Editors-in-Chief

Associate Editors

Preface

In the early 1980s, Bernie Fields originated the idea of a virology reference textbook that combined the molecular aspects of viral replication with the medical features of viral infections. This broad view of virology reflected Bernie's own research, which applied molecular and genetic analyses to the study of viral pathogenesis, providing an important part of the foundation for the field of molecular pathogenesis. Bernie led the publication of the first three editions of *Virology*.

Unfortunately, we lost Bernie to pancreatic cancer soon after the third edition went into production. The third edition became *Fields Virology* in his memory, and it is entirely fitting that the fourth edition continues to carry his name.

We have retained the general organization of the first three editions for the fourth edition. Part I contains chapters on general aspects of virology, and Part II contains chapters on replication and medical aspects of specific virus families and specific viruses of medical importance. In Part I, we have added new chapters on principles of virology, virus entry and uncoating, replication strategies of RNA viruses and DNA viruses, virus assembly, and virus vectors to enhance the utility of this book as well as that of *Fundamental Virology* as textbooks. In Part II we have added new chapters on the arteriviruses, the *Bornaviridae*, and Kaposi's sarcoma-associated herpes virus. We have also expanded the retrovirus section to include chapters on the nonhuman lentiviruses as well as human and primate viruses other than the lentiviruses and the lymphotropic retroviruses. The main emphasis continues to be on viruses of medical importance and interest, but other viruses are described in specific cases where more is known about their mechanisms of replication or pathogenesis. Although not formally a virus, prions are still included in this edition for historical reasons and because of the intense interest in the infectious spongiform encephalopathies. All of the chapters have been updated to reflect the rapid advances in virology during the last five years.

We wish to thank Anne Snyder, Robin Cook, and Jonathan Pine at Lippincott Williams & Wilkins and Lisa Holik at Harvard Medical School for all of their many important contributions to the preparation of this book.

CHAPTER 1 The Origins of Virology

Arnold J. Levine

Virology, as a subject matter, has had a remarkable history. Viruses, because of their predatory nature, have shaped the history and evolution of their hosts. Virtually all living organisms, when studied carefully, have viral parasites, and so these smallest of living entities exert significant forces on all life forms, including themselves. The medical consequences of viral infections of humans have altered our history and have resulted in extraordinary efforts on the part of virologists to study, understand, and eradicate these agents. These virologists have elucidated new principles of life processes and taken major new directions in science. Many of the concepts and tools of molecular biology have been derived from the study of viruses and their host cells. This chapter is an attempt to review selected portions of this history as it relates to the development of new concepts in virology (50,51).

THE DEVELOPMENT OF THE CONCEPT OF VIRUSES

The Early Period: The 19th Century

By the last half of the 19th century, the existence of a diverse microbial world of bacteria, fungi, and protozoa was well established. As early as 1840, the noted German anatomist Jacob Henle of Gottingen (the discoverer of Henle's loop and the grandfather of 20th-century virologist Werner Henle) hypothesized the existence of infectious agents that were too small to be observed with the light microscope and that were able to cause specific diseases. In the absence of any direct evidence for such entities, however, his ideas failed to be accepted. It was at this time that three major advances in microbiology came together to set the stage for the development of the concept of a submicroscopic agent that would come to be called a virus.

The first of these ideas was the demonstration that the spontaneous generation of organisms did not occur. This notion had a long history, with experiments both supporting and refuting it. The credit, however, for finally disproving this hypothesis is commonly given to Louis Pasteur (1822–1895), who employed his swan-neck flasks to strike a mortal blow to the concept of spontaneous generation. Pasteur went on to study fermentation by different microbial agents. During these studies, he made it clear that “different kinds of microbes are associated with different kinds of fermentations” and he extended this concept to disease processes. Building on this, Robert Koch (1843–1910), a student of Jacob Henle and a country doctor in a small German village, demonstrated that the anthrax bacillus was the cause of this disease (1876) and that the tubercle bacillus was the cause of tuberculosis in humans (1882). Little of this would have been possible without the third major contribution by Joseph Lister (1827–1912). Once it was clear that organisms reproduce new organisms, the importance of a sterile field, whether in surgery or for the isolation of new organisms, became clear. Lister contributed the technique of limiting dilution to obtain pure cultures of organisms, and Koch developed solid media, the isolation of separate individual colonies of bacteria to obtain pure cultures, and the use of stains to visualize these microorganisms. Although many scientists of that day contributed to these tools and concepts, it was principally Pasteur, Lister, and Koch who put together a new experimental approach for medical science.

These studies formalized some of Jacob Henle's original ideas in what are now termed Koch's postulates for defining whether an organism was indeed the causative agent of a disease. These postulates state that (a) the organism must be regularly found in the lesions of the disease, (b) the organism must be isolated in pure culture, (c) inoculation of such a pure culture of organisms into a host should initiate the disease, and (d) the organism must be recovered once again from the lesions of the host. By the end of the 19th century, these concepts became the dominant paradigm of medical microbiology. They outlined an experimental method to be used in all situations. It was only when these rules broke down and failed to yield a causative agent that the concept of a virus was born.

The Discovery Period: 1886–1903

Adolf Mayer (1843–1942), a German scientist trained in the field of chemical technology (who had studied fermentation and plant nutrition), became the director of the Agricultural Experiment Station at Wageningen, Holland, in 1876. A few years later (1879), he began his research on diseases of tobacco and, although he was not the first to describe such diseases, he named the disease tobacco mosaic disease after the dark and light spots on infected leaves. In one of Mayer's experiments, he inoculated healthy plants with the juice extracted from diseased plants by grinding up the infected leaves in water. This was the first experimental transmission of a viral disease of plants, and Mayer reported that, “in nine cases out of ten (of inoculated plants), one will be successful in making the healthy plant ... heavily diseased” (109). Although these studies established the infectious nature of the disease, neither a bacterial nor a fungal agent could be consistently cultured or detected in these extracts, so Koch's postulates could not be satisfied. In a preliminary communication in 1882 (108), he speculated that the cause could be a “soluble, possibly enzyme-like

contagium, although almost any analogy for such a supposition is failing in science.” However, 4 years later, in his definitive paper on this subject, Mayer concluded that the mosaic disease “is bacterial, but that the infectious forms have not yet been isolated, nor are their forms and mode of life known” (109).

The next step was taken by Dimitri Ivanofsky (1864–1920), a Russian scientist working in St. Petersburg. In 1887 and again in 1890, Ivanofsky was commissioned by the Russian Department of Agriculture to investigate the cause of a tobacco disease on plantations in Bassarabia, Ukraine, and the Crimea. Ivanofsky rapidly repeated Mayer's observations, demonstrating that the sap of infected plants contained an agent able to transmit the disease to healthy plants, and he added one additional step. He passed the infected sap through a filter that blocked the passage of bacteria—the Chamberland filter, made of unglazed porcelain. The Chamberland filter, perfected to purify water by Charles Chamberland, one of Pasteur's collaborators, contained pores small enough to retard most bacteria. On February 12, 1892, Ivanofsky reported to the Academy of Sciences of St. Petersburg that “the sap of leaves infected with tobacco mosaic disease retains its infectious properties even after filtration through Chamberland filter candles” (79). The importance of this experiment is that it provided an operational definition of viruses, an experimental technique by which an agent could qualify as a virus.

Ivanofsky, like Mayer before him, failed to culture an organism from the filtered sap and failed to satisfy Koch's postulates. He, too, was bound by the paradigm of the times suggesting that the filter might be defective or something might be wrong with his methods. He even suggested the possibility that a toxin (not a living/reproducing substance) might pass through the filter and cause the disease. As late as 1903, when Ivanofsky published his thesis (80), he could not depart from the possibility that bacteria caused this disease and that he and others had somehow failed to culture them. The dogma of the times and the obvious success of Koch's postulates kept most scientists from interpreting their data in a different way. It is equally curious that, at this time (1885), Pasteur was working with viruses and developing the rabies vaccine (117) but never investigated the unique nature of that infectious agent.

The third scientist to play a key role in the development of the concept of viruses was Martinus Beijerinck (1851–1931), a Dutch soil microbiologist who collaborated with Adolf Mayer at Wageningen. Beijerinck also showed that the sap of infected tobacco plants could retain its infectivity after filtration through a Chamberland candle filter. [He was unaware of Ivanofsky's work at the time (1898).] He then extended these studies by showing that the filtered sap could be diluted and then regain its “strength” after replication in living, growing tissue of the plant. The agent could reproduce itself (which meant that it was not a toxin) but only in living tissue, not in the cell-free sap of the plant. This explained the failure to culture the pathogen outside its host, and it set the stage for discovery of an organism smaller than bacteria (a filterable agent), not observable in the light microscope, and able to reproduce itself only in living cells or tissue. Beijerinck called this agent a “*contagium vivum fluidum*” (9), or a contagious living liquid. This concept began a 25-year debate about the nature of viruses; were they liquids or particles? This conflict was laid to rest when d'Herelle developed the plaque assay in 1917 (33) and when the first electron micrographs were taken of tobacco mosaic virus (TMV) in 1939 (88).

Thus, Mayer, Ivanofsky, and Beijerinck each contributed to the development of a new concept: a filterable agent too small to observe in the light microscope but able to cause disease by multiplying in living cells. Loeffler and Frosch (101) rapidly described and isolated the first filterable agent from animals, the foot-and-mouth disease virus, and Walter Reed and his team in Cuba (1901) recognized the first human filterable virus, yellow fever virus (122). The term *virus* [from the Latin for slimy liquid or poison (76)] was at that time used interchangeably for any infectious agent and so was applied to TMV. The literature of the first decades of the 20th century most often referred to these infectious entities as filterable agents, and this was indeed the operational definition of viruses. Sometime later, the term *virus* became restricted in use to those agents that fulfilled the criteria developed by Mayer, Ivanofsky, and Beijerinck and that were the first agents to cause a disease that could not be proven by using Koch's postulates.

The Plant Viruses and the Chemical Period: 1929–1956

Tobacco mosaic virus (TMV) continued to play a central role in exploring the nature and properties of viruses. The early decades of the 20th century saw the development of techniques to purify enzymes (proteins). The notion that viruses were proteins and so could be purified in the same way was first appreciated and applied by Vinson and Petre (1927–1931) at the Boyce Thompson Institute in Philadelphia. They precipitated the infectious TMV agent [using an infectivity assay developed by Holmes (75)] from the crude sap of infected plants using selected salts, acetone, or ethyl alcohol (144). They showed that the infectious virus could move in an electric field, just as proteins did. At the same time, H. A. Purdy-Beale, also at the Boyce Thompson Institute, produced in rabbits antibodies directed against TMV that could neutralize the infectivity of this agent (121). At the time, this was taken as further proof of the protein nature of viruses. With the advent of purification procedures for viruses, both physical and chemical measurements of the virus became possible. The strong flow birefringence of purified preparations of TMV was interpreted (correctly) to show an asymmetric particle or rod-shaped particle (136). Max Schlesinger (129), working on purified preparations of bacteriophages in Frankfurt, Germany, showed that they were composed of proteins and contained phosphorus and deoxyribonucleic acid. This led to the first suggestion that viruses were composed of nucleoproteins. The crystallization of TMV in 1935 by Wendell Stanley (132), working at the Rockefeller Institute branch in Princeton, New Jersey, brought this infectious agent into the world of the chemists. Within a year, Bawden and Pirie (7,8) had demonstrated that crystals of TMV contained 0.5% phosphorus and 5% RNA. The first “view” of a virus came from x-ray crystallography using these crystals to show rods of a constant diameter aligned in hexagonal arrays containing RNA and protein (14). The first electron micrographs of any virus, those of TMV, were taken with a microscope built in Germany, and they confirmed the rod shape of the virus particle (88).

The x-ray diffraction patterns (14) suggested that TMV was built up from repeating subunits. These data and other considerations led Crick and Watson (29) to realize that most simple viruses had to consist of one or a few species of identical protein subunits. By 1954–1955, several techniques had been developed to dissociate TMV protein subunits, and TMV could be reconstituted from its RNA and protein subunits (57) to produce infectious virus. The principles of virus self-assembly (20) were appreciated using TMV, and in 1962 Caspar and Klug (23) elegantly described the geometric principles of icosahedral virus structure for many of the isometric viruses. Thus, from 1929 to 1962, both the structures

and the chemical compositions of viruses were elucidated.

As early as 1926, H. H. McKinney (110) reported the isolation of “variants” of TMV with a different plaque morphology that bred true and could be isolated from several geographic locations (111). In 1933, Jensen (85) confirmed McKinney's observations and demonstrated reversion mutations for this phenotype. Thus, viruses, like all living and replicating entities, could mutate and therefore had genetic information. That the genetic information resides in the RNA of TMV was shown 30 years later by an infectious RNA assay (56,65). This was the first demonstration that RNA could be a genetic material. This followed Avery's DNA transformation experiments with pneumococcus (4) and the Hershey-Chase experiment with bacteriophages (73), both of which demonstrated that DNA was the more common genetic material. TMV RNA and its nucleotide sequence helped to confirm codon assignments for the genetic code, added clear evidence for the universality of the genetic code, and helped to elucidate the mechanisms of mutation by several diverse mutagens (55). TMV and its related plant viruses have contributed significantly to both the origins and the development of virology.

THE BACTERIOPHAGES

The Early Period: 1915–1940

In 1915, Frederick W. Twort was the superintendent of the Brown Institution in London. In his research, Twort was looking for variants of vaccinia virus, used in the smallpox vaccine, that would replicate in simple defined media outside living cells. In one of his experiments, he inoculated a culture dish of nutrient agar with an aliquot of the smallpox vaccine and, although the virus failed to replicate, bacterial contaminants grew in the agar dish very readily. As Twort continued to incubate his cultures, he noticed that some bacterial colonies underwent a visible change and became “watery looking” (i.e., more transparent). Such colonies were no longer able to replicate when subcultured (i.e., the bacteria had been killed). Twort called this phenomenon glassy transformation, and he went on to show that infecting a normal colony of bacteria with the glassy transforming principle would kill the bacteria. The glassy entity readily passed through a porcelain filter, could be diluted a million-fold, and when placed upon fresh bacteria would regain its strength, or titer (140,141 and 142).

Twort (140) published a short note describing all this and suggested that one explanation of his observation was a virus of bacteria. Twort's research was interrupted by World War I, in which he served. When he returned to London, he did not continue this line of research and made no further contributions in this area.

At the same time, Felix d'Herelle, a Canadian medical bacteriologist, was working at the Pasteur Institute in Paris. In August 1915, a cavalry squadron of French soldiers were quartered in Maisons-Lafitte, just outside Paris, and a rampant *Shigella* dysentery infection was devastating the entire outfit. D'Herelle readily isolated the dysentery bacillus from filtered emulsions of the feces of sick men and cultured them. As the bacteria grew and covered the surface of the Petri dish, d'Herelle occasionally observed clear circular spots where no bacteria grew, and he called these *taches vierges*, or plaques. D'Herelle (33,34) was able to follow the course of an infection in a single patient, noting when the bacteria were most plentiful and when the plaques appeared. He was able to demonstrate that the plaques appeared on the fourth day after infection and killed the bacteria in the culture dish; interestingly, the patient began to improve on the fourth day after infection.

D'Herelle named these viruses bacteriophages, and he went on to develop techniques utilized to this day in virology. He developed the use of limiting dilutions with the plaque assay to titer the virus preparation. He reasoned that the appearance of plaques showed that the virus was particulate, or “corpuscular.” D'Herelle also demonstrated that the first step of a virus infection was for the agent to attach (adsorb) to the host cell, which he showed by the co-sedimentation of virus and host after mixing the two. (He showed that the virus was lost from the supernatant fluid.) The attachment of a virus occurred only when bacteria sensitive to the virus were mixed with it, demonstrating the host range specificity of a virus at the adsorption step. He described cell lysis and the release of infectious virus in clear and modern terms. D'Herelle (34,35) was in many ways one of the founders of the principles of modern virology.

By 1921, an increasing number of lysogenic bacterial strains had been isolated, and it became impossible to separate the virus from its host in some experiments. This led Jules Bordet (18) of the Pasteur Institute in Brussels to suggest that the transmissible agent described by d'Herelle was nothing more than a bacterial enzyme that stimulates its own production. Although that was an incorrect conclusion, it is remarkably close to the present ideas of prion structure and replication (see Chapter 90).

Throughout the decades of the 1920s and 1930s, d'Herelle focused his efforts on the potential medical applications of his research, but it never bore fruit. What basic research was being carried out at that time was often confused by the interpretations that resulted from the strong personalities of individual scientists in the field. Although it was clear that there were many diverse bacteriophages and that some were lytic while some were lysogenic, their interrelationships remained ill-defined. The highlight of this period was the demonstration by Max Schlesinger (128,130) that purified phages had a maximum linear dimension of 0.1 micron and a mass of about 4×10^{-16} grams and that they were composed of protein and DNA in roughly equal proportions. In 1936, no one quite knew what to make of that observation, but it would begin to make a great deal of sense over the next 20 years.

The Modern Period: 1938–1970

Max Delbrück was trained as a physicist at the University of Gïttingen, and his first position was at the Kaiser Wilhelm Institute for Chemistry in Berlin. There he joined a diverse group of individuals actively discussing how quantum physics related to an understanding of heredity. Delbrück's interest in this area led him to develop a quantum mechanical model of the gene, and in 1937 he applied for and obtained a fellowship to study at the California Institute of Technology. Once at Caltech, he teamed up with another research fellow, Emory Ellis (44), who was working with a group of bacteriophages, T2, T4, T6 (the T-even phages). Delbrück soon appreciated that these viruses were ideal for the study of virus replication. These phages represented a way to probe how genetic information could determine the structure and

function of an organism. From the beginning, these viruses were viewed as model systems for understanding cancer viruses or even for understanding how a sperm fertilizes an egg and a new organism develops. Ellis and Delbrück (45) designed the one-step growth curve experiment, in which an infected bacterium liberates hundreds of phages synchronously after a one-half hour latent or eclipse period. This experiment defined the latent period, when viral infectivity was lost. This became the experimental paradigm of the phage group.

At the outbreak of World War II, Delbrück remained in the United States (at Vanderbilt University) and met an Italian refugee, Salvador E. Luria, who had fled to America and was working at Columbia University in New York (with phages T1 and T2). They met at a meeting in Philadelphia on December 28, 1940, and spent the next 2 days planning experiments at Columbia. These two scientists were to recruit and lead a growing group of researchers focused on using bacterial viruses as a model for understanding life processes. Central to their success was an invitation to spend the summer of 1941 at Cold Spring Harbor Laboratory doing experiments. The result was that a German physicist and an Italian geneticist joined forces throughout the years of World War II to travel throughout the United States and recruit a new generation of biologists who came to be known as the phage group.

