to promote bleeding. Persons exposed to HBsAg-positive material from a known source should provide their own blood sample to the laboratory for evaluation and storage. Following this, they should immediately be given HBIG (0.06 mL/kg) and HBsAg vaccine at different sites unless records indicate prior immunity or active hepatitis B disease in the exposed individual, in which case no course of action is required. Under no circumstances should the injection of HBIG be delayed until the results of the HBV serologic tests become available. If a significant delay is anticipated in obtaining or dispensing the HBIG, conventional IG (0.06 mL/kg) containing anti-HBs could be substituted for the HBIG. This provides immediate (and perhaps sufficient) protection at a lower concentration of anti-HBs until the proper tests can be performed or HBIG can be located and dispensed. There is no precedent for recommending HBIG prophylaxis if HBV exposure has occurred more than 7 days earlier, but unusual circumstances occasionally warrant extending this time period up to 14 days.

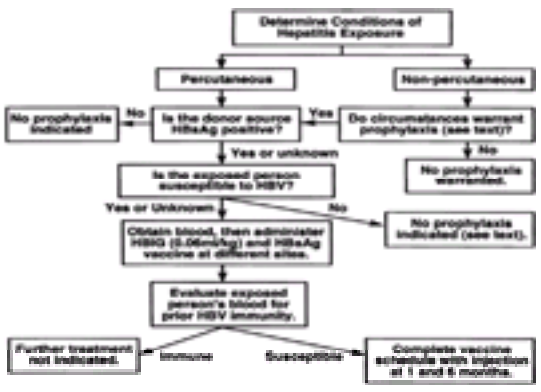

FIG. 15. Algorithm for postexposure prophylaxis of health care personnel exposed to a potentially infectious source of HBV. HBIG, high-titered specific hepatitis B immune globulin.

CHALLENGES FOR THE FUTURE

Both pre- and postexposure hepatitis B immunizations have been shown to provide immediate and long-term protection against HBV infection and to have significantly reduced the incidence of chronic infection and the onset of HCC. In comparing 1991 and 1997 birth cohorts, it is estimated that current vaccination programs have prevented more than 2.4 million people from becoming carriers and have reduced the number of hepatitis B–related deaths by 460,000. Combination vaccines are in production and experimental vaccines are continuing to be researched.

Although many vaccinees lose anti-HBs over 10 to 15 years of followup, no disease and no carriers have been detected in adults, and no clinical disease and only rare carriers have been observed in infant responders. Carrier prevalence has been reduced to below 1% in many countries where perinatal transmission is high and a national immunization program

is in place (Fig. 16). Because older carriers lose HBeAg, they are less likely to transmit disease, and when transmission does occur in an adult, the risk of chronicity is infrequent. As a result, the impact of vaccine programs has been greater than expected. Already, a reduction in liver cancer is being observed in Taiwan and The Gambia. This is significant as HCC is 100% fatal, represents a major cause of death in young men in Asia and sub-Saharan Africa, and is preventable by vaccination.

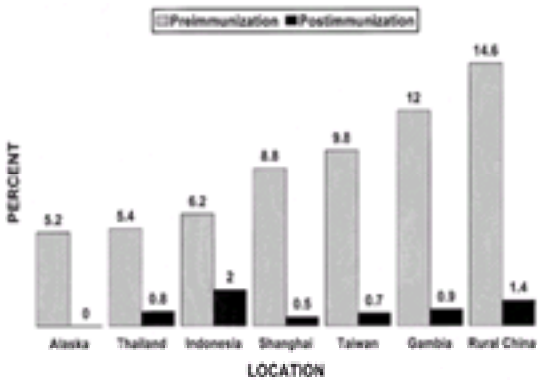

FIG. 16. HBsAg prevalence before and after the introduction of hepatitis B vaccination programs in selected high-risk areas in the world. (From M. Kane, personal communication, 2000.)

More than 60% of the countries of the world have a national program. Significantly, many Asian-Pacific countries have a national universal immunization policy that has achieved vaccination coverage rates of better than 70%. Countries with the lowest gross national product per capita are less likely to implement a program. The challenge for WHO and other international organizations is to (a) sustain existing programs, (b) assist those with economic problems to introduce the vaccine into their national immunization program by providing free vaccine, (c) increase coverage, (d) expand use to adolescent groups (catch-up immunization), (e) monitor and evaluate programs, and (f) encourage the development and deployment of combination vaccines. Unfortunately, many persons in sub-Saharan Africa, the Indian subcontinent, and in the Newly Independent States are not being vaccinated through national programs. The WHO has added hepatitis B vaccine to their recommended EPI schedule.

CHAPTER 88 Hepatitis Delta Virus

John L. Gerin, John L. Casey, and Robert H. Purcell

HISTORY

In the mid-1970s, Mario Rizzetto, a gastroenterologist in Turin, Italy, detected a previously unrecognized nuclear antigen in hepatocytes of patients with chronic type B hepatitis. The antigen resembled hepatitis B core antigen (HBcAg) in its obligatory association with hepatitis B virus (HBV) infection, but it rarely coexisted with HBcAg. The antigen was never found in biopsy samples from patients with non-B hepatitis, and it was not found in every patient with type B hepatitis. Similarly, only a proportion of such patients had antibody to the new antigen. The antigen was initially believed to be a previously unrecognized hepatitis B–specific antigen; it was called delta antigen and its antibody, anti-delta, and it was first reported in 1977 (79).

By 1980, transmission experiments in chimpanzees had confirmed that the delta antigen was a component of a transmissible pathogen that was defective and required co-infection with HBV for its replication (80). Simultaneously, a radioimmunoassay for anti-delta was developed (85), and it showed a high prevalence of anti-delta among hemophiliacs and drug users (83). In addition, it was established that hepatitis associated with expression of delta antigen was highly endemic in Italy, especially in the southern part of the country. Also, by the early 1980s, delta antigen was shown to be an internal component of a virus-like particle (Fig. 1 and Fig. 2) (81). The particle contained a small RNA, approximately 1.7 kb in size (Fig. 3), and both the delta antigen and RNA were enveloped with hepatitis B surface antigen (HBsAg), the envelope of HBV. In addition, the virus-like delta agent was shown to be associated with the most severe forms of acute and chronic hepatitis in many HBsAg-positive patients (96). Thus, in some cases, severe disease thought to be caused by HBV was actually the result of concurrent infection with the delta agent.

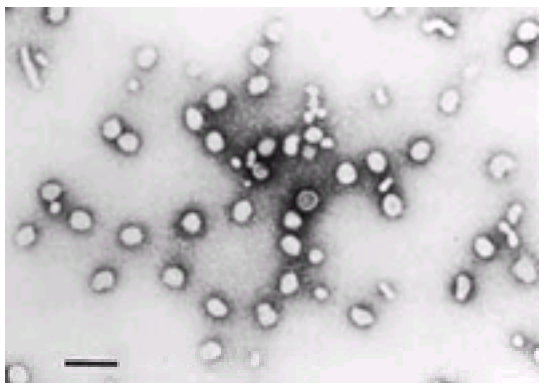

FIG. 1. Electron micrograph of the hepatitis delta virus. Peak fraction from a sucrose gradient. Stained with 1% phosphotungstic acid. Bar = 100 nm. (From ref. 35, with permission.)

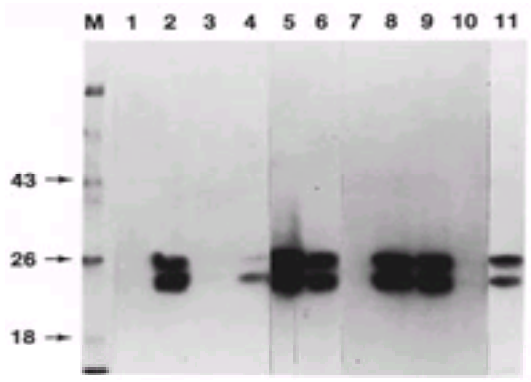

FIG. 2. Structural proteins of the hepatitis delta virus. Western blot of serum-derived HDAg with a human monoclonal antibody to HDAg. Extracts of HDAg from sera of five humans infected with HDV (*lanes 2 through 6*), two chimpanzees (*lanes 8 and 9*), and an HDV-infected woodchuck (*lane 11*) were analyzed. *Lane 1* contains an extract of an HDV-negative human serum; *lane 7*, an HDV-negative chimpanzee serum; and *lane 10*, an HDV-negative woodchuck serum. *Lane M* contains molecular-weight markers, and the relative molecular masses in kilodaltons are indicated on the left margin. (From ref. 4, with permission.)

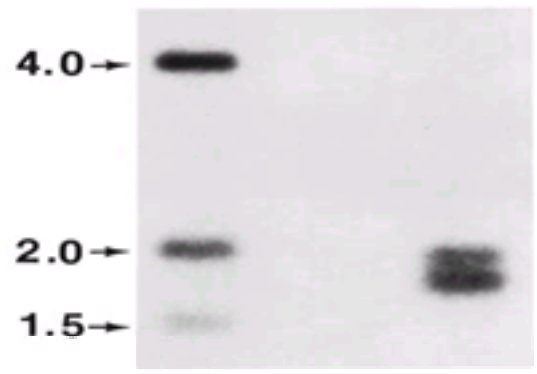

FIG. 3. Forms of hepatitis delta virion (genomic) RNA. Northern blot of RNA extracted from HDV particles and electrophoresed in 6% formaldehyde/1% sucrose gel. The two apparent sizes of HDV RNA represent linear and circular forms of the genome. Size markers (molecular weights in kilobases) are on the left margin. (Courtesy of F. Negro.)

By 1983, evidence for infection with the delta agent had been found on every populated continent (76). A year later, the virus was found to be the cause of severe hepatitis among indigenous populations of Venezuela (32), the first evidence outside of Italy, and the agent was making a major medical impact on populations not frequently exposed to blood. Subsequently the medical importance of the delta agent in South America was extended to include etiologic associations with traditionally severe hepatitis in Colombia (hepatitis de Sierra Nevada de Santa Marta) (48), and Brazil (Labrea black fever) (26), as well as more recently described severe hepatitis in Peru (94) and indigenous populations of Ecuador (53).

Also by 1983, the delta agent was considered sufficiently unique and medically important to be designated a distinct hepatitis virus, hepatitis delta virus (HDV), and the disease it caused was designated delta or type D hepatitis (78). By 1984, similarities between HDV and certain pathogens of plants, especially plant virus satellites, were noted. The cloning and sequencing of the HDV in 1986 confirmed the uniqueness of HDV among animal viruses and its similarity to a broad group of plant pathogens, including the viroids (110). Recent advances in our understanding of molecular features of HDV biology have revealed novel biologic pathways; these and the frequently devastating consequences of infection drive further research on this cause of acute and chronic liver disease. Thus, a chance observation by an inquisitive gastroenterologist resulted in the discovery of one of the most interesting and unusual of human pathogens.

INFECTIOUS AGENT

Classification and Structure

The approximately 36-nm hepatitis delta virus consists of an RNA genome and approximately 70 copies of a virus-specified nucleocapsid protein, hepatitis delta antigen (HDAg), which are enveloped by the surface antigens of the helper HBV. At 1.7 kb, the HDV genome is the smallest of the known human pathogens, and its limited coding capacity is reflected in the simple composition of the HDV particle. Because the sole viral protein is encoded by antigenomic RNA, HDV is a negative-stranded RNA virus. The envelope protein, which is required for HD virion formation and infection, is the only helper function provided by HBV. Its circular RNA genome and mode of RNA replication (see later) most closely resemble subviral plant pathogens, viroids, and virusoids. HDV is currently the only member of the *Deltavirus* genus (106).

Key Antigens

The nucleocapsid protein of HDV consists of two peptides, 24 and 27 kd in size (4,6) (see Fig. 2). The two species are related in that they share the same initiation codon and have common amino-terminal sequences, but they use different termination codons (110,111). Each is translated from a distinct mRNA species arising from a unique RNA editing event (64). The 24-kd and 27-kd species are referred to as HDAg-S and HDAg-L, respectively; both are serine-linked phosphoproteins with differing biologic functions in the virus life cycle (44,47). Dissection of the functional features of

HDAg has identified several essential elements: a nuclear localization signal (13,116) that targets HDAg to the nucleus where replication occurs; a coiled-coil domain (109) that mediates formation of HDAg dimers and higher-order structures; and arginine-rich motifs that are necessary for HDV RNA binding activity. The two forms of HDAg (S and L), which differ by the presence of an additional 19 to 20 amino acids at the C-terminus of HDAg-L, have distinct and opposed functions. HDAg-S is required for HDV replication, whereas HDAg-L inhibits HDV replication and is required for virion formation. An isoprenylation signal sequence at the C-terminus of HDAg-L is required for direct interaction between HDAg-L and HBsAg (28). The specific mechanism by which HDAg-S supports HDV RNA replication (and by which HDAg-L inhibits the process) is unknown. HDAg is not believed to act catalytically. It contains no known polymerase motifs, and no polymerase activity has been identified.

The HDV envelope consists of products of the HBV S and pre-S genes (see Chapter 86 and Chapter 87). The pre-S/S genes of HBV contain three start signals and a single termination codon. All three potential gene products are synthesized, and differential glycosylation results in six proteins or glycoproteins of varying molecular weights. The two smallest molecules are the most abundant, both in the HBV virion and in HBsAg-particles; they are designated *major* or *small* envelope proteins. The two intermediate-sized molecules are more abundant in virions than in HBsAg and are designated the *middle* proteins. The two largest proteins are also most abundant in virions and are called *large* proteins. The middle proteins contain a site encoded by the pre-S2 portion of the HBV genome that is a receptor for polymerized human albumin. The large proteins contain a separate site, encoded by the pre-S1 portion of the HBV genome, that is thought to bind directly to hepatocytes and mediate entry of the virus into cells. The large forms of HBsAg appear to be essential for initiation of infection because antibodies to pre-S1 and pre-S2 epitopes can neutralize the infectivity of HDV (103), and HDV particles containing only the small and large HBV surface proteins are infectious (100,101).

There is no evidence to date that the HBV-derived envelope proteins are further modified when they become the envelope for HDV, and surface epitopes unique to HDV have not been detected. As described later, HDV can use different hepadnaviruses as helpers under experimental conditions, and in each case the envelope of HDV has the physical and antigenic characteristics of the helper virus.

The HDV Genome and Its Replication

The 1.7-kb HDV RNA is structurally and functionally similar to plant viroid and virusoid RNAs (Fig. 4). It is single-stranded and circular, and it forms an unbranched rod structure with intramolecular base-pairing over 70% of its sequence (41,52,110). The only known gene product, HDAg, is coded for by the antigenomic strand. The RNA contains several functional and structural features (ribozyme sites, RNA editing, replication by host DNA-dependent RNA polymerase) that are essential for replication, and that distinguish HDV as a particularly interesting model system for RNA biology.

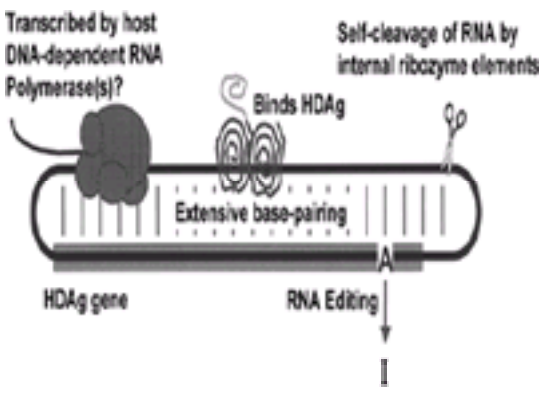

FIG. 4. Structure of the HDV RNA Genome. The single-stranded circular RNA genome is indicated by the *heavy black continuous line.* The genome has the ability to form an unbranched rod structure, in which approximately 70% of the bases are engaged in Watson-Crick pairs with counterparts from the opposite side of the circular RNA. In this unbranched rod structure, the region encoding HDAg (nt 1598-957) is on one side. The RNA editing site is at position 1012 in the antigenome. The region on the right-hand side contains the autocatalytic cleavage sites (ribozymes), one in the genome (nt 686) and the other in the antigenome (nt 900). The genome binds HDAg and is transcribed by a host DNA–dependent RNA polymerase. Numbering is according to Wang et al. (110).

Both the RNA genome and the antigenome contain closely related RNA structural elements of about 85 nucleotides (nt), termed ribozymes, that cleave the viral RNA at specific sites (43,91,112). Both ribozymes are present at one end of the unbranched rod structure (see Fig. 4), one in the genome and the other in the complementary antigenome. The ribozymes are central to the double-rolling-circle mechanism by which HDV RNA is replicated (7). According to this model, replication of genome and antigenome RNA from a circular template produces linear multimeric RNAs; these are processed by autocatalytic cleavage at the ribozyme sites to yield linear RNAs of unit length. In the final step of this process, unit-length RNAs are ligated to form circles; recent results suggest that a host RNA ligase is involved (75).

The HDV ribozymes are the only such elements known to be present in human viruses. They have been extensively studied biochemically, and a crystal structure was recently determined for the genome ribozyme (1,24). The HDV ribozymes are functionally similar to other ribozymes, including “hammerhead” ribozymes present in virusoid RNAs, in that they produce cleavage products with a 5'-hydroxyl and a 2',3'-cyclic phosphate. However, the HDV genome and antigenome ribozymes form similar complex, nested, double pseudoknot structures in which the active site is buried in a stable core reminiscent of protein catalytic sites (24,108). The catalytic sites formed by these unique structures enhance the cleavage rate, making the HDV ribozymes the fastest known self-cleaving RNAs—nearly 100-fold faster than hammerhead ribozymes.

HDV RNA replication begins with the circular RNA genome serving as the template for the synthesis of antigenome transcripts (Fig. 5). In step 1, two types of antigenomic RNAs are produced: a 0.8-kb mRNA that encodes HDAg-S, and greater-than-full-length transcripts. The mRNA is translated to yield HDAg-S, which promotes the transcription/replication process. The multimeric transcripts are processed to circular monomeric antigenome RNAs, as discussed previously. These circular RNAs then serve as templates for synthesis of circular genomic RNA by similar processing, with the exception that no genomic-sense mRNA is produced. Infected cells may produce over 100,000 copies of HDV genomic RNA.

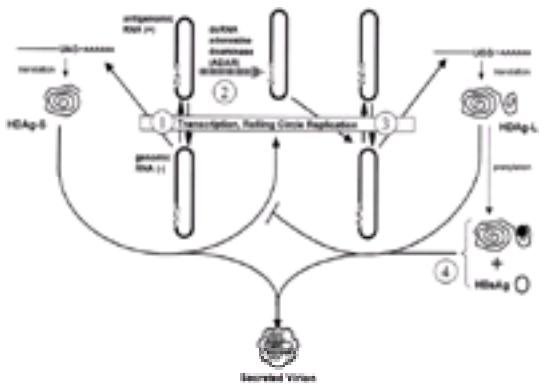

FIG. 5. Replication scheme of hepatitis delta virus. **1:** Replication begins with transcription of genomic RNA encoding the short form of HDAg (HDAg-S). Two types of antigenomic RNAs are produced: an mRNA that encodes HDAg, and a greater-than-unit-length antigenome. The latter undergoes autocatalytic cleavage via an internal ribozyme and is ligated by a host enzyme to yield circular antigenomes, which then serve as template for genome synthesis by a similar mechanism. HDAg-S is required for RNA replication. **2:** The adenosine within the stop codon for HDAg-S is deaminated to inosine in approximately 30% of antigenomic RNAs by a host enzyme. **3:** During subsequent RNA transcription, this change appears in the mRNA, which now encodes the long form of HDAg (HDAg-L), which inhibits RNA replication. **4:** The C-terminus of HDAg-L is prenylated by a host farnesyltransferase, facilitating interaction with the envelope protein (HBsAg) and subsequent virion formation.

The mechanism by which HDV RNA replicates its RNA is one of the more intriguing aspects of HDV biology. The virus does not encode a polymerase and there is no known RNA-dependent RNA polymerase in humans, the only known natural host of HDV. It is thus likely that HDV, by an undefined mechanism, corrupts the normal function of a host DNA–dependent RNA polymerase such that it functions on an RNA template. Sensitivity to alpha-amanitin and the presence of a 5' cap and poly(A) tail implicate RNA polymerase II for mRNA synthesis (29,37,49,50,56). Genome and antigenome synthesis are less sensitive to alpha-amanitin and appear to be differentially sensitive to inhibition by HDAg-L (55,56). The significance of these differences is not yet clear, but it could be explained by the involvement of different polymerase complexes for replication and transcription.

As noted previously, HDAg-S is required for HDV RNA replication, but HDAg-L, which inhibits RNA synthesis, is necessary for virion formation. HDV balances the conflicting but essential functions of these two gene products by using a cellular function known as RNA editing. Infectious RNA encodes HDAg-S. During RNA replication (see Fig. 5, step 2), a fraction (30% to 50%) of antigenome transcripts are “edited” by a cellular enzyme known as double-stranded RNA adenosine deaminase (9,64,65). This enzyme converts specific adenosines in RNAs to inosine. In HDV RNA, the edited position is within the stop codon for HDAg-S. Because of the different base-pairing tendencies for adenosine (which base-pairs with U) and inosine (which base-pairs with C), the edited antigenome eventually (after a round of replication and transcription; see Fig. 5, step 3) yields mRNA in which the HDAg-S stop codon has been changed to a tryptophan codon, allowing synthesis of HDAg-L. As increasing amounts of HDAg-L are produced, the mode of replication switches from RNA synthesis to packaging.

Propagation in Cell Culture and Biologic Characteristics

There is no practical *in vitro* cell culture system for the propagation of HDV. Primary hepatocyte cultures from woodchucks and chimpanzees have been infected with HDV, but replication was limited to a single cycle in a small proportion of cells (16,102,104). Although the HDV genome can replicate in a number of cells after transfection of HDV complementary DNA or RNA, infection appears to be limited to primary hepatocytes (27,42,102,104). Complete replication of the virus, including assembly and release, is limited to primary hepatocytes that are infected with a hepadnavirus or cultured cells cotransfected with HDV and hepadnavirus cDNAs (12,88,100,103,113). Such *in vitro* systems, which are capable of producing infectious HDV, have contributed greatly to our understanding of the molecular biology of this pathogen.

Infection in Experimental Animals

The host range for productive replication of HDV is limited to those species that support the replication of a hepadnavirus capable of supplying the essential helper function, the surface antigen envelope. These include the chimpanzee (hepatitis B virus) (80) and the eastern woodchuck (woodchuck hepatitis virus) (66).

Chimpanzees were shown to be susceptible to infection with HDV shortly after the discovery of delta antigen (80). Infection of the chimpanzee mimics that of humans, and much of our understanding of HDV infection is based on studies in this experimental model; both co-infection (simultaneous infection with HBV and HDV) and superinfection (infection of an HBsAg-positive subject) have been documented (74). Co-infection results in moderately severe hepatitis consisting of

a unimodal or bimodal elevation of alanine aminotransferase (ALT) activity and associated hepatitis. In unimodal disease, both HBcAg and HDAg are simultaneously expressed in the nuclei of infected hepatocytes; in bimodal hepatitis, one of the two antigens is usually predominant in the first episode and the other is expressed predominantly in the second episode (74). The order in which HBcAg and HDAg are expressed is probably determined by the relative titers of HBV and HDV in the infectious source. Regardless of the order, HBsAg is detected before HDAg in the blood. Co-infection of chimpanzees with HBV and HDV is followed by a transient immunoglobulin M (IgM) anti-HD response and a longer-lived immunoglobulin G (IgG) response. Superinfections of HBV carrier chimpanzees with HDV result in more severe disease. During acute HDV superinfection of HBV carrier animals, expression of markers of the HBV infection (HBsAg, HBV DNA) are suppressed. Co-infections of HDV and HBV usually result in acute, self-limiting hepatitis D. Superinfections of HBV carrier chimpanzees with HDV also have usually resulted in apparent acute, self-limiting hepatitis D, perhaps because most HBV carrier chimpanzees demonstrated relatively low-level replication of HBV, as measured by absence of HBeAg and presence of anti-HBe at the time of challenge. However, subsequent analysis with more sensitive assays of such anti-HBe–positive HBV carrier chimpanzees that had been superinfected with HDV showed that more than 50% of the animals actually had evidence of recurring low-level HDV replication (57). Furthermore, a chimpanzee that was HBeAg positive when challenged with HDV (25) demonstrated recurrent hepatitis D, with persistence of HDAg and other markers of HDV infection in the blood. The liver appears to be the only organ involved in HDV infection of chimpanzees. Hepatitis D in chimpanzees is generally more severe than other types of human viral hepatitis in this animal model (70).

Hepatitis D virus of human origin also infects woodchucks (*Marmota monax*) that are infected with the woodchuck hepatitis virus (WHV), causing acute or chronic hepatitis in a high proportion of animals (66,69). Hepatitis D in woodchucks is similar to that seen in chimpanzees; the liver is the only organ involved, despite the occurrence of WHV replication in extrahepatic tissues (58). Replication of HDV in woodchucks depends on the presence of replicating WHV, and the HBsAg envelope of HDV is replaced by the WHV envelope (WHsAg) (66). Hepatitis D virus that was passaged up to five times in woodchucks was readily transmitted back to chimpanzees with undiminished virulence (69,74). Serial passage of HDV in woodchucks resulted in a progressive shortening of the incubation period and the establishment of chronic HDV infection in most of the animals.

Transmission of HDV to mice has been reported (60). Infection, which could be achieved by intravenous or intraperitoneal inoculation, resulted in a single round of replication of the HDV genome in hepatocytes. The limitation to a single cycle of replication was probably the absence of a helper hepadnavirus to supply an envelope to the HDV nucleocapsid, thereby preventing release of complete virus and secondary infection of other cells. Efforts to develop transgenic mouse models of HDV RNA replication have been successful, and HDAg expression in a number of tissues has been demonstrated (62); also, DNA vaccination into skeletal muscles of mice leads to the development of anti-HD antibodies in nontransgenic animals, indicating that translation occurs in mouse cells (63).

Pathology and Pathogenesis

Direct pathologic changes in type D hepatitis are limited to the liver, the only organ in which HDV has been shown to replicate. The histologic changes, consisting of hepatocellular necrosis and inflammation, are those of acute or chronic viral hepatitis. There are no distinguishing features of the liver histology that differentiate type D hepatitis from other forms of viral hepatitis, except that the former tends to be more severe. The liver biopsy may contain only elements of acute hepatitis if co-infection with HBV and HDV has occurred, or elements of both acute and chronic hepatitis if acute HDV infection is superimposed on chronic HBV infection, or only the characteristics of chronic hepatitis if the patient is chronically infected with both HBV and HDV. In acute hepatitis, inflammatory cells, primarily lymphocytes and macrophages, are prominent in parenchyma and portal areas. Hepatocytes may be swollen and undergoing eosinophilic necrosis. Pathologic changes are often patchy and focal, except in more severe cases, when there may be confluent, submassive, or massive necrosis.

The histologic changes in chronic viral hepatitis are also those of inflammation and hepatocellular necrosis, but inflammation is largely portal and consists of lymphocytes, macrophages, and histiocytes. Necrosis of hepatocytes is usually evident but less severe than in acute viral hepatitis, and its distribution is typically periportal. A histologic lesion peculiar to HDV infection in northern South America, especially in the Amazon basin, is a microvesicular steatosis that gives rise to a characteristic alteration of the hepatocyte [a morula cell (71)] (Fig. 6). However, similar cells have been seen in severe hepatitis D elsewhere, including Africa and Italy. This severe form of HDV hepatitis in northern South America has been associated with a unique genotype of the virus (8) (see later).

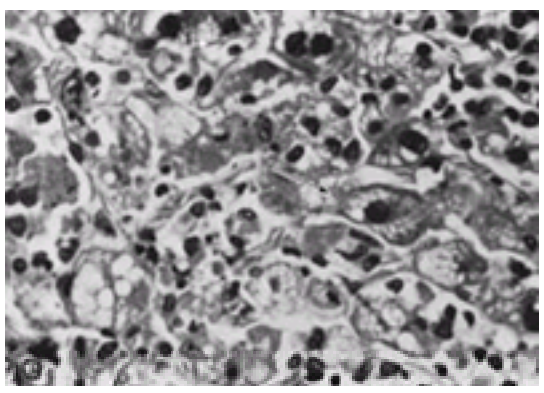

FIG. 6. Typical morula cells from a patient with hepatitis caused by HDV. (Courtesy of S. Thung.)

Only nonspecific electron microscopic changes have been observed in natural and experimental HDV infections, best

visualized in liver biopsy samples of experimentally infected chimpanzees (39). The most prominent of such changes are cytoplasmic tubular structures that represent alterations of the endoplasmic membrane and microtubular structures. Such structures are considered to be manifestations of exposure of hepatocytes to interferon, presumably produced in response to the viral infection (93).

The pathogenesis of type D hepatitis is poorly understood. A direct cytopathic effect of the small form of delta antigen, HDAg-S, in the absence of replication of the HDV genome has been reported (17). However, this has not been supported by data from liver biopsies (59); and the observation that some HDV-infected cell lines can survive for at least several cell divisions, indicating that HDV RNA replication is not acutely cytopathic (5); and from the failure to observe pathology of HDV expression in the transgenic mouse model (62). Nevertheless, the rate of loss of HDV-infected mice is most consistent with virus-mediated cell death (60). None of the hepatitis viruses have been shown to be directly cytopathic, and there is strong evidence supporting the notion that damage to hepatocytes is immunologically mediated, particularly for HBV (15). As with the other hepatitis viruses, peak replication of HDV precedes the peak histopathologic changes. In addition, replication of the virus has often been markedly diminished and the immune response begun by the peak of pathology; this adds credence to the belief that humoral or cellular immune mechanisms are involved. In the chimpanzee model of experimental acute HBV infection, viral clearance was associated with the noncytopathic antiviral effects of cytokines produced by non-T cells, whereas acute disease was associated temporally with T cells (30).

In addition to acute and chronic type D hepatitis, a third form of HDV infection, called latent infection, has been described in the orthotopic liver transplant setting in end-stage hepatitis D patients. Markers of HDV infection occurred in the absence of detectable markers of HBV infection, suggesting that HDV might replicate at low levels in the absence of HBV (97). Subsequent analysis with more sensitive assays showed that low-level HBV replication was occurring coincident with HDV replication, thus reaffirming the dependence of HDV on the HBV helper function and the absence of a true latent phase (95).

CLINICAL FEATURES

The clinical course of type D hepatitis is variable but is usually more severe than that of other viral hepatitides. After an incubation period of 3 to 7 weeks, the pre-icteric phase begins with the onset of nonspecific clinical symptoms of fatigue, lethargy, anorexia, and nausea, usually of 3 to 7 days duration. During the pre-icteric phase, biochemical markers of hepatitis, such as serum ALT and aspartate aminotransferase (AST) activities become abnormal. Viral replication is usually diminished during this phase.

The onset of the icteric phase, if it occurs, is characterized by the appearance of jaundice. Fatigue and nausea usually persist, and the serum bilirubin level becomes abnormal; this coincides with the appearance of clay-colored stools and dark urine, evidence of the liver's diminished ability to conjugate and excrete bilirubin. The most severe stage of clinical disease may coincide with a further decrease in the level of markers of viral replication. In patients with acute, self-limiting infection, convalescence begins with the disappearance of clinical symptoms. Anorexia and nausea disappear relatively early, but fatigue and lethargy may persist for weeks or months.

Fulminant viral hepatitis, the most severe form of acute disease, is a rare sequela of acute viral hepatitis but is approximately 10 times more common in type D hepatitis than in the other types of viral hepatitis. It is characterized by hepatic encephalopathy that is manifested by changes in personality, disturbances in sleep, confusion and difficulty concentrating, and, in severe cases, abnormal behavior, somnolence, and coma. Jaundice may be profound, but serum ALT and AST values may decrease as massive hepatic necrosis leaves few viable hepatocytes. The mortality rate of fulminant hepatitis is approximately 80%. Fulminant hepatitis is an indication for orthotopic liver transplantation.

Chronic viral hepatitis is a frequent sequela of type D hepatitis (see later). Unlike other forms of chronic viral hepatitis, chronic type D hepatitis is usually initiated by a clinically apparent acute infection. Symptoms are those of acute hepatitis but often less severe. Serum ALT and AST values are elevated, but serum bilirubin and albumin levels and prothrombin times may be normal, at least before cirrhosis develops. Approximately 60% to 79% of patients with chronic type D hepatitis develop cirrhosis (86), a figure almost three times higher than for type B hepatitis and type C hepatitis; a high proportion die of hepatic failure. Hepatocellular carcinoma (HCC) has been reported in some patients with chronic type D hepatitis. In a recent study of western European patients with compensated cirrhosis type B, HDV infection increased the risk for HCC threefold and for mortality twofold (23). It is unknown whether HCC is an effect of the underlying cirrhosis, a known risk factor for HCC, or a direct carcinogenic effect of the virus (2).

Because HDV infection has an absolute requirement for an associated HBV infection, acute disease occurs as one of two patterns, depending on the prior HBsAg status of the HDV-infected subject. Simultaneous infection of a susceptible individual with HBV and HDV (co-infection pattern) results in both acute type B hepatitis and acute type D hepatitis. The incubation period generally depends on the HBV titer of the infecting inoculum because the incubation of type B hepatitis is inversely related to the dose of virus. Depending on the relative titers of HBV and HDV, a single bout of hepatitis or two bouts of hepatitis, characterized by a biphasic pattern of serum ALT and AST values, may be seen. Usually, the first bout of hepatitis is HBV related; however, hepatitis B followed by hepatitis D and hepatitis D followed by hepatitis B have both been observed in experimental infections of chimpanzees (74). Co-infections of HBV and HDV are usually acute, self-limited infections.

In contrast, HDV infection of an individual chronically infected with HBV (superinfection pattern) causes a generally severe acute hepatitis with a relatively short incubation period that leads to chronic type D hepatitis in over 70% of cases. Superinfection with HDV is often associated with fulminant acute hepatitis and the most severe form of chronic hepatitis, chronic active hepatitis, often with cirrhosis. A subacute, rapidly progressive form of HDV superinfection has been seen in HBsAg carriers among the Yucpa Indians, an indigenous population of Venezuela (72). Such patients often die within 18 months of disease onset. This disease pattern may be related to a particular HDV genotype (see later).

DIAGNOSIS

Differential Diagnosis

Type D hepatitis should be considered in individuals who are HBsAg positive or who have evidence of recent HBV infection, especially if they have been exposed to blood or blood products or if they are members of a high-risk population or from a high-risk environment (see later). Other conditions to be differentiated from type D hepatitis include co-infection of hepatitis A virus or hepatitis C virus with HBV, superinfection of an HBsAg carrier with one of these two viruses, and exacerbation of a chronic HBV infection, with recurrence of clinical disease.

Laboratory Diagnosis

The typical serologic course of acute HDV co-infection is shown in Figure 7. Hepatitis B surface antigen, hepatitis B e antigen (HBeAg), and HBV DNA appear in the serum during the incubation period in a pattern characteristic of acute type B hepatitis. Antibody to HBcAg appears, coincident with onset of clinical disease; evidence of active viral replication has often disappeared by the peak of illness. Antibody to HBsAg appears later, during convalescence. The diagnosis of acute type D hepatitis is made on the basis of serologic tests for this virus. Antibody to HDAg (anti-HD) develops late in the acute phase of infection and may be present only transiently and in low titer. Assays for IgM anti-HD (21) and for virion-associated HDV RNA or HDAg in the serum (51,57,117) are more reliable markers of acute HDV infection. In the co-infection pattern, all markers of viral replication disappear in early convalescence, and IgM anti-HD and even IgG anti-HD disappear within months to years after recovery.

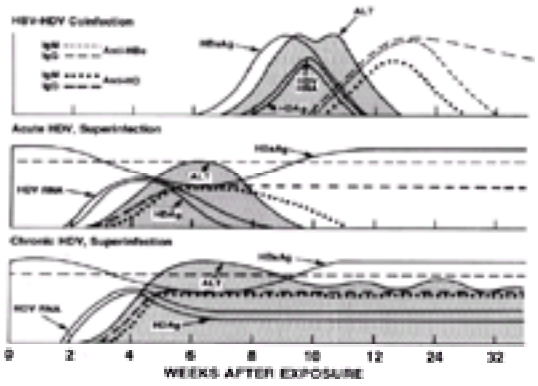

FIG. 7. The serologic patterns of type D hepatitis: Co-infection and superinfection. **Top:** Coexistent acute hepatitis B and hepatitis D. **Middle:** Acute hepatitis D superimposed on a chronic hepatitis B virus infection. **Bottom:** Acute hepatitis D progressing to chronic hepatitis, superimposed on a chronic hepatitis B virus infection. (From ref. 73, with permission.)

In contrast, superinfection with HDV usually results in persistent HDV infection. A typical serologic pattern for such hepatitis is shown in Figure 7. Evidence for HD viremia appears in the serum during the pre-acute phase and is followed by the appearance of IgM anti-HD and IgG anti-HD during the acute phase. Suppression of markers of HBV replication usually occurs during the acute phase but may be difficult to demonstrate without comparison with pre-HDV levels. Progression to chronicity is associated with high levels of IgM ant-HD and IgG anti-HD. These antibodies persist, as do positive tests for serum virion-associated RNA and HDAg (evidence for viremia) and intrahepatic HDV RNA and HDAg. In some experimental chronic infections of chimpanzees, only the antibodies persisted at constantly detectable levels. Viremia is indicative of virus replication and is associated with active liver disease (98). There is increasing use of molecular methods, such as polymerase chain reaction (PCR), to assess viremia in laboratory diagnosis of clinical disease (54).

TREATMENT

There is no specific treatment for type D hepatitis (77). Immunosuppressive therapy has been found to be of no clinical value (86) and is probably contraindicated, a situation that applies to the other forms of acute and chronic viral hepatitis as well. Because of the absolute dependence of HDV on HBV, therapies for HBV might be expected to control HDV also, but it is not certain that this is the case. For example, low to moderate doses of alpha-interferon have been shown to have an inhibitory effect on HDV replication (36,84), but, as with interferon treatment of HBV infection, beneficial effects were only transient. Massive doses of alpha-interferon [9 million units three times a week for 12 months, or 5 million units daily for up to 12 months (19,22)] have yielded a somewhat higher rate of remission, although most patients remained positive for HDV RNA whether or not their hepatitis improved, and despite the fact that relapse was common in the posttreatment period. In studies of the effectiveness of lamivudine in HDV-infected patients, neither HDV viremia nor liver disease was reduced (46). As mentioned previously, the only helper function that HBV provides for HDV is the envelope, and HBsAg circulates at very high levels in most HBV carriers. An effective therapy would probably require a marked suppression of HBsAg levels in order to impact on HDV, and current therapies for HBV do not achieve this.

Orthotopic liver transplantation has been relatively useful for treating fulminant acute and end-stage chronic hepatitis D. The results have been somewhat better than the disappointing results obtained with chronic HBV infection (97,107). Markers of continuing HDV replication are sometimes found in transplant patients shortly after transplantation, but liver disease does not recur unless significant HBV replication occurs. Recurrence of HBV in patients with both HBV and HDV infections is less frequent than in patients with HBV alone.

EPIDEMIOLOGY

Geographic Distribution

Seroprevalence studies of anti-HD in HBsAg-positive individuals have shown a worldwide, but nonuniform, distribution (32,68,82). Areas of high prevalence include the Mediterranean basin, the Middle East, central Asia, East Africa, the Amazon basin, and certain islands of the South Pacific (Fig. 8). Hepatitis D is less common in eastern Asia, although HDV has been implicated in up to 20% of cases of acute hepatitis in some populations of HBsAg-positive individuals in Taiwan, China, and India. High-risk populations in industrialized countries include hemophiliacs, users of illicit parenteral drugs, and others exposed to blood or blood products. HDV has been less frequent than infection with HBV or human immunodeficiency virus (HIV) infection among sexually promiscuous homosexual and heterosexual groups, suggesting that it is not typically a sexually transmitted disease, although such transmission may sometimes occur (18,99). Prevalence studies probably represent minimal values, because anti-HD can disappear after acute, self-limiting infection.

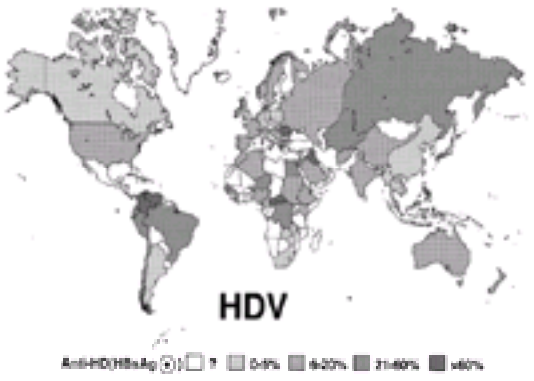

FIG. 8. The worldwide distribution of HDV infection, as measured by the prevalence of anti-HDAg in HBsAg-positive individuals with acute or chronic hepatitis. (Modified from refs. 31,68, and 82, with permission.)

Molecular studies of HDV isolates have revealed the existence of at least three major genotypes, with different geographic distributions (Fig. 9) (8,14,61,90,114). Whereas genotype I is found worldwide, genotypes II and III appear to be more geographically constricted to the Far East and northern South America, respectively. Genotype-specific support of HDV RNA replication by HDAg-S suggests that the genotype classifications have a functional as well as phylogenetic basis (11).

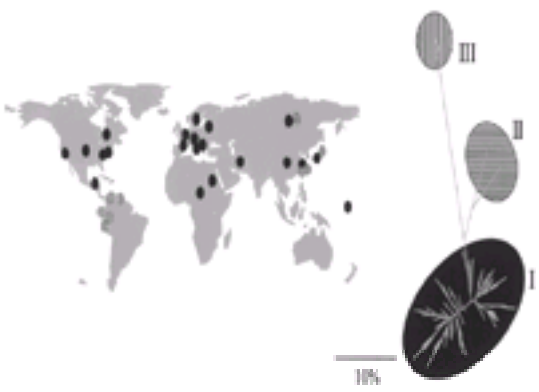

FIG. 9. Geographic distribution of HDV genotypes. Sequences of HDV isolates from different areas were compared by maximum likelihood phylogenetic analysis. *Horizontal bar* indicates approximately 10% sequence divergence. *Circles* on the map correspond approximately to geographic origin of isolates. *Filled circles*, genotype I; *horizontal stripes*, genotype II; *vertical stripes*, genotype III.

Morbidity and Mortality

The ratio of clinical to subclinical cases of HDV co-infection and superinfection is unknown, but the general severity of both forms of infection suggests that most cases are clinically important. The chronicity rate is 1% to 3% for co-infection and 70% to 80% for superinfection. The mortality rate of hepatitis D is 2% to 20%, 10 times higher than the rate for hepatitis B, the next most severe type of viral hepatitis. The patterns of disease associated with chronic HDV infection, however, vary in different epidemiologic settings, particularly with genotype I. In areas where HDV infection is endemic, such as southern Italy, a more slowly progressing, stable disease pattern appears to predominate, whereas in areas where HDV infection is not endemic, such as northern Europe and North America, the most severe forms of type D hepatitis frequently occur among intravenous drug users.