Shortly thereafter, Tom Anderson, an electron microscopist at the RCA Laboratories in Princeton, New Jersey, met Delbrück, and by March 1942 the first clear pictures of bacteriophages had been obtained (104). About the same time, the first mutants of these phages were isolated and characterized (102). By 1946, the first phage course was being taught at Cold Spring Harbor, and in March 1947, the first phage meeting attracted eight people. From these humble beginnings grew the field of molecular biology, which focused on the bacterial host and its viruses.

The next 25 years (1950–1975) was an intensely productive period of virus research with bacteriophages. Hundreds of virologists produced thousands of publications that covered three major areas: (a) lytic infection of *E. coli* with the T-even phages; (b) the nature of lysogeny, using lambda phage; and (c) the replication and properties of several unique phages such as fX174 (single-stranded circular DNA), the RNA phages, T7, and so forth. It is simply not possible here to review all this literature, which laid the foundations for modern molecular virology and biology, so only selected highlights of this era will be mentioned.

By 1947–1948, the idea of examining, at the biochemical level, the events occurring in phage-infected cells during the latent period had come into its own. Seymour Cohen [who had trained first with Erwin Chargaff at Columbia University, studying lipids and nucleic acids, and then with Wendell Stanley working on TMV RNA, and who had taken Delbrück's phage course (1946) at Cold Spring Harbor] examined the effects of phage infection on DNA and RNA levels in infected cells using a colorimetric analysis (26,27). These studies showed a dramatic alteration of macromolecular synthesis in phage-infected cells: (a) The net accumulation of RNA stopped in these cells. [Later this would be the basis for detecting a rapidly turning over species of RNA and the first demonstration of messenger RNA (3)]. (b) There was a cessation of DNA synthesis for 7 minutes, followed by a resumption of DNA synthesis at a 5- to 10-fold increased rate. (c) At the same time, Monod and Wollman (112) showed that the synthesis of a cellular enzyme, the inducible b-galactosidase, was inhibited after phage infection. These experiments divided the viral latent period into early (prior to DNA synthesis) and late times. These results, more importantly, made the clear point that a virus could redirect cellular macromolecular synthetic processes in infected cells (28).

By the end of 1952, two experiments had a critical effect on this field. First, Hershey and Chase (73) utilized differentially labeled viral proteins ($^{35}SO_4$) and nucleic acids ($^{32}PO_4$) to follow phage attachment to bacteria. They were able to shear the viral protein coats from the bacteria using a Waring blender and thus leave only the DNA associated with the infected cells. This enabled them to prove that the DNA had all the information needed to reproduce 100 new viruses. The Hershey-Chase experiment came at the right time to be appreciated in light of the novel structure of DNA elucidated by Watson and Crick 1 year later (145). Together, these experiments formed a cornerstone of the molecular biology revolution (21).

The second experiment in virology carried out in 1953, which was to have an important influence, was done by G. R. Wyatt and S. S. Cohen (155). They identified a new base, hydroxymethylcytosine, in T-even phage DNA; this new base took the place of cytosine, which was present in bacterial DNA. This began a 10-year study of how deoxyribonucleotides were synthesized in bacteria and phage-infected cells, and it led to the critical observation that the virus introduces genetic information for a new enzyme into the infected cell (53). By 1964, Mathews et al. (28) had proved that hydroxymethylase does not exist in uninfected cells and must be encoded for by the virus. These experiments introduced the concept of early enzymes, utilized in deoxypyrimidine biosynthesis and DNA replication (90), and provided clear biochemical proof that the virus encoded new information expressed as proteins in an infected cell. A detailed genetic analysis of these phages identified and mapped the genes encoding these phage proteins and added to this concept. Indeed, the genetic analysis of the rII A and B cistrons of T-even phages became one of the best-studied examples of “genetic fine structure” (10,11). The replication of viral DNA using phage mutants and extracts to complement and purify enzyme activities *in vitro* contributed a great deal to our modern understanding of how DNA duplicates itself (1). Finally, a detailed genetic analysis of phage assembly, utilizing the complementation of phage assembly mutants *in vitro*, is a lucid example of how complex structures are built by living organisms using the principles of self-assembly (41). The genetic and biochemical analysis of phage lysozyme helped to elucidate the molecular nature of mutations (135), and phage (amber) mutations provided a clear way to study second-site suppressor mutations at the molecular level (12). The circular genetic map of the T-even phages (134) was explained by the circularly permuted, terminally redundant (giving rise to phage heterozygotes) conformation of these DNAs (139).

The remarkable reprogramming of viral and cellular protein synthesis in phage-infected cells was dramatically revealed by an early use of sodium dodecyl sulfate (SDS)-polyacrylamide gels (93), showing that viral proteins are made in a specific sequence of events ever subdividing the early and late proteins. The underlying mechanism of this temporal regulation led to the discovery of sigma factors modifying RNA polymerase and conferring gene specificity (67). The study of gene regulation at almost every level (transcription, RNA stability, protein synthesis, protein processing) was revealed from a set of original contributions derived from an analysis of phage infections.

Although this remarkable progress had begun with the lytic phages, no one knew quite what to make of the lysogenic phages. This changed in 1949 when André Lwoff at the Pasteur Institute began his studies with *Bacillus megaterium* and its lysogenic phages. By use of a micromanipulator, single bacteria were shown to divide up to 19 times, never liberating a virus. When lysogenic bacteria were lysed from without, no virus was detected. But from time to time a bacterium spontaneously lysed and produced many viruses (106). The influence of ultraviolet light in inducing the release of these viruses was a key observation that began to outline this curious relationship between a virus and its host (107). By 1954, Jacob and Wollman (82,83) at the Pasteur Institute had made the important observation that a genetic cross between a lysogenic bacterial strain (Hfr, lambda) and a nonlysogenic recipient resulted in the induction of the virus after conjugation, a process they called zygotic induction. In fact, the position of the lysogenic phage or prophage in the chromosome of its host *E. coli* could be mapped by the standard interrupted mating experiment after a genetic cross (83). This was one of the most critical experiments in the conceptual understanding of lysogenic viruses for several reasons: (a) It showed that a virus behaved like a bacterial gene on a chromosome in a bacteria; (b) it was one of the first experimental results to suggest that the viral genetic material was kept quiescent in bacteria by negative regulation, which was lost as the chromosome passed from the lysogenic donor bacteria to the nonlysogenic recipient host; and (c) this helped Jacob and Monod to realize as early as 1954 that the “induction of enzyme synthesis and of phage development are the expression of one and the same phenomenon” (106). These experiments laid the foundation for the operon model and the nature of coordinate gene regulation.

Although the structure of DNA was elucidated in 1953 (145) and zygotic induction was described in 1954, the relationship between the bacterial chromosome and the viral chromosome in lysogeny was still referred to as the attachment site and literally thought of in those terms. It was not until Campbell (22) proposed the model for lambda integration of DNA into the bacterial chromosome, based on the fact that the sequence of phage markers was different in the integrated state than in the replicative or vegetative state, that the truly close relationship between a virus and its host was appreciated. This led to the isolation of the negative regulator or repressor of lambda, a clear understanding of immunity in lysogens, and one of the early examples of how genes are regulated coordinately (120). The genetic analysis of the lambda bacteriophage life cycle is one of the great intellectual adventures in microbial genetics (72). It deserves to be reviewed in detail by all students of molecular virology and biology.

The lysogenic phages such as P22 of *Salmonella typhimurium* provided the first example of generalized transduction (157), whereas lambda provided the first example of specialized transduction (114). That viruses could carry within them cellular genes and transfer such genes from one cell to another provided not only a method for fine genetic mapping but also a new concept in virology. As the genetic elements of bacteria were studied in more detail, it became clear that there was a remarkable continuum from lysogenic phages to episomes, transposons and retrotransposons, insertion elements, retroviruses, hepadnoviruses, viroids, virosoids (in plants), and prions. Genetic information moves between viruses and their hosts to the point where definitions and classifications begin to blur.

The genetic and biochemical concepts that derive from the study of bacteriophages made the next phase of virology possible. The lessons of the lytic and lysogenic phages were often relearned and modified as the animal viruses were studied.

ANIMAL VIRUSES

The Early Period (1898–1965): Discovery and Cell Culture

Some of the highlights of the early period of animal virology are summarized in Table 1. Once the concept of a filterable virus took hold, this experimental procedure was applied to many diseased tissues. Filterable agents, unable to be seen in a light microscope, that replicate only in living animal tissue were found. There were truly some surprises, such as a virus—yellow fever virus—transmitted by a mosquito vector (122), specific visible pathologic inclusion bodies (viruses) in infected tissue (80,116), and even viral agents that can “cause cancer” (43,123). Throughout this early time period (1900–1930), a wide variety of viruses were found (see Table 1) and characterized with regard to their size (using the different pore sizes of filters), resistance to chemical or physical agents (e.g., alcohol, ether), and pathogenic effects. Just based on these properties, it became clear that viruses were a very diverse group of agents. Some were even observable in the light microscope (vaccinia in dark-field optics). Some were inactivated by ether, whereas others were not. The range of viral diseases affected every tissue type. Viruses gave rise to chronic or acute disease; they were persistent agents or recurred in a periodic fashion. Viruses might cause cellular destruction or induce cellular proliferation. For the early virologists, unable to see their agents in a light microscope and often confused by this great diversity, there had to be an element of faith in their studies. In 1912, S. B. Wolbach, an American pathologist, remarked, “It is quite possible that when our knowledge of filterable viruses is more complete, our conception of living matter will change considerably, and that we shall cease to attempt to classify the filterable viruses as animal or plant” (151).

Date	Virologist	Discovery
1898	F. Loeffler, P. Frosch	First demonstration of a filterable animal virus (foot-and-mouth disease virus)
1898	G. Sanarelli	Myxomatous virus
1901	W. Reed et al.	First human virus (yellow fever virus)
1901	A. Lode, J. Gruber	Fowl plague virus
1903	P. Remlinger, Riffat Bey	Rabbit virus
1903	A. Negri	The inclusion bodies of rabies virus
1908	V. Ellerman, O. Bang	First demonstration of a leukemia-causing virus
1909	K. Landsteiner, E. Popper	Poliovirus
1911	P. Rous	First demonstration of a solid tumor virus, Rous sarcoma virus
1912	A. Carrel	Tissue culture of chick embryo explant
1913	E. Steinhardt et al.	An early example of virus propagation in tissue culture
1931	J. Furth	Use of mice as a host for viruses
1931	A. Woodruff, E. Goodpasture	Use of the embryonated chicken egg as a host for viruses
1931	R. Shope	Swine influenza virus
1933	W. Smith et al.	Human influenza virus
1933	R. Shope	Rabbit papilloma virus (first DNA tumor virus)
1933	Staff of the Jackson Memorial Laboratory	Mouse mammary tumors
1936	P. Rous, J. Beard	Rabbit papilloma virus induces carcinomas in a different species
1941–50	G. Hirst	Influenza virus hemagglutination (HA), HA inhibition by antibody, receptor-destroying enzyme (neuraminidase—the first virus-associated enzyme)
1948–50	Sanford et al.	Culture of single animal cells
	J. Enders et al.	Nonneural tissue (human) supports poliovirus replication in culture
	G. Gey et al.	Single cell cultures, HeLa cervical carcinoma
	H. Eagle	The optimal medium for growing cells
1952–65	Dulbecco, Dulbecco, Vogt, Temin, Rubin, Baltimore, et al.	Plaque assay and origins of the molecular biology of animal viruses using polioviruses

TABLE 1. *Landmarks in animal virus research: The early period (1898–1965)*

The way out of this early confusion was led by the plant virologists and the development of techniques to purify viruses and characterize both the chemical and physical properties of these agents (see previous section, The Plant Viruses and the Chemical Period: 1929–1956). The second path out of this problem came from the studies with bacteriophages, where single cells infected with viruses in culture were much more amenable to experimental manipulation and clear answers than were virus infections of whole animals. Whereas the plant virologists of that day were tethered to their greenhouses and the animal virologists were bound to their animal facilities, the viruses of bacteria were studied in Petri dishes and test tubes. Progress in simplifying the experimental system under study came one step at a time; from studying animals in the wild, to laboratory animals, such as the mouse (59) or the embryonated chicken eggs (152), to the culture of tissue, and then to single cells in culture. Between 1948 and 1955, a critical transition converting animal virology into a laboratory science came in four important steps: (a) Sanford et al. (126) at the National Institutes of Health (NIH) overcame the difficulty of culturing single cells, (b) George Gey (64) and his colleagues at Johns Hopkins Medical School cultured and passaged human cells for the first time and developed a line of cells (HeLa) from a cervical carcinoma, (c) Harry Eagle (40) at the NIH developed an optimal medium for the culture of single cells, and (d) in a demonstration of the utility of all this, Enders and his colleagues (46) showed that poliovirus could replicate in a nonneuronal human explant of embryonic tissues.

These ideas, technical achievements, and experimental materials had two immediate effects in virology. First, they led to the development of the polio vaccine as the first vaccine produced in cell culture. From 1798 to 1949, all the vaccines in use (smallpox, rabies, yellow fever, influenza) had been grown in animals or embryonated chicken eggs. Poliovirus was grow in monkey kidney cells (74,98) incubated in flasks. Second, the exploitation of cell culture for the study of viruses began the modern era of molecular virology. The first plaque assay for an animal virus in culture was with poliovirus (36), and it led to an analysis of poliovirus every bit as detailed and important as the contemporary work with bacteriophages. The simplest way to document this statement is for the reader to compare the first edition of General Virology by S. E. Luria in 1953 (103) to the second edition by Luria and J. E. Darnell in 1967 (105) and to examine the experimental descriptions of poliovirus infection of cells. The present era of virology had arrived, and it would continue to be full of surprises.

The Modern Period: 1960 to the Present

In this chapter, information has been presented chronologically or in separate virus groups (plant viruses, bacteriophages, and animal viruses), which reflects the historical separation of these fields. In this section, the format changes because the motivation for studying viruses began to change during this period. Virologists began to use viruses to probe questions central to understanding all life processes. Because viruses replicate in and are dependent on their host cells, they must use the rules, signals, and regulatory pathways of the host. Virologists began to make contributions to all facets of biology. These ideas began with the phage group and were continued by the animal virologists. Second, during this period (1970 to the present), the recombinant DNA revolution began, and both bacteriophages and animal viruses played a critical and central role in this revolution. Viruses were used to probe many diverse questions in biology. For these reasons, the organization of this section focuses on the accomplishments of cellular and molecular biology, where viruses were used. Some of the landmarks in virology since 1970 are listed in Table 2.

TABLE 2. *Landmarks in virology: 1970 to present*

The Role of Animal Viruses in Understanding the Basic Outlines of Eukaryotic Gene Regulation

The closed circular and superhelical nature of polyoma virus DNA was first elucidated by Dulbecco and Vogt (37) and Weil and Vinograd (147). The underlying reason for this structure of DNA was first shown to be the packaging of the DNA of simian vacuolating virus 40 (SV40), wound around nucleosomes (63), which produced a superhelix when the histones were removed. These observations proved to be excellent models for the *E. coli* genome (153) and the mammalian chromosome (94). The unique genomes of viruses, with single-stranded DNA (131), plus or minus strand RNA, or double-stranded RNA, are the only life forms that have adopted these modes of information storage.

Important elements of the eukaryotic transcription machinery have been elucidated with viruses. The first transcriptional enhancer element (acts in an orientation- and distance-independent fashion) was described in the SV40 genome (68), as was a distance- and orientation-dependent promoter element observed with the same virus. The transcription factors that bind to the promoter, SP-1 (38), or to the enhancer element, such as AP-1, AP-2 (96), and which are essential to promote transcription along with the basal factors, were first described with SV40. AP-1 is composed of fos and jun family member

proteins, demonstrating the role of transcription factors as oncogenes (17). Indeed, the great majority of experimental data obtained for basal and accessory transcription factors come from *in vitro* transcription systems using the adenovirus major late promoter or the SV40 early enhancer–promoter (146). Our present-day understanding of RNA polymerase III promoter recognition comes, in part, from an analysis of the adenovirus VA gene transcribed by this polymerase (54).

Almost everything we know about the steps of messenger RNA (mRNA) processing began with observations made with viruses. RNA splicing of new transcripts was first described with the adenoviruses (13,25). Polyadenylation of mRNA was first observed with poxviruses (86) using a system where the first DNA-dependent RNA polymerase in a virion was discovered (87). The signal for polyadenylation in the mRNA was first found using SV40 (52). The cap and methylation of bases at the 5' end of mRNA was first detected using reoviruses (60). What little is known about the process of RNA transport out of the nucleus has shown a remarkable discrimination of viral and cellular mRNAs by the adenovirus E1B-55Kd protein (118).

Translational regulation has been profitably studied using poliovirus RNA (or TMV RNA), where internally regulated initiation entry sites (IRES) have been described (84). The discovery of the role of interferon in inducing a set of gene products that act on translational regulatory events owes its origins to virology (77,78). Similarly, the viral defenses against interferon by the adenovirus VA RNA has provided unique insight to the role of eIF-2 phosphorylation events (89). Posttranslational processing of proteins by proteases, carbohydrate addition to proteins in the Golgi apparatus, phosphorylation by a wide variety of important cellular protein kinases, or the addition of fatty acids to membrane-associated proteins have all been profitably studied using viruses. Indeed, a good deal of our present-day knowledge in cell biology of how protein trafficking occurs and is regulated in cells comes from the use of virus-infected cell systems. Clearly, the field of gene regulation has relied on virology for many of its central tenets.

The Role of Animal Viruses in the Recombinant DNA Revolution

The discovery of the enzyme reverse transcriptase in retroviruses (5,138) not only helped to prove how retroviruses replicate but also provided an essential tool to produce complementary DNAs (cDNAs). The first restriction enzyme map of a chromosome, *Hin*dII plus III, was with SV40 DNA (30,31), and the first DNA to show the specificity of a restriction enzyme was SV40 DNA with *Eco*RI (113,115). Some of the earliest DNA cloning experiments used SV40 DNA into lambda, or human b-hemoglobin genes into SV40 DNA, to construct the first mammalian expression vectors (81). Indeed, a debate about these very experiments led to a temporary moratorium on all such recombinant experiments. From the beginning, several animal viruses had been developed into expression vectors for foreign genes, including SV40 (66), the retroviruses (148), the adenoviruses (62,70), and adeno-associated virus (125), which has the remarkable property of site preferential integration (91). Modern day strategies of gene therapy will surely rely on some of these recombinant viruses. The first cDNA cloning of hemoglobin sequences utilized lambda vectors for the cloning and replication of these mRNA copies. In a nice twist of events, the long-elusive hepatitis virus C (non-A, non-B) was cloned from serum using recombinant DNA techniques, reverse transcriptase, and lambda phage vectors (24).