A very different pattern appears to be found in northern South America in association with genotype III. Whereas HDV is endemic in some communities, disease frequently follows a rapidly progressive course that is associated with significant morbidity and mortality. The varying patterns of disease could be related to a number of factors, including HDV genotype, characteristics of the HBV, variable responses in the host immune system, infection with other viruses, and substance abuse. The possible associations of genotypes II and III with mild and severe forms of type D hepatitis, respectively, is

particularly intriguing (8,10,115). Additional clinical, epidemiologic, and laboratory investigation of these genotypes will prove valuable in determining whether these associations are definitely related to HDV genotype, and in evaluation of disease mechanisms.

Age

Hepatitis D virus infects all age groups. It has been transmitted perinatally (with HBV) in Italy, but fortunately, HDV is not common in regions of the world, such as Asia, where perinatal transmission of HBV is common. Type D hepatitis affects children in the Amazon basin and has occurred among children with hemophilia in industrialized countries, especially before blood was screened for HBV. It also occurs among young adults over most of its geographic distribution and especially among users of illicit drugs in industrialized countries.

Epidemics

The epidemiology of HDV, which is principally transmitted by blood and blood products, is not conducive to epidemics in the classical sense. However, contamination of lots of clotting factor with HDV, as well as HBV, hepatitis C virus (HCV), and HIV, in past years (87) was responsible for the high incidence of chronic hepatitis among recipients of these products and the high prevalence of serologic evidence of infection (105). Small epidemics of severe type D hepatitis have occurred among drug addicts, and prolonged epidemics, leading to high cumulative attack rates, have occurred in some populations of drug addicts upon introduction of HDV into those populations (20,33,34,45,92). Ongoing outbreaks of HDV hepatitis are occurring in various regions of northern South America, especially the Amazon basin, and often involving fragile indigenous Amerind populations, such as the Waorani (53).

Immunity

Second cases of type D hepatitis have not been reported, suggesting that some form of immunity after acute, self-limiting infection exists; as mentioned previously, this may involve cellular immune mechanisms. Hepatitis B virus carrier chimpanzees superinfected with HDV were resistant to rechallenge with HDV 6 months later (74). Similar chimpanzees rechallenged 3 to 5 years after initial HDV infection, were protected or developed mild transient hepatitis. All of the chimpanzees were anti-HD positive at the time of challenge, but most lacked antibodies to the envelope of HDV (i.e., HBsAg). However, some of these chimpanzees still may have been replicating HDV at low levels at the time of rechallenge (57), and protection by interference rather than immunity could not be ruled out.

There is some experimental evidence in woodchucks that immunity to epitopes of the internal HDAg of HDV modifies the course of HDV infection (3,40). Indeed, vaccination against the internal HBcAg of HBV has also been shown to protect against type B hepatitis; again, cell-mediated immune mechanisms appear to be responsible. Clearly, antibodies to internal antigens such as HDAg and HBcAg do not protect, because both viruses are transmitted perinatally to infants who have high levels of these maternally derived antibodies.

Prevention and Control

Situations in which there is opportunity for repeated exposure to HBV constitute the major risks for co-infection or superinfection with HDV. The current policy of excluding blood donors with serologic markers of HBV infection has markedly diminished the chances of HDV transmission by blood transfusion. Similarly, screening of donors to large plasma pools used for the fractionation of blood products has diminished the risk of types B and D hepatitis from such preparations, but the inadvertent introduction of a single unit of plasma positive for HDV and HBV could contaminate the whole lot because of the high infectivity titers of these two viruses in blood (67). Practices designed to minimize the transmission of HBV, HCV, and HIV among drug addicts will also diminish the transmission of HDV to the extent that they are implemented. Implementation of better hygiene, especially control of weeping skin lesions, thought to be involved in the transmission of HDV in some primitive settings, may help control the spread of HDV and other blood-borne viruses.

Immunoprophylaxis against HDV is achieved by vaccination against HBV, because HDV uses the envelope proteins of HBV and has no detectable unique surface antigens. Hepatitis B vaccines currently available are highly effective in preventing HBV infection and the disease sequelae. Public health measures to interdict the transmission of blood-borne pathogens, combined with aggressive HBV vaccination programs at the national level, offer great promise for the control of type D hepatitis. Indeed, reports from Taiwan and Italy indicate decreasing rates of HDV transmission in these populations as a result of these wide-ranging control efforts (38,89). Unfortunately, some high-risk populations are among the most difficult to reach with such programs.

PERSPECTIVES

Over 300 million people in the world who are chronically infected with HBV are also at risk of contracting type D hepatitis. Such HBsAg carriers are refractory to vaccination with current HBsAg vaccines, and public health control measures depend on those strategies that limit reexposure to HDV through high-risk behavior. Future opportunities, based on laboratory animal studies, include the possibility of HDV-specific vaccines, but for the most part, limiting the burden of HDV disease will depend on the aggressive pursuit of HBV control, through both prophylactic and therapeutic intervention.

Fundamental studies of the HDV genome and its replication in recent years have permitted the application of modern molecular techniques to define the role of HDV in the evolution of liver disease. Additionally, our understanding of the similarity of HDV and other unusual subviral pathogens has stimulated a search for other unique transmissible agents with similar characteristics in humans and other animal species.

CHAPTER 89 Hepatitis E Virus

Robert H. Purcell and Suzanne U. Emerson

HISTORY

Hepatitis E was not recognized as a distinct clinical entity until 1980, when sensitive and specific tests for antibody to hepatitis A virus (anti-HAV) were first applied to the study of epidemic waterborne hepatitis in India (49,107). Such disease had long been thought to be caused by HAV, based on the epidemiologic and clinical similarities between these epidemics and well-characterized epidemics of hepatitis A occurring elsewhere. However, the patients in the Indian epidemics were all found to have serologic evidence of past, not recent, infection with HAV; the epidemics were therefore not epidemics of hepatitis A. Indeed, the studies of Indian hepatitis epidemics were initiated because previous seroepidemiologic studies had revealed a virtually universal exposure to HAV during infancy and early childhood in developing countries and it was therefore difficult to understand how large epidemics of waterborne hepatitis A could occur in young adults who would be expected to have immunity to infection with HAV. In fact, very few epidemics of waterborne hepatitis in developing countries of Asia and Africa have been linked to hepatitis A (3,48,79).

The first direct experimental evidence for the existence of an additional waterborne hepatitis agent was reported in 1983 by Balayan et al. (9), who described the successful fecal–oral transmission of hepatitis to a volunteer from patients with hepatitis A-like disease in Tashkent, Uzbekistan. The volunteer developed severe clinical hepatitis 36 days after ingestion of a fecal suspension from the patients. Virus-like particles, 27 to 30 nm in diameter, were detected by immunoelectron microscopy (IEM) in the feces collected from the volunteer between 28 and 45 days after exposure. After ingestion of the feces, the volunteer, who had been infected with HAV in the past, did not have a serologic response to HAV or HBV but did develop antibodies to the virus-like particles recovered from his feces. Balayan et al. also reported the transmission of hepatitis to cynomolgus monkeys inoculated with the fecal sample from Tashkent and the recovery of virus-like particles from their feces (9).

This form of non-A, non-B hepatitis came to be known as epidemic non-A, non-B or enterically transmitted non-A, non-B (ENANB) hepatitis, and the agent of this disease was subsequently found to be the major cause of sporadic hepatitis cases in regions where the epidemic form was known to exist (4,51,74). IEM and transmission to primates (see later) remained the only means of studying ENANB hepatitis until 1990, when Reyes et al. succeeded in cloning and sequencing a part of the genome of the virus (83). The complete sequence of the viral genome is now known, and the agent has been renamed hepatitis E virus (HEV) (79,83).

INFECTIOUS AGENT

Classification

The taxonomic classification of HEV is uncertain at present. Initial analysis of the HEV genome revealed three open reading frames (ORFs); putative, nonstructural proteins were localized at the 5' end, and structural protein(s) at the 3' end of the genome; and subgenomic messenger RNAs, detected in infected liver tissue, were superficially suggestive of a relationship with the caliciviruses (87), so the virus was classified in the *Caliciviridae* family. However, the order of the genes of HEV is not identical to that of typical caliciviruses: ORF 3 of the caliciviruses is located at the 3' end of the genome, whereas it overlaps the ends of ORF 1 and ORF 2 in HEV. Furthermore, although the sequence of HEV is not closely related to that of any other recognized virus, it most closely resembles the sequences of rubella virus, currently classified as a togavirus, and beet necrotic yellow vein virus, a plant furovirus (30). In addition, codon usage most closely resembles that of rubella virus (87). For these and other reasons, HEV was recently removed from the *Caliciviridae* family and is again unclassified (76). It has been proposed that, on the basis of genetic relatedness and genomic organization, the taxonomy of positive-sense RNA viruses should be reorganized. Under such a scheme, rubella virus, beet necrotic yellow vein virus, and HEV would be placed in separate but related families (55).

Virion Structure

Morphology

Hepatitis E virus is a nonenveloped, spherical particle, approximately 30 to 34 nm in diameter (9,11,90), with an indefinite surface substructure that is slightly less pronounced than that of the Norwalk agent (a calicivirus) but distinguishable from the smooth, featureless surface of hepatitis A virus (a picornavirus) (Fig. 1). However, on the basis of morphology, HEV cannot be reliably distinguished from other “small round viruses” found in feces. Analysis of electron micrographs of HEV particles by Markham rotational analysis provided images that suggested an icosahedral symmetry for HEV virions (90).

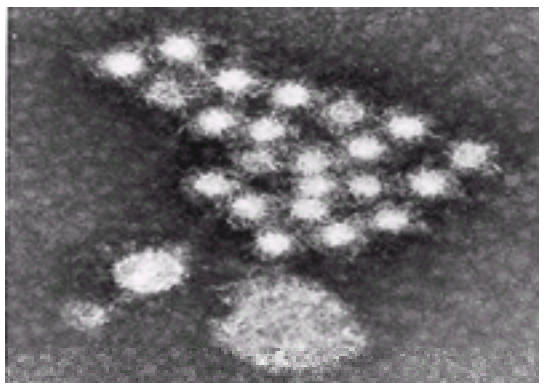

FIG. 1. Antibody-coated hepatitis E virus particles recovered from the stool of a patient with hepatitis E, in Mexico. Immunoelectron microscopy (×223,000). (Courtesy of D. Bradley.)

Chemistry

The buoyant density of hepatitis E viral antigen and/or virus particles has been reported to be 1.35 g/cm ^{3} (9) and 1.39 to 1.40 g/cm^3 (28) in CsCl. The buoyant density of HEV is 1.29 g/cm^3 in potassium tartrate/glycerol (11). The sedimentation coefficient of HEV is 183S (12). Hepatitis E virions appear to be unaltered by exposure to trifluorotrichloroethane (90). Survival of HEV in the intestinal tract suggests that the virus is relatively stable to acid and mild alkaline conditions. Although not specifically tested, HEV is likely to be inactivated by the same agents that inactivate hepatitis A virus. Hepatitis E virus contains an RNA genome enclosed within a capsid that is composed of one or possibly two proteins, but insufficient virus has been available for purification and direct chemical analysis to yield reliable information (87). It is not known whether subgenomic RNA transcripts are packaged in virions.

Genome Structure and Organization

The genome of HEV is a single-stranded, positive-sense, polyadenylated RNA molecule of approximately 7.5 kb in length (87) (Fig. 2). The genome of HEV consists of a 5' noncoding (NC) region of 27 to 35 nucleotides that is capped at its 5' end (42), followed by an ORF (ORF 1) of 5,073 to 5,124 bases. A second ORF (ORF 2) begins in coding frame two, 37 nucleotides 3' of the termination codon of ORF 1, and consists of 1,977 to 1,980 nucleotides. A 65- to 74-nucleotide 3' NC region is contiguous with the termination of ORF 2 and is terminated by a 3' stretch of 150 to 200 or more adenosine residues, at least in some strains. A third ORF (ORF 3), 366 to 369 nucleotides in length, overlaps ORF 1 by one nucleotide at its 5' end and extends 325 to 328 nucleotides into ORF 2 in coding frame 3. Thus, the HEV genome consists of three overlapping ORFs and utilizes all three coding frames.

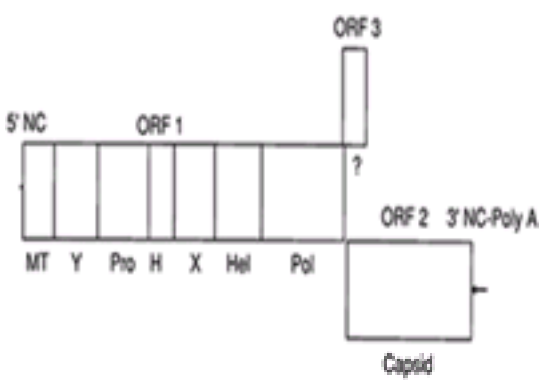

FIG. 2. Organization of the hepatitis E virus genome. The genome is a capped, single-stranded, positive-sense polyadenylated RNA molecule, approximately 7.5 kb in length. It has short 5' and 3' noncoding regions and three overlapping ORFs. All three coding frames are utilized. The nonstructural proteins are thought to be encoded within the large 5' ORF (*ORF 1*), and the capsid protein is encoded by the 3' ORF (*ORF 2*). The small, overlapping third ORF (*ORF 3*) encodes an immunogenic protein of unknown function. See refs. 30,34,35,42,54,55,82,87,94.

The functions of proteins encoded by the ORFs of HEV have not been directly demonstrated but, based on extensive sequence analysis of the HEV genome and identification of conserved motifs found in other viral proteins, ORF 1 is believed to encode the nonstructural proteins; ORF 2 is believed to encode the principal (or only) structural protein, the capsid polypeptide; and ORF 3 encodes a small immunogenic protein of unknown function (30,55,87). Starting from the 5' end of ORF 1 and extending to its 3' end, motifs characteristic of the following viral proteins have been identified (55):

1. A methyl transferase, consistent with the finding that the 5' end of the viral genome is capped (42)

2. A Y domain, a sequence of unknown function found in certain other viruses, including rubella virus
3. A papain-like cysteine protease, a type of protease found predominantly in alphaviruses and rubella virus (35)
4. A proline-rich “hinge region” that is thought to impart flexibility to the molecule and that contains a region of hypervariable sequence (82,94)
5. An X domain of unknown function that flanks papain-like protease domains in the polyproteins of other positive-strand RNA viruses (35)
6. A domain containing helicase-like motifs that are most closely related to the helicases of superfamily I (34)
7. The motifs of an RNA-dependent RNA polymerase, most closely related to supergroup III of viral RNA polymerases (54)

ORF 2 encodes a protein that contains a typical signal sequence near its 5' end, immediately followed by a region rich in codons for arginine and highly basic in charge. This region is believed to be involved in the encapsidation of the genomic transcript (87). The ORF 2–encoded protein contains potential glycosylation sites that are glycosylated *in vitro*, but it has not been established that these are functional *in vivo* (93,109). ORF 2 encodes a major immunogenic epitope at the extreme 3' end (108), as well as other important epitopes in the central region of the protein (61,97).

ORF 3 encodes a phosphoprotein that contains a signal sequence near its 5' end but lacks other identifiable motifs (110). It binds to the cellular cytoskeleton, but its function is unknown (82,110). This protein also contains an immunogenic epitope near its 3' end (87).

Genetic Heterogeneity of HEV

The genomes of several HEV strains from Asia (Burma, Pakistan, India, China, Nepal, Taiwan), Africa (Egypt, Algeria, Morocco, Chad, Nigeria), Europe (Italy, Greece, Spain, Austria), South America (Argentina), and North America (Mexico, United States) have been entirely or partially sequenced and are available through GenBank. Overall, the HEV strains appear to fall into at least four major and several minor genetic groups: Asian/African (Burmese, Indian, Pakistani, Central Asian, North African, and some Chinese strains), a second major Chinese genotype (China and Taiwan), Mexican, and U.S. strains. Other strains, recovered in Italy and Greece, are significantly different from all of these but are more closely related to the U.S. strains (Fig. 3) (85). Thus, genetic heterogeneity is regionally istributed, suggesting that HEV is an old virus that was geographically dispersed in the distant past. Although many strains of HEV from Africa are distinct members of the Asian/African genotype, there is evidence that other strains of HEV in the region have been introduced from Asia in recent times by religious pilgrims and laborers (32).

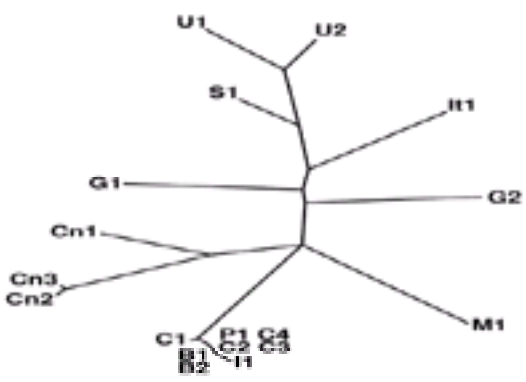

FIG. 3. Unrooted phylogenetic tree depicting the relationship of partial nucleotide sequences from ORF1 and/or ORF2 of HEV strains. Branch lengths are roughly proportional to the evolutionary relationship between sequences. Designations of these strains: B, Burmese; C, Chinese; P, Pakistani; I, Indian; M, Mexican; S, swine; U, United States; G, Greek; It, Italian; Cn, new Chinese. The isolates can be separated into Asian-African, Mexican, new Chinese, and United States-European groups. The last is very heterogeneous. (Modified from ref. 85, with pemission.)

Propagation and Assay in Cell Culture and Biologic Characteristics

Although the replication of HEV in cell culture has been reported (25,38,45), the utility of these systems has yet to be proved. The replication of HEV in primary cynomolgus monkey hepatocyte cultures has also been reported (88). Genomic and antigenomic HEV RNA was detected by reverse transcription–polymerase chain reaction (RT-PCR), and viral antigen was detected by immunofluorescence microscopy in cultures inoculated with stool suspension containing HEV. Infection of cultures has also been prevented by neutralization with sera containing anti-HEV, but not with normal sera (67,88).

Key Antigens

Hepatitis E virus encodes antigens reactive in IEM, enzyme-linked immunosorbent assay (ELISA), Western blot, and immunofluorescence microscopy. The first assay for detecting anti-HEV and the test with which the agent was first identified was IEM (9). From 1983 until 1990, IEM was the only assay for anti-HEV, and serodiagnosis was therefore extremely difficult. Antigens expressed from cloned cDNA derived from the genome of HEV were first used as the basis for serologic tests in 1991 (108). Major epitopes appear to exist in ORF 2 and ORF 3 (56,108). ORF 2 is relatively highly conserved (108). In contrast, ORF 3 is more heterogeneous (108). Thus, it is not surprising that serologic tests based on ORF 2 sequences are broadly reactive, whereas tests containing ORF 3 sequences may be more strain-specific (37,46), but exceptions have been reported (24). Mapping of linear B-cell epitopes in the three ORFs of HEV by the Geysen pin method revealed twelve such epitopes in ORF 1, three in ORF 2, and one in ORF 3 (44). Most of the epitopes identified in ORF 1 were clustered in the putative RNA polymerase gene region, near the carboxyl end of this ORF. It is not yet

clear how useful tests that incorporate expressed nonstructural proteins of HEV encoded by ORF 1 will be for diagnostic purposes. However, such a test may be important for differentiating between vaccine-induced and infection-induced immune responses when nonreplicating HEV vaccines are commercially available.

Although the B-cell epitope found in ORF 3 appeared to coincide with the epitope found in this region in expressed proteins, the major epitope found in expressed proteins of ORF 2 was not detected in the search for linear B-cell epitopes (44). Similarly, epitope mapping of ORFs 2 and 3 with longer synthesized peptides in standard ELISA tests confirmed some, but not all, of the results obtained with the Geysen pin method, suggesting that conformational epitopes are important in the immune response to HEV (47,60). In total, as many as 26 antigenic epitopes distributed among six antigenic domains have been reported to exist in the ORF2 gene product (47). However, only one neutralization epitope has been identified. It has been mapped approximately to amino acids 575 to 610 of this 660-amino-acid protein (86a).

Diagnostic tests based on synthetic peptides have been developed (66). Antigens derived from ORF 2 and expressed in *Escherichia coli* or insect cells have also been used for detection of anti-HEV by Western blot and ELISA (60,66). Western blot assays, although apparently specific, have been somewhat less sensitive than ELISA for detecting anti-HEV in some, but not all, studies. The entire ORF 2 has been expressed in insect cells (37,98), and at least a part of the expressed antigen spontaneously forms virus-like particles (61,98). In an extensive comparison of 12 different assays for IgG antibody to HEV, truncated proteins (approximately 56 kd) expressed from ORF 2 in insect cells were superior to proteins expressed in *E. coli* for detecting anti-HEV (66). Proteins expressed from ORF 3 were less sensitive for detecting anti-HEV. Peptides, whether expressed from ORF 2 or ORF 3, were the least useful in serologic tests (66). HEV antigens derived from ORFs 2 and 3 and expressed in *E. coli* have been incorporated into assays that are commercially available in Europe and Asia (24,62). These assays are useful for diagnosing hepatitis E, but they have failed to detect infections with some recently discovered genetic variants of HEV (85) and they are not sufficiently sensitive for seroepidemiologic studies (66).