The Role of Animal Virology in Oncology

It is not too strong a statement to say that we owe a great proportion of our present understanding of the origins of human cancers to two major groups of animal viruses, the retroviruses and DNA tumor viruses. The oncogenes were first discovered and proven to exist in a virus and then in the host cell genome using Rous sarcoma virus (133). A wide variety of retroviruses have captured, altered, and delivered oncogenes to the virologists (see Chapter 10). The insertion of retroviruses into the genomes of cancerous cells also helped to locate additional oncogenes (69). The second group of genes that contribute to the origins of human cancers, the tumor suppressor genes (97), has been shown to be intimately associated with the DNA tumor viruses. Genetic alterations at the p53 locus are the single most common mutations known to occur in human cancers (60% to 65% of the time) (99). The p53 protein was first discovered in association with the SV40 large T-antigen (95,100). SV40, the human adenoviruses, and the human papillomaviruses all encode oncogenes that produce proteins that interact with and inactivate the functions of two tumor suppressor gene products, the retinoblastoma susceptibility gene product (Rb) and p53 (32,39,95,100,127,149,150). The cellular oncogenes and the tumor suppressor genes in human cancers have been studied and understood most profitably using these viruses.

The viruses that cause cancers have provided some of the most extraordinary episodes in modern animal virology. The recognition of a new disease and the unique geographic distribution of Burkitt's lymphomas in Africa (19) set off a search for viral agents that cause cancers in humans. From D. Burkitt (19) to Epstein, Achong, and Barr (47) to W. Henle and G. Henle (71), the story of the Epstein-Barr virus and its role in several cancers, as well as in infectious mononucleosis, provides us with the best in detective story science. The story is not yet complete and many mysteries remain. Similarly, the identification of a new pathologic disease, adult T-cell leukemia, in Japan by K. Takatsuki (137,143) led to the isolation of a virus that causes the disease by I. Miyoshi and Y. Hinuma (156) and the realization that this virus [human T-cell leukemia virus (HTLV-1)] had been found previously (119) by Gallo and his colleagues. Although this discovery provided the virus, there is yet to be a satisfactory explanation of how this virus contributes to adult T-cell leukemia.

Equally interesting is the road to the hepatitis B virus and hepatocellular carcinomas. By 1967, S. Krugman and his colleagues (92) had good evidence distinguishing between hepatitis A and B viruses, and in the same year B. Blumberg et al. (16) detected the Australia antigen. Through a tortuous path, it eventually became clear that the Australia antigen was a diagnostic marker (a coat protein) for hepatitis B. Although this freed the blood supply of this dangerous virus, Hilleman at Merck, Sharp and Dohme and the Chiron Corporation (which later isolated the hepatitis C virus) went on to produce the first human vaccine that prevents hepatitis B infections and very likely hepatocellular carcinomas associated with chronic virus infections (see Chapter 87). The idea of a vaccine that can prevent cancer [first proven with the Mareck's disease virus and T-cell lymphomas in chickens (15,42)] comes some 82 to 85 years after the first discoveries of tumor viruses by Ellerman, Bang, and Rous. At present, an experiment is under way in Taiwan, where 63,500 newborn infants have been inoculated to prevent hepatitis B infections. Based on the epidemiologic predictions, this vaccination program should result in 8,300 fewer cases of liver cancer in that population some 40 to 50 years from now.

Vaccines

The Salk and then Sabin poliovirus vaccines were the first beneficial products of the cell culture revolution. In the early 1950s in the United States, just before the introduction of the Salk vaccine, about 21,000 cases of poliomyelitis were reported annually. Today, the number is fewer than 10 (see Chapter 21) (98).

Among the most remarkable achievements of our century is the complete eradication of smallpox, a disease with a history of over 2,000 years (154). In 1966, the World Health Organization began a program to immunize all individuals who had come into contact with an infected person. This strategy, as opposed to trying to immunize an entire population (which simply was not possible), worked and, in October 1977, Ali Maolin of Somalia was the last person in the world to have a naturally occurring case of smallpox (barring laboratory accidents). Because smallpox has no animal reservoir and requires person-to-person contact for its spread, most scientists agree that we are free of this disease (154). What most scientists do not agree on is whether we should store smallpox virus samples as a reference for the future (2).

The viral vaccines used in the past have included live attenuated vaccines, killed virus vaccines, and subunit vaccines. Both the killed virus vaccine (Salk) and the recombinant subunit vaccine (hepatitis B, S antigen) were new to the modern era of virology. In the future, we will see one virus (e.g., vaccinia virus) presenting the antigens of a different virus, the injection of DNA-encoding viral antigens, and the use of specific interleukins or hormones with vaccines to stimulate immunity at specific locations in the host and to elucidate specific immunoglobulin classes. Considering that the first vaccines (for smallpox) were reported in the Chinese literature of the 10th century (48), these ideas can be traced back in time to the origins of virology.

Although vaccines have been extraordinarily successful in preventing specific diseases, there had been very few natural products or chemotherapeutic agents that cured or reduced the symptoms of virus infections. That changed dramatically with the development of acyclovir by Burrows-Wellcome, which requires both a viral enzyme (thymidine kinase) to activate it (by phosphorylation) and a second enzyme to incorporate it into viral DNA, employing its specificity for the viral encoded DNA polymerase. This drug blocks HSV-2 reactivation from latency and stopped a growing epidemic in the 1970s and 1980s (Chapter 15). Similarly, the interferons (Chapter 12) have come into use clinically for hepatitis B and C infections, cancer therapy, and multiple sclerosis. The interferons, found in the course of studying virus interference (77,78), will modulate the immune response and have an increasing role to play in treatments of many clinical syndromes.

An overview of the modern period of animal virology would not be complete without mentioning the appearance of an apparently new virus during the decades of the 1970s and 1980s, the human immunodeficiency virus. It was first recognized as a new disease entity by clinicians and epidemiologists, and they rapidly tracked down the venereal mode of virus transmission. Blood products and transplants provided the fluid and tissue samples for virologists to detect this virus. The first published report of acquired immunodeficiency syndrome (AIDS) was in June 1981. The first publications describing a candidate virus for this disease were in 1983 (6) and then 1984 (61). Had this virus and disease begun in 1961 instead of 1981, neither the nature of retroviruses nor the existence of its host cell (CD-4 helper T-cell) would have been understood. The rapid development of a diagnostic test has helped to remove the virus from the blood supply and to test individuals for the virus.

The development of the first drugs to treat human immunodeficiency virus (HIV) infections (e.g., zidovudine) proved disappointing because of the rapid development of resistance to the drug via mutations in the reverse transcriptase gene. The mutation rates by retroviruses (1 in 10^4 to 10^5 nucleotides polymerized) are very high and the solution to this problem is to give multiple drugs simultaneously, requiring mutations at different loci to develop resistance. The use of two different drugs directed against reverse transcriptase and a third drug that is an HIV protease inhibitor provides a cocktail that can reduce the viral load to a nondetectable level in a patient. Eliminating the integrated and silent copies of the viral DNA from the host cell does not look promising. The highest priority will be the development of an HIV vaccine. This is clearly a major challenge for the future.

Epidemiologic Adventures in Virology

The field of the epidemiology of viruses (see Chapter 14) got a terrific boost in the last half of the 20th century with the advent of specific molecular tools [antibodies, polymerase chain reaction (PCR), rapid diagnostic tests] to detect viruses in body fluids or tissue samples, to compare and classify these agents rapidly, and to determine the relationships between virus strains. The marriage of behavioral, geographic, and molecular epidemiology made this a most powerful science. The previous section reviewing advances in oncology pays tribute to this strategy by D. Burkitt and K. Takatsuki, leading to the identification of Epstein-Barr virus (EBV) and HTLV-1. Similarly, the recombinant DNA revolution overcame the problems of propagating the human papillomaviruses, permitting the isolation of new virus serotypes and setting off epidemiologic correlations for high- or low-risk cancer viruses (158). The human papillomaviruses (see Chapter 65 and Chapter 66) differ in transmission, location on the body, their nature of pathogenesis, persistence, and so forth. Similarly, the first recognition of the so-called slow viruses, which cause spongiform encephalopathies (Chapter 90), came from epidemiologic studies with humans and animals.

With the evolutionary development of a sophisticated immune system in vertebrates, the viruses of these hosts faced a new challenge in that they could no longer productively infect their hosts more than once. For their part, these viruses responded with the establishment of latency (herpesviruses), attacking directly the cells involved in the immune response (HIV), setting up persistent or chronic infections, or devising rapid methods for antigenic changes (influenza A virus). This ability of influenza A to undergo antigenic drift and shift resulted in the development of a lifestyle that uses Darwinian principles in a time frame shorter than that of any other organism. G. Hirst and his colleagues (1941–1950) developed the diagnostic tools to follow this. This permitted both the typing of the hemagglutinin of influenza A strains and the monitoring of the antibody response to it in patients (see Chapter 46 and Chapter 47). This has been used, with more and more sophisticated molecular approaches, to prove the presence of animal reservoirs for this virus, the reassortment of chromosomes between human and animal virus strains (antigenic shift), and a high rate of mutation

(antigenic drift) caused by RNA-dependent RNA synthesis with no known RNA editing or corrective mechanisms. How these molecular events led to episodic local epidemics and worldwide pandemics has now been explained in broad outline. Although most viruses tend to come to equilibrium with their hosts and become endemic [see, for example, the introduction of the North American myxoma–fibroma virus into the wild European rabbit population in Australia (49)], influenza A virus remains epidemic, changing from local to pandemic via an antigenic shift of its HA subunit gene. These studies (Chapter 46 and Chapter 47) have revealed an extraordinary lifestyle. Similarly, the study of the mechanisms of viral pathogenesis and the role of the immune system in this process have led to new insights in the virus–host relationship.

The field of viral epidemiology is changing rapidly with the advent of a new branch termed molecular epidemiology. The PCR technologies permit rapid sampling of viruses without growth in culture or plaque purification. Rapid genome sequencing has revealed sequence relationships between viruses, and sequence heterogeneity within a virus population. Mutation rates are documented and localized in the genome, and their biologic consequences are tested. Just two mutations altered the feline panleukopenia virus into a canine parvovirus, for the first time highly pathogenic and transmissible in dogs. Similarly, the earliest isolates of HIV (ZR 1959) suggest an HIV origin in the 1940s to 1950s derived from a chimpanzee lentivirus in Africa. Rapid mutation forming a population of viruses or clades followed.

Molecular epidemiology will now be required to detect and follow emerging viruses. Whether the next emerging epidemic will result from a novel variant of Ebola virus, Hantan virus, or Norwalk virus, or the more common possibility of a new pandemic variant of influenza virus remains to be seen. What is much clearer, however, is that the demographics of the human population on earth have begun to change. Even as birth rates slow, earth will house 8 to 10 billion people by 2050 to 2100. For the first time, there will be three to four times more people above the age of 60 than below 3 to 4 years of age. We will become an increasingly urban population, with more than 20 to 30 cities containing more than 10 million people. Clearly, human behavioral patterns (increased population density, increased travel, increased ages of the population) will provide the environment for the selection of emerging viruses and the challenges to the new field of molecular epidemiology.

Host–Virus Interactions and Viral Pathogenesis

The modern era of virology (1960 to present), which was developed largely with studies in cell culture, described in great detail the replicative cycles of viruses. Virologists demonstrated the elaborate interactions between viral genomes or viral proteins and host cell proteins. As indicated previously, this resulted in an extraordinary inquiry into the functions of infected or uninfected host cells using the tools of both molecular and cell biology. As this approach matured, the questions became more detailed and of less general interest, and so virologists turned back to the natural host animal, or a related animal model, to address new sets of questions. Chief among these questions was, how does a virus cause disease processes in the animal? How do we quantitate viral virulence and what is the genetic basis of an attenuated virus? These studies have identified, in selected viruses, a set of genes and functions that broadly impact on viral virulence.

Six categories of such factors have been explored to date. First, mutations in genes that impair virus replication in the host reduce the number of viruses produced below a level required to produce disease. These are essential genes (essential for life) *in vivo*. A second class of mutations has been identified in viral genes: These mutations impair virulence but do not alter normal virus replication at least in some cell or tissue types. Here, host or tissue range mutations are most common. Mutations can change the pattern of virus adsorption to a particular cell type and so prevent viral entry into a cell. Mutations in viral enhancer elements can alter the ability of a virus to transcribe its genes in selected cell types. All three strains of the Sabin poliovirus attenuated vaccine contain mutations in the viral RNA 5' untranslated region, which reduce translation of these RNAs in selected cells (i.e., neurons) but still allow replication in other cells and immunization of the host. A third class of genes critical to regulating viral virulence produce gene products that modify the host defenses. HIV infection kills CD-4 T-cells and eliminates an immune response. Some viruses encode genes that produce virokines that are secreted from infected cells and modify the immune response to infection. Other viruses produce proteins that alter the human leukocyte antigen (HLA) presentation of viral antigens in infected cells, whereas some viruses produce superantigens that stimulate or eliminate lymphoid cells of a selected specificity or with a class of receptors. Many viruses produce proteins that block infected cells from undergoing apoptosis in response to a virus infection. Some viruses, such as African swine fever virus, secrete a pro-apoptotic factor that kills lymphocytes and enhances its virulence. A fourth class of genes and products produced by viruses that impacts on virulence enhances the spread of a virus in the host organism. Some viruses contain signals that permit the virus to bud from an infected cell specifically at the apical or basolateral surfaces of a tissue, permitting selected spread *in vivo*. Some of the RNA viruses acquire infectivity by budding out of a cell using specific proteolytic cleavage of their glycoproteins. This is done in some cases by a viral protease and in others by a cellular protease, each requiring a specific amino acid sequence in the glycoprotein for proper cleavage and spread of the virus. Altering this sequence alters the host cell, which can then give rise to infectious virus, and it can also impact on virulence.

A wide variety of polymorphisms or mutations in the host animal can modulate resistance or virulence of a virus. These mutations can even be selected for during viral epidemics, thus changing the hosts' gene pool. In humans, polymorphisms in a cytokine or cytokine receptor gene imparts resistance to HIV infection at the level of viral absorption. Variations in the immune responses of diverse hosts in a population will result in large variations in the virulence of a virus. The mechanisms used by the host to minimize viral diseases after infection will be a major subject for study in the future.

Finally, changes in population density, life styles, cultural traditions, and economic factors have all played a major role in virus virulence. Poliovirus was a minor endemic virus infection for 3,000 years prior to the introduction of improved sanitation in the last century. This created a population that was infected with this virus for the first time at a later age and resulted in poliovirus epidemics that included tens of thousands of cases. It may not have been a coincidence that the worst influenza epidemic in the century, killing 40 million people, started about 1918 toward the end of World War I, with so many people dislocated and moving about the world in very poor conditions. Cultural and environmental changes will

surely play a role in the virulence of viruses.

AFTERWORD: D'HERELLE'S DREAM AND KOCH'S POSTULATES

It was d'Herelle's dream to use bacteriophages as a “magic bullet” to kill bacteria and cure diseases caused by these agents. The ultimate historical irony of that dream was played out by some of the participants described in this chapter over the same time frame.

The story begins in 1884, when Friedrich Johannes Loeffler in Germany used Koch's postulates to isolate and identify the bacterium that causes diphtheria. [Fourteen years later, he and Paul Frosch (both had been trained by R. Koch) would isolate the foot-and-mouth disease virus, the first animal virus to be isolated.] Loeffler was surprised to note, however, that when he inoculated the bacteria into an animal, the bacilli were detected only at the site of the local injection, whereas the abnormalities responsible for the disease were visible in the heart, liver, kidneys, and so forth. Loeffler hypothesized that the bacilli produced a toxin that caused the disease at remote sites in the body with no detectable bacteria. In the next step (in 1888), Emile Roux and A. Yersin (at the Pasteur Institute) demonstrated a heat-labile soluble toxin in the fluid phase above the diphtheria bacillus cultures. An injection of the toxin (which could be filtered through a Chamberland filter) into animals reproduced the symptoms. Emile Roux was a student of Pasteur's who worked with Chamberland on his filters. When Ivanofsky suggested that the filterable agent in his TMV preparations was a toxin, he credited Roux for this idea and his work on diphtheria toxin as precedence (76). In 1898, E. I. E. Nocard and Roux isolated from cows a pleuropneumonia organism that could pass through a Chamberland filter, could be seen as microscopic dots in the light microscope, and could be replicated in collodion sacs in a cell-free meat infusion in the peritoneal cavity of a rabbit. In this way they discovered mycoplasma, a bacteria that violated the “filterable agent” concept of a virus or a liquid that could replicate only in an intracellular environment. In fact, in 1903, Roux challenged Beijerinck's idea of a fluid contagium by calling it “very original” but not distinguishable from his tiny mycoplasma spores, which were microorganisms. In 1903, Roux (124) wrote the first review article on viruses, entitled “Sur les microbes dits 'invisible.'”

By 1890 in Germany, von Behring and Kitasato treated the diphtheria toxin with chemical agents to inactivate it and then immunized animals with it. They demonstrated that serum from immunized animals protected other animals from the toxin and, on Christmas night in 1891 in Berlin, this antitoxin was first given to a child with diphtheria. Shibasaburo Kitasato had also developed a microorganism filter with somewhat finer pores than the Chamberland filter, and he even sold it commercially. Loeffler, in 1898, used both the Chamberland and the Kitasato filters to test whether foot-and-mouth disease virus was retained by or passed through these two filters. This virus readily passed through the Chamberland filter but lost virulence by repeated filtration through a Kitasato filter. Loeffler used these data to claim that the virus was particulate, or corpuscular, partly stopped by the Kitasato filter, and he thus challenged Beijerinck's concept of a fluid contagium (a liquid virus). Beijerinck responded that he felt that the foot-and-mouth disease virus was adsorbed to the Kitasato filter and was not stopped by its smaller pore size. The scientific arguments concerning the nature of viruses continued.

In 1923, G. Ramon introduced a formalin-treated diphtheria toxin as an immunizing agent, and an effective vaccine was in hand that all but eliminated this disease from countries that had an active vaccination program. Although that should have been the end of a good story, it was not. In 1951, V. J. Freeman (58) made the unexpected observation that all virulent strains of *Corynebacterium diphtheriae* are lysogenic with a phage called beta. If the bacteria are cured of this prophage, they fail to produce toxin and are avirulent. Indeed, the gene for this toxin is encoded by the phage genome and is regulated by the metabolic state of the bacteria. The lysogenic virus causes this disease. Koch's postulates had been circumvented by the intimate association of a virus and its host as first described by Lwoff and his colleagues. D'Herelle's dream of a phage curing a disease was given a cruel twist of fate in this case. These filterable agents, be they toxins, viruses, or even viruses that produce toxins when lysogenic in their host and so cannot pass a filter, all have the power to present a most confusing or at the very least a complex picture to the observer.

It is a tribute to the scientists of those times that they came so close to describing reality, while inferring the existence of organisms that could not be seen except by their effect on a host. These 100 years of virology have forged new concepts and provided novel insights into the processes of life.

CHAPTER 2 Principles of Virology

Richard C. Condit

Viruses are unique in nature. They are the smallest of all self-replicating organisms, historically characterized by their ability to pass through filters that retain even the smallest bacteria. In their most basic form, viruses consist solely of a small segment of nucleic acid encased in a simple protein shell. They have no metabolism of their own but rather are obliged to invade cells and parasitize subcellular machinery, subverting it to their own purposes. Many have argued that viruses are not even living, although to a seasoned virologist they exhibit a life as robust as any other creature.

The apparent simplicity of viruses is deceptive. As a group, viruses infect virtually every organism in nature, they display a dizzying diversity of structures and lifestyles, and they embody a profound complexity of function.

The study of viruses, virology, must accommodate both the uniqueness and the complexity of these organisms. The singular nature of viruses has spawned novel methods of classification and experimentation entirely peculiar to the discipline of virology. The complexity of viruses is constantly challenging scientists to adjust their thinking and their research to describe and understand some new twist in the central dogma revealed in a “simple” virus infection.

This chapter explores several concepts fundamental to virology as a whole, including virus taxonomy, virus cultivation and assay, and virus genetics. The chapter is not intended as a comprehensive or encyclopedic treatment of these topics but rather as a relatively concise overview with sufficient documentation for more in-depth study. In addition to primary resources and practical experience, the presentation draws heavily on previous editions of *Fields Virology* (29,30 and 31) for both the taxonomy and the genetics material, plus several excellent texts for material on virus cultivation and assay (16,28,35,50,57,60,65). It is hoped that this chapter will be of value to anyone learning virology at any stage: a novice trying to understand basic principles for the first time, an intermediate student of virology trying to understand the technical subtleties of virologic protocols in the literature, or a bewildered scientist in the laboratory wondering why the temperature-sensitive mutant sent by a colleague does not seem to be temperature sensitive.

VIRUS TAXONOMY

A coherent and workable system of classification, a taxonomy, is a critical component of the discipline of virology. However, the unique nature of viruses has defied the strict application of many of the traditional tools of taxonomy used in other disciplines of biology. Thus, scientists who concern themselves with global taxonomy of organisms have traditionally left the viruses scattered throughout the major kingdoms, reasoning that viruses have more in common with their individual hosts than they do with each other (66). By contrast, for practical reasons at least, virologists agree that viruses should be considered together as a separate group of organisms regardless of host, be it plant, animal, fungus, protist, or bacterium, a philosophy borne out by the observation that in several cases viruses now classified in the same family, for example family *Rhabdoviridae*, infect hosts from different kingdoms. Interestingly, the discipline of virus taxonomy brings out the most erudite and thought-provoking, virtually philosophical discussions about the nature of viruses, probably because the decisions that must be made to distinguish one virus from another require the deepest thought about the nature of viruses and virus evolution. In the end, all of nature is a continuum, and the business of taxonomy has the unfortunate obligation of drawing boundaries within this continuum, an artificial and illogical task but necessary nevertheless. The execution of this obligation results today in a free-standing virus taxonomy, overseen by the International Committee on Taxonomy of Viruses (ICTV), with rules and tools unique to the discipline of virology. The process of virus taxonomy that has evolved uses some of the hierarchical nomenclature of traditional taxonomy, identifying virus species and grouping them into genera, genera into families, and families into orders, but at the same time, to cope with both the uniqueness and diversity of viruses as a group, the classification process has been deliberately nonsystematic and thus is “based upon the opinionated usage of data” (73).

Most important, the virus taxonomy that has been developed works well. For the trained virologist, the mention of a virus family or genus name, such as family *Herpesviridae* or genus *Rotavirus*, immediately conjures forth a set of characteristics that form the basis for further discussion or description. Virus taxonomy serves an important practical purpose as well, in that the identification of a limited number of biologic characteristics, such as virion morphology, genome structure, or antigenic properties, quickly provides a focus for identification of an unknown agent for the clinician or epidemiologist and can significantly impact further investigation into treatment or prevention of a virus disease. Virus

taxonomy is an evolving field, and what follows is a summary of the state of the art, including important historical landmarks that influenced the present system of virus taxonomy, a description of the system used for virus taxonomy and the means for implementation of that system, and a very brief overview of the taxonomy of viruses that infect humans and animals.

History and Rationale

Virology as a discipline is scarcely 100 years old, and thus the discipline of virus taxonomy is relatively young. In the early 1900s, viruses were initially classified as distinct from other organisms simply by virtue of their ability to pass through unglazed porcelain filters known to retain the smallest of bacteria. As increasing numbers of filterable agents became recognized, they were distinguished from each other by the only measurable properties available, namely the disease or symptoms caused in an infected organism. Thus animal viruses that caused liver pathology were grouped together as hepatitis viruses, and viruses that caused mottling in plants were grouped together as mosaic viruses. In the 1930s, an explosion of technology spawned a description of the physical properties of many viruses, providing numerous new characteristics for distinguishing viruses one from another. The technologies included procedures for purification of viruses, biochemical characterization of purified virions, serology, and, perhaps most important, electron microscopy, in particular negative staining, which permitted detailed descriptions of virion morphology, even in relatively crude preparations of infected tissue. In the 1950s, these characterizations led to the distinction of three major animal virus groups, the myxoviruses, the herpesviruses, and the poxviruses. By the 1960s, because of the profusion of data describing numerous different viruses, it became clear that an organized effort was required to classify and name viruses, and thus the ICTV (originally the International Committee on the Nomenclature of Viruses, ICNV) was established in 1966. The ICTV functions today as a large, international group of virologists organized into appropriate study groups, whose charge it is to develop rules for the classification and naming of viruses, and to coordinate the activities of study groups in the implementation of these rules.

Early in its history, the ICTV wrestled with the fundamental problem of developing a taxonomic system for classification and naming of viruses that would accommodate the unique properties of viruses as a group, and that could also anticipate advancements in the identification and characterization of viruses. Perhaps the most critical issue was whether the classification of viruses should consider virus properties in a monothetical, hierarchical fashion, or in a polythetical, hierarchical fashion (definition to follow). A monothetical, hierarchical classification, modeled after the Linnean system used for classification of plants and animals, would effectively rank individual virus properties, such as genome structure or virion symmetry, as being more or less important relative to each other, and use these individual characteristics to sort viruses into subphyla, classes, orders, suborders, and families (63). Whereas the hierarchical ordering of viruses into groups and subgroups is desirable, a strictly monothetical approach to using virus properties in making assignments to groups was problematic because both the identification of individual properties to be used in the hierarchy, and the assignment of a hierarchy to individual properties seemed too arbitrary.

A polythetic approach to classification would group viruses by comparing simultaneously numerous properties of individual viruses, without assigning a universal priority to any one property. Thus, using the polythetic approach, a given virus grouping is defined by a collection of properties rather than a single property, and virus groups in different branches of the taxonomy may be characterized by different collections of properties. One argument against the polythetic approach is that a truly systematic and comprehensive comparison of dozens of individual properties would be at least forbidding if not impossible. However, this problem could be avoided by the adoption of a nonsystematic approach, namely, using study groups of virologists within the ICTV to consider together numerous characteristics of a virus and make as rational an assignment to a group as possible. Therefore, the system that is currently being used is a nonsystematic, polythetical, hierarchical system. This system differs from any other taxonomic system in use for bacteria or other organisms, but it is effective and useful, and it has withstood the test of time (72). As our understanding of viruses increases, and as new techniques for characterization are developed, notably comparison of gene and genome sequences, the methods used for taxonomy will undoubtedly continue to evolve.

As a consequence of the polythetic approach to classification, the virus taxonomy that exists today has been filled initially from the middle of the hierarchy by assigning viruses to genera, and then elaborating the taxonomy upward by grouping genera into families and to a limited extent families into orders. By 1970, the ICTV had established two virus families, each containing two genera, 24 floating genera, and 16 plant “groups” (106). A rigorous species definition (100), discussed later, was not approved by the ICTV until 1991, but it has now been applied to the entire taxonomy and has become the primary level of classification for viruses. As of this writing, the complete virus taxonomy comprises 3 orders, 69 families, 9 subfamilies, 243 genera, 1550 species, and 2404 tentative species (101). The complete virus taxonomy is far too extensive to relate here, but examples of the results of the taxonomy are offered in Table 1 and Table 2. Table 1 lists the distinguishing characteristics of the major animal virus families detailed in this edition of *Fields Virology,* and Table 2 provides an example of the entire taxonomic classification of one virus order, the order *Mononegavirales.*

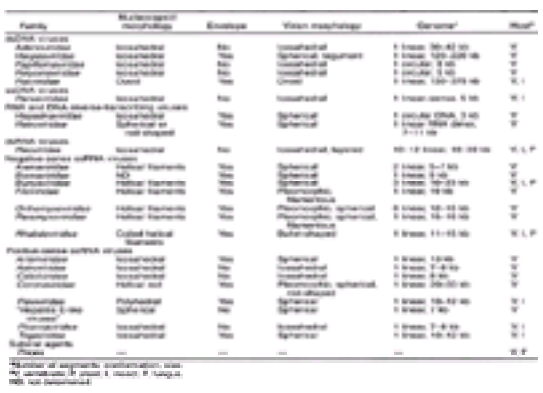

TABLE 1. *Summary of characteristics of major animal virus families*

Order Family	Subfamily	Genus	Type species	Host
Mononegavirales				
Bornaviridae		*Bornavirus*	*Borna disease virus*	Vertebrates
Filoviridae		Marburg-like viruses	*Marburg virus*	Vertebrates
		Ebola-like viruses	*Zaire Ebola virus*	Vertebrates
Paramyxoviridae	Paramyxovirinae	*Respirovirus*	*Sendai virus*	Vertebrates
		Rubulavirus	*Mumps virus*	Vertebrates

The ICTV Universal System of Virus Taxonomy

Structure and Function of the ICTV

The ICTV is a committee of the Virology Division of the International Union of Microbiological Societies. The objectives of the ICTV are to develop an internationally agreed-upon taxonomy and nomenclature for viruses, to maintain an index of virus names, and to communicate the proceedings of the committee to the international community of virologists. The ICTV publishes an update of the taxonomy at approximately 3-year intervals (27,33,68,69,73,106). At the time of this writing, the most recent report is the seventh (101). The ICTV also supports a web site (http://www.ncbi.nlm.nih.gov/ICTV/), which contains all its published information in a conveniently interactive format, plus links to additional sites of interest, including the universal virus database of the ICTV (ICTVdB), described later.

Virus Properties and Their Use in Taxonomy

As introduced previously, the taxonomic method adopted for use in virology is polythetic, meaning that any given virus group is described using a collection of individual properties. The description of a virus group is nonsystematic in that there exists no fixed list of properties that must be considered for all viruses, and no strict formula for the ordered consideration of properties. Instead, a set of properties describing a given virus is simply compared with other viruses described in a similar fashion to formulate rational groupings. Dozens of properties can be listed for description of a virus, but they break down generally into virion morphology, including size, shape, capsid symmetry, and presence or absence of an envelope, virion physical properties, including genome structure, sensitivity to physical or chemical insults; specific features of viral lipids, carbohydrates, and structural and nonstructural proteins; antigenic properties; and biologic properties including replication strategy, host range, mode of transmission, and pathogenicity (72,73).

The Hierarchy

The ICTV has adopted a universal classification scheme that employs the hierarchical levels of order, family, subfamily, genus, and species. Because the polythetic approach to classification introduces viruses into the middle of the hierarchy, and because the ICTV has taken a relatively conservative approach to grouping taxa, levels higher than order are not currently used. Levels lower than species, such as strains and variants, are not officially considered by the ICTV but are left to specialty groups.

A virus species is defined as “a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche” (100). The formal definition of a polythetic class is “a class whose members always have several properties in common although no single common attribute is present in all of its members” (101). Thus, no single property can be used to define a given species, and application of this formal definition of a polythetic class to species accounts nicely for the inherent variability found among members of a species. The qualification of a replicating lineage implies that members of a species experience evolution over time with consequent variation, but that members share a common ancestor. The qualification of occupation of an ecologic niche acknowledges that the biology of a virus, including such properties as host range, pathogenesis, transmission, and habitat, are fundamental components of the characterization of a virus. In the most recent report of the ICTV, study group members have listed the criteria that identify each species, then listed species according to the criteria. In addition, some viruses are listed as tentative species because their taxonomic status cannot currently be unambiguously determined. Last, a type species, the species used to define the taxon, has been identified for each genus.

Taxonomic levels higher than species are formally defined by the ICTV only in a relative sense—namely, a genus is a group of species sharing certain common characters, a subfamily is a group of genera sharing certain common characters, a family is a group of genera or subfamilies sharing certain common characters, and an order is a group of families sharing certain common characters. As the virus taxonomy has evolved, these higher taxa have acquired some monothetic character. They remain polythetic in that they may be characterized by more than one virus property, but they violate the formal definition of a polythetic class in that one or more defining properties may be required of all candidate viruses for membership in the taxon. Not all taxonomic levels need be used for a given grouping of viruses, thus whereas most species are grouped into genera and genera into families, not all families contain subfamilies, and only a few families have been grouped into orders. Consequently, the family is the highest consistently used taxonomic grouping, it therefore carries the most generalized description of a given virus group, and as a result it has become the benchmark of the taxonomic system. Most families have distinct virion morphology, genome structure, and/or replication strategy (Table

1).

Nomenclature

The ICTV has adopted a formal nomenclature for viruses, specifying suffixes for the various taxa, and rules for written descriptions of viruses. Names for genera, subfamilies, families, and orders must all be single words, ending with the suffixes -virus, -virinae, -viridae, and -virales, respectively. Species names may contain more than one word and have no specific ending. In written usage, the formal virus taxonomic names are capitalized and written in italics, and they are preceded by the name of the taxon, which is neither capitalized nor italicized. For species names that contain more than one word, the first word plus any proper nouns are capitalized. As an example, the full formal written description of human respiratory syncytial virus is order *Mononegavirales*, family *Paramyxoviridae*, subfamily *Pneumovirinae*, genus *Pneumovirus*, species *Human respiratory syncytial virus.*

Order of Presentation of the Viruses

For convenience in presenting or tabulating the virus taxonomy, informal categorical groupings of taxa have been created and together are called an order of presentation. Although superficially the order of presentation appears to function as a higher taxonomic level, it is important to understand that no hierarchy or official taxonomic classification is intended. Currently, the criteria used to specify the order of presentation are nature of the viral genome, strandedness of the viral genome, polarity of the genome, and reverse transcription. In addition, two categories have been created for subviral agents, one for viroids and another for satellites and prions. Finally, a category exists for unassigned viruses. These criteria give rise to nine groupings in the order of presentation, specifically dsDNA viruses, ssDNA viruses, dsRNA viruses, negative-sense ssRNA viruses, positive-sense ssRNA viruses, DNA and RNA reverse transcribing viruses, subviral agents (viroids), subviral agents (satellites and prions), and unassigned viruses. Table 1 provides an example of the usage of the order of presentation.

Universal Virus Database of the ICTV

To facilitate the management and distribution of virologic data, the ICTV has established the universal virus database of the ICTV (ICTVdB). The ICTVdB is accessible on the worldwide web at http://life.anu.edu.au/viruses/welcome.htm, with mirror sites in Europe (http://www.res.bbsrc.ac.uk/mirror/auz/welcome.htm) and North America (http://www.ncbi.nlm.nih.gov/ICTVdB/welcome.htm). The ICTVdB, constructed from virus descriptions in the published reports of the ICTV, comprises searchable descriptions of all virus families, genera, and type species, including microscopic images of many viruses. The ICTVdB is a powerful resource for management of and access to virologic data, and it promises to considerably extend the reach and capability of the ICTV.

VIRUS CULTIVATION AND ASSAY

Different branches of science are defined in large part by their techniques, and virology is no exception. Although the study of viruses uses some general methods that are common to other disciplines, the unique nature of viruses and virus infections requires a unique set of technical tools designed specifically for their investigation. Conversely, what we know and can know about viruses is delimited by the techniques used, and therefore a genuine understanding of virology requires a clear understanding of virologic methods. What follows therefore is a summary of the major techniques essential and unique to all of virology, presented as fundamental background for understanding the discipline.

Initial Detection and Isolation

The presence of a virus is evidenced initially by effects on a host organism, or, in the case of a few animal viruses, by effects on cultured cells. Effects on animal hosts include a broad spectrum of symptoms, including skin and mucous membrane lesions; digestive, respiratory, or neurologic disorders; immune dysfunction; or specific organ failure such as hepatitis or myocarditis. Effects on cultured cells include a variety of morphologic changes in infected cells, termed cytopathic effects and described in detail later in this chapter and in Chapter 18. Both adenovirus (87) and the polyomavirus SV40 (98) were discovered as cell culture contaminants before they were detected in their natural hosts.

Viruses can be isolated from an affected host by harvesting excreted or secreted material, blood, or tissue and testing for induction of the original symptoms in the identical host, or for induction of some abnormal pathology in a substitute host or in cell culture. Historically, dogs, cats, rabbits, rats, guinea pigs, hamsters, mice, and chickens have all been found to be useful in laboratory investigations (57), although most animal methods have now been replaced by cell culture methods (65). Once the presence of a virus has been established, it is often desirable to prepare a genetically pure clone, either by limiting serial dilution or by plaque purification.

Viruses that are cultivated in anything other than the natural host may adapt to the novel situation through acquisition of genetic alterations that provide a replication advantage in the new host. Such adaptive changes may be accompanied by a loss of fitness in the original host, most notably by a loss of virulence or pathogenicity. Although this adaptation and attenuation may present problems to the basic scientist interested in understanding the replication of the virus in its natural state, it also forms the basis of construction of attenuated viral vaccines.

Hosts for Virus Cultivation

Laboratory Animals and Embryonated Chicken Eggs

Prior to the advent of cell culture, animal viruses could be propagated only on whole animals or embryonated chicken eggs. Whole animals could include the natural host—laboratory animals such as rabbits, mice, rats, and hamsters. In the case of laboratory animals, newborn or suckling rodents often provide the best hosts. Today, laboratory animals are

seldom used for routine cultivation of virus, but they still play an essential role in studies of viral pathogenesis.

The use of embryonated chicken eggs was introduced to virology by Goodpasture et al. in 1932 (38) and developed subsequently by Beveridge and Burnet (3). The developing chick embryo, 10 to 14 days after fertilization, provides a variety of differentiated tissues, including the amnion, allantois, chorion, and yolk sac, which serve as substrates for growth of a wide variety of viruses, including orthomyxoviruses, paramyxoviruses, rhabdoviruses, togaviruses, herpesviruses, and poxviruses (57). Members of each of these virus families may replicate in several tissues of the developing egg, or replication may be confined to a single tissue. Several viruses from each of the groups just mentioned cause discrete and characteristic foci when introduced onto the chorioallantoic membrane (CAM) of embryonated eggs, thus providing a method for identification of virus types, or for quantifying virus stocks or assessing virus pathogenicity (Fig. 1). Although the embryonated eggs have been almost wholly replaced by cell culture techniques, they are still the most convenient method for growing high-titer stocks of some viruses, and they thus continue to be used both in research laboratories and for vaccine production. In addition, pock formation on the CAM still provides a specialized method for assay of variants of poxviruses: wild type rabbitpox and cowpox viruses cause red hemorrhagic pocks on the CAM, whereas viruses deficient in specific virulence genes cause white pocks as a result of the infiltration of the lesions with inflammatory cells (34,77) (Fig. 1).