Serologic Heterogeneity

Although moderate genetic heterogeneity has been identified among HEV strains (see earlier), evidence for serologic heterogeneity is limited and has been detected primarily with expressed antigens of ORF 3 (46,47,108). Cross-challenge experiments with the most diverse HEV strains in primates have demonstrated cross-protection following infection (14,90,98). Thus, all HEV strains studied to date appear to belong to a single serotype.

Infection in Experimental Animals, and Host Range

Various species of primates have been the animals of choice for transmission studies of HEV. Primates found to be susceptible to infection with HEV include Old World species such as chimpanzees, macaques (cynomolgus, rhesus, and pigtail monkeys), and African green monkeys; and New World species such as tamarins, owl monkeys, and squirrel monkeys (13,90,98). The most useful of these have been cynomolgus and rhesus macaques. The host range of HEV may be influenced by strain differences: chimpanzees and tamarins have yielded discrepant results in different laboratories (13,98). Hepatitis E has been transmitted to primates by the intravenous and oral routes, but the latter is less sensitive (36,100).

The course of infection in experimentally infected primates is similar to that in man (Fig. 4). The incubation period to peak serum levels of liver enzymes is generally 3 to 8 weeks, but shorter and longer incubation periods have been observed (13,92,98,102). Enzyme elevations are usually unimodal, but bimodal curves have also been observed (7,13,92,95,98,102). Peak viremia and peak shedding of HEV into the feces occurs during the incubation period and early acute phase of disease (9,14,63,95). Detection of HEV antigens in the liver generally precedes or parallels viremia and fecal shedding (57,63). Histopathologic changes in the liver parallel biochemical evidence of hepatitis, with resolution in all cases. As in hepatitis A, the immune response to hepatitis E in primates appears late in the incubation period or during the acute phase of illness and is characterized by a brisk IgM and IgG anti-HEV response. Also as seen in hepatitis A, viremia may persist for some time after the appearance of serum antibodies, suggesting the presence of immune complexes (96). Naturally acquired anti-HEV has been detected in wild-caught cynomolgus monkeys (7) and wild-caught (5) and captive rhesus monkeys (99); such animals are generally resistant to experimental infection with HEV (99).

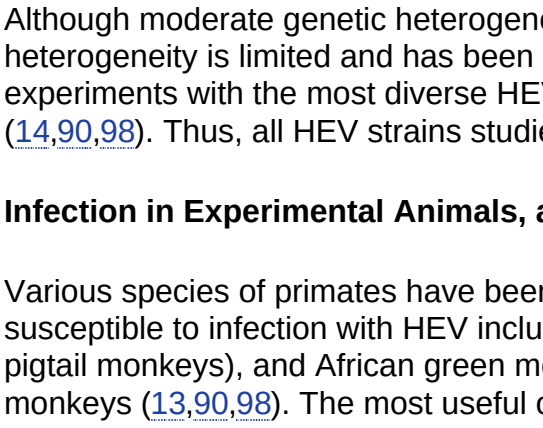

FIG. 4. Diagrammatic illustration of the clinical and serologic events in a typical case of acute hepatitis E. Antibody pattern is depicted as measured by ELISA. Viremia and fecal shedding patterns are based on PCR data. (Modified from ref. 78, with permission.)

Several other species of animals have been reported to be susceptible to infection with HEV or agents serologically

related to HEV. These include swine (10,70,75,104), sheep (103), rats (43,64), and mice (43). This has been established by the direct isolation of HEV from swine (70) and the transmission of HEV strains derived from humans to swine (69), lambs (103), and rats (64). In addition, anti-HEV has been detected in a high percentage of swine tested in many countries throughout the world, including the United States (21,68,70), in 70% to 80% of wild rats in the United States (41), and in varying percentages of other species of wild and domestic animals worldwide. An HEV-like agent has been recovered from cases of “big liver and spleen disease” of chickens, but its exact relationship to other HEV strains remains to be determined (74a). The role of animals as a reservoir of HEV for infection of humans is currently a subject of debate.

Stages of Replication

Because evidence for propagation of HEV in cell culture is quite limited (38,45,88), and because HEV is not closely related to any other well-characterized virus, little is known about its strategy for replication. The mechanism of attachment, entry, and uncoating of HEV is unknown, but it is assumed that the virus attaches to receptor sites on hepatocytes and possibly cells in the biliary tract and intestine. After uncoating, the 7.5-kb genome is probably translated via cellular mechanisms that recognize capped RNA. Cleavage of translated ORF 1 is probably achieved by cellular proteases. The motif of a papain-like protease has been detected in the sequence of ORF 1 (55), but it is not known whether it is functional. Replicative intermediate negative-strand RNA is probably synthesized by the viral polymerase, as are subsequent strands of positive-sense full-length (genomic and messenger) RNA, as well as at least two other messenger RNAs, a 3.7-kb subgenomic one and a 2.0-kb coterminal one (87).

Nothing is known about assembly and transport. The gene products of both ORF 2 and ORF 3 contain hydrophobic, signal-like sequences at their 5' ends (82), but it is not known whether they have a function. Nothing is known about release of the virus from infected cells.

PATHOGENESIS AND PATHOLOGY

The pathogenesis of hepatitis E is poorly understood. However, some speculative conclusions can be drawn from an analysis of the clinical and serologic events of a typical HEV infection (Fig. 4). Entry of the virus into the host is believed to be primarily by the oral route. The site of primary replication has not been identified, but it is presumed to be in the intestinal tract. It is not clear how the virus reaches the liver, but it is presumably via the portal vein. It replicates in the cytoplasm of hepatocytes (57) and is released into the bile and blood by mechanisms that are not understood. Based on limited studies of oral infection in a volunteer, viremia was first detected by RT-PCR 22 days after exposure and over a week before onset of disease on day 30 (20). Virus-like particles were found by IEM in the feces by 34 days after exposure. Liver enzyme values peaked on day 46. Anti-HEV was first detected on day 41 and was still detectable 2 years later. Similarly, in another, earlier volunteer study, HEV was detected in feces by IEM on day 28, and liver enzyme levels peaked on approximately day 42 (9). The individual volunteers in each of these studies recovered completely. Protracted viremia of 45 to 115 days has been reported in a small number of naturally infected patients (22,73).

As in hepatitis A, specific IgM and IgG immune responses occur early in the disease, usually by the time of onset of clinical illness. IgM anti-HEV disappears after several months; IgG anti-HEV persists, but at relatively rapidly decreasing levels shortly after infection (15). Anti-HEV can be detected for as long as 14 years after infection (52). It is not known whether such antibody eventually disappears or remains at low but detectable levels. Anti-HEV of the IgA class has also been detected in the serum of naturally infected individuals (19). The significance of such antibody is unknown.

Virus found in the feces of infected humans or animals is presumed to be the primary source of infectious virus in the environment. Because large quantities of HEV have been found in the bile of experimentally infected primates, it is assumed that the bulk of the virus in the intestinal tract originates in the liver (83). In this respect, hepatitis E is similar to hepatitis A.

The severity of HEV infections is, on average, somewhat greater than the severity of HAV infections. Mortality of hepatitis E has varied in different reports but has been as high as 1%, compared to 0.2% for hepatitis A (78). More important, however, is the severity of hepatitis E in pregnant women (1,8,16,48,79). The mortality of hepatitis E in pregnancy increases with each succeeding trimester and may reach 20%. In contrast, none of the other four recognized hepatitis viruses causes such severe hepatitis in pregnancy (71). The reason for the excessive mortality of hepatitis E in pregnancy is unknown. Fulminant NANB hepatitis occurring in nonendemic areas appears not to be caused by HEV (58).

Certain histologic changes in the liver of patients with hepatitis E are thought by some to be characteristic (81). The changes include focal necrosis with minimal infiltration and no localization to a particular zone of the lobule. Modest inflammation consisting predominantly of Kupffer cells and polymorphonuclear leukocytes is seen, and the focal lesions resemble drug-associated toxic hepatitis. Cholestatic hepatitis is often present, characterized by ballooning hepatocytes, cytoplasmic cholestasis, and focal cytolytic necrosis. An unusual “pseudoglandular” alteration of the hepatocyte plates has also been recognized in some epidemics and sporadic cases. The discrepancy between the time of appearance of viral replication in the liver and histopathologic and biochemical evidence of hepatitis suggests that HEV is not cytopathic and that the pathogenesis of hepatitis E is immunologically mediated, but there is no direct evidence for or against this hypothesis. It is not known whether HEV causes other sequelae or extrahepatic manifestations of infection. None has been recognized, except for excess fetal wastage, which has been reported in some (86,101), but not all (53), studies of pregnant females with fulminant hepatitis E. Premature deliveries with a high infant mortality (33%) have also been reported (86).

CLINICAL FEATURES AND COURSE

Individual cases of hepatitis E cannot be differentiated from other cases of hepatitis on the basis of clinical presentation (32,79). In fact, clinical features are of limited usefulness in the diagnosis of acute hepatitis caused by any of the recognized viruses (78). Sensitive serologic tests have revealed that not all HEV infections are clinically apparent (15).

However, in epidemics, the majority of patients will experience jaundice, anorexia, and hepatomegaly. Approximately half of the patients will experience abdominal pain and tenderness, nausea and vomiting, and fever. Like hepatitis A, hepatitis E never progresses to chronicity. However, persistence of IgM anti-HEV for at least 21 months was reported in one case (59). Recurrent (bimodal) hepatitis A is not uncommon, but comparable recurrence of hepatitis E has not been reported except in experimental infections of primates (7).

DIAGNOSIS

Hepatitis E should be suspected in outbreaks of waterborne hepatitis occurring among citizens of developing countries, especially if the disease is more severe in pregnant women. In the United States and Europe, hepatitis E should be suspected in a patient with hepatitis who has recently returned from an endemic region. Rarely, hepatitis E will occur in an individual who has not traveled to an endemic region. As with all types of viral hepatitis, serologic tests are necessary to establish a definite diagnosis. Specific tests for IgM and IgG antibodies to HEV have been developed and are commercially available in Europe, Asia, and Canada. As there are no plans at present to market them in the United States, the diagnosis of hepatitis E remains an experimental procedure here. Current tests are capable of detecting IgM anti-HEV in up to 90% of acute infections if a serum sample is obtained 1 to 4 weeks after the onset of disease (Fig. 5) (15,27,33,72). IgM anti-HEV reaches peak titers of 1:1,000 to 1:10,000 during the first 4 weeks after the onset of hepatitis (3,15). By 3 months after the onset of disease, IgM anti-HEV is no longer detectable in 50% or more of patients with hepatitis E (3,72).

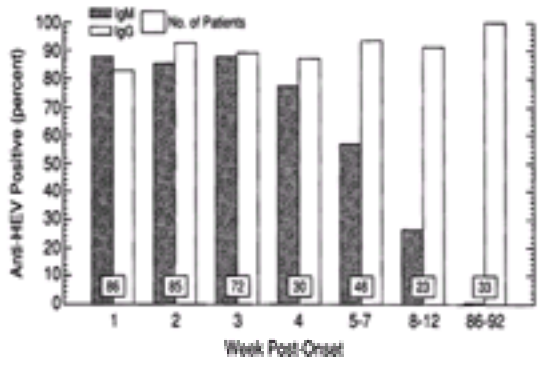

FIG. 5. Prevalence of IgM anti-HEV and IgG anti-HEV, as measured by ELISA, in patients with hepatitis E, by 1 week after onset of illness. (Data from refs. 3 and 15, with permission.)

A rising titer of IgG anti-HEV is also diagnostic. IgG anti-HEV peaks in titer (1:1,000 to 1:100,000) between 2 and 4 weeks after onset of hepatitis and diminishes relatively rapidly thereafter (3,15,24). It is not clear how long IgG anti-HEV persists at detectable levels: One study found that two thirds of pediatric patients became seronegative by 9 months after the onset of disease, whereas 100% of young adults were still positive 20 months after onset (15,33), and in another study, adults were still positive after 14 years (52). However, currently available serologic tests vary greatly in sensitivity and specificity (66).

IEM is an insensitive test that is positive in only approximately 10% of cases (91). Molecular approaches to diagnosis of hepatitis E have replaced IEM. RT-PCR is useful for detecting HEV in the blood and feces during the acute phase of infection. It has contributed to the identification of new genetic variants of HEV (69,85), but the sensitivity of the technique depends on a proper match between the HEV strain and the PCR primers (85). Because of this, serologic approaches to diagnosis remain the methods of choice.

TREATMENT

There is no specific treatment for hepatitis E. Aggressive management of fulminant hepatitis E may reduce the mortality of this complication in pregnant women (38a).

EPIDEMIOLOGY

Hepatitis with the clinical and epidemiologic characteristics of hepatitis E (peak clinical attack rate in young adults, high rate of fulminant disease in pregnancy, epidemics of waterborne disease) has been reported from Southeast and central Asia, the Middle East, northern and western Africa, and North America (Mexico). Epidemics in most of these regions have been confirmed serologically as hepatitis E, as has sporadic hepatitis occurring in many of the same regions (Fig. 6) (77). In fact, HEV is believed to be the most common cause of sporadic hepatitis in regions where the virus is endemic.

FIG. 6. Countries in which there is serologic confirmation or strong epidemiologic evidence of endemic and/or epidemic hepatitis E. (Modified from refs. 65 and 79, with permission.)

The age-specific clinical attack rate, with its peak among young adults, is striking (Fig. 7) (49,106,107). However, clinical disease has been found with similar frequency in all age groups in some epidemics (72), and clinical hepatitis E in children has also been reported (2,26,33,72). A male preponderance has been observed in some, but not all, epidemics. With the exception of several food-borne epidemics in China, all serologically confirmed epidemics of hepatitis E to date have been associated with fecally contaminated water. Cases of probable sporadic hepatitis E have been linked epidemiologically to consumption of raw or uncooked shellfish (17). The epidemiologic risk factors associated with most sporadic cases of hepatitis E have been difficult to identify. Person-to-person spread from cases to contacts has been reported, but this appears to be relatively uncommon (16,26). However, contact with a jaundiced person was reported in as many as 21% to 33% of sporadic HEV cases in three studies (32,50,51). Travel to an area where HEV is endemic has been a risk factor in a number of cases (18,29,32), and one hospital-related outbreak has been reported (84).

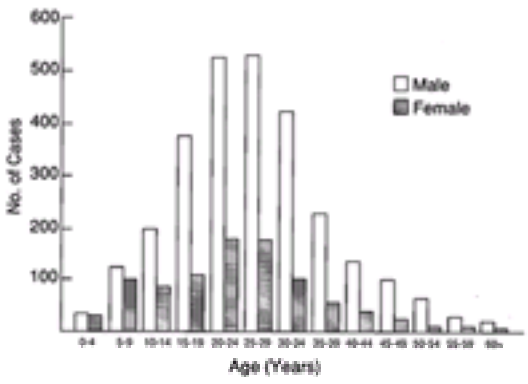

FIG. 7. The age-specific clinical attack rate of hepatitis in the large, waterborne epidemic of hepatitis that occurred in Delhi, India, in the winter of 1955 to 1956. [The epidemic was subsequently shown to be caused by hepatitis E virus (3).] (Data from ref. 106, with permission.)

The recent development of sensitive serologic tests for infection with HEV has permitted, for the first time, a more complete analysis of the worldwide distribution and seroprevalence of HEV infection. Surprisingly, with a few exceptions (28a), the prevalence of IgG antibody to HEV in suspected or documented endemic regions has been much lower than expected (3% to 26%), and the prevalence of such antibody in nonendemic regions has been much higher than anticipated (1% to >20%) (77). Except in epidemic settings (72) and a limited number of other instances (28a), the prevalence of anti-HEV in infants and children has also been quite low (6,59,62,72). The greatest increase in prevalence of anti-HEV appears to occur in young adults, the age group at highest risk of clinical disease (6,59,62). Above that age, the prevalence of anti-HEV has remained constant at 10% to 40%, with no difference between male and female prevalences (6,59,62). Although such a pattern of age-specific anti-HEV might suggest a cohort effect, signaling the disappearance of HEV from endemic regions similar to the disappearance of HAV from some regions previously (79), this appears not always to be the case: Virtually identical age-specific anti-HEV patterns were detected in the same population over a decade (6). Thus, in some settings, the epidemiologic characteristics of HEV appear to be quite different from those of most viruses, such as HAV, that are transmitted by the fecal–oral route (Fig. 8). The relatively rapid acquisition of antibody during adolescence and early adulthood is suggestive of a sexual component to the transmission of this virus, possibly through facilitation of the fecal–oral mechanism of transmission by intimate contact. However, there is no direct evidence for this at present. Interestingly, peak acquisition of anti-HEV in wild rat populations also occurs in juveniles and young adults (41).

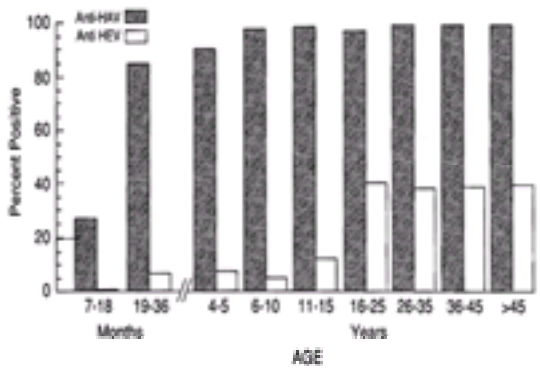

FIG. 8. The age-specific prevalences of antibody to hepatitis A virus and hepatitis E virus in a population of low socioeconomic status in Pune, India. Data were obtained by ELISA on sera collected in 1992. Virtually identical results were obtained with sera collected in 1982. Infection with hepatitis A virus occurred at an earlier age and in a higher proportion of the population than infection with hepatitis E virus. (Modified from ref. 6, with permission.)

The impact of HEV infections in various wild and domesticated animals on the epidemiology of hepatitis E in humans is the subject of much debate. The close genetic relationship between U.S. swine HEV strains and strains of HEV isolated from humans living in the same geographic regions suggests that some transmission from swine to humans may occur. This hypothesis is strengthened by the demonstration that swine and human HEV strains from the United States can infect both swine and chimpanzees (a surrogate of man) (69). In India, a similar association between waterborne hepatitis E epidemics and geographic proximity to wild rhesus monkeys (which appear to be naturally infected with HEV-like agents) has been suggested. An equally likely scenario is the zoonotic spread of HEV from wild rats to humans, as these animals can be found in close proximity to man worldwide. Until HEV strains recovered from rats can be fully characterized, this hypothesis cannot be tested.

The prevalence of anti-HEV in countries where hepatitis E is rarely, if ever, diagnosed is 10 times greater than the prevalence of antibody to hepatitis C virus in these same countries, where hepatitis C accounts for 10% to 20% or more of clinical hepatitides. This finding of anti-HEV in populations where clinical hepatitis E is rarely diagnosed suggests that subclinical infection, perhaps with attenuated or animal strains of HEV (zoonosis), occurs in these regions, or that currently available tests yield nonspecific results in some instances.

Molecular approaches to the epidemiology of HEV hold some promise. The relatively low titer of HEV in blood and feces limits the usefulness of hybridization without amplification. RT-PCR has been useful for confirming the results of serologic tests and for estimating the duration of infectivity of individual cases (20). RT-PCR has been used to detect HEV in contaminated water (40). However, it is much less sensitive than serologic tests for diagnosis of acute hepatitis E and of limited value for molecular-epidemiologic studies because of the relatively short duration of viremia and fecal shedding. Its main value in this regard has been the identification of HEV genotypes and their relationship to specific epidemics and geographic locations.

PREVENTION AND CONTROL

Interdiction

Improved personal and public hygiene has resulted in a marked reduction in the incidence of hepatitis A virus infections. It is assumed that such changes have had a similar, and probably earlier, effect on the incidence of hepatitis E (79). Indeed, hepatitis occurring in Europe prior to the 20th century, and believed then to have been hepatitis A, had the epidemiologic characteristics of hepatitis E (23). Thus, HEV, reportedly more labile and shed in lower titers than HAV, may have disappeared from more industrialized countries in the recent past, just as HAV is currently diminishing in importance in these countries. However, regions where HAV is still highly endemic may also harbor endemic HEV (6,59) (Fig. 8). Finally, the high prevalence of anti-HEV in domestic and wild animals, even in industrialized countries, suggests that possible zoonotic spread of HEV may continue in such regions, despite improved sanitation (5,41,68).

Immunoprophylaxis

Attempts to prevent or modify hepatitis E by the administration of normal immune globulin manufactured from source plasma obtained in the areas where HEV is endemic have been unsuccessful (16,39,50,105) or uncertain (89). Because most of these studies were performed before the development of sensitive and quantitative tests for anti-HEV, the lots of globulin employed were not tested for the presence or titer of anti-HEV. Because even populations in regions where HEV is endemic have a relatively low prevalence and titer of anti-HEV (see preceding), it is perhaps not surprising that unselected lots of normal immune globulin may not contain protective quantities of anti-HEV. Preliminary experimental studies in primates suggest that passively acquired anti-HEV does modify but does not prevent HEV infection (96). Hepatitis E immune globulin, prepared from plasma donors with high titers of anti-HEV or from neutralizing monoclonal antibodies to HEV (86a), may be useful for preventing hepatitis E during epidemics in the future.

There are at present no commercially available vaccines for the prevention of hepatitis E. However, candidate recombinant hepatitis E vaccines, expressed from ORF 2 in *E. coli* (80) or in insect cells (31,96,97), have protected against hepatitis E in nonhuman primates. One such vaccine is currently in clinical trials (97). It was safe and immunogenic in volunteers and is being tested for efficacy in Nepal, which has annual epidemics of waterborne hepatitis E.