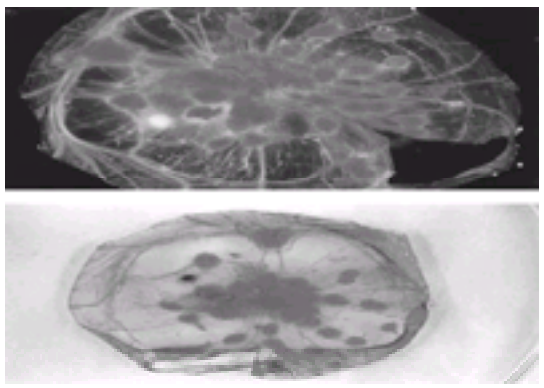

FIG. 1. Cowpox-induced pock formation on the chorioallantoic membrane of chick embryos. The CAMs of intact chicken embryos, 11 days old, were inoculated with cowpox and the eggs were incubated for an additional 3 days at 37.5°C. CAMs were then dissected from the eggs and photographed. The membrane shown at the *top* was untreated, and the membrane at the *bottom* was stained with nitroblue tetrazolium (NBT), an indicator of activated heterophils (34). Wild-type cowpox forms hemorrhagic pocks on the membrane (*top and bottom*). Spontaneous deletion mutants of cowpox virulence genes occur at a high frequency, resulting in infiltration of inflammatory cells into the pock. This infiltration of inflammatory cells causes the pocks to appear white in unstained membrane preparations or dark on NBT-stained membranes. The unstained membrane preparation contains a single white pock; the NBT-stained preparation contains a single dark pock. (Courtesy of Dr. R. Moyer.)

Cell Culture

The maintenance of animal cells *in vitro*, described generally (albeit incorrectly) as tissue culture, can be formally divided into three different techniques: organ culture, primary explant culture, and cell culture. In organ culture, the original three-dimensional architecture of a tissue is preserved under culture conditions that provide a gas–liquid interface. In primary explant culture, minced pieces of tissue placed in liquid medium in a culture vessel provide a source for outgrowth of individual cells. In cell culture, tissue is disaggregated into individual cells prior to culturing. Only cell culture will be discussed in detail here, as it is the most commonly used tissue culture technique in virology.

Cultured cells currently provide the most widely used and most powerful hosts for cultivation and assay of viruses. Cell cultures are of three basic types: primary cell cultures, cell strains, and cell lines, which may be derived from many animal species, and which differ substantially in their characteristics. Viruses often behave differently on different types of cultured cells, and in addition each of the culture types possesses technical advantages and disadvantages. For these reasons, an appreciation of the use of cultured cells in animal virology requires an understanding of several fundamentals of cell culture itself. A detailed description of the theory and practice of cell and tissue culture is provided by Freshney (35), and several additional texts provide excellent summaries of cell culture as it specifically applies to virology (16,28,50).

Primary Cell Culture

A primary cell culture is defined as a culture of cells obtained from the original tissue that have been cultivated *in vitro* for the first time, and that have not been subcultured. Primary cell cultures can be established from whole animal embryos, or from selected tissues from embryos, newborn animals, or adult animals of almost any species. The most commonly used cell cultures in virology derive from primates, including humans and monkeys; rodents, including hamsters, rats, and mice; and birds, most notably chickens. Cells to be cultured are obtained by mincing tissue, and dispersing individual cells by treatment with proteases and/or collagenase to disrupt cell–cell interactions and interactions of cells with the extracellular matrix. With the exception of cells from the hemopoietic system, normal vertebrate cells will grow and divide only when attached to a solid surface. Dispersed cells are therefore placed in a plastic flask or dish, the surface of which has been treated to promote cell attachment. The cells are incubated in a buffered nutrient medium in the presence of blood serum, which contains a complex mixture of hormones and factors required for the growth of normal cells. The blood serum may come from a variety or sources, but bovine serum is most commonly used. Under these conditions, cells will attach to the surface of the dish, and they will divide and migrate until the surface of the dish is covered with a single layer of cells, a monolayer, whereupon they will remain viable but cease to divide. If the cell monolayer is

“wounded” by scraping cells from an isolated area, cells on the border of the wound will resume division and migration until the monolayer is reformed, whereupon cell division again ceases. These and other observations led to the conclusion that the arrest of division observed when cells reach confluency results from cell–cell contact, and it is therefore called contact inhibition. Primary cultures may contain a mixture of cell types, and they retain the closest resemblance to the tissue of origin.

Subcultivation

Cells from a primary culture may be subcultured to obtain larger numbers of cells. Cells are removed from the culture dish and disaggregated by treating the primary cell monolayer with a chelating agent, usually ethylenediamine tetra-acetic acid (EDTA), or a protease, usually trypsin, or both, giving rise to a single-cell suspension. This suspension is then diluted to a fraction of the original monolayer cell density and placed in a culture dish with fresh growth medium, whereupon the cells attach to the surface of the dish and resume cell division until once again a monolayer is formed and cell division ceases. Cultures established in this fashion from primary cell cultures may be called secondary cultures. Subsequently, cells may be repeatedly subcultured in the same fashion. Each subculturing event is called a passage, and each passage may comprise a number of cell generations, depending on the dilution used during the passage. Most vertebrate cells divide at the rate of approximately one doubling every 24 hours at 37°C. Thus, a passage performed with an eightfold dilution will require three cell doublings over 3 days before the cells regain confluency.

Cell Strains

Normal vertebrate cells cannot be passaged indefinitely in culture. Instead, after a limited number of cell generations, usually 20 to 100 depending on the age and species of the original animal, cultured normal cells cease to divide and they degenerate and die, a phenomenon called crisis or senescence (Fig. 2) (45). Starting with the establishment of a secondary culture and until cells either senesce or become transformed (as will be described later), the culture is termed a cell strain, to distinguish it from a primary culture on the one hand, or a transformed, immortal cell line, on the other hand. During culture, cells in a strain retain their original karyotype and are thus called euploid; however, culturing induces profound changes in the composition and characteristics of the cell strain, and these changes are manifested early during the passage history and may continue during passage. Whereas primary cell cultures may contain a mixture of cell types that survive the original plating of cells, only a few cell types survive subculturing, so that by the second or third passage typically only one cell type remains in the cell strain.

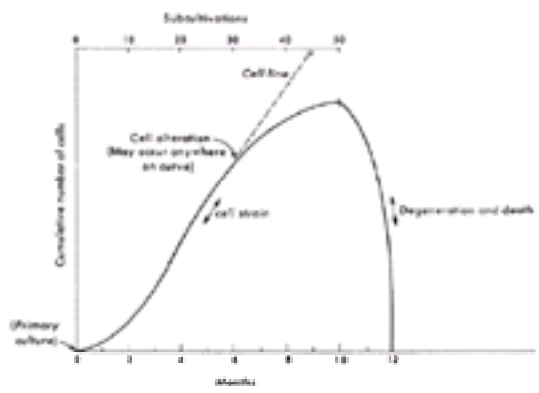

FIG. 2. Growth of cells in culture. A primary culture is defined as the original plating of cells from a tissue, grown to a confluent monolayer, without subculturing. A cell strain (*solid line*) is defined as a euploid population of cells subcultivated more than once *in vitro*, lacking the property of indefinite serial passage. Cell strains ultimately undergo degeneration and death, also called crisis or senescence. A cell line (*dashed line*) is an aneuploid population of cells that can be grown in culture indefinitely. Spontaneous transformation or alteration of a cell strain to an immortal cell line can occur at any time during cultivation of the cell strain. The time in culture and corresponding number of subcultivations or passages are shown on the abscissas. The ordinate shows the total number of cells that would accumulate if all were retained in culture. (From ref. 16 and adapted from ref. 45, with permission.)

Cell strains are usually composed of one of two basic cell types, fibroblast-like or epithelial-like, characterized based on their morphology and growth characteristics (Fig. 3). Fibroblasts have an elongated, spindle shape, whereas epithelial cells have a polygonal shape. Although after only a few passages only one cell type may remain in a cell strain, continued passage may select for faster-growing variants, such that the characteristics of a cell strain may change with increasing passage number. Despite the fact that normal cell strains experience senescence in culture, they may be maintained for many years by expanding the culture to a large number of cells early during the passage history and storing numerous small samples of low-passage cells by freezing. Thus, as a given strain approaches high passage number and senescence, low-passage cells of the same strain may be thawed and cultured.

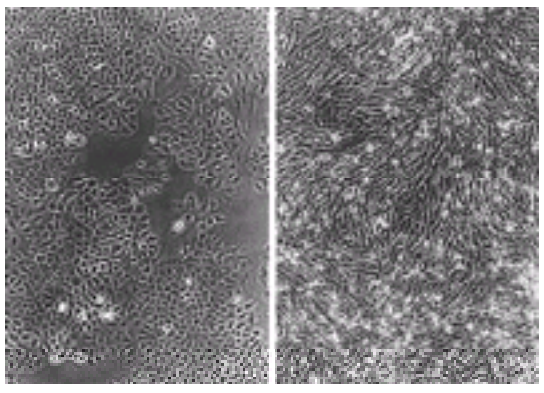

FIG. 3. Cultured cell types. Phase-contrast photomicrographs are shown. *Left*: Epithelial-like cells, A549, a human lung carcinoma cell line, a slightly subconfluent monolayer. *Right*: Fibroblast-like cells, BHK, a baby hamster kidney cell line. (A549 cell culture, courtesy of J. I. Lewis. BHK cell culture, courtesy of D. Holmes and S. Moyer.)

Cell Lines

At any time during the culture of a cell strain, cells in the culture may become transformed, meaning that they are no longer subject to crisis and senescence but can be passaged indefinitely. Transformation is a complex phenomenon, discussed in more detail later and in Chapter 10, but in the context of cell culture, the most important characteristic of transformation is that the transformed cells become immortalized. Immortal cell cultures are called cell lines, or sometimes continuous cell lines, to distinguish them from primary cultures and cell strains. Immortalization can occur spontaneously during passage of a cell strain, or it can be induced by treatment with chemical mutagens, infection with tumorigenic viruses, or transfection with oncogenes. In addition, cells cultured from tumor tissue frequently readily establish immortal cell lines in culture. Spontaneous immortalization does not occur in cultured cells from all animal species. Thus, immortalization occurs frequently during culture of rodent cells, for example in mouse and hamster cell strains, and it has been observed in monkey kidney cells, but it occurs rarely if at all during the culture of chicken or human cells. Immortalization is typically accompanied by genetic changes—such cells become aneuploid, containing abnormalities in the number and structure of chromosomes relative to the parent species, and not all cells in a culture of a continuous cell line necessarily display the same karyotype. Like cell strains, cell lines are usually composed of cells that are either fibroblast-like or epithelial-like in morphology.

As with the propagation of cell strains, continued culture of a cell line may result in selection of specific variants that outgrow other cells in the culture over time, and thus with passage the character of a cell line may change substantially, and cell lines of the same origin cultured in different laboratories over a period of years may have significantly different characteristics. It is prudent, therefore, to freeze stocks of cell lines having specific desirable properties so that these cells can be recovered if the properties disappear during culture. Likewise, it makes sense to obtain a cell line showing certain desired characteristics directly from the laboratory that described those characteristics, because cells from alternative sources may differ in character.

Transformation

Transformed cells are distinguished from normal cells by a myriad of properties, which can be grouped into three fundamental types of changes: immortalization, aberrant growth control, and malignancy. Immortalization refers simply to the ability to be cultured indefinitely, as described in the preceding section. Aberrant growth control comprises a number of properties, several of which have relevance to experimental virology, including loss of contact inhibition, anchorage independence, and tumorigenicity. Loss of contact inhibition means that cells no longer cease to grow as soon as a monolayer is formed and will now grow on top of one another. Anchorage independence means that the cells no longer need to attach to a solid surface to grow. Anchorage independence is often assayed as the ability to form colonies suspended in a semisolid medium such as agar, and a practical consequence of anchorage independence is the ability to grow in liquid suspension. Tumorigenicity refers to the ability of cells to form a tumor in an experimental animal, and malignancy refers to the ability to form an invasive tumor *in vivo.* Of course, malignancy is of vital importance as a phenomenon in its own right, but it has limited application in virology except within the specific discipline of tumor virology (Chapter 10).

It is important to note that the many properties of transformed cells are not necessarily interdependent, and no one property is an absolute prerequisite for another. Thus, transformation is thought to be a multistep genetic phenomenon, and varying degrees of transformation are measurable. Tumorigenicity is often regarded as the most stringent assay for a fully transformed cell, and it is most closely correlated with anchorage independence.

The fact that the various characteristics of transformed cells are not interdependent has important consequences for experimental virology, especially in the assay of tumor viruses. Specifically, a transformed cell line that is immortalized but still contact-inhibited may be used in a viral transformation assay that measures the further transformation to loss of contact inhibition. When cells in a monolayer are transformed by a tumor virus and lose contact inhibition, they grow on top of a confluent monolayer forming a *focus*, or a pile of cells, which is readily distinguishable from the rest of the monolayer. This property forms the basis for quantitative biologic assay of tumor viruses (102), described in more detail later.

Advantages and Disadvantages of Different Cultured Cell Types

The various types of cultured cells just described have specific application to different problems encountered in experimental virology. For most applications, an adherent cell line provides the most useful host cell. Cell lines are

relatively easy to maintain because they can be passaged indefinitely, and adherence is a prerequisite for a plaque assay (described later). A distinct technical advantage of adherent cells is that the culture medium can easily be changed for the purposes of infection or metabolic labeling by simply aspirating and replacing fluid from a monolayer, a process that requires repeated centrifugations with suspension cells. By contrast, relative to adherent cell lines, suspension cell lines are easier to sample than adherent cells, and they produce large numbers of cells from a relatively small volume of medium in a single culture vessel, which has significant advantages for some high-volume applications in virology. Unfortunately, not all viruses will grow on a cell line, and often under these circumstances, a primary cell culture will suffice. This may reflect a requirement for a particular cell type found only under conditions of primary cell culture, or it may reflect a requirement for a state of metabolism or differentiation closely resembling the *in vivo* situation, which is more likely to exist in a primary culture than it is in a cell line.

Last, some viruses do not grow in cell culture at all, and in these cases investigators are reliant either on the old expedients of natural hosts, laboratory animals, or embryonated eggs, or on some more modern advances in tissue culture and recombinant DNA technology. The papilloma viruses, which cause warts, provide an enlightening example of this situation (Chapter 65). Although the viral nature of papillomatosis was demonstrated over 90 years ago, progress on the study of papilloma viruses was seriously hampered in the virology heyday of the mid-20th century because the viruses grow well only on the natural host; they do not grow in culture. The inability to grow in culture is now reasonably well understood: It results from a tight coupling of the regulation of viral gene expression with the differentiation state of the target epithelial cell, which in turn is tightly coupled to the three-dimensional architecture of the epidermis, which is lost in culture. Specialized tissue culture techniques have now been developed that result in the faithful reconstruction of an epidermis by seeding primary keratinocytes on a *feeder* layer composed of an appropriate cell line, and incubating these cells on a *raft*, or grid, at a liquid–air interface. On these raft cultures the entire replication cycle of a papilloma virus can be reproduced *in vitro*, albeit with difficulty (6). In the meantime, it is significant that a large fraction of the genetics and biology of papillomaviruses was determined primarily through the use of recombinant DNA technology, without ever growing virus in culture. Thus, the genetic structure of both the model bovine papillomavirus and many human papillomaviruses has been determined by cloning genomic DNA from natural infections, and regulation and function of many genes can be gleaned from sequence alone, from *in vitro* assays on individual gene products expressed *in vitro*, and from cell transformation assays that use all or parts of a papillomavirus genome. In summary, the inability to grow a virus in culture, while it increases the challenge, no longer presents an insurmountable impediment to understanding a virus.

Recognition of Viral Growth in Culture

Three principal methods exist for the recognition of a virus infection in culture: cytopathic effect, formation of inclusion bodies, and hemadsorption. Cytopathic effect refers to pronounced morphologic changes induced in individual cells or groups of cells by virus infection, which are easily recognizable under a light microscope. Inclusion bodies are more subtle alterations to the intracellular architecture of individual cells. Hemadsorption refers to indirect measurement of viral protein synthesis in infected cells, detected by adsorption of erythrocytes to the surface of infected cells. Cytopathic effect is the simplest and most widely used criterion for infection, but not all viruses cause a cytopathic effect, and in these cases other methods must suffice.

Cytopathic effects, or CPE, comprise a number of cell phenomena, including rounding, shrinkage, increased refractility, fusion, aggregation, loss of adherence, or lysis. CPE caused by a given virus may include several of these phenomena in various combinations, and the character of the CPE may change reproducibly during the course of infection. CPE caused by a given virus are very reproducible and can be so precisely characteristic of the virus type that significant clues to the identity of a virus can be gleaned from the CPE alone (Chapter 18). Fig. 4 depicts different CPE caused by two viruses, measles and vaccinia. Most important to the trained virologist, a simple microscopic examination of a cell culture can reveal whether an infection is present, what fraction of cells are infected, and how advanced the infection is. In addition, because cytopathology results directly from the action of virus gene products, virus mutants can be obtained that are altered in cytopathology, yielding either a conveniently marked virus or a tool to study cytopathology per se.

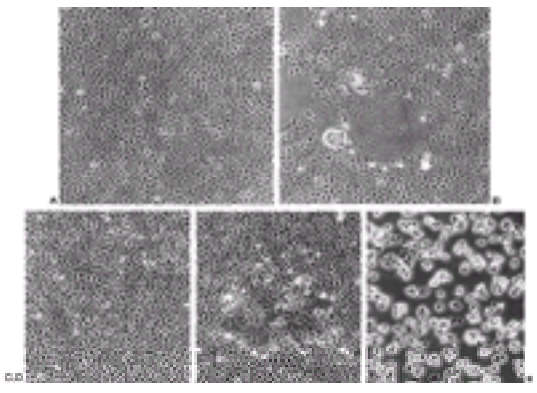

FIG. 4. Virus-induced cytopathic effects (CPE). Phase-contrast photomicrographs are shown. **A:** Uninfected A549 cells, a human lung carcinoma cell line. **B:** A549 cells infected with measles virus at a multiplicity of infection (moi) of less than 0.01 pfu/cell. Individual plaques can be discerned. Measles fuses cells, causing formation of syncytia. In mid field is a large syncytium containing multiple nuclei. Surrounding this area are additional syncytia, including two that have rounded and are separating from the dish. **C:** Uninfected BSC40 cells, an African green monkey cell line. **D:** BSC40 cells infected with vaccinia virus at an moi of less than 0.01 pfu/cell. A single plaque is shown in the middle of the field. **E:** BSC40 cells infected with vaccinia virus at an moi of 10 pfu/cell, 48 hours after infection. All cells are infected and display complete CPE. (Cultures of vaccinia infections courtesy of J. I. Lewis. Cultures of measles infections courtesy of S. Smallwood and S. Moyer.)

The term *inclusion bodies* refers generally to intracellular abnormalities specific to an infected cell and discernible by light microscopy. The effects are highly specific for a particular virus type, so that, as is the case with CPE, the presence of a specific type of inclusion body can be diagnostic of a specific virus infection. Electron microscopy, combined with a more detailed understanding of the biology of many viruses, reveals that inclusion bodies usually represent focal points of virus replication and assembly, which differ in appearance depending on the virus. For example, Negri bodies formed during a rabies virus infection represent collections of virus nucleocapsids (67).

Hemadsorption refers to the ability of red blood cells to attach specifically to virus-infected cells (90). Many viruses synthesize cell attachment proteins, which carry out their function wholly or in part by binding substituents such as sialic acid that are abundant on a wide variety of cell types, including erythrocytes. Often, these viral proteins are expressed on the surface of the infected cell, for example in preparation for maturation of an enveloped virus through a budding process. Thus, a cluster of infected cells may be easily detectable to the naked eye as areas that stain red after exposure to an appropriate preparation of red blood cells. Hemadsorption can be a particularly useful assay for detecting infections by viruses that cause little or no CPE.

Virus Cultivation

From the discussion just presented, it should be clear that ultimately the exact method chosen for growing virus on any particular occasion will depend on a variety of factors, including (a) the goals of the experiment—namely, whether large amounts of one virus variant or small amounts of several variants are to be grown, (b) limitations in the in vitro host range of the virus—namely, whether it will grow on embryonated eggs, primary cell cultures, continuous adherent cell lines, or suspension cell lines, and (c) the relative technical ease of alternative possible procedures. Furthermore, the precise method for harvesting a virus culture will depend on the biology of the virus—for example, whether it buds from the infected cell, lyses the infected cell, or leaves the cell intact and stays tightly cell associated. As a simple example, consider cultivation of a budding, cytopathic virus on an adherent cell line. Confluent monolayers of an appropriate cell line are exposed to virus diluted to infect a fraction of the cells, and the progress of the infection is monitored by observing the development of the CPE until the infection is judged complete based on experience with the relationship between CPE and maximal virus yield. A crude preparation of virus can be harvested simply by collecting the culture fluid; it may not even be necessary to remove cells or cell debris. Most viruses can be stored frozen indefinitely either as crude or purified, concentrated preparations.

Quantitative Assay of Viruses

Two major types of quantitative assays for viruses exist, physical and biologic. Physical assays, such as hemagglutination, electron microscopic particle counts, optical density measurements, and immunologic methods, quantify only the presence of virus particles, whether or not the particles are infectious. Biologic assays, such as the plaque assay or various endpoint methods that have in common the assay of infectivity in cultured cells or *in vivo*, measure only the presence of infectivity, and they may not count all particles present in a preparation, even many that are in fact infectious. Thus a clear understanding of the nature and efficiency of both physical and biologic quantitative virus assays is required to make effective use of the data obtained from any assay.

Biologic Assays

The Plaque Assay

The plaque assay is the most elegant, the most quantitative, and most useful biologic assay for viruses. Developed originally for the study of bacteriophage by d'Herelle in the early 1900s (15), the plaque assay was adapted to animal viruses by Dulbecco and Vogt in 1953 (22), an advance that revolutionized animal virology by introducing a methodology that was relatively simple and precisely quantitative, that enabled the cloning of individual genetic variants of a virus, and that permitted a qualitative assay for individual virus variants that differ in growth properties or cytopathology.

The plaque assay is based simply on the ability of a single infectious virus particle to give rise to a macroscopic area of cytopathology on an otherwise normal monolayer of cultured cells. Specifically, if a single cell in a monolayer is infected with a single virus particle, new viruses resulting from the initial infection can infect surrounding cells, which in turn produce viruses that infect additional surrounding cells. Over a period of days, the exact length of time depending on the particular virus, the initial infection thus gives rise through multiple rounds of infection to an area of infection called a plaque. Photomicrographs of plaques are shown in Fig. 4, and stained monolayers containing plaques are shown in Fig. 5.

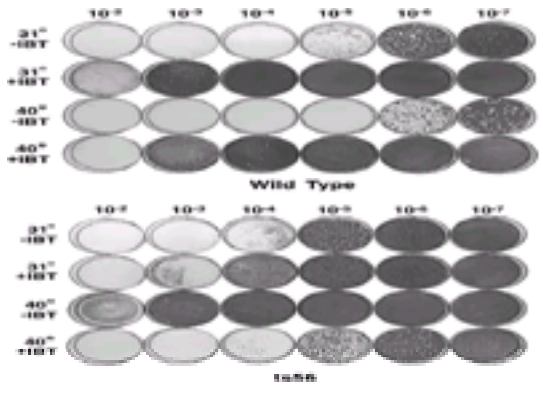

FIG. 5. Plaque assay. Monolayers of the African green monkey kidney cell line BSC40 were infected with 0.5-ml portions of 10-fold serial dilutions of wild-type vaccinia virus or the temperature-sensitive vaccinia mutant, *ts*56, as indicated. Infected monolayers were overlaid with semisolid medium and incubated at 31°C or 40°C, the permissive and

nonpermissive temperatures for *ts*56, in the presence of 45 μM isatin-b-thiosemicarbasone (IBT) or in the absence of drug as indicated, for 1 week. Agar overlays were removed and monolayers were stained with crystal violet. Wild-type vaccinia virus forms plaques at both 31°C and 40°C, but plaque formation is inhibited by IBT. Spontaneous IBT-resistant mutants in the wild-type virus stock are revealed as plaques forming at 10^{-3} and 10^{-4} dilutions in the presence of IBT. The *ts*56 mutant carries a single-base missense mutation in the vaccinia gene G2R (70). G2R is an essential gene that when completely inactivated renders the virus dependent on IBT, hence *ts*56 is not only temperature sensitive, forming plaques at 31°C but not at 40°C in the absence of IBT, but it is also IBT dependent at 40°C, forming plaques in the presence but not the absence of IBT. The *ts*56 mutant is slightly defective at 31°C: It forms smaller-than-wild-type plaques, and it is IBT resistant, forming plaques both in the presence and in the absence of drug, a phenotype intermediate between the wild-type IBT-sensitive phenotype and the null G2R mutant IBT-dependent phenotype. Wild-type, temperature-insensitive revertants present in the *ts*56 stock are revealed as plaques growing on the 10^{-3} plate at 40°C. Based on this assay, the titer of the wild-type stock is 1.6×10^{9} pfu/ml, and the titer of the *ts*56 stock is 2.0×10^{8} pfu/ml. (Plaque assays courtesy of J. I. Lewis.)

The plaque assay can be used to quantify virus in the following manner (Fig. 5). A sample of virus of unknown concentration is serially diluted in an appropriate medium, and measured aliquots of each dilution are seeded onto confluent monolayers of cultured cells. Infected cells are overlaid with a semisolid nutrient medium usually consisting of growth medium and agar. The semisolid medium prevents formation of secondary plaques through diffusion of virus from the original site of infection to new sites, ensuring that each plaque that develops in the assay originated from a single infectious particle in the starting inoculum. After an appropriate period of incubation to allow development of plaques, the monolayer is stained so that the plaques can be visualized. The staining technique depends on the cytopathology, but vital dyes such as neutral red are common. Neutral red is taken up by living cells but not by dead cells, so that plaques become visible as clear areas on a red monolayer of cells. In cases where the virus cytopathology results in cell lysis or detachment of cells from the dish, plaques exist literally as holes in the monolayer, and a permanent record of the assay can be made by staining the monolayer with a general stain such as crystal violet, prepared in a fixative such as ethanol. The goal of the assay is to identify a dilution of virus that yields 20 to 100 plaques on a single dish—that is, a number large enough to be statistically significant yet small enough that individual plaques can be readily discerned and counted. Usually a series of four to six 10-fold dilutions are tested, a number that is estimated to bracket the target dilution. Dishes inoculated with low dilutions of virus will contain only dead cells or too many plaques to count, whereas dishes inoculated with high dilutions of virus will contain very few if any plaques (Fig. 5). Dishes containing an appropriate number of plaques are counted, and the concentration of infectious virus in the original sample can then be calculated by taking into account the serial dilution. The resulting value is called a titer, and it is expressed in plaque-forming units per milliliter, or pfu/ml, to emphasize specifically that only viruses that are capable of forming plaques have been quantified. Titers derived by serial dilution are unavoidably error prone simply because of the additive error inherent in multiple serial pipetting steps; errors of up to 100% are normal, but titers that approximate the real titer to within a factor of 2 are satisfactory for most purposes.

A critical benefit of the plaque assay is that it measures infectivity, but it is important to understand that infectivity does not necessarily correspond exactly to the number of virus particles in a preparation. In fact, for most animal viruses, only a fraction of the particles, as few as 1 in 10 to 1 in 10,000, may be infections as judged by comparison of a direct particle count (described later) with a plaque assay. This low efficiency of plating, or high particle-to-infectivity ratio, may have several causes. First, to determine a particle to infectivity ratio, virus must be purified to determine the concentration of physical particles, and then it must be subjected to plaque assay. If the purification itself damages particles, the particle-to-infectivity ratio will be increased. Second, some viruses produce empty particles, or particles that are for other reasons defective during infection, resulting in a high particle-to-infectivity ratio. Last, it is possible that not all infectious particles will form plaques in a given plaque assay. For example, an infectious virus may require that cells exist in a specific metabolic state or in a specific stage of the cell cycle; thus, if not all cells in a culture are identical in this regard, only a fraction of the potentially infectious virions may be able to successfully launch an infection and form a plaque.

In addition to its utility as a quantitative assay, the plaque assay also provides a way to detect genetic variants of a virus that possesses altered growth properties, and it provides a very convenient method to clone genetically unique variants of a virus (Fig. 5). Genetic variants are considered in detail in the genetics section later, but, in brief, they may comprise viruses that form plaques only under certain conditions of temperature or drug treatment, or form plaques of altered size or shape. Because each plaque results from infection with a single infectious virus particle, unique genetic variants of a virus can be cloned simply by “picking” plaques—that is, literally excising a small plug of agar and infected cells from a plaque using a Pasteur pipette.

The Focus Assay

Some tumor viruses, most notably retroviruses, normally transform cells rather then killing them but can nevertheless be quantified by taking advantage of the transformation cytopathology (94,102). For example, retrovirus-transformed cells may lose contact inhibition and therefore grow in foci, or piles of transformed cells, on top of a contact-inhibited cell monolayer. Dense foci of transformed cells stain more darkly than cells in a monolayer and thus can be quantified by treating an infected monolayer with an appropriate stain. Otherwise, the focus assay is similar to the plaque assay in both technique and function. Photomicrographs of foci and stained monolayers containing foci are shown in Fig. 6.

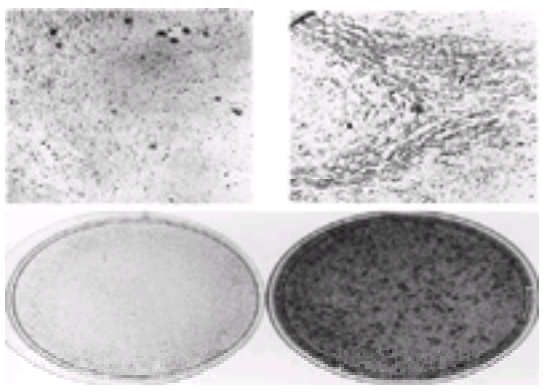

FIG. 6. Focus assay. Monolayers of the NIH3T3 mouse fibroblast cell line were infected with Maloney murine sarcoma virus. The *top two panels* show photomicrographs of uninfected cells (*left*) and a single virus-induced focus (*right*). The *bottom two panels* show stained dishes of uninfected (*left*) and infected (*right*) cells. Foci are clearly visible as darker areas on the infected dish. (Courtesy of D. Blair.)

Pock Formation

As mentioned previously in the discussion of embryonated eggs, many viruses will cause focal lesions on the CAM of eggs. Although cumbersome, this assay can be used to quantify viruses in a fashion similar to a plaque assay. The pock assay found utility before the adaptation of the plaque assay to animal virology, but now it has largely been replaced by other assays utilizing cultured cells and is used only for specialized purposes as noted previously. An example of a pock assay is shown in Fig. 1.

Endpoint Method

Viruses that cannot be adapted to either a plaque or a focus assay, but that nevertheless cause some detectable pathology in cultured cells, embryonated eggs, or animals, can be quantified using an endpoint method. Briefly, virus is serially diluted and multiple replicate samples of each dilution are inoculated into an appropriate assay system. After a suitable incubation period, an absolute judgment is made as to whether or not an infection has taken place. The dilution series is constructed so that low dilutions show infection in all replicate inoculations, high dilutions show infection in none of the inoculations, but some dilutions result in infection in some but not all inoculations. Statistical methods, described in more detail later, have been devised to calculate the dilution of virus that results in infection in 50% of replicate inoculations, and titers are expressed as the infectious dose 50, or ID_{50}. Assay systems are various and include, for example, observation of CPE in cultured cells, yielding tissue culture infective dose 50 (or $TCID_{50}$); cytopathology or embryonic death in inoculated embryonated chicken eggs, yielding egg infectious dose 50 (or EID_{50}); or death of an experimental laboratory animal, yielding lethal dose 50 (or LD_{50}). Like the plaque assay, the focus assay, and the pock assay, the endpoint method has the advantage of measuring infectivity, but it is important to note that the unit of infectivity measured by the endpoint method may require more than one infectious particle.

A sample determination of a $TCID_{50}$ (65) is shown in Table 3. The data for this experiment would be collected by infecting replicate cell monolayers in a multiwell dish with serial dilutions of virus, and after an appropriate incubation period inspecting the wells for the presence of CPE. Inspection of the data reveals that a 10^{-6} dilution of virus results in infection in more than 50% of replicate wells, whereas a 10^{-7} dilution of virus results in infection in fewer than 50% of replicate wells. Thus, the dilution that would yield infection in exactly 50% of samples lies between 10^{-6} and 10^{-7}. The precise dilution required for infection of 50% of the wells can be calculated by either of two methods, the Spearman Karver method (53,92) (not shown) or the Reed-Muench method (83).

Log of virus dilution	Infected test units	Cumulative infected (A)	Cumulative uninfected (B)	Ratio of A/(A + B)	Percent infected
-5	5/5	9	1	9/9	100.0
-6	3/5	4	2	4/6	66.7
-7	1/5	1	6	1/7	14.3
-8	0/5	0	11	0/11	0.0

TCID, tissue culture infective dose.

TABLE 3. *Data for calculation of $TCID_{50}$*

The Reed-Muench method is carried out as follows. First, the cumulative number of infected (column A in Table 3) or uninfected (column B in Table 3) samples is determined by progressively summing the infected samples from the highest dilution to the lowest dilution, and the uninfected samples from the lowest dilution to the highest dilution. Using these numbers, a ratio or percent of infection is calculated for each dilution. The dilution that would yield 50% infected samples is then estimated by determining the proportionate distance between the 10^{-6} and 10^{-7} dilutions that would correspond to 50% infection. This distance is the ratio of the distance between 50% infection and the percent positive above 50%,

divided by the total distance between the percent positive above 50% and the percent positive below 50%:

$$\frac{(\%\text{ positive above }50\%) - 50\%}{(\%\text{ positive above }50\%) - (\%\text{ positive below }50\%)} = \text{proportionate distance},$$

or

$$\frac{66.7\% - 50\%}{66.7\% - 14.3\%} = 0.3.$$

Knowing the proportionate distance between dilutions, the endpoint is calculated taking into consideration the exact dilutions used:

$$(\log \text{dilution above } 50\%) + (\text{proportionate distance} \times \log \text{dilution factor}) = \log \text{TCID}_{50},$$

or

$$(-6) + (0.3 \times 1.0) = -6.3.$$

Therefore the $TCID_{50} = 10^{-6.3}$. The reciprocal of this number is used to express the titer in infectious units per unit volume. Thus, if 0.1 ml had been used for inoculation of each test well in the assay, the final titer would be $10^{7.3}$ $TCID_{50}$/ml.

Physical Assays

Direct Particle Count

The concentration of virus particles in a sample of purified virus can be counted directly using an electron microscope (62,104). Briefly, a purified preparation of virus is mixed with a known concentration of microscopic marker particles such as latex beads, which can be easily distinguished from virus particles with the electron microscope. Samples of the solution containing virus and beads are then applied to an electron microscope grid and visualized after shadowing or staining. The volume of liquid applied to a given area of the grid can be determined by counting the beads. The virus particles in the same area can then be counted, resulting in an accurate determination of the concentration of virus particles in the original solution. An example of an electron microscopic count of vaccinia virus is shown in Fig. 7. Given a solution of virus with a known concentration determined by microscopic particle count, the same solution can be subjected to any number of chemical or spectophotometric analyses to yield a conversion from protein content, nucleic acid content, or simply absorbance at a fixed wavelength to a concentration of virus in particles per unit volume. Thus, once a microscopic particle count has been performed, future quantitative assays of purified virus are greatly simplified. It is important to note that the direct particle count does not distinguish infectious from noninfectious particles.

FIG. 7. Direct electron microscopic particle count. An electron micrograph of a spray droplet containing 15 latex beads (*spheres*) and 14 vaccinia virus particles (*slightly smaller, brick-shaped particles*). (From ref. 23, with permission.)

Hemagglutination

As noted previously in the discussion of hemadsorption, many viruses synthesize cell attachment proteins, which carry out their function wholly or in part by binding substituents such as sialic acid that are abundant on a wide variety of cell types, including erythrocytes. Because these cell attachment proteins decorate the surface of the virion, virions may bind directly to erythrocytes. Because both the virions and the erythrocytes contain multiple binding sites for each other, erythrocytes will agglutinate, or form a network of cells and virus, when mixed with virus particles in sufficiently high concentration. Agglutinated erythrocytes can be easily distinguished from cells that are not agglutinated, and thus hemagglutination can be used as a simple quantitative assay for the presence of a hemagglutinating virus.

In practice, a hemagglutination assay is carried out as follows (Fig. 8). Virus is serially diluted and mixed with a fixed concentration of erythrocytes. The mixture is allowed to settle in a specially designed hemagglutination tray containing

wells with rounded bottoms. Erythrocytes that are not agglutinated are free to roll to the bottom of the well, forming a dense, easily recognizable button, or cluster of cells. Erythrocytes that are agglutinated are not free to roll to the bottom of the well, but instead evenly coat the bottom surface of the well. One hemagglutination (HA) unit is defined as the minimum amount of virus required to cause agglutination, and the titer of the virus solution, expressed as HA units/ml, can be calculated taking into account the serial dilution. It is noteworthy that, like the direct particle count assay, the hemagglutination assay does not distinguish infectious from noninfectious particles. In addition, since it may require many particles to cause a detectable hemagglutination, one HA unit may represent many physical particles.