CHAPTER 90 Prions

Stanley B. Prusiner

Prions are infectious proteins that cause fatal neurodegeneration in humans and animals (156). The prion diseases, also referred to as the transmissible spongiform encephalopathies, are uniquely manifest as sporadic, genetic, and infectious illnesses. The only known component of the prion is a protein designated PrP ^{Sc}. The prion protein (PrP) gene found on the short arm of chromosome 20 of humans encodes a protein of 253 amino acids termed PrP ^{C}. Both PrP^{C} and PrP^{Sc} have the same covalent structure, but through a poorly understood process, PrP ^{C} is refolded into PrP ^{Sc}. The accumulation of PrP^{Sc} in the central nervous system (CNS) causes neurologic disease, and the refolding of PrP ^{C} is stimulated by the product of the reaction PrP ^{Sc}.

For many years, investigators classified scrapie, the prototypic prion disease of sheep, as a slow viral illness. Many aspects of scrapie in sheep and goats mimic viral diseases (Table 1). The term *slow viruses* was introduced by Bjorn Sigurdsson in 1954 to characterize the sheep diseases called visna and scrapie (184). He suggested that the long latency periods between inoculation and the onset of disease was a special feature of slow- or delayed-acting viruses. Eventually, the visna agent was shown to be a lentivirus, the same family to which the human immunodeficiency virus (HIV) belongs.

Scrapie is a transmissible disease.
Infectious pathogen is small and filterable.
Accumulation of the scrapie pathogen causes disease.
Distinct strains of the scrapie agent cause different patterns of disease, as measured by the length of the incubation time and the neuropathologic lesion profile.

TABLE 1. *Features of scrapie suggesting that it might be caused by a virus*

As early as 1967, several experimental findings by Tikvah Alper and her colleagues suggested that the infectious pathogen causing scrapie might be unusual (1,2). Most notable were the results of radiation inactivation studies suggesting that the scrapie might not contain a nucleic acid and that the infectious particle might be extremely small. On

one hand, those conclusions were vigorously challenged (165,166,167 and 168), and on the other, they prompted a myriad of hypotheses (Table 2). The most prescient of these speculations were those suggesting that the scrapie agent might be a protein. I. Pattison (143) proposed that the scrapie agent was a basic protein, and J. S. Griffith (72) published three hypotheses: that it was (a) a protein that induces its own gene transcription, (b) an antibody-like molecule stimulating more of itself, and (c) a protein that acquires a disease-inducing conformation. Although the first two hypotheses proved to be incorrect, the last resembles what was eventually discovered. Interestingly, the conformational proposal violated considerable data arguing that each protein has only one biologically active conformation (5,6).

Sarcosporida-like parasite
"Filterable" virus
Small DNA virus
Replicating protein
Replicating abnormal polysaccharide with membrane
DNA subvirus controlled by a transmissible linkage substance
Provirus consisting of recessive genes generating RNA particles
Naked nucleic acid similar to plant viroids
Unconventional virus
Aggregated conventional virus with unusual properties
Replicating polysaccharide
Nucleoprotein complex
Nucleic acid surrounded by a polysaccharide coat
Spiroplasma-like microorganism
Multicomponent system with one component quite small
Membrane-bound DNA
Virino (virus-like DNA complexed with host proteins)
Filamentous animal virus [scrapie-associated fibrils (SAF)]
Aluminum-silicate amyloid complex
Amyloid-inducing virus
Complex of apo- and co-prions (unified theory)
Nemavirus (SAF surrounded by DNA)
Retrovirus
Soil bacterium

TABLE 2. *Hypothetical structures proposed for the scrapie agent*

The tortuous path of the scientific investigation that led to an understanding of familial Creutzfeldt-Jakob disease (CJD) chronicles a remarkable scientific odyssey. By 1930, the high incidence of familial (f) CJD in some families was known (127,189). Almost 60 years were to pass before the significance of this finding could be appreciated (84,120,152). CJD remained a curious, rare neurodegenerative disease of unknown etiology throughout this period of threescore years (102). Only with the transmission of disease to apes after inoculation of brain extracts prepared from patients who died of CJD did the story begin to unfold (67).

Once CJD was shown to be an infectious disease, relatively little attention was paid to the familial form of the disease, as most cases were not found in families. It is interesting to speculate how the course of scientific investigation might have proceeded had transmission studies not been performed until after the molecular genetic lesion had been identified. Had that sequence of events transpired, then the prion concept, which readily explains how a single disease can have a genetic or infectious etiology, might have been greeted with much less skepticism (154).

Epidemiologic studies designed to identify the source of the CJD infection were unable to identify any predisposing risk factors, although some geographic clusters were found (19,45,74,117). Libyan Jews living in Israel developed CJD about 30 times more frequently than other Israelis (94). This finding prompted some investigators to propose that the Libyan Jews had contracted CJD by eating lightly cooked brain from scrapie-infected sheep when they lived in Tripoli prior to emigration. Subsequently, the Libyan Jewish patients were all found to carry a mutation at codon 200 in their PrP gene (61,70,85).

Although the brains of patients appear grossly normal upon postmortem examination, they usually show spongiform degeneration and astrocytic gliosis under the light microscope (Fig. 1). In all cases of Gerstmann-Sträussler-Scheinker disease (GSS) and variant (v) CJD, PrP amyloid plaques are found (213). Before PrP immunostaining was available, histochemical staining was used to examine brains from patients with kuru, and 70% of cases were thought to have amyloid plaques (103). The presence or absence of PrP amyloid plaques in sporadic and inherited CJD is quite variable (50).

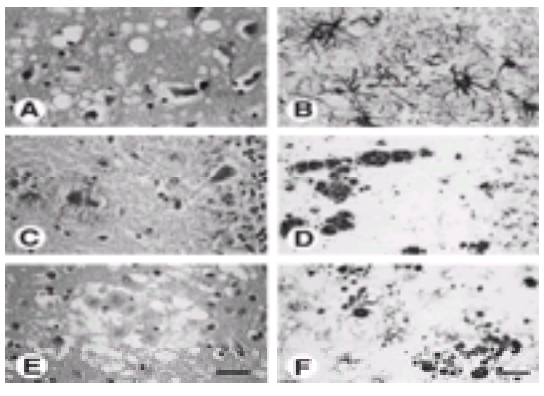

FIG. 1. Neuropathology of human prion diseases. Sporadic Creutzfeldt-Jakob disease (CJD) is characterized by vacuolation of the neuropil of the gray matter, by exuberant reactive astrocytic gliosis, the intensity of which is proportional to the degree of nerve cell loss, and rarely by PrP amyloid plaque formation (not shown). The neuropathology of familial CJD is similar. GSS(P102L), as well as other inherited forms of Gerstmann-Sträussler-Scheinker disease (GSS) (not shown), is characterized by numerous deposits of PrP amyloid throughout the CNS. New variant CJD (nvCJD) has clinical and epidemiologic features that suggest it was acquired by infection with prions. The neuropathologic features of nvCJD are unique among CJD cases because of the abundance of PrP amyloid plaques that are often surrounded by a halo of intense vacuolation. **A:** Sporadic CJD. Cerebral cortex demonstrates widespread spongiform degeneration (H&E). **B:** Sporadic CJD. Cerebral cortex immunostained with anti-GFAP (glial fibrillary acidic protein) antibodies demonstrates the widespread reactive gliosis. **C:** GSS. Cerebellum with most of the GSS plaques in the molecular layer (left 80% of micrograph); many but not all are periodic acid Schiff

(PAS)–reaction positive. Granule cells and a single Purkinje cell are seen in the right 20% of the panel. **D:** GSS. Cerebellum at the same location as (C). PrP immunohistochemistry after hydrolytic autoclaving reveals more PrP plaques than seen with the PAS reaction. **E:** Variant CJD. Cerebral cortex, showing the plaque deposits uniquely located within vacuoles (H&E). With this histology, these amyloid deposits have been referred to as florid plaques. **F:** Variant CJD. Cerebral cortex stained with PrP immunohistochemistry after hydrolytic autoclaving reveals numerous PrP plaques, often occurring in clusters as well as minute PrP deposits surrounding many cortical neurons and their proximal processes. *Bar* in (E) = 50 μm, and scale applies also to (A), (B), and (C). *Bar* in F = 100 μm, and scale applies also to (D). (Photomicrographs prepared by Stephen DeArmond.)

Human prion disease should be considered in any patient who develops a progressive subacute or chronic decline in cognitive or motor function. Typically, adults between 40 and 80 years of age are affected (169). The young age of more than 100 people who have died of vCJD in Britain and France has raised the possibility that these individuals were infected with bovine prions that contaminated beef products (34,46,213). Over 100 young adults have also been diagnosed with iatrogenic CJD from 4 to 30 years after receiving human growth hormone (HGH) or gonadotrophin derived from cadaveric pituitaries (105,148). The longest incubation periods (20 to 30 years) are similar to those associated with more recent cases of kuru (65,104).

In scrapie, kuru, CJD, and all the other disorders now referred to as prion diseases (Table 3), spongiform degeneration and astrocytic gliosis are found on microscopic examination of the CNS (215). The degree of spongiform degeneration is quite variable, whereas the extent of reactive gliosis correlates with the degree of neuron loss (121).

Disease	Host	Mechanism of pathogenesis
A. Kuru	Fore people	Infection through ritualistic cannibalism
iCJD	Humans	Infection from prion-contaminated HGH, dura mater grafts, etc.
vCJD	Humans	Infections from bovine prions?
fCJD	Humans	Germline mutations in PrP gene
GSS	Humans	Germline mutations in PrP gene
FFI	Humans	Germline mutation in PrP gene (D178N, M129)
sCJD	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
sFI	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
B. Scrapie	Sheep	Infection in genetically susceptible sheep
BSE	Cattle	Infection with prion-contaminated MBM
TME	Mink	Infection with prions from sheep or cattle
CWD	Mule deer, elk	Unknown
FSE	Cats	Infection with prion-contaminated beef
Exotic ungulate encephalopathy	Greater kudu, nyala, oryx	Infection with prion-contaminated MBM

BSE, bovine spongiform encephalopathy; CJD, Creutzfeldt-Jakob disease; sCJD, sporadic CJD; fCJD, familial CJD; iCJD, iatrogenic CJD; vCJD, (new) variant CJD; CWD, chronic wasting disease; FFI, fatal familial insomnia; FSE, feline spongiform encephalopathy; sFI, sporadic fatal insomnia; GSS, Gerstmann-Sträussler-Scheinker disease; HGH, human growth hormone; MBM, meat and bone meal; TME, transmissible mink encephalopathy

TABLE 3. *The prion diseases*

THE PRION PARTICLE

Perhaps the best current working definition of a prion is that it is a proteinaceous infectious particle that lacks nucleic acid (155). A wealth of data supports the contention that scrapie prions are devoid of nucleic acid and seem to be composed exclusively of a modified isoform of PrP, designated PrP^{Sc}. The normal cellular PrP, denoted PrP^{C}, is converted into PrP^{Sc} through a process whereby a portion of its a-helical and coil structure is refolded into b-sheet (139). This structural transition is accompanied by profound changes in the physicochemical properties of the PrP. Whereas PrP^{C} is soluble in nondenaturing detergents, PrP^{Sc} is not. PrP^{C} is readily digested by proteases, whereas PrP^{Sc} is partially resistant (137). Because prions appear to be composed entirely of a protein that adopts an abnormal conformation, it is not unreasonable to think of prions as infectious proteins (139,198). But we hasten to add that we still cannot eliminate the possibility of a small ligand bound to PrP^{Sc} as an essential component of the infectious prion particle.

In a broader view, prions are elements that impart and propagate variability through multiple conformers of a normal cellular protein. The species of a particular prion is encoded by the sequence of the chromosomal PrP gene of the mammal in which it last replicated. In contrast to pathogens with a nucleic acid genome that encode strain-specific properties in genes, prions seem to encipher these properties in the tertiary structure of PrP^{Sc} (12,155,198).

The discovery that mutations of the PrP gene caused dominantly inherited prion diseases in humans linked the genetic and infectious forms of prion diseases and presented another hurdle for investigators who continued to argue that prion diseases are caused by viruses. More than 20 mutations of the PrP gene are now known to cause the inherited human prion diseases, and significant genetic linkage has been established for five of these mutations (84, and reviewed in ref. 155). The prion concept readily explains how a disease can manifest as a heritable as well as an infectious illness. Moreover, the hallmark common to all of the prion diseases, whether sporadic, dominantly inherited, or acquired by infection, is that they involve the aberrant metabolism of the PrP (153).

Although PrP^{Sc} is the only known component of the infectious prion particles, these unique pathogens share several phenotypic traits with other infectious entities such as viruses. Because some features of the diseases caused by prions and viruses are similar, some scientists have difficulty accepting the existence of prions despite a wealth of scientific data supporting this concept (37,38,112,119).

MOLECULAR GENETICS OF PRION DISEASES

Once a PrP cDNA probe became available, molecular genetic studies were undertaken to determine whether the PrP gene controls scrapie incubation times in mice. Independent of the enriching of brain fractions for scrapie infectivity that led to the discovery of PrP^{Sc}, the PrP gene was shown to be genetically linked to a locus controlling the incubation time (28). Subsequently, mutation of the PrP gene was shown to be genetically linked to the development of familial prion disease (84). At the same time, expression of a Syrian hamster (SHa) PrP transgene in mice was shown to render the animals highly susceptible to SHa prions, which demonstrated that expression of a foreign PrP gene could abrogate the species barrier (176). Later, PrP-deficient (*Prnp*$^{0/0}$) mice were found to be resistant to prion infection and failed to replicate prions, as expected (23,157). The results of these studies indicated that PrP must play a central role in the transmission and pathogenesis of prion disease, but equally important, they established that the abnormal isoform is an essential component of the prion particle (153).

PrP Gene Dosage Controls Length of Incubation Time

Scrapie incubation times in mice were used to distinguish prion strains and to identify a gene controlling incubation length (53,177). This gene was initially called *Sinc*, based on genetic crosses between C57Bl and VM mice that exhibited short and long incubation times, respectively (53). Because the distribution of VM mice was restricted, we searched for another mouse with long incubation times. I/Ln mice proved to be a suitable substitute for VM mice; eventually, I/Ln and VM mice were found to be derived from a common ancestor. Subsequently, the PrP gene was shown to control the length of the scrapie incubation time in mice (27,131).

Overexpression of wt PrP Transgenes

Mice were constructed expressing different levels of the wild-type (wt) SHaPrP transgene (Tg) (176). Inoculation of these Tg(SHaPrP) mice with SHa prions demonstrated abrogation of the species barrier, resulting in abbreviated incubation times as a result of a nonstochastic process (159). The length of the incubation time after inoculation with SHa prions was inversely proportional to the level of $SHaPrP^{C}$ in the brains of Tg(SHaPrP) mice (159). Bioassays of brain extracts from clinically ill Tg(SHaPrP) mice inoculated with mouse (Mo) prions revealed that only Mo prions but no SHa prions were produced. Conversely, inoculation of Tg(SHaPrP) mice with SHa prions led only to the synthesis of SHa prions. Thus, the rate of PrP^{Sc} synthesis appears to be a function of the level of PrP^{C} expression in Tg mice; however, the level to which PrP^{Sc} accumulates appears to be independent of PrP^{C} concentration (159).

PrP-Deficient Mice

The development and life span of two lines of *Prnp*$^{0/0}$ mice denoted Zrch and Npu were indistinguishable from controls (24,118), whereas another line (Ngsk) exhibited ataxia and Purkinje cell degeneration at about 70 weeks of age (172). In the former two lines, with normal development, altered sleep–wake cycles (201) and synaptic behavior in brain slices have been reported (44), but the synaptic changes could not be confirmed by others (78,116). The lack of severe defects in these two lines of *Prnp*$^{0/0}$ mice were ascribed to adaptation, because PrP was absent throughout embryogenesis. However, bigenic mice expressing inducible PrP transgenes that were rendered PrP deficient as adults by the administration of doxycycline have remained healthy for more than 1.5 years (202). This argues against the adaptation hypothesis and raises the likelihood of surrogate proteins with functions overlapping that of PrP^{C}.

Prnp$^{0/0}$ mice are resistant to prions (23,157). *Prnp*$^{0/0}$ mice were sacrificed 5, 60, 120, and 315 days after inoculation with Rocky Mountain Laboratory (RML) prions, and brain extracts were bioassayed in CD-1 Swiss mice (Table 4). Except for residual infectivity from the inoculum detected at 5 days after inoculation, no infectivity was detected in the brains of the *Prnp*$^{0/0}$ mice (157). One group of investigators found that *Prnp*$^{0/0}$ mice inoculated with RML prions and sacrificed 20 weeks later had $10^{3.6}$ ID_{50} units/mL of homogenate by bioassay (23). Others have used this report to argue that prion infectivity replicates in the absence of PrP (38,112). Neither we nor the authors of the initial report could confirm the finding of prion replication in *Prnp*$^{0/0}$ mice (157,171).

Mouse	Time of sacrifice after inoculation with RML scrapie prions				
	5 days	60 days	120 days	315 days	522 days
	Log scrapie prion titers (ID_{50} units/mL ± SE)[a]				
Prnp$^{+/+}$	<1	3.9 ± 0.4	6.4 ± 0.3		
	<1	4.8 ± 0.3	7.1 ± 0.1		
	<1	4.6 ± 0.2	6.8 ± 0.2		
Prnp$^{+/0}$	<1	<1	5.1 ± 0.2		
	0.6 ± 0.7	<1	5.2 ± 0.6		
	1.2 ± 0.1[b]	3.4 ± 0.2	2.8 ± 0.1		
Prnp$^{0/0}$	<1[c]	<1	<1	<1	<1
	<1[d]	<1	<1	<1	<1
		<1			<1
					<1

[a]Titers are for 10% (wt/v) brain homogenates. Log titers of <1 reflect no signs of CNS dysfunction in CD-1 mice for >250 days after inoculation, except as noted.
[b]2/9 mice developed scrapie between 206 and 210 days after inoculation.
[c]2/9 mice developed scrapie between 206 and 225 days after inoculation.
[d]1/10 mice developed scrapie between 208 and 225 days after inoculation.

Doppel Up-regulation in *Prnp*$^{0/0}$ Mice

Since a common approach to determining the function of a gene is the analysis of related genes, we searched for PrP-related genes by hybridization; however, these studies were uninformative (208). Vertebrate genomes contain a number of protein families sharing sequence homology and showing overlapping function (77), and because a number of them have been shown to be organized in clusters, we undertook sequencing of large cosmid clones containing the PrP

gene (113). Studies of regions flanking the human, sheep, and mouse PrP genes in cosmid clones failed to reveal additional open reading frames (ORFs) (113). Only when the sequencing of a cosmid clone isolated from a *Prnp*$^{b/b}$ mouse (I/LnJ-4) was extended downstream of PrP was a novel PrP-like gene found.

The locus *Prnd* is 16-kb downstream of the PrP gene, *Prnp*, and it encodes a 179-residue PrP-like protein designated doppel (Dpl) (132). *Prnd* generates major transcripts of 1.7 and 2.7 kb, as well as some unusual chimeric transcripts generated by intergenic splicing with *Prnp.* Like PrP, Dpl mRNA is expressed during embryogenesis, but in contrast to PrP, it is expressed minimally in the CNS. Unexpectedly, Dpl is up-regulated in the CNS of two *Prnp*$^{0/0}$ lines of mice (Ngsk and Rcm0), both of which develop a late-onset ataxia, raising the possibility that Dpl may provoke neurodegeneration (130,172). It has been suggested that PrP may have a role in the long-term survival of Purkinje neurons; however, it was puzzling that Ngsk and Rcm0 *Prnp*$^{0/0}$ mice should develop a fatal ataxia, whereas two other lines (Zrch and Npu) of *Prnp*$^{0/0}$ mice did not exhibit CNS dysfunction. In an effort to determine the role of PrP in this phenotype, Ngsk *Prnp*$^{0/0}$ mice were crossed with transgenic (Tg) mice overexpressing wild-type mouse PrP. This rescued the phenotype in Ngsk *Prnp*$^{0/0}$ offspring expressing PrP (135).

Our findings suggest that Dpl may provoke neurodegeneration in PrP-deficient mice—an observation that may explain why some lines of *Prnp*$^{0/0}$ mice develop cerebellar dysfunction and Purkinje cell death while others do not. The homology between Dpl and PrP suggests that these two proteins may share some biologic properties, and as such, Dpl may open new avenues of investigation in prion biology.

Our findings suggesting that Dpl may provoke degeneration in Purkinje cells force a reevaluation of Tg mice generated using the I/LnJ-4 cosmid. One explanation for spontaneous neurodegeneration reported in Tg(MoPrP-B) mice with high copy-number arrays of the I/LnJ-4 cosmid transgene is the overexpression of *Prnd* (206). In the case of the Tg(MoPrP,P101L) mice constructed with the I/LnJ-4 cosmid transgene (86,87), *Prnd* overexpression is an unlikely explanation, because similar results were obtained with Tg(MoPrP,P101L) mice constructed using the SHa Cos. Tet vector, which does not contain the *Prnd* gene (178,197,200).

Whether cerebellar degeneration in Zrch *Prnp*$^{0/0}$ mice expressing N-terminally truncated PrP transgenes is explained by Dpl overexpression remains to be established. The expression of N-terminally truncated PrPs carrying either codon 32–121 or 32–134 deletions caused degeneration of granule cells in the cerebellum of neonates, but the smaller 32–106 deletion did not (183). Interestingly, this granule cell dysfunction was mitigated by expression of wild-type MoPrP ^{C}. One interpretation of these studies is that PrP carrying either the 32–121 or 32–134 deletion assumes a Dpl-like conformation that is neurotoxic and results in the killing of granule cells because the transgene construct used in those Tg mice is expressed in granule cells but not Purkinje cells (57).