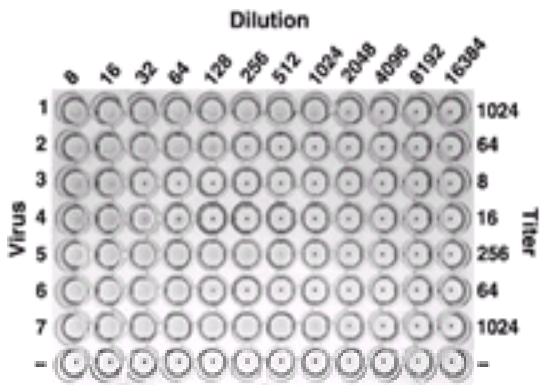

FIG. 8. Hemagglutination assay. Seven different samples of influenza virus, numbered 1 through 7 at the left, were serially diluted as indicated at the *top*, mixed with chicken red blood cells (RBC), and incubated on ice for 1 to 2 hours. Wells in the bottom row contain no virus. Agglutinated RBCs coat wells evenly, in contrast to nonagglutinated cells, which form a distinct button at the bottom of the well. The HA titer, shown at the right, is the last dilution that shows complete hemagglutination activity. (Courtesy of J. Talon and P. Palese.)

Quantitative Considerations in Virus Assay, Cultivation, and Experimentation

Dose Response in Plaque and Focus Assays

With few exceptions, the number of infectious units observed on a given plate in a plaque assay is a linear function of the dilution of the virus, thus the development of plaques follows single-hit kinetics, proving that each plaque results from infection with a single virus particle. Exceptions include the murine sarcoma viruses, assayed in a focus assay, which require co-infection with both a defective transforming virus and a nondefective helper virus, in which case the number of foci observed relative to the dilution used follows two-hit kinetics (40).

Comparison of Quantitative Assays

As noted in the individual descriptions, the various quantitative assays of viruses measure different physical and biologic properties, and a one-to-one correlation between assays cannot be assumed. Table 4 summarizes the titers of an influenza virus preparation as measured by several different assays, providing an example of the magnitude of differences that might be expected between the various assays. Hence, relative to a direct particle count, the efficiency of plating the influenza sample shown in Table 4 is 10^{-1} as assayed in eggs, 10^{-2} as assayed in a plaque assay, and 10^{-7} as assayed in a hemagglutination assay. As indicated in the forgoing discussion, some of the differences result from different properties being measured—for example, physical particles versus infectivity—and some differences result from differences in the sensitivity of the assay—for example, direct particle count versus assay of particles by hemagglutination.

Method	Amount (per ml)
Direct electron microscope (EM) count particles	10^{10} EM
Quantal infectivity assay in eggs	10^{9} egg ID_{50}
Quantal infectivity assay by plaque formation	10^{8} pfu
Hemagglutination (HA) assay	10^{3} HA units

ID, infectious dose; pfu, plaque-forming units.

TABLE 4. *Comparison of quantitative assay efficiency*

Multiplicity of Infection

Multiplicity of infection, often abbreviated moi, measures the average amount of viru $_{s\ added\ per\ c}$ell in an infection. Multiplicity of infection can be expressed using any quantitative measure of virus titer, for example particles per cell, HA units per cell, $TCID_{50}$ per cell, or pfu per cell. Because the efficiency of plating varies depending on the method of quantitation used, some knowledge of the infectivity of the sample or the efficiency of plating is required to correctly

anticipate the consequences of a particular moi. The moi used in different protocols can have a profound outcome on the procedure. For example, some viruses, if serially passaged at an moi of greater than one infectious unit per cell, will accumulate spontaneously deleted defective particles, which are maintained during passage by the presence of complementing wild-type helper virus (103). Passage of the same virus at very low moi, for example 0.01 infectious units per cell, discourages the accumulation of defective particles because few cells will be co-infected with an infectious and a defective particle, and defective particles cannot replicate in the absence of a wild-type helper. On the other hand, most metabolic labeling experiments are done at a high moi, for example 10 infectious units per cell, to ensure that all cells in the culture are infected and that the infection is as synchronous as possible. For such experiments, use of too low an moi may result in an apparently asynchronous infection and a high background because of the presence of uninfected cells in the culture.

The Poisson distribution can be used to predict the fraction of cells in a population infected with a given number of particles at different mois. As applied to virus infections, the Poisson distribution can be written as follows:

$$P(k) = e^{-m}m^k/k!,$$

where P(*k*) = the probability that any cell is infected with *k* particles, *m* = moi, and *k* = number of particles in a given cell.

Note that to determine the fraction of uninfected cells in any experiment, that is when *k* = 0, the equation simplifies to

$$P(0) = e^{-m}$$

For practical purposes, solution of this equation for given values of *m* and *k* (other than 0) is most easily accomplished using published tables (109). Sample solutions are shown in Table 5 for commonly used mois. Inspection of this table and consideration of the error inherent in any virus titration involving a serial dilution leads to some significant practical guides in experimental design. Note first that in a culture infected at an moi of 1 pfu/cell, 37% of cells remain uninfected, an unacceptably high number for an experiment designed to measure a single round of synchronous infection. An moi of at least 3 is required to infect 95% of the cells in culture. Given that titers can easily be inaccurate by a factor of 2, use of a calculated moi of 10 ensures that 99% of the cells in a culture will be synchronously infected even if the measured titer is twofold higher than the actual titer.

	moi (m)			
#/cell (k)	1	3	5	10
0	0.37	0.05	0.01	0.00
1	0.37	0.15	0.03	0.00
2	0.18	0.22	0.08	0.00
3	0.06	0.22	0.14	0.01
4	0.02	0.17	0.18	0.02
5	0.00	0.10	0.18	0.04
6	0.00	0.05	0.15	0.06
7	0.00	0.02	0.10	0.09
8	0.00	0.00	0.07	0.11
9	0.00	0.00	0.04	0.13
10	0.00	0.00	0.02	0.13

TABLE 5. *The Poisson distribution: values of* P(k) *for various values of* m *and* k

One-Step Growth Experiment

A classic experiment developed initially for bacteriophage (24) and still frequently used to determine the essential growth properties of a virus is the one-step growth experiment. The goal of the one-step growth experiment is to measure the time course of virus replication and the yield of virus per cell during a single round of infection. The experiment is carried out as follows. Several dishes containing confluent monolayers or an appropriate culture cell are infected simultaneously with virus at a high moi, for example 10 pfu/cell. After an adsorption period, monolayers are washed to remove unabsorbed virus and then incubated in culture medium. At various times after infection, virus from individual dishes is harvested, and at the completion of the experiment, the virus titer in samples representing each time point is determined. The virus yield at each point can be converted to pfu/cell by dividing the total amount of virus present in the sample by the number of cells originally infected in the sample.

The results from one example of a one-step growth experiment, in this case comparing growth of wild-type vaccinia virus and a temperature-sensitive (*ts*) mutant at permissive and nonpermissive temperatures, are shown in Fig. 9. Several features of the growth curve are noteworthy. First, during the first several hours of the wild-type infection or the *ts*56 infection at the permissive temperature, the titer in the cultures decreases and then increases. This dip in the growth curve, called *eclipse*, results from the following sequence: Early during the experiment, the virus that attaches to the cell surface but is not yet uncoated remains infectious. Then, infectivity is lost during the first few hours of infection (the eclipse phase), when the virus is uncoated. Infectivity is then recovered only after new virus is produced. The infection then enters a rapid growth phase, followed by a plateau. The plateau results from the fact that all infected cells have reached the maximal yield of virus, or they have died or lysed, depending on the type of virus infection. The time interval from infection to plateau represents the time required for a single cycle of growth, and the yield of virus at plateau shows the amount of virus produced per cell.

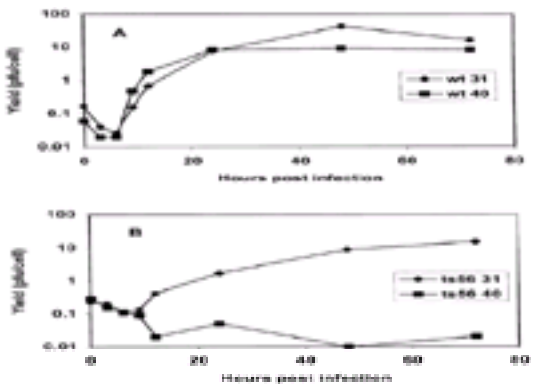

FIG. 9. One-step growth experiment. Monolayers of the African green monkey kidney cell line BSC40 were infected at an moi of 6 pfu/cell with wild-type vaccinia virus (*top panel*) or the temperature-sensitive vaccinia mutant, *ts*56 (*bottom panel*), and incubated at the permissive temperature, 31°C, or the nonpermissive temperature, 40°C, as indicated. Samples were harvested at various times and the titer determined by plaque titration on BSC40 cells at 31°C. The wild-type virus grows equally well at 31°C and 40°C. The *ts*56 grows more slowly than the wild type at 31°C but ultimately produces a yield of virus comparable to wild type. The *ts*56 does not grow at 40°C. (From ref. 41, with permission.)

The experiment in Fig. 9 demonstrates the utility of the one-step growth experiment. As judged by this experiment, wild-type virus grows with identical kinetics and to the identical yields at both 31°C and 40°C, permissive and nonpermissive temperatures for the temperature-sensitive mutant, respectively. The temperature-sensitive mutant, *ts*56 (70), grows more slowly than wild-type virus at 31°C, indicating some defective character even at the permissive temperature, although at plateau the yields of mutant virus at 31°C are equivalent to those of the wild-type virus. The experiment demonstrates conclusively that the mutant does not grow at all at the nonpermissive temperature, 40°C.

Multiplicity of infection is a critical factor in the design of a virus growth experiment. A true one-step growth experiment can be done only at high moi. If the moi is too low and a large fraction of cells are left uninfected, then virus produced during the first round of infection will replicate on previously uninfected cells, and thus multiple rounds of infection rather than one round will be measured. A growth experiment done at low moi has utility in that it measures both growth and spread of a virus in culture, but the time from infection to plateau does not accurately reflect the time required for a single cycle of infection. It is also noteworthy that some mutant phenotypes are multiplicity dependent (5).

VIRUS GENETICS

Viruses are subject to the same genetic principles at work in other living systems, namely mutation, selection, complementation, and recombination. Genetics impacts all aspects of virology, including the natural evolution of viruses, clinical management of virus infections, and experimental virology. For example, antigenic variation, a direct result of mutation and selection, plays a prominent role in the epidemiology of influenza virus and human immunodeficiency virus (HIV) in the human population, and mutation to drug resistance offers a significant challenge to the clinical management of virus infections with antiviral drugs. This section deals primarily with the application of experimental genetic techniques to basic virology.

The ultimate goal of experimental virology is to understand completely the functional organization of a virus genome. In a modern context, this means determination of the structure of a virus genome at the nucleotide sequence level, coupled with isolation of mutational variants of the virus altered in each gene or control sequence, followed by analysis of the effects of each mutation on the replication and/or pathogenesis of the virus. Thus, genetic analysis of viruses is of fundamental importance to experimental virology.

Before the advent of modern nucleic acid technology, that is during a “classical” period of “forward” genetics, genetic analysis of viruses consisted of the random, brute-force isolation of large numbers of individual virus mutants, followed first by complementation analysis to determine groupings of individual mutants into genes, then recombination analysis to determine the physical order of genes on the virus genome, and finally the phenotypic analysis of mutants to determine gene function. This approach, pioneered in the 1940s, 1950s, and 1960s in elegant studies of several bacteriophage, notably lambda, T4, and T7 (Chapter 22), was the primary method for identifying, mapping, and characterizing virus genes. The application of cell culture techniques to animal virology opened the door to classical genetic analysis of animal viruses, resulting in a flurry of activity in the 1950s through the 1970s, during which time hundreds of mutants were isolated and analyzed in prototypical members of most of the major animal virus families (32). Modern nucleic acid technology introduced in the 1970s brought with it a variety of techniques for physical mapping of genomes and mutants, including restriction enzyme mapping, marker rescue, and DNA sequence analysis, which together replaced recombination analysis as an analytic tool. Mutants and techniques from that classical period continue to be of enormous utility today, but recombinant DNA technology has brought with it reverse (or “punk”) genetics, in which the structure of the genome is determined first, using entirely physical methods, and then the function of individual genetic elements is determined by analyzing mutants constructed in a highly targeted fashion.

The genetic approach to experimental virology, or any field of biology for that matter, has the profound advantage of asking of the organism under study only the most basic question, “What genes do you need to survive, and why do you need them?” without imposing any further bias or assumptions on the system. And organisms often respond with surprises that the most ingenious biochemist or molecular biologist would never have imagined. What follows is a summary of the critical elements of both the classical and modern approaches to virus genetics as applied to experimental virology.

Mutants

Wild-Type Virus

It is important to understand that in the context of experimental virus genetics, a virus designated as wild type can differ significantly from the virus that actually occurs in nature. For example, virus genetics often relies heavily on growth and assay of viruses in cell culture, and, as noted previously, natural isolates of viruses may undergo significant genetic change during adaptation to cell culture. In addition, viruses to be designated wild type should be plaque purified before initiating a genetic study, to ensure a unique genetic background for mutational analysis. Last, viruses may be specifically adapted for use in genetic analysis, for example by passage under conditions that are to be restrictive for conditionally lethal mutants so that the analysis can be initiated with a preparation free of spontaneous mutants.

Fundamental Genetic Concepts

Concepts fundamental to genetic analysis of other organisms apply to genetic analysis of viruses, and a clear understanding of these concepts is essential to understanding virus genetics. The most important of these concepts, including distinctions between genotype and phenotype, a selection and a screen, and essential and nonessential genes, are briefly summarized here.

Genotype/Phenotype

Genotype reflects the actual genetic change from wild type in a particular virus mutant, whereas phenotype reflects the measurable manifestation of that change in a given assay system. This distinction is emphasized by the fact that a single genotype may express different phenotypes depending on the assay applied. Thus, for example, the same missense mutation in a virus gene may cause temperature sensitivity in one cell line but not in another, or a deletion in another virus gene may have no effect on the replication of virus in culture but may alter virulence in an animal model.

Selection/Screen

Selection and screen refer to two fundamentally different methods of identifying individual virus variants contained in a mixed population of viruses. Selection implies that a condition exists in which only the desired virus will grow, while growth of unwanted viruses is suppressed. Thus, a drug-resistant virus can be identified by plating a mixture of wild-type, drug-sensitive viruses, and mutant, drug-resistant viruses together on the same cell monolayer in the presence of the inhibitory drug, thereby selecting for drug-resistant viruses, which grow, and selecting against wild-type viruses, which do not grow (Fig. 5). A screen implies that both the desired virus variant and one or several other unwanted virus types grow under a given condition, so that many viruses must be analyzed individually to identify the desired variant. For example, in searching for a temperature-sensitive mutant—that is, a virus whose growth is inhibited relative to wild-type virus at an elevated temperature—no condition exists under which the mutant alone will grow. Therefore, virus must be plated at a low temperature at which both wild-type and mutant virus will grow, and plaques must be tested individually for temperature sensitivity.

Sometimes, a screen can be streamlined by introducing a phenotypic marker into the variant of choice. For example, a knockout virus might be constructed by inserting the beta-galactosidase gene into the virus gene to be inactivated. In the presence of an appropriate indicator dye, viruses containing the insertional knockout produce blue plaques and can therefore be distinguished from unmodified viruses, which form clear plaques, growing on the same plate (107). This example is still a screen, because both wild-type and mutant viruses grow under the conditions used, but the screen is simplified because mutant viruses can be readily identified by their color, obviating the need to pick and test individual plaques. Selections have considerable advantages over screens but are not always possible.

Essential/Nonessential

The terms *essential* and *nonessential* describe phenotypes, specifically whether a given gene is required for growth under a specific condition. Most viruses are finely tuned through selection to fit a specific niche. Not all viral genes are absolutely required for virus replication in that niche; some may simply confer a subtle selective advantage. Furthermore, if the niche is changed, for example from a natural animal host to a cell line in a laboratory, some genes that may have been essential for productive infection in the animal may not be required for replication in cell culture. Genes that are required for growth under a specific condition are termed essential, and those that are not required are termed nonessential. Because as a phenotype, essentiality may be a function of the specific test conditions, the test conditions need to be specified in describing the mutation; for example, the herpesvirus thymidine kinase gene is nonessential for virus replication in cell culture. A genes that is essential or nonessential under a given condition presents unique characteristics for analysis. Thus, mutants in nonessential genes may be easy to isolate because the gene can be deleted, but the function of the gene may be difficult to determine because, by definition, nonessential genes have no phenotype. On the other hand, genes that are essential can be used to study gene function by characterizing the precise replication defect caused by a mutation in the gene, but acquiring the appropriate mutant is confounded by the necessity for identifying a condition that will permit growth of the virus for study.

Mutation

Spontaneous Mutation

Spontaneous mutation rates in viruses are measured by fluctuation analysis (51), a technique pioneered by Luria and Delbruck (61) for analysis of mutation in bacteria, and later adapted to viruses by Luria (59). Fluctuation analysis consists of measuring the proportion of spontaneous mutants with a particular phenotype in many replicate cultures of virus, and applying the Poisson distribution to these data to calculate a mutation rate. It is important to note that, because

spontaneous mutations occur at random and may occur only rarely, the raw data in a fluctuation analysis display enormous scatter, with some cultures containing a high proportion of mutants and some containing no mutants. Thus, from a practical perspective, although the proportion of mutants in a single culture of virus may reflect the mutation rate, it does not necessarily provide an accurate measure of mutation rate.

Both DNA and RNA viruses undergo spontaneous mutation, but the spontaneous mutation rate in RNA viruses is usually much higher than in DNA viruses. In general, the mutation rate at a specific site in different DNA viruses ranges from 10^{-8} to 10^{-11} per replication, whereas in RNA viruses it is at least 100-fold higher, between 10^{-3} and 10^{-6} per replication. The difference in mutation rate observed between RNA and DNA viruses is thought to result primarily from differences in the replication enzymes. Specifically, the DNA-dependent DNA polymerases used by DNA viruses contain a proofreading function, whereas the reverse transcriptases used by retroviruses and the RNA-dependent RNA polymerases used by RNA viruses lack a proofreading function. The difference in spontaneous mutation rate has profound consequences for both the biology of the viruses and for laboratory genetic analysis of viruses. Specifically, RNA viruses exist in nature as "quasi-species" (19)—that is, populations of virus variants in relative equilibrium with the environment but capable of swift adaptation because of their high spontaneous mutation rate (Chapter 13). On the other hand, DNA viruses are genetically more stable but less adaptable. In the laboratory, the high mutation rate in RNA viruses presents difficulties in routine genetic analysis because mutants easily revert to a wild-type virus that can outgrow the mutant virus.