Dpl is the first PrP-like protein to be described in mammals, and because Dpl seems to be similar to PrP in causing neurodegeneration, the linked expression of the *Prnp* and *Prnd* genes may play a previously unrecognized role in the pathogenesis of prion diseases or other illnesses.

PRION PROTEIN STRUCTURE

Once cDNA probes for PrP became available, the PrP gene was found to be constitutively expressed in adult, uninfected brain (39,137). This finding eliminated the possibility that PrP ^{Sc} stimulated production of more of itself by initiating transcription of the PrP gene, as proposed nearly two decades earlier (72). Determination of the structure of the PrP gene eliminated a second possible mechanism that might explain the appearance of PrP ^{Sc} in brains already synthesizing PrP^{C}. As the entire protein coding region was contained within a single exon, there was no possibility that the two PrP isoforms were the products of alternatively spliced mRNAs (8). Next, a posttranslational chemical modification that distinguishes PrP ^{Sc} from PrP^{C} was considered but none was found in an exhaustive study (187), and we considered it likely that PrP^{C} and PrP^{Sc} differed only in their conformations, a hypothesis also proposed earlier (72).

When the secondary structures of the PrP isoforms were compared by optical spectroscopy, they were found to be markedly different (139). Fourier transform infrared (FTIR) and circular dichroism (CD) spectroscopy studies showed that PrP^{C} contains about 40% a-helix and little b-sheet, whereas PrP ^{Sc} is composed of about 30% a-helix and 45% b-sheet (139). That the two PrP isoforms have the same amino acid sequence runs counter to the widely accepted view that the amino acid sequence specifies only one biologically active conformation of a protein (5).

Prior to comparative studies on the structures of PrP ^{C} and PrP^{Sc}, metabolic labeling studies showed that the acquisition of PrP^{Sc} protease resistance is a posttranslational process (15). In a search for chemical differences that would distinguish PrP ^{Sc} from PrP^{C}, we identified ethanolamine in hydrolysates of PrP 27–30, which signalled the possibility that PrP might contain a glycosylphosphatidyl inositol (GPI) anchor (188). Both PrP isoforms were found to carry GPI anchors, and PrP^{C} was found on the surface of cells where it could be released by cleavage of the anchor. Subsequent studies showed that PrP^{Sc} formation occurs after PrP^{C} reaches the cell surface (31) and is localized to caveolae-like domains (71,195).

Computational Models and Optical Spectroscopy

Modeling studies and subsequent nuclear magnetic resonance (NMR) investigations of a synthetic PrP peptide containing residues 90 to 145 suggested that PrP ^{C} might contain an a-helix within this region (Fig. 2) (88). This peptide contains the residues 113 to 128, which are most highly conserved among all species studied (see Fig. 2A) and correspond to a transmembrane region of PrP that was delineated in cell-free translation studies. A transmembrane form of PrP was found in brains of patients with GSS caused by the A117V mutation and in Tg mice overexpressing either the mutant or wt PrP (76). That no evidence for an a-helix in this region has been found in NMR studies of recombinant PrP in an aqueous environment (54,93,162) suggests that these recombinant PrPs correspond to the secreted form of PrP

that was also identified in the cell-free translation studies. This contention is supported by studies with recombinant antibody fragments (Fabs) showing that GPI-anchored PrP^{C} on the surface of cells exhibits an immunoreactivity similar to that of recombinant PrP prepared with an a-helical conformation (146).

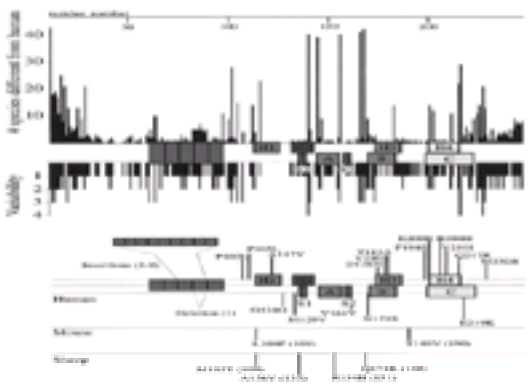

FIG. 2. Species variations and mutations of the prion protein gene. **A:** Species variations. The x-axis represents the human PrP sequence, with the five octarepeats and H1–H4 regions of putative secondary structure shown, as well as the three a-helices A, B, and C and the two b-strands S1 and S2. *Vertical bars* above the axis indicate the number of species that differ from the human sequence at each position. Below the axis, the length of the *bars* indicates the number of alternative amino acids at each position in the alignment. **B:** Mutations causing inherited human prion disease and polymorphisms in human, mouse, and sheep. Above the line of the human sequence are mutations that cause prion disease. Below the lines are polymorphisms, some but not all of which are known to influence the onset as well as the phenotype of disease. (Data compiled by Paul Bamborough and Fred E. Cohen.)

Models of PrP^{Sc} suggest that formation of the disease-causing isoform involves refolding of a region corresponding roughly to residues 108 to 144 into b-sheets (89); the single disulfide bond joining the COOH-terminal helices would remain intact, as the disulfide is required for PrP^{Sc} formation (Fig. 3D) (134). Deletion of each of several regions of putative secondary structure in PrP, except for the NH_2-terminal 66 amino acids (residues 23 to 88) and a 36-amino-acid stretch (Mo residues 141 to 176), prevented formation of PrP^{Sc} as measured in scrapie-infected cultured neuroblastoma cells (134). With a-PrP Fabs selected from phage display libraries and two monoclonal antibodies (MAb) derived from hybridomas, a major conformational change that occurs during conversion of PrP^{C} into PrP^{Sc} has been localized to residues 90 to 112 (146). Studies with an a-PrP IgM MAb, which was reported to immunoprecipitate PrP^{Sc} selectively (107), support this conclusion. Although these results indicate that PrP^{Sc} formation involves a conformational change at the NH_2-terminus, mutations causing inherited prion diseases have been found throughout the protein (see Fig. 2B). Interestingly, all of the known point mutations in PrP with biologic significance occur either within or adjacent to regions of secondary structure in PrP and as such could destabilize the structure of PrP^{C} or stabilize a transition state between PrP^{C} and PrP^{Sc} (42,88,162,163).

NMR Structure of Recombinant PrP

The NMR structure of recombinant (r) SHaPrP(90–231) was determined after the protein was purified and refolded (see Fig. 3A). Residues 90 to 112 are not shown in the figure, because marked conformational heterogeneity was found in this region, whereas residues 113 to 126 constitute the conserved hydrophobic region that also displays some structural plasticity (93,115). Although some features of the structure of rPrP(90–231) are similar to those reported earlier for the smaller recombinant MoPrP(121–231) fragment (162), substantial differences were found. For example, the loop at the NH_2-terminus of helix B is defined in rPrP(90—231) but is disordered in MoPrP(121–231); in addition, helix C is composed of residues 200 to 227 in rPrP(90–231) but extends only from 200 to 217 in MoPrP(121–231). The loop and the COOH-terminal portion of helix C are particularly important, as described later (see Fig. 3B). Whether the differences between the two recombinant PrP fragments are the result of (a) their different lengths, (b) species-specific differences in sequences, or (c) the conditions used for solving the structures remains to be determined.

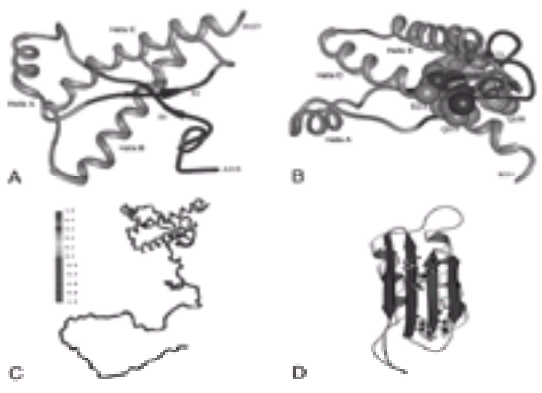

FIG. 3. Structures of prion proteins. **A:** NMR structure of Syrian hamster (SHa) recombinant (r) PrP(90–231). Presumably, the structure of the a-helical form of rPrP(90–231) resembles that of PrP^{C}. rPrP(90–231) is viewed from the interface where PrP^{Sc} is thought to bind to PrP^{C}. The color scheme is as follows: a-helices A (residues 144–157), B (172–193), and C (200–227) in *pink*; disulfide between Cys-179 and Cys-214 in *yellow*; conserved hydrophobic region composed of residues 113–126 in *red*; loops in *gray*; residues 129–134 in *green* encompassing strand S1, and residues 159–165 in *blue* encompassing strand S2. The *arrows* span residues 129–131 and 161–163, as these show a closer resemblance to the b-sheet (93). **B:** NMR structure of rPrP(90–231) is viewed from the interface where protein X is

thought to bind to PrP^C. Protein X appears to bind to the side chains of residues that form a discontinuous epitope. Some amino acids are in the loop composed of residues 165–171 and at the end of helix B (Gln-168 and Gln-172 with a low-density van der Waals rendering), and others are on the surface of helix C (Thr-215 and Gln-219 with a high-density van der Waals rendering) (96). **C:** Schematic diagram showing the flexibility of the polypeptide chain for PrP(29–231) (54). The structure of the portion of the protein representing residues 90–231 was taken from the coordinates of PrP(90–231) (93). The remainder of the sequence was hand-built for illustration purposes only. The color scale corresponds to the heteronuclear ^1H–^{15}N NOE data: *red* for the lowest (most negative) values, where the polypeptide is most flexible, to *blue* for the highest (most positive) values in the most structured and rigid regions of the protein. **D:** Plausible model for the tertiary structure of human PrP^{Sc} (89). Color scheme is as follows: S1 b-strands are 108–113 and 116–122 in *red*; S2 b-strands are 128–135 and 138–144 in *green*; a-helices H3 (residues 178–191) and H4 (residues 202–218) in *gray*; loop (residues 142–177) in *yellow.* Four residues implicated in the species barrier are shown in ball-and-stick form (Asn-108, Met-112, Met-129, Ala-133).

Recent NMR studies of full-length MoPrP(23–231) and SHaPrP(29–231) have shown that the NH_2-termini are highly flexible and lack identifiable secondary structure under the experimental conditions employed (see Fig. 3C) (54). Studies of SHaPrP(29–231) indicate transient interactions between the COOH-terminal end of helix B and the highly flexible, NH_2-terminal random-coil containing the octarepeats (residues 29 to 125) (54).

PrP Appears to Bind Copper

The highly flexible NH_2-terminus of recombinant PrP may be more structured in the presence of copper. Each SHaPrP(29–231) molecule was found to bind two Cu^{2+} ions at pH 6.5; peptide studies suggest that four Cu^{2+} ions will bind at pH 7.4 (17,203). Using tryptophan fluorescence assay, only Cu^{2+} was found to bind recombinant SHaPrP(29–231); other divalent cations including Ca^{2+}, Co^{2+}, Mg^{2+}, Mn^{2+}, Ni^{2+}, and Zn^{2+} did not bind to PrP (190). Earlier studies with synthetic peptides corresponding to the octarepeat sequence demonstrated the binding of Cu^{2+} ions (81,82), and optical spectroscopy showed that Cu^{2+} induced an a-helix formation in these peptides (128). More recently, PrP-deficient (*Prnp*$^{0/0}$) mice were found to have lower levels of Zn/Cu superoxide dismutase (SOD) activity than controls (18); SOD activity has been shown to mirror the state of copper metabolism (75). Measurements of membrane extracts from brains of *Prnp*$^{0/0}$ mice showed low levels of Cu, whereas Fe and Zn were unchanged, suggesting PrP^C might function as a Cu^{2+} binding protein (17). Interestingly, endocytosis of chicken PrP seems to be increased by Cu^{2+} (144), and renaturation of PrP^{Sc} appears to be enhanced by Cu^{2+} (125). Both Cu^{2+} and Zn^{2+} ions have been reported to modify the N-terminal truncation of PrP^{Sc} catalyzed by proteinase K, but the molecular basis underlying this phenomenon is not understood (205).

Disturbances in Cu^{2+} homeostasis leading to dysfunction of the CNS are well documented in humans and animals but are not known to be caused by abnormalities in PrP metabolism; Menkes disease is manifest at birth and is caused by a mutation of the MNK gene on the X chromosome, and Wilson's disease appears in childhood and is caused by a mutation of the WD gene on chromosome 13 (26,35,147,204). Both the MNK and WD genes encode copper transporting ATPases. Although both Menkes and Wilson's diseases are recessive disorders, only Menkes disease can be treated with copper chelating reagents. Interestingly, cuprizone, a Cu^{2+} chelating reagent, has been used in mice to induce neuropathologic changes similar to those found in the prion diseases (101,142).

PRION REPLICATION

In an uninfected cell, PrP^C with the wild-type sequence exists in equilibrium in its monomeric, a-helical, protease-sensitive state or bound to protein X (Fig. 4). We denote the conformation of PrP^C that is bound to protein X as PrP* (41); this conformation is likely to be different from that determined under aqueous conditions for monomeric recombinant PrP. The PrP*–protein X complex will bind PrP^{Sc}, thereby creating a replication-competent assembly. Additional experiments demonstrate that for PrP^C, protein X binding precedes productive PrP^{Sc} interactions (96). A conformational change takes place whereby PrP, in a shape competent for binding to protein X and PrP^{Sc}, represents the initial phase in the formation of infectious PrP^{Sc}.

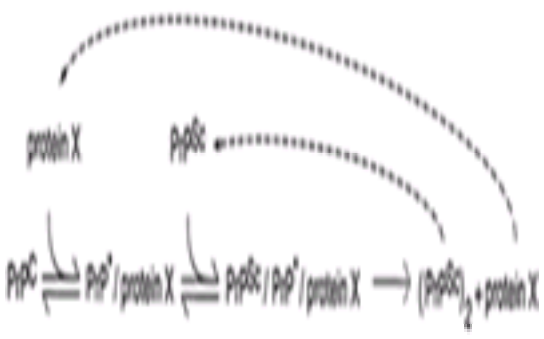

FIG. 4. Schematic diagram showing template-assisted PrP^{Sc} formation. In the initial step, PrP^C binds to protein X to form the PrP*–protein X complex. Next, PrP^{Sc} binds to PrP* that has already formed a complex with protein X. When PrP* is transformed into a nascent molecule of PrP^{Sc}, protein X is released and a dimer of PrP^{Sc} remains. The inactivation target size of an infectious prion suggests that it is composed of a dimer of PrP^{Sc} (10). In the model depicted here, a fraction of infectious PrP^{Sc} dimers dissociate into uninfectious monomers as the replication cycle proceeds, whereas most of the dimers accumulate in accordance with the increase in prion titer that occurs during the incubation period. The precise

stoichiometry of the replication process remains uncertain.

Several lines of evidence argue that the smallest infectious prion particle is an oligomer of PrP^{Sc}, perhaps as small as a dimer (10). On purification, PrP^{Sc} tends to aggregate into insoluble multimers that can be dispersed into liposomes (60). Some investigators argue that insolubility is a prerequisite for PrP^{Sc} formation and prion infectivity (30,64). Whether such arguments are correct remains to be established.

In attempts to form PrP^{Sc} *in vitro*, PrP^{C} has been exposed to 3 M guanidinium (Gdn) HCl and then diluted 10-fold prior to binding to PrP^{Sc} (95,106). Based on these results, we presume that exposure of PrP^{C} to GdnHCl converts it into a PrP*-like molecule. Whether this PrP*-like protein is converted into PrP^{Sc} is unclear. Although the PrP*-like protein bound to PrP^{Sc} is protease resistant and insoluble, this protease-resistant PrP has not been reisolated to assess whether or not it was converted into PrP^{Sc}. It is noteworthy that recombinant PrP can be refolded into either a-helical or b-sheet forms, but none have been found to possess prion infectivity as judged by bioassay.

INFECTIOUS PRION DISEASES

Transmission of infection is a rare cause of prion disease in humans. The infectious prion diseases include kuru of the Fore people in New Guinea, where prions were transmitted by ritualistic cannibalism (3,4,63). With the cessation of cannibalism at the urging of missionaries, kuru began to decline long before it was known to be transmissible. Sources of prions causing infectious CJD on several different continents include improperly sterilized depth electrodes, transplanted corneas, HGH, gonadotrophin derived from cadaveric pituitaries, and dura mater grafts (20). Over 90 young adults have developed CJD after treatment with cadaveric HGH; the incubation periods range from 3 to more than 20 years (13,148). Dura mater grafts implanted during neurosurgical procedures seem to have caused more than 60 cases of CJD; these incubation periods range from 1 to more than 14 years (33,56,110).

New Variant Creutzfeldt-Jakob Disease

In 1994, the first cases of CJD in teenagers and young adults that were eventually labeled new variant (nv) CJD occurred in Britain (212,213). The young age of these patients was unusual (9,16), and their brains showed numerous PrP amyloid plaques surrounded by a halo of intense spongiform degeneration (92). One French patient meeting these criteria later followed (34). These unusual neuropathologic changes have not been seen in CJD cases in the United States, Australia, or Japan (32). Both macaque monkeys and marmosets developed neurologic disease several years after inoculation with bovine prions (7), but only the macaques exhibited numerous PrP plaques similar to those found in nvCJD (111).

Have Bovine Prions Been Transmitted to Humans?

The restricted geographical occurrence and chronology of vCJD have raised the possibility that bovine spongiform encephalopathy (BSE) prions have been transmitted to humans. From 1994 until the last quarter of 1998, the incidence of vCJD seemed to be constant at about eight cases per year. This now seems to have changed with the report of 27 new cases in 2000 (212). This dramatic change in the incidence of vCJD raises the possibility that we are beginning to see a substantial increase in the number of patients dying of vCJD. Still, epidemiologic studies have not identified a set of dietary habits that distinguishes vCJD patients from apparently healthy people. Moreover, there is no explanation for the predilection of vCJD for teenagers and young adults. Why have older individuals not developed vCJD-based neuropathologic criteria? It is noteworthy that epidemiologic studies over the past three decades have failed to find evidence for transmission of sheep prions to humans (45). Attempts to predict the future number of cases of vCJD, assuming exposure to bovine prions prior to the offal ban, have been uninformative because so few cases of vCJD have occurred (46).

Strain of BSE Prions

Was a particular conformation of bovine (Bo) PrP^{Sc} selected for heat resistance during the rendering process and then reselected multiple times as cattle, infected by ingesting prion-contaminated meat and bone meal (MBM), were slaughtered and their offal rendered into more MBM? Recent studies of PrP^{Sc} from brains of patients who died of vCJD show a pattern of PrP glycoforms different from those found for sporadic (s) or iatrogenic (i) CJD (43,80). But the utility of measuring PrP glycoforms is questionable in trying to relate BSE to vCJD (185), because PrP^{Sc} is formed after the protein is glycosylated (15,31) and enzymatic deglycosylation of PrP^{Sc} requires denaturation. Alternatively, it may be possible to establish a relationship between the conformations of PrP^{Sc} from cattle with BSE and those from humans with vCJD by using Tg mice, as was done for strains generated in the brains of patients with the familial form of fatal insomnia (FFI) or fCJD (179,198). A relationship between vCJD and BSE has been suggested by finding similar incubation times in non-Tg RIII mice 310 days after inoculation with Hu or Bo prions (22).

Transgenetic Studies of BSE Prions

When Tg(BoPrP)$Prnp^{0/0}$ mice are inoculated with either nvCJD prions from humans or BSE prions previously passaged once through these same Tg(BoPrP)$Prnp^{0/0}$ mice (179), the resulting lesion profiles as measured by neuronal vacuolation, PrP^{Sc} distribution on histoblots, and PrP amyloid deposition as well as the incubation times were all indistinguishable (179a). Interestingly, Tg(BoPrP)$Prnp^{0/0}$ mice are also highly susceptible to natural and experimental sheep scrapie. Although the incubation times are similar, the neuronal vacuolation, PrP^{Sc} distribution on histoblots, and PrP amyloid deposition are extremely different.

We believe these data provide the first rational experimental studies that establish a clear link between BSE and nvCJD. Indeed, there is an eerie symmetry about these experimental results, where the one passage of BSE prions from humans is equivalent to the first passage from cattle through Tg(BoPrP) *Prnp*$^{0/0}$ mice.

Inherited and Sporadic Prion Diseases

For inherited and sporadic prion diseases, the major question is how the first PrP^{Sc} molecules are formed. Once these are formed, replication presumably follows the mechanism outlined for infectious disease. Several lines of evidence suggest that PrP^{Sc} is more stable than PrP^{C}, and a kinetic barrier precludes the formation of PrP^{Sc} under normal conditions. In the case of the initiation of inherited prion diseases, the barrier to PrP^{Sc} formation must be lower for the mutant ($DPrP^{C}$) than the wild-type, and thus DPrP* can spontaneously rearrange to form $DPrP^{Sc}$. Although the known mutations would appear to be destabilizing to the structure of PrP^{C}, we lack useful information about the structure of the transition state for either the mutant or wild-type sequences. Studies of PrP in the brains of patients who were heterozygous for the E200K mutation revealed $DPrP^{Sc}$(E200K) molecules that were both detergent insoluble and resistant to limited proteolysis, whereas most wild-type PrP was detergent insoluble but protease sensitive (62). These results suggest that in familial (f) CJD(E200K), insoluble wt PrP might represent a form of PrP* (62). In studies with Chinese hamster ovary (CHO) cells, expression of DPrP(E200K) was found to be accompanied by the posttranslational acquisition of resistance to limited proteolysis (114), but whether such cell lines expressing DPrP(E200K) produce infectious prions is unknown. It is noteworthy that levels of proteinase K used in the studies where D PrP(E200K) was expressed in CHO cells were lower by a factor of 10 to 100 compared to digestions of PrP^{Sc} derived from brain or scrapie-infected neuroblastoma (ScN2a) cells. Whether these alterations in the properties of DPrP(E200K) in CHO cells provide evidence for DPrP*, or such changes lie outside the pathway of $DPrP^{Sc}$(E200K) formation, remains to be determined.

Initiation of sporadic disease may follow from a somatic mutation and thus follows a path similar to that for germline mutations in inherited disease. In this situation, the mutant PrP^{Sc} must be capable of co-opting wt PrP^{C}, a process known to be possible for some mutations (e.g., E200K, D178N) but less likely for others (e.g., P102L) (198,200). Alternatively, the activation barrier separating wt PrP^{C} from PrP^{Sc} could be crossed on rare occasions when viewed in the context of a population. Most individuals would be spared, although presentations in the elderly with an incidence of about one per million would be seen.

Transgenic Mice Expressing Mutant PrP

With the identification of mutant genes causing familial forms of neurodegeneration, it became possible to model this process in Tg mice. The first mice expressing a mutant gene that developed CNS degeneration were those expressing the P102L mutation of GSS disease in a mutant PrP transgene (87). The age of onset of CNS dysfunction was found to depend on the level of expression of the mutant PrP transgene in Tg(MoPrP,P101L) mice. The higher the level of expression of the mutant PrP transgene, the earlier the age of onset (197). Additionally, Tg(MoPrP,P101L) *Prnp*$^{0/0}$ mice that were deficient for wild-type MoPrP exhibit a relatively uniform age onset of disease. Not only did the Tg(MoPrP,P101L) mice develop neurodegeneration spontaneously but they also transmitted disease to inoculated recipients that express the same transgene at a much lower level (86,197). These recipient mice, designated Tg(MoPrP,P101L)196/*Prnp*$^{0/0}$ (or Tg196), infrequently develop spontaneous neurodegeneration. Recently, a 55-residue synthetic peptide carrying the P102L mutation in a b-sheet conformation has been shown to induce disease in Tg196 mice (96a). This mutant 55-mer polypeptide can be refolded into at least two distinct conformations. When inoculated intracerebrally into Tg196 mice, 20 of 20 mice receiving the b-form of this peptide developed signs of CNS dysfunction at about 360 days, with neurohistologic changes that are pathognomonic of GSS. By contrast, 8 of 8 mice receiving a non-b-form of the peptide failed to develop any neuropathologic changes more than 600 days after peptide injections. We conclude that a chemically synthesized peptide refolded into the appropriate conformation can accelerate or possibly initiate prion disease. Also noteworthy is the production of neurodegeneration in Tg mice expressing mutant PrP with an expanded octarepeat region (40). This mutation is known to produce inherited prion disease in humans (138,150).

Mechanism of Prion Propagation?

From the foregoing formalism, we can ask, What is the rate-limiting step in prion formation? First, we must consider the impact of the concentration of PrP^{Sc} in the inoculum, which is inversely proportional to the length of the incubation time. Second, we must consider the sequence of PrP^{Sc} that forms an interface with PrP^{C}. When the sequences of the two isoforms are identical, the shortest incubation times are observed. Third, we must consider the strain-specific conformation of PrP^{Sc}. Some prion strains exhibit longer incubation times than others; interestingly, the levels of protease-sensitive PrP^{Sc} increase with prolongation of the incubation time, as described later (170). From these considerations, there exists a set of conditions under which initial PrP^{Sc} concentrations can be rate limiting. These effects presumably relate to the stability of the PrP^{Sc}, its targeting to the correct cells and subcellular compartments, and its ability to be cleared. Once infection in a cell is initiated and endogenous PrP^{Sc} production is operative, then the following discussion of PrP^{Sc} formation seems most applicable. If the assembly of PrP^{Sc} into a specific dimeric or multimeric arrangement was difficult, then a nucleation-polymerization (NP) formalism would be relevant. In NP processes, nucleation is the rate-limiting step and elongation or polymerization is facile. These conditions are frequently observed in peptide models of aggregation phenomena (30); however, studies with Tg mice expressing foreign PrP genes suggest that a different process is occurring. From investigations with mice expressing both the SHaPrP transgene and the endogenous MoPrP gene, it is clear that PrP^{Sc} provides a template for directing prion replication, where we define a template as a catalyst that leaves its imprint on the product of the reaction (159). Inoculation of these mice with $SHaPrP^{Sc}$ leads to the production of nascent $SHaPrP^{Sc}$ and not $MoPrP^{Sc}$. Conversely, inoculation of the Tg(SHaPrP) mice with $MoPrP^{Sc}$ results in $MoPrP^{Sc}$ formation and not $SHaPrP^{Sc}$. Even stronger evidence for templating has emerged from studies of prion strains passaged in Tg(MHu2M) *Prnp*$^{0/0}$ mice expressing a chimeric Hu/MoPrP gene as described in more detail later (155,198). Even though the conformational templates were initially generated with PrP^{Sc} molecules having

different sequences in patients with inherited prion diseases, these templates are sufficient to direct replication of distinct PrP^{Sc} molecules when the amino acid sequences of the substrate PrPs are identical. If the formation of this template were rate limiting, then an NP model could apply. However, studies of PrP^{Sc} formation in ScN2a cells point to a distinct rate-limiting step.

Cell biologic and transgenetic investigations argue for the existence of a chaperone-like molecule referred to as protein X that is required for PrP^{Sc} formation (200). As described later, mutagenesis experiments have created dominant negative forms of $DPrP^{C}$ that inhibit the formation of wt PrP^{Sc} by binding protein X (96). This implies that the rate-limiting step *in vivo* in prion replication, under conditions where PrP^{Sc} is sufficient, must be the conversion of PrP^{C} to PrP* because a dominant negative derived from a single point mutation could gate only a kinetically critical step in a cellular process. In the template-directed model, the conversion of PrP^{C} to PrP* is a first-order process. By contrast, NP processes follow higher-order kinetics [$(monomer)^{m}$, where m is the number of monomers in the nucleus]. The experimental implications of these rate relationships are apparent in transgenic studies; if first-order kinetics operate, halving the gene dose (hemizygotes) should double the incubation time, whereas doubling the dose of a transgene array should halve the time to disease. This quantitative behavior has been observed in several studies in mice with altered levels of PrP expression (25,27,157,159). The existence of prion strains that are conformational isoforms of PrP^{Sc} with distinct structures, incubation times, and neurohistopathology must also be considered in an analysis of the kinetics of PrP^{Sc} accumulation. Because the rate-limiting step in PrP^{Sc} formation cannot involve the unique template provided by a strain, differential rates of intercellular spread, cellular uptake, and clearance seem most likely to account for the variation in incubation times. This is consistent with results described later for eight prion strains in which the levels of protease-sensitive PrP^{Sc} correlate with the length of the incubation times (170). We have suggested that protease-sensitive PrP^{Sc} might serve as a surrogate marker for PrP^{Sc} clearance. In addition to these findings, different patterns of protease sensitivity and glycosylation for distinct prion strains support the proposal of clearance of PrP^{Sc} features in determining the length of the incubation time (12,43,185,198).

However, we hasten to add that NP models can provide a useful description of other biologic phenomena. Under conditions when the monomer is relatively rare and/or the conformational change is facile (e.g., short peptides), the NP model will dominate. However, when the monomer is sufficiently abundant and/or the conformational conversion is difficult to accomplish, the template assistance formalism provides a more likely description of the process.

Evidence for Protein X

Protein X was postulated to explain the results on the transmission of human (Hu) prions to Tg mice (Table 5) (199,200). Mice expressing both Mo and HuPrP were resistant to Hu prions, whereas those expressing only HuPrP were susceptible. These results argue that $MoPrP^{C}$ inhibited transmission of Hu prions—that is, the formation of nascent $HuPrP^{Sc}$. In contrast to the foregoing studies, mice expressing both MoPrP and chimeric MHu2M PrP were susceptible to Hu prions, and mice expressing MHu2M PrP alone were only slightly more susceptible. These findings contend that $MoPrP^{C}$ has only a minimal effect on the formation of chimeric $MHu2MPrP^{Sc}$.

Inoculum	Host	MoPrP gene	Incubation time (days ± SEM) (n/n_0)
sCJD	Tg(HuPrP)	*Prnp*$^{+/+}$	721 (1/10)
sCJD	Tg(HuPrP)/*Prnp*$^{0/0}$	*Prnp*$^{0/0}$	253 ± 2 (6/6)
sCJD	Tg(MHu2M)	*Prnp*$^{+/+}$	238 ± 3 (8/8)
sCJD	Tg(MHu2M)/*Prnp*$^{0/0}$	*Prnp*$^{0/0}$	191 ± 3 (10/10)

TABLE 5. *Evidence for protein X from transmission studies of human prions*

When the data on Hu prion transmission to Tg mice were considered together, they suggested that $MoPrP^{C}$ prevented the conversion of $HuPrP^{C}$ into PrP^{Sc} by binding to another Mo protein but that it had little effect on the conversion of MHu2M into PrP^{Sc}. We interpreted these results in terms of $MoPrP^{C}$ binding to this Mo protein with a higher affinity than does $HuPrP^{C}$. We postulated that $MoPrP^{C}$ had little effect on the formation of PrP^{Sc} from MHu2M (see Table 5) because MoPrP and MHu2M share the same amino acid sequence at the COOH-terminus. This also suggested that $MoPrP^{C}$ only weakly inhibited transmission of SHa prions to Tg(SHaPrP) mice because SHaPrP is more closely related to MoPrP than is HuPrP.

Using scrapie-infected mouse neuroblastoma cells transfected with chimeric Hu/Mo PrP genes, we extended our studies of protein X. Substitution of a Hu residue at position 214 or 218 prevented PrP^{Sc} formation (see Fig. 3B) (96). The side chains of these residues protrude from the same surface of the COOH-terminal a-helix, forming a discontinuous epitope with residues 167 and 171 in an adjacent loop. Substitution of a basic residue at positions 167, 171, or 218 prevented PrP^{Sc} formation; these mutant PrPs appear to act as “dominant negatives” by binding protein X and rendering it unavailable for prion propagation. Our findings seem to explain the protective effects of basic polymorphic residues in PrP of humans and sheep (90,181,209).

Is Protein X a Molecular Chaperone?

Because PrP undergoes a profound structural transition during prion propagation, it seems likely that other proteins such as chaperones participate in this process. Whether protein X functions as a classical molecular chaperone or participates in PrP binding as part of its normal function, but can also facilitate pathogenic aspects of PrP biology, is unknown. Interestingly, scrapie-infected cells in culture display marked differences in the induction of heat-shock proteins (Hsp) (196), and Hsp70 mRNA has been reported to increase in scrapie of mice (99). Although attempts to isolate specific proteins that bind to PrP have been disappointing (136), PrP has been shown to interact with Bcl-2, Hsp60, and the laminin receptor protein by two-hybrid analysis in yeast (108,161). Although these studies are suggestive, no molecular chaperone involved in prion formation in mammalian cells has been identified.

MINIPRIONS

Using the four-helix-bundle model of PrP^{C} (88), each region of proposed secondary structure was systematically deleted and the mutant constructs expressed in ScN2a cells and Tg mice (133,134). Deletion of any of the four putative helical regions prevented PrP^{Sc} formation, whereas deletion of the NH_2-terminal region containing residues 23 to 89 did not affect the yield of PrP^{Sc}. In addition to the 67 residues at the NH_2-terminus, 36 residues from position 141 to 176 could be deleted without altering PrP^{Sc} formation. The resulting PrP molecule of 106 amino acids was designated PrP106. In this mutant PrP, helix A as well as the S2 b-strand were removed. Whether the structure of $PrP^{Sc}106$ can be more readily determined than that of full-length PrP^{Sc} remains uncertain.

Transgene-Specified Susceptibility

Tg(MHM2PrP106)*Prnp*$^{0/0}$ mice that expressed PrP106 developed neurologic dysfunction about 300 days after inoculation with RML prions previously passaged in CD-1 Swiss mice (191). The resulting prions containing $PrP^{Sc}106$ produced CNS disease in about 66 days on subsequent passage in Tg(MHM2PrP106) *Prnp*$^{0/0}$ mice. Besides widespread spongiform degeneration and PrP deposits, the pyramidal cells of the hippocampus comprising the CA-1, CA-2, and CA-3 fields disappeared in Tg(MHM2PrP106)*Prnp*$^{0/0}$ mice inoculated with prions containing $PrP^{Sc}106$. In no previous study of Tg mice have we seen similar neuropathologic lesions. The Tg(MoPrP-A) mice overexpressing MoPrP are resistant to RML106 miniprions but are highly susceptible to RML prions. These mice require more than 180 days to produce illness after inoculation with miniprions but develop disease in about 50 days when inoculated with RML prions containing full-length $MoPrP^{Sc}$.

Smaller Prions and Mythical Viruses

The unique incubation times and neuropathology in Tg mice caused by miniprions are difficult to reconcile with the notion that scrapie is caused by an as-yet-unidentified virus. When the mutant or wild-type PrP^{C} of the host matched PrP^{Sc} in the inoculum, the mice were highly susceptible. However, when there was a mismatch between PrP^{C} and PrP^{Sc}, the mice were resistant to the prions. This principle of homologous PrP interactions—which underlies the species barrier—is recapitulated in studies of PrP106 in which the amino acid sequence has been drastically changed by deleting nearly 50% of the residues. Indeed, the unique properties of the miniprions provide another persuasive argument supporting the contention that prions are infectious proteins.

Strains of Prions

The existence of prion strains raises the question of how heritable biologic information can be enciphered in any molecule other than nucleic acid (53). Strains or varieties of prions have been defined by incubation times and the distribution of neuronal vacuolation (53,59). Subsequently, the patterns of PrP^{Sc} deposition were found to correlate with vacuolation profiles, and these patterns were also used to characterize strains of prions (21,49,51).

The typing of prion strains in C57Bl, VM, and F1(C57Bl × VM) inbred mice began with isolates from sheep with scrapie. The prototypic strains called Me7 and 22A gave incubation times of about 150 and about 400 days in C57Bl mice, respectively (53). The PrPs of C57Bl and I/Ln (and later VM) mice differ at two residues and control incubation times (27,131).

Until recently, support for the hypothesis that the tertiary structure of PrP^{Sc} enciphers strain-specific information (153) was minimal except for the DY strain isolated from mink with transmissible encephalopathy (12). PrP^{Sc} in DY prions showed diminished resistance to proteinase K digestion as well as an anomalous site of cleavage. The DY strain presented a puzzling anomaly because other prion strains exhibiting similar incubation times did not show this altered susceptibility to proteinase K digestion of PrP^{Sc} (177). Also notable was the generation of new strains during passage of prions through animals with different PrP genes (177).

PrP^{Sc} Conformation Enciphers Variation in Prions

Persuasive evidence that strain-specific information is enciphered in the tertiary structure of PrP^{Sc} comes from transmission of two different inherited human prion diseases to mice expressing a chimeric MHu2M PrP transgene (198). In FFI, the protease-resistant fragment of PrP^{Sc} after deglycosylation has an M_r of 19 kd, whereas in fCJD(E200K) and most sporadic prion diseases, it is 21 kd (Table 6) (129). This difference in molecular size was shown to be the result of different sites of proteolytic cleavage at the NH_2-termini of the two human PrP^{Sc} molecules, reflecting different tertiary structures (129). These distinct conformations were not unexpected, because the amino acid sequences of the PrPs

differ.

Inoculum	Host species	Host PrP genotype	Incubation time (days ± SEM) (n/n)	PrP^{Sc} (kd)
Inherited prion diseases—mutant PrP^{Sc}				
None	Human	FFI(D178N,M129)		19
FFI	Mouse	Tg(MHu2M)	191 ± 4 (10/10)	19
FFI → Tg(MHu2M)	Mouse	Tg(MHu2M)	136 ± 1 (6/6)	19
None	Human	fCJD(E200K)		21
fCJD	Mouse	Tg(MHu2M)	170 ± 2 (10/10)	21
fCJD → Tg(MHu2M)	Mouse	Tg(MHu2M)	167 ± 4 (13/13)	21
Infectious and sporadic prion diseases—wild-type PrP^{Sc}				
BSE	Human	wt(M/M129)		19
nvCJD	Mouse	Tg(MHu2M)	483 ± 44 (6/6)	19
nvCJD → Tg(MHu2M)	Mouse	Tg(MHu2M)	169 ± 3 (6/6)	19
None	Human	wt(M/M129)		21
sCJD	Mouse	Tg(MHu2M)	191 ± 3 (9/9)	21
sCJD → Tg(MHu2M)	Mouse	Tg(MHu2M)	177 ± 3 (10/10)	21

Data from ref. 198.

TABLE 6. *Distinct prion strains generated in humans with inherited, infectious, and sporadic prion diseases and transmitted to transgenic mice*

Extracts from the brains of FFI patients transmitted disease into mice expressing a chimeric MHu2M PrP gene about 200 days after inoculation and induced formation of the 19-kd PrP^{Sc}, whereas fCJD(E200K) and sCJD produced the 21-kd PrP^{Sc} in mice expressing the same transgene (198). On second passage, Tg(MHu2M) mice inoculated with FFI prions showed an incubation time of about 136 days and a 19-kd PrP^{Sc}, whereas those inoculated with fCJD(E200K) prions exhibited an incubation time of about 170 days and a 21-kd PrP^{Sc} (155). The experimental data demonstrate that MHu2MPrP^{Sc} can exist in two different conformations based on the sizes of the protease-resistant fragments; yet, the amino acid sequence of MHu2MPrP^{Sc} is invariant.

The results of our studies argue that PrP^{Sc} acts as a template for the conversion of PrP^{C} into nascent PrP^{Sc}. Imparting the size of the protease-resistant fragment of PrP^{Sc} through conformational templating provides a mechanism for both the generation and the propagation of prion strains.

Interestingly, the protease-resistant fragment of PrP^{Sc} after deglycosylation, with an M_r of 19 kd, has been found in patients who died after developing a clinical disease similar to FFI (66,124,140). Since both PrP alleles encoded the wild-type sequence and a Met at position 129, these cases were designated sporadic fatal insomnia (sFI). At autopsy, the spongiform degeneration, reactive astrogliosis, and PrP^{Sc} deposition were confined to the thalamus as found in FFI (123,124,126). Extracts from the thalamus of an sFI patient transmitted disease to Tg(MHu2M)*Prnp*$^{0/0}$ mice. PrP^{Sc} accumulated primarily in the thalamus of these Tg mice and after deglycosylation, a 19-kd protease-resistant fragment was identified (124). These findings are similar to those noted earlier for FFI transmission to Tg mice (198). The results of FFI and sFI studies argue persuasively that the clinicopathologic phenotype is determined by the conformation of PrP^{Sc} and not the amino acid sequence (124).

Evidence for Different Conformations of PrP^{Sc} in Eight Prion Strains

Using a highly sensitive conformation-dependent immunoassay for measurement of PrP^{Sc} in tissue homogenates, eight different prion strains passaged in SHas were examined (170). Brains from SHas were collected when the animals displayed signs of neurologic dysfunction; the incubation times for the prion strains varied from 70 to 320 days. Most of the PrP in the brains of SHas with signs of neurologic disease was PrP^{Sc}, as defined by the b-sheet conformation. The level of PrP^{Sc} in the brains of these clinically ill animals exceeded that of PrP^{C} by 3- to 10-fold (Fig. 5A). The highest levels of PrP^{Sc} were found in the brains of SHas infected with the Me7-H strain; in contrast, the lowest levels were found in the brains of SHas inoculated with the SHa(Me7) strain (see Fig. 5A). Interestingly, the Me7-H and SHa(Me7) strains, both derived from Me7 passaged in mice (177), possessed similar denatured-to-native PrP ratios, but they accumulated PrP^{Sc} at quite different levels (see Fig. 5A and Fig. 5B). The highest denatured-to-native PrP ratio of all tested strains was SHa(RML).

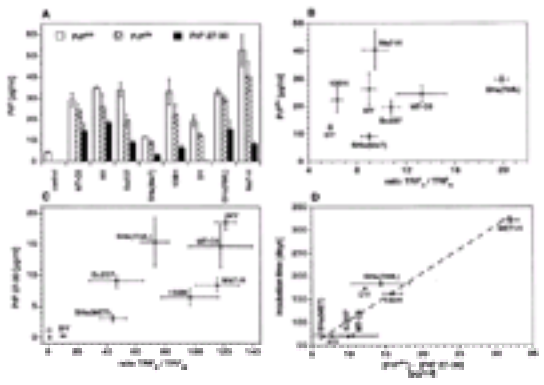

FIG. 5. Eight prion strains distinguished by the conformation-dependent immunoassay. **A:** Concentration of PrP^{Sc} and PrP 27–30. The *columns* and *bars* represent the average ±SEM obtained from three different brains of LVG/LAK Syrian hamsters infected with different prion strains and measured in three independent experiments. **B:** Ratio of antibody binding to denatured/native PrP and a function of concentration of PrP^{Sc} in the brains of Syrian hamsters (SHa) infected with different prion strains. Concentration of PrP^{Sc} and the ratio of antibody binding to denatured/native PrP were measured by the conformation-dependent immunoassay. **C:** Brain homogenates of SHa inoculated with different scrapie

strains and uninoculated controls, denoted *C*, were digested with 50 µg/mL of proteinase K for 2 hours at 37°C prior to the conformation-dependent immunoassay. **D:** Incubation time plotted as a function of the concentration of the proteinase K–sensitive fraction of PrP^{Sc} ([PrP^{Sc}]-[PrP 27–30]).

The apparent independence of the ratio of denatured-to-native PrP from the concentration of PrP^{Sc} became apparent after plotting both parameters in a single graph (see Fig. 5B). Each strain occupied a unique position, indicating differences in the conformation of accumulated PrP^{Sc}. Because the PrP^{C} concentration in each strain was less than or equal to 5 µg/mL and the PrP ratio for PrP^{C} was less than or equal to 1.8, the expected impact of the presence of PrP^{C} on the final PrP ratio was less than or equal to 15%.

Because only the most tightly folded conformers of PrP^{Sc} are likely to be protease resistant, we digested each of the brain homogenates with proteinase K prior to measuring the ratio of denatured-to-native PrP (see Fig. 5C). As shown, the positions of many strains changed when the protease-sensitive conformers of PrP^{Sc} were enzymatically hydrolyzed (see Fig. 5C). Most notable was the DY strain, which was readily detectable before limited proteolysis by immunoassay (see Fig. 5B) but became almost undetectable after digestion (see Fig. 5C), in accordance with earlier Western blot studies (11,12). Equally important, strains such as Sc237 and HY were marginally separated prior to proteinase K digestion (see Fig. 5B) but became quite distinct afterwards (see Fig. 5C).

These findings argue that Sc237 and HY are distinct strains although they exhibit similar incubation times of about 70 days when passaged in SHas (177). It is noteworthy that limited proteolysis of PrP^{Sc} from Sc237- and HY-infected brains produced PrP 27–30 proteins that were indistinguishable by migration in sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) as detected by Western immunoblotting (177).

When the incubation times of these eight strains were plotted as a function of the concentration of either PrP^{Sc} or PrP 27–30, no relationship could be discerned. Incubation times were also plotted as a function of the ratio of denatured-to-native PrP, and again no correlation could be found.

To assess the fraction of PrP^{Sc} that is sensitive to proteolysis during limited digestion with proteinase K, we subtracted the protease-resistant PrP 27–30 fraction (see Fig. 5C) from the total PrP^{Sc} (see Fig. 5B) for each of the eight prion strains. We asked whether the proteinase K-sensitive fraction of PrP^{Sc} ([PrP^{Sc}]–[PrP 27–30]) might reflect those PrP^{Sc} molecules that are most readily cleared by cellular proteases. The clearance of PrP^{Sc} is of considerable interest with respect to control of the length of the incubation time and other phenotypic features of prion strains (160). When the [PrP^{Sc}]–[PrP 27–30] fraction was plotted as a function of the incubation time, a linear relationship was found with an excellent correlation coefficient (r = 0.94) (see Fig. 5D).

The preceding results demonstrate that eight different strains possess at least eight different conformations (see Fig. 5B and Fig. 5C). Additional data argue that each strain is composed of a spectrum of conformations as revealed by limited protease digestion and GdnHCl denaturation studies (170). These findings contrast with the until-recently held notion that the primary structure of a protein determines a single tertiary structure (5).

How many distinct tertiary and quaternary structures can PrP^{Sc} adopt? The conformation-dependent immunoassay described here provides a rapid tool capable of discriminating the secondary, tertiary, and perhaps quaternary structures of a substantial number of PrP^{Sc} molecules.

As noted, for studies of strains passaged from humans with fCJD(E200K) and FFI, PrP^{Sc} must act as a template in the replication of nascent PrP^{Sc} molecules. Also as discussed, it appears likely that the binding of PrP^{C} or a metastable intermediate PrP* to protein X is the initial step in PrP^{Sc} formation, and that this is the rate-limiting step in prion replication (42,96,160). PrP^{Sc} interacts with PrP^{C} but not protein X in the PrP^{C}–protein X complex. When PrP^{C} or PrP* is converted into a nascent PrP^{Sc} molecule, protein X is released.

It also follows from these observations that the different incubation times of various prion strains should arise predominantly from distinct rates of PrP^{Sc} clearance rather than from the different rates of PrP^{Sc} formation (160). Thus, prion strains that are readily cleared should have prolonged incubation times, whereas those that are poorly cleared should display abbreviated incubation periods. We investigated this hypothesis by relying on the difference in brain PrP^{Sc} concentrations before and after proteinase K treatment as a surrogate for *in vivo* clearance of each prion strain. When clearance, as approximated by [PrP^{Sc}]–[PrP 27–30], was plotted as a function of the incubation time for eight strains, a linear relationship was found (see Fig. 5D). It is important to recognize that proteinase K sensitivity is an imperfect model for *in vivo* clearance and that only one strain with a long incubation time (exceeding 300 days) has been studied.

Although it has been suggested that asparagine (Asn)-linked carbohydrates (CHOs) specify prion strains (43), this proposal is difficult to reconcile with the addition of high-mannose oligosaccharides to Asn-linked consensus sites on PrP in the endoplasmic reticulum (ER) and with the subsequent remodeling of the sugar chains in the Golgi (55). Modification of the complex CHOs attached to PrP^{C} is clearly completed prior to PrP^{C} trafficking to the cell surface (15,31), which indicates that the Asn-linked CHOs of PrP^{Sc} do not instruct the addition of such complex-type sugars to PrP^{C}. It remains a formal possibility that specific prion strains preferentially recognize subsets of PrP^{C} glycoforms generated during protein maturation in the Golgi and then facilitate the conformational conversion of these glycoforms into nascent PrP^{Sc}.

Recently, evidence against the proposal that variations in the glycoform ratio encrypt prion strain properties has emerged. Patients with FFI have symptoms and neuropathologic profiles indistinguishable from patients with sFI (124,140). Although PrP^{Sc} from FFI patients shows relatively large amounts of the diglycosylated glycoform because of

the D178N mutation adjacent to one of the consensus Asn-linked glycosylation sites (129), wtPrP^{Sc} from sFI patients shows substantially less of the diglycosylated form (124,140). Following transmission to Tg(MHu2M) mice, FFI prions produced an identical pattern of neuropathology to that found in Tg mice infected with sFI prions, arguing that the same prion strain is responsible for the two forms of the disease (124,198). Furthermore, deglycosylated PrP 27–30 migrated at 19 kd whether it was obtained from patients with FFI or sFI, as well as from Tg mice inoculated with FFI or sFI prions (124). These findings with FFI and sFI also argue that the conformation of PrP ^{Sc}, not the amino acid sequence, determines the strain-specified disease phenotype. Further evidence arguing against any involvement of the pattern of glycosylation in specifying strain properties has emerged through the discovery that the PrP ^{Sc} glycoform ratios found in tonsil tissue differed markedly from those found in the brain of the same patient with nvCJD (79).

Mutagenesis of the complex-type sugar attachment sites (NXT ® NXA) seemed to increase the rate of PrP ^{Sc} formation in cultured cells (194) but resulted in prolonged incubation times in Tg mice and differences in the patterns of PrP ^{C} distribution and PrP ^{Sc} deposition in mice expressing mutant PrPs (51). These studies suggest that Asn-linked glycosylation might alter the stability of PrP, and, in the case of PrP ^{Sc}, that it results in various patterns of PrP ^{Sc} deposition. Thus, different clearance rates of PrP ^{Sc} may be important in determining not only strain-specific neuropathology but also the length of the incubation time (160).

Mechanism of Selective Neuronal Targeting?

In addition to incubation times, neuropathologic profiles of spongiform change have been used to characterize prion strains (59). However, recent studies with PrP transgenes argue that such profiles are not an intrinsic feature of strains (29,51). The mechanism by which prion strains modify the pattern of spongiform degeneration was perplexing because earlier investigations had shown that PrP ^{Sc} deposition precedes neuronal vacuolation and reactive gliosis (49). When FFI prions were inoculated into Tg(MHu2M) mice, PrP ^{Sc} was confined largely to the thalamus (Fig. 6A), as is the case for FFI in humans (198). In contrast, fCJD(E200K) prions inoculated into Tg(MHu2M) mice produced widespread deposition of PrP^{Sc} throughout the cortical mantel and many of the deep structures of the CNS (see Fig. 6B), as is seen in fCJD(E200K) of humans. To examine whether the diverse patterns of PrP ^{Sc} deposition are influenced by Asn-linked glycosylation of PrP ^{C}, we constructed Tg mice expressing PrPs mutated at one or both of the Asn-linked glycosylation consensus sites (51). These mutations resulted in aberrant neuroanatomic topologies of PrP ^{C} within the CNS, whereas pathologic point mutations adjacent to the consensus sites did not alter the distribution of PrP ^{C}. Tg mice with a mutation of the second PrP glycosylation site exhibited prion incubation times of more than 500 days and unusual patterns of PrP^{Sc} deposition. These findings raise the possibility that glycosylation can modify the conformation of PrP and affect either the turnover of PrP ^{C} or the clearance of PrP ^{Sc}. Regional differences in the rate of deposition or clearance would result in specific patterns of PrP ^{Sc} accumulation.

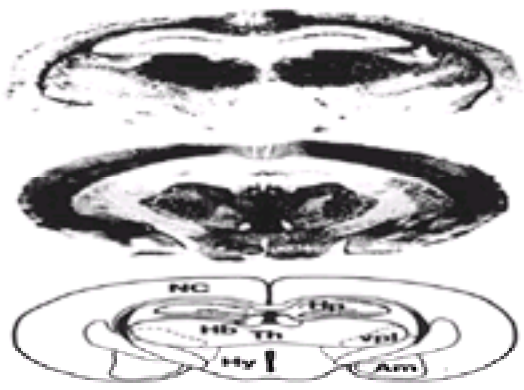

FIG. 6. Regional distribution of PrP ^{Sc} deposition in Tg(MHu2M)*Prnp*$^{0/0}$ mice inoculated with prions from humans who died of inherited prion diseases. Histoblot of PrP ^{Sc} deposition in a coronal section of a Tg(MHu2M) *Prnp*$^{0/0}$ mouse through the hippocampus and thalamus (198). **A:** The Tg mouse was inoculated with brain extract prepared from a patient who died of familial fatal insomnia (FFI). **B**: The Tg mouse was inoculated with extract from a patient with fCJD(E200K). Cryostat sections were mounted on nitrocellulose and treated with proteinase K to eliminate PrP ^{C} (193). To enhance the antigenicity of PrP ^{Sc}, the histoblots were exposed to 3-guanidinium isothiocyanate before immunostaining using a-PrP 3F4 monoclonal antibody (98). **C:** Labelled diagram of a coronal section of the hippocampus/thalamus region. NC, neocortex; Hp, hippocampus; Hb, habenula; Th, thalamus; vpl, ventral posterior lateral thalamic nucleus; Hy, hypothalamus; Am, amygdala.

FUNGAL PRIONS

Although prions were originally defined in the context of an infectious mammalian pathogen (151), it is now becoming widely accepted that prions are elements that impart and propagate variability through multiple conformers of a normal cellular protein. Such a mechanism must surely not be restricted to a single class of transmissible pathogens. Indeed, it is likely that the original definition will need to be extended to encompass other situations in which a similar mechanism of information transfer occurs.

Two notable prion-like determinants, [URE3] and [PSI], have already been described in yeast, and one in another fungus denoted [Het-s*] has been reported (36,47,210). Studies of candidate PrPs in yeast may prove particularly helpful in the dissection of some of the events that feature in PrP ^{Sc} formation. Interestingly, different strains of yeast prions have been identified (52). Conversion to the prion-like [PSI] state in yeast requires the molecular chaperone Hsp104; however, no homolog of Hsp104 has been found in mammals (36). The NH_2-terminal prion domains of Ure2p and Sup35 that are

responsible for the [URE3] and [PSI] phenotypes in yeast have been identified. In contrast to PrP, which is a GPI-anchored membrane protein, both Ure2p and Sup35 are cytosolic proteins (211). When the prion domains of these yeast proteins were expressed in *Escherichia coli*, the proteins were found to polymerize into fibrils with properties similar to those of proteolytically trimmed PrP and other amyloids (83,145).

Whether prions explain some other examples of acquired inheritance in lower organisms is unclear (109). For example, studies on the inheritance of positional order and cellular handedness on the surface of small organisms have demonstrated the epigenetic nature of these phenomena, but the mechanism remains unclear (58).

THERAPEUTIC APPROACHES TO PRION DISEASES

It seems likely that it will be possible to design effective therapeutics for prion diseases as our understanding of prion propagation increases. Because people at risk for inherited prion diseases can now be identified decades before neurologic dysfunction is evident, the development of an effective therapy for these fully penetrant disorders is imperative. Although we have no way of predicting the number of individuals who may develop neurologic dysfunction from bovine prions in the future, seeking an effective therapy now seems most prudent (155). Interfering with the conversion of PrP^{C} to PrP^{Sc} seems to be the most attractive therapeutic target. Both stabilizing the structure of PrP^{C} via the formation of a PrP^{C}-drug complex, and modifying the action of protein X, which might function as a molecular chaperone (see Fig. 3B), are reasonable strategies. Whether it is more efficacious to design a drug that binds to PrP^{C} at the protein X binding site or one that mimics the structure of PrP^{C} with basic polymorphic residues that seem to prevent scrapie and CJD remains to be determined (96,181). As PrP^{Sc} formation seems limited to caveolae-like domains (71,195), drugs designed to inhibit this process need not penetrate the cytosol of cells, but they do need to be able to enter the CNS. Alternatively, drugs that destabilize the structure of PrP^{Sc} might also prove useful.

The production of domestic animals that do not replicate prions may also be important with respect to preventing prion disease. Sheep encoding the R/R polymorphism at position 171 seem to be resistant to scrapie (90,209); presumably, this was the genetic basis of James Parry's scrapie eradication program in Great Britain 30 years ago (141). A more effective approach, using dominant negatives for producing prion-resistant domestic animals, including sheep and cattle, is probably the expression of PrP transgenes encoding R171 or basic residues at the protein X binding site (see Fig. 3B) (96). Such an approach can be readily evaluated in Tg mice and, once shown to be effective, could be instituted by artificial insemination of sperm from males homozygous for the transgene. Less practical is the production of PrP-deficient cattle and sheep. Although such animals would not be susceptible to prion disease (23,157), they might suffer some deleterious effects from ablation of the PrP gene (44,116,172,201).

Whether gene therapy for the human prion diseases will prove feasible using the dominant negative approach described earlier for prion-resistant animals depends on the availability of efficient vectors for delivery of the transgene to the CNS.

CONCLUDING REMARKS

Although the study of prions has taken several unexpected directions over the past three decades, a novel and fascinating story of prion biology is emerging. Investigations of prions have elucidated a previously unknown mechanism of disease in humans and animals. Although learning the details of the structures of PrPs and deciphering the mechanism of PrP^{C} transformation into PrP^{Sc} will be important, the fundamental principles of prion biology have become reasonably clear. Although some investigators prefer to view the composition of the infectious prion particle as unresolved (37,112,119), such a perspective denies an enlarging body of data, none of which refutes the prion concept. Moreover, the discovery of prion-like phenomena mediated by proteins unrelated to PrP in yeast and other fungi serves not only to strengthen the prion concept but also to widen it.

The discovery that prion diseases in humans are uniquely both genetic and infectious greatly extended the prion concept. To date, 20 different mutations in the human PrP gene, all resulting in nonconservative substitutions, have been found either to be genetically linked to or to segregate with the inherited prion diseases (see Fig. 2B). Yet, the transmissible prion particle is composed largely, if not exclusively, of an abnormal isoform of the PrP designated PrP^{Sc} (153).

Aberrant PrP Metabolism

The hallmark of all prion diseases—whether sporadic, dominantly inherited, or acquired by infection—is that they involve the aberrant metabolism and resulting accumulation of the PrP (see Table 3) (153). The conversion of PrP^{C} into PrP^{Sc} involves a conformation change whereby the a-helical content diminishes and the amount of b-sheet increases (139). These findings provide a reasonable mechanism to explain the conundrum presented by the three different manifestations of prion disease.

Understanding how PrP^{C} unfolds and refolds into PrP^{Sc} will be of paramount importance in transferring advances in the prion diseases to studies of other degenerative illnesses. The mechanism by which PrP^{Sc} is formed must involve a templating process whereby existing PrP^{Sc} directs the refolding of PrP^{C} into a nascent PrP^{Sc} with the same conformation. Not only will knowledge of PrP^{Sc} formation help in the rational design of drugs that interrupt the pathogenesis of prion diseases, but it may also open new approaches to deciphering the causes of and to developing effective therapies for the more common neurodegenerative diseases, including Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis (ALS). Indeed, the expanding list of prion diseases and their novel modes of transmission and pathogenesis (Table 3), as well as the unprecedented mechanisms of prion propagation and information transfer, indicate that much more attention to these fatal disorders of protein conformation is urgently needed.

Over the past two decades, advances in our understanding of the prion diseases have helped refine our definition of neurodegenerative diseases. In addition to the more common neurodegenerative diseases just mentioned, there are less

prevalent maladies, including frontotemporal dementia, Huntington's disease, and the prion diseases (Table 7). With the exception of Huntington's disease, a minority of all of these neurodegenerative disorders exhibit an autosomal dominant pattern of inheritance, and the majority are sporadic. In all of these illnesses, including Huntington's disease, the onset of CNS dysfunction is usually seen in adults and the neurologic deterioration is progressive.

Neurodegenerative disease	CNS protein deposits	Mutant genes in familial disorders
Prion diseases	PrP^{Sc}; PrP amyloid plaques	PrP
Alzheimer's disease (AD)	Aβ; Aβ amyloid plaques Tau; neurofibrillary tangles	APP, PS1, PS2, $Apo\varepsilon^a$
Parkinson's disease	α-Synuclein; Lewy bodies	α-Synuclein, Parkin
Amyotrophic lateral sclerosis (ALS)		Superoxide dismutase
Frontotemporal dementia (FTD)	Tau; fibrils and pick bodies	Tau
Huntington's disease (HD)	HD; nuclear HD aggregates	HD

[a]ApoE genotype modulates the age of onset of both familial and sporadic AD.

TABLE 7. *Neurodegenerative diseases*

Abnormal protein deposits are found in all these diseases and the pathogenic process seems to evade immune surveillance. In Alzheimer's disease and the prion diseases, amyloid plaques are found, but the proteins in these plaques are different (68,122,158). In Alzheimer's disease, the plaques contain a peptide called Ab, which is derived from a large protein designated the amyloid precursor protein, or APP (97). In the prion diseases, the plaques are a nonobligatory feature of the illness (159); the plaques contain substantial amounts of PrP fragments (48,158,192). Mutations in the genes encoding these proteins are found in inherited forms of the disease (69,84). In familial Alzheimer's disease, mutations in the presenilin genes have also been implicated and are thought by some investigators to operate by modifying the processing of APP into Ab (14,164,180,214).

The time of onset of the prion diseases in experimental animals is determined by the level of PrP^{C} expression, the sequence of PrP, and the strain of prions (53,159,207). In Alzheimer's disease, the haplotype of apolipoprotein E (ApoE) greatly influences the age of onset of both the familial and sporadic forms of the illness (174). In Huntington's disease, the age of onset is governed by the size of the triplet repeat expansion encoding the polyglutamine segment (100).

Protein aggregates in the nuclei of some neurons can be observed in Huntington's disease (173,175), whereas in Parkinson's disease, intraneuronal inclusions called Lewy bodies are often found (186). Similarly, mutations in the genes encoding these proteins are found in inherited forms of the disease (73,149). In the inherited frontotemporal dementias and Pick's disease, mutations in the tau gene are the cause (91). In all of these diseases, astrocytic gliosis is seen. In some of these diseases, vacuolation in the neuropil is seen, but the most prominent vacuolation can be seen in the prion diseases where vacuoles may coalesce to create spongiform change. The degree of spongiform change is quite variable, whereas the extent of reactive gliosis correlates with the degree of neuron loss in CJD (121).

But prions may have even wider implications than those noted for the common neurodegenerative diseases. If we think of prion diseases as disorders of protein conformation and do not require the diseases to be transmissible, then what we have learned from the study of prions may reach far beyond these common illnesses.

Conformational Diversity

The discovery that proteins may have multiple biologically active conformations may prove no less important than the implications of prions for diseases. How many different tertiary structures can PrP^{Sc} adopt? This query not only addresses the issue of the limits of prion diversity but also applies to proteins as they normally function within the cell or act to affect homeostasis in multicellular organisms. The expanding list of chaperones that assist in the folding and unfolding of proteins promises much new knowledge about this process. For example, it is now clear that pro-proteases can carry their own chaperone activity where the *pro* portion of the protein functions as a chaperone in cis to guide the folding of the proteolytically active portion before it is cleaved (182). Such a mechanism might well feature in the maturation of polypeptide hormones. Interestingly, mutation of the chaperone portion of prosubtilisin resulted in the folding of a subtilisin protease with different properties from the one folded by the wild-type chaperone. Such chaperones have also been shown to work in trans (182). Besides transient metabolic regulation within the cell and hormonal regulation of multicellular organisms, it is not unreasonable to suggest that assembly of proteins into multimeric structures such as intermediate filaments might be controlled, at least in part, by alternative conformations of proteins. Such regulation of multimeric protein assemblies might occur either in the proteins that form the multimers or in the proteins that function to facilitate the assembly process. Additionally, apoptosis during development and throughout adult life might also be regulated, at least in part, by alternative tertiary structures of proteins.

Future Studies

The wealth of data establishing the essential role of PrP in the transmission of prions and the pathogenesis of prion diseases has provoked consideration of how many biologic processes are controlled by changes in protein conformation. The extreme radiation resistance of the scrapie infectivity suggested that the pathogen causing this disease and related illnesses would be different from viruses, viroids, and bacteria (1). Indeed, an unprecedented mechanism of disease has been revealed whereby an aberrant conformational change in a protein is propagated. The future of this emerging area of biology should prove even more interesting and productive as many new discoveries emerge.