It is noteworthy that whereas the actual mutation rate at a single locus is probably relatively constant for a given virus, the apparent mutation rate to a given phenotype depends on the nature of the mutation(s) that can give rise to that phenotype. For example, spontaneous mutation to bromodeoxyuridine (BUdR) resistance in vaccinia virus may occur at least 10 to 100 times more frequently than spontaneous reversions of temperature-sensitive mutations to a wild-type, temperature-insensitive phenotype. In the case of BUdR resistance, any mutation that inactivates the thymidine kinase causes resistance to BUdR, and thus there are literally hundreds of different ways in which spontaneous mutation can give rise to BUdR resistance. By contrast, a temperature-sensitive mutation is usually a single-base missense mutation: There may exist only one possible mutational event that could cause reversion to the wild-type phenotype, and thus the apparent spontaneous mutation rate for the revertant phenotype is lower than the apparent spontaneous mutation rate to the BUdR resistance phenotype.

From a practical perspective, the apparent spontaneous mutation rate for specific selectable phenotypes may be sufficiently high that induction of mutants is unnecessary for their isolation. Note, for example, that the wild-type vaccinia virus culture titered in Fig. 5 contains numerous spontaneous isatin-beta-thiosemicarbasone (IBT)-resistant viruses that could easily be plaque-purified from assays done in the presence of IBT. However, for most mutants (e.g., temperature-sensitive mutants), in which the desired mutational events are rare and a screen must be used rather than a selection, induced mutation is required for efficient isolation of mutants.

Induced Mutation

Under most circumstances, the incidence of spontaneous mutations is low enough that induction of mutation is a practical prerequisite for isolation of virus mutants. It is usually desirable to induce limited, normally single-base changes, and for this purpose, chemical mutagens are most appropriate. Commonly used chemical mutagens are of two types, *in vitro* mutagens and *in vivo* mutagens (20). *In vitro* mutagens work by chemically altering nucleic acid and can be applied by treating virions in the absence of replication. Examples of *in vitro* mutagens include hydroxylamine, nitrous acid, and alkylating agents, which through chemical modification of specific bases cause mispairing leading to missense mutations. *In vivo* chemical mutagens comprise compounds such as nucleoside analogs, which must be incorporated during viral replication and thus must be applied to an infected cell. One of the most effective mutagens is an alkylating agent, nitrosoguanidine, which, although it is capable of alkylating nucleic acid *in vitro*, is most effective when used *in vivo*, where it works by alkylating guanine residues at the replication fork, ultimately causing mispairing.

The effectiveness of a mutagenesis is often assayed by observing the killing effect of the mutagen on the virus, the assumption being that many mutational events will be lethal, and thus an effective mutagenesis will decrease a virus titer relative to an untreated control. However, killing does not always correlate precisely with mutagenesis, especially with an *in vitro* mutagen that can damage virion structure without necessarily causing mutation. An alternative method for assessing mutagenesis is to monitor an increase in the mutation frequency to a selectable phenotype where possible. For example, in vaccinia virus, mutagenesis causes a dose-dependent increase in resistance to phosphonoacetic acid, a drug that prevents poxvirus replication by inhibiting the viral DNA polymerase (11). In summary, use of mutagens can increase the mutation frequency several hundred fold, such that desired mutants may comprise as much as 0.5% of the total virus population.

Double Mutants/Siblings

The existence of double mutants and siblings can theoretically complicate genetic analysis of a virus. Double (or multiple) mutants may contain more than one mutation contributing to a phenotype. Theoretically, because the probability that a double mutant will be created increases as the dose of a mutagen is increased, there is a practical limit to the amount of induced mutation that is desirable. Double mutants are usually revealed as mutants that are noncomplementing with more than one mutant, or that are impossible to map by recombination or physical methods. Siblings result from replication of mutant virus either through amplification of a mutagenized stock, or during an *in vivo* mutagenesis. The only completely reliable method to avoid isolation of sibling mutants is to isolate each mutant from an independently plaque-purified stock of wild-type virus. In practice, siblings seldom present a problem serious enough to justify the effort required to avoid them.

Mutant Genotypes

There exist two basic categories of mutation, base substitution and deletion/insertion mutations. Both mutation types can occur with consequence in either a protein coding sequence or in a control sequence, such as a transcriptional promoter,

a replication origin, or a packaging sequence. Base substitution mutations consist of the precise replacement of one nucleotide with a different nucleotide in a nucleic acid sequence. In coding sequences, base substitution mutations can be silent, causing no change in amino acid sequence of a protein; they can be missense, causing replacement of the wild-type amino acid with a different residue; or they can be nonsense, causing premature translation termination during protein synthesis. Deletion and insertion mutations comprise deletion or insertion of one or more nucleotides in a nucleic acid sequence. In a coding sequence, deletion or insertion of multiples of three nucleotides can result in precise deletion or insertion of one or more amino acids in a protein sequence. In a coding sequence, deletions or insertions that do *not* involve multiples of three nucleotides result in a shift in the translational reading frame, which almost invariably results in premature termination at some distance downstream of the mutation. In general, nonsense mutations, frameshift mutations, or large in-frame insertions or deletions are expected to inactivate a gene, whereas missense mutations may cause much more subtle phenotypes such as drug resistance or temperature sensitivity.

Mutant Phenotypes

In the context of experimental virology, where the goal is to understand the function of individual virus genes, the most useful mutants are those that inhibit virus replication by inactivating a virus gene. The nonproductive infections with these lethal mutants can be studied in detail to determine the precise aspect of virus replication that has been affected, thus providing information about the normal function of the affected gene. However, one must be able to grow the mutant to conduct experiments, so a condition must be found in which the mutation in question is not lethal, hence the general class of mutant phenotypes called conditional lethal. Conditional lethal mutants comprise by far the largest and most useful class of mutant phenotypes; they consist of host-range, nonsense, temperature-sensitive, and drug-dependent phenotypes, and they will be described individually later. Two additional classes of mutant phenotypes, resistance and plaque morphology, which have very specific application to genetic analysis of viruses, will also be described.

Host-Range

A host-range virus mutant is broadly defined as a mutant that grows on one cell type and not on another, in contrast to the wild-type virus, which grows on both cell types. Two general subcategories of host-range mutants exist, natural and engineered. Natural host-range virus mutants are relatively rare, primarily because they must be identified by brute-force screen or serendipity, in many cases in the absence of a viable rationale for the targeted host range. The existence of a host-range phenotype implies that a specific virus–host interaction is compromised, which also implies that for any specific host-range phenotype, only one virus gene (or a limited number) will be targeted. A classic example of a natural host-range mutants are the *hrt* mutants of mouse polyoma virus, which affect both small and middle T antigens, and which grow on primary mouse cells but not continuous mouse 3T3 cell lines (2). Engineered host-range mutants are constructed by deleting an essential gene of interest in the virus while at the same time creating a cell line that expresses the gene. The engineered cell line provides a permissive host for growth of the mutant virus because it complements the missing virus function, whereas the normal host lacking the gene of interest provides a nonpermissive host for study of the phenotype of the virus. This technology has been useful for studying a variety of viruses, notably herpes simplex virus, where it has facilitated study of several essential virus genes (17,107).

Nonsense Mutants

Nonsense mutants are those that contain a premature translation termination mutation in the coding region of the mutant gene. Nonsense mutants are formally a specific class of conditionally lethal, host-range mutants. Specifically, the permissive host is one that expresses a tRNA containing an anticodon mutation that results in insertion of an amino acid in response to a nonsense codon, thus restoring synthesis of a full-length polypeptide and suppressing the effects of the virus nonsense mutation. The nonpermissive host is a normal cell in which a truncated, nonfunctional polypeptide is made. In practice, most nonsense mutants in existence have been isolated by random mutagenesis followed by a brute-force screen for host range. Nonsense mutants have three distinct advantages for the conduct of virus genetics: (a) Mutants can be isolated in virtually any essential virus gene using one set of permissive and nonpermissive hosts and one set of techniques, (b) the mutations result in synthesis of a truncated polypeptide, thereby facilitating identification of the affected gene, and (c) virus mutants can be relatively easily engineered, as the exact sequence of the desired mutation is predictable.

Nonsense mutants have provided the single most powerful genetic tool in the study of bacteriophage, where efficient, viable nonsense-suppressing bacteria are readily available. Unfortunately, attempts to isolate nonsense-suppressing mammalian cells have met with only limited success, probably because the nonsense-suppressing tRNAs are lethal in the eucaryotic host (89).

Temperature Sensitivity

Temperature sensitivity is a type of conditional lethality in which mutants can grow at a low temperature but not at a high temperature, in contrast to wild-type virus, which grows at both temperatures. Genotypically, temperature-sensitive mutants are usually relatively subtle, single amino acid substitutions that render the target protein unstable and hence nonfunctional at an elevated or nonpermissive temperature, while leaving the protein stable and functional at a low, permissive temperature. In practice, temperature-sensitive mutants are usually isolated by random mutagenesis followed by brute-force screening for growth at two temperatures. Screening can be streamlined by a plaque enlargement technique in which mutagenized virus is first plated at a permissive temperature, then stained and shifted to a nonpermissive temperature after marking the size of plaques, to screen for plaques that do not increase in size at the nonpermissive temperature (91). Replica plating techniques that permit relatively straightforward screening of thousands of mutant candidates in yeast and bacteria have not been successfully adapted to virology, and thus a screen for temperature sensitivity, even when streamlined with plaque enlargement, ultimately depends on the laborious but reliable process of picking and testing individual plaques.

Temperature-sensitive mutants have the profound advantage of theoretically accessing any essential virus gene using a

single set of protocols. Temperature-sensitive mutants have proved enormously useful in all branches of virology, but they have been particularly useful for the study of animal viruses, where nonsense suppression has not been a viable option. Cold-sensitive mutants—that is, mutants that grow at a high but not a low temperature—comprise a relatively rare but nevertheless useful alternative type of temperature-sensitive mutants.

Temperature-sensitive mutants can actually be divided into two subclasses, thermolabile and temperature-sensitive-for-synthesis mutants (108). Thermolabile mutants are those in which the gene product can be inactivated following synthesis by a shift from the permissive to the nonpermissive temperature. Mutants that are temperature sensitive for synthesis display gene dysfunction only if the infection is held at the nonpermissive temperature during synthesis of the mutant gene product; if the gene product is made at the permissive temperature, it cannot be inactivated by raising the temperature. Clearly, the two mutant types can be distinguished by performing appropriate temperature-shift experiments. Thermolability obviously implies that a protein preformed at the permissive temperature is directly destabilized by raising the temperature. Temperature-sensitive-for-synthesis mutations commonly involve multisubunit structures or complex organelles: Theoretically, the quaternary structure of a complex formed correctly at the permissive temperature stabilizes the mutant protein, making the mutation resistant to temperature shift. If a temperature-sensitive-for-synthesis mutant protein is synthesized at the nonpermissive temperature, it may be degraded before assembly or may not assemble properly because of misfolding. For most purposes, the thermolabile and temperature-sensitive-for-synthesis mutant types are equally useful.

Drug Resistance/Dependence

A number of antiviral compounds have now been identified, and virus mutants that are resistant to or that depend on these compounds have found utility in genetic analysis of viruses. A few compounds have been identified that target similar enzymes in different viruses, including phosphonoacetic acid, which inhibits DNA polymerases (44,93), and BUdR, which targets thymidine kinases (21,97). More often, however, antiviral drugs are highly specific for a gene product of one particular virus—for example, guanidine, which targets the polio 2C NTPase (78,79); acyclovir, which targets the herpes simplex virus thymidine kinase and DNA polymerase (8,88); amantidine, which targets the influenza virus M2 virion integral membrane ion channel protein (43); and IBT, which is highly specific for poxviruses and targets at least two genes involved in viral transcription (10,70). Drugs that are most useful are those that inhibit wild-type virus growth in a plaque assay without killing cells in a monolayer, so that resistant or dependent viruses can be selected by virtue of their ability to form plaques on a drug-treated monolayer. Examples of both drug resistance and drug dependence are shown in Fig. 5.

Drug-resistant or -dependent virus mutants have two general uses in virus genetics. First, they can be useful for identifying the target or mechanism of action of an antiviral drug. For example, studies of influenza virus mutants resistant to amantidine were of importance in characterizing both the M2 gene and the mechanism of action of amantidine (80). Second, resistant or dependent mutants provide selectable markers for use in recombination mapping, for the assessment of specific genetic protocols, or for selection of recombinant viruses in reverse genetic protocols. For example, guanidine resistance has been used as a marker for use in three-factor crosses in recombination mapping of poliovirus temperature-sensitive mutants (14); phosphonoacetic acid resistance and IBT dependence have been used in vaccinia virus to assess the efficiency of marker rescue protocols (26,41); and acyclovir resistance and BUdR resistance, resulting from mutation of the herpesvirus or poxvirus thymidine kinase genes, have been used both in herpes viruses and in poxviruses to select for insertion of engineered genes into the viral genome (9,64,74).

Plaque Morphology

Plaque morphology mutants are those in which the appearance of mutant plaques is readily distinguishable from that of wild-type plaques. Most commonly, the morphologic distinction is plaque size—that is, mutant plaques may be larger or smaller than wild-type plaques. However, other morphologic distinctions are possible—for example, formation of clear versus turbid bacteriophage plaques. Most plaque morphology mutants affect very specific virus functions, which in turn affect the virus–host relationship in a fashion that impacts on the appearance of a plaque. Notable examples from bacteriophage research include clear plaque mutants of bacteriophage lambda and rapid lysis mutants of the T-even bacteriophage. Wild-type lambda forms turbid plaques because some percentage of cells are lysogenized and thus survive the infection, leaving intact bacteria within a plaque. Clear mutants of lambda typically affect the lambda repressor so that lysogeny is prevented and all infected bacteria lyse, resulting in a clear plaque (52). Wild-type T-even phages produce small plaques with a turbid halo because only a fraction of infected bacteria lyse during a normal infection, a phenomenon called lysis inhibition. Rapid lysis mutants, which affect a phage membrane protein, do not display lysis inhibition and as a result form large, clear plaques (46). Examples from animal virus research include large plaque mutants of adenovirus and syncytial mutants of herpes simplex virus. The large plaque phenotype in adenovirus results from faster-than-normal release of virus from infected cells (56). Syncytial mutants of herpes virus affect virus surface glycoproteins and result in fusion of infected cells, whereas wild-type virus causes cells to round and clump without significant fusion. Thus, *syn* mutants form large clear plaques readily distinguishable from the smaller dense foci caused by wild-type virus (86). All of these specific plaque morphology mutants have value either in the study of the actual functions affected, or as specific phenotypic markers for use in recombination studies, where they can be used in the same fashion as drug-resistance markers, described previously.

In addition to the existence of specific plaque morphology loci in several viruses, it is noteworthy that any mutation that effects virus yield or growth rate may result in the production of a smaller-than-wild-type plaque, which can be useful in genetic experiments. Thus, many temperature-sensitive mutants form smaller-than-wild-type plaques even at the permissive temperature because the mutant gene may not be fully functional even under permissive conditions, and this property is often useful in mutant isolation or for distinguishing wild-type from mutant virus in plaque assays involving several virus variants. Note, for example, in Fig. 5 that the vaccinia virus temperature-sensitive mutant *ts*56 forms smaller-than-wild-type plaques at the permissive temperature, 31°C. Last, intragenic or extragenic suppressors of conditional lethal virus mutants may grow poorly relative to the wild-type virus and form small plaques as a result, facilitating their isolation from a mixture containing true wild-type revertant viruses (13).

Neutralization Escape

Neutralization escape mutants are a specific class of mutants selected as variant viruses that form plaques in the presence of neutralizing antibodies. Such mutants affect the structure or modification of viral surface proteins. They have been of value in studies of virus structure, antigenic variation, and virus–cell interactions (37,47).

Reversion

Reversion may be defined as mutation that results in a change from a mutant genotype to the original wild-type genotype. Accordingly, revertants in a stock of mutant virus are revealed as viruses that have acquired a wild-type phenotype. For example, Fig. 5 shows that when the vaccinia virus temperature-sensitive mutant *ts*56 is plated at the nonpermissive temperature, a number of plaques with wild-type morphology, probably revertants, are detectable at low dilutions of virus. Spontaneous reversion of missense mutations probably results from misincorporation during replication, as the reversion frequency of different viruses often reflects the error rate of the replication enzyme. Spontaneous reversion of significant deletion mutations occurs rarely if at all, as reversion would require replacement of missing nucleotides with the correct sequence.

Reversion impacts on viral genetics in two ways. First, in any genetic experiment involving mixed infections with two genetically different viruses, wild-type viruses can arise either through reversion or recombination, and in most cases it is important to be able to distinguish between these two processes. This is discussed in more detail later in the sections describing complementation and recombination. Second, as described previously in the description of spontaneous mutation, if the spontaneous reversion rate is extremely high, revertants can easily come to dominate a mutant virus stock, thus obscuring the mutant phenotype and causing serious difficulties in both genetic and biochemical analysis of mutants.

Leakiness

Not all conditionally lethal mutants are completely defective in replication under nonpermissive conditions, and leakiness is a quantitative measure of the ability of a mutant virus to grow under nonpermissive conditions. Leakiness can be quantified with a one-step growth experiment. To quantify leakiness of a temperature-sensitive mutant, for example, cells are infected at a high moi with wild-type or mutant virus, infected cells are incubated at either permissive or nonpermissive temperatures, and maximal virus yields are then determined by plaque titration under permissive conditions so that the growth of mutant and wild-type virus can be quantitatively compared. Ideally, for wild-type virus the ratio of the yield for infections done at the nonpermissive temperature relative to the permissive temperature should be 1—that is, the virus should grow equally well at both temperatures. For mutant viruses, the ratio of the yield for infections done at the nonpermissive temperature relative to the permissive temperature may range from less than 10% to as much as 100%, even for mutants that are clearly defective in plaque formation under nonpermissive conditions. Mutants that are “tight” (i.e., that grow poorly under nonpermissive conditions) are desirable for phenotypic characterization relative to leaky mutants, because leaky mutants will logically display considerable wild-type phenotypic behavior.

In special cases, extreme leakiness is an expected and desirable trait. Specifically, virus mutants that are wild type for replication and production of infectious virions but defective in cell-to-cell spread have a phenotype characterized by defective plaque formation, which requires spread, but 100% leakiness, which does not require spread if assayed in a high moi, one-step growth protocol (4).

Genetic Analysis of Mutants

Complementation

Complementation analysis provides a general method for determining whether two different virus mutants affect the same or different genes. The quantitative test to determine complementation is a two-step procedure in which co-infections are first done to induce an interaction between two mutants, then the results of those infections are quantitatively assessed by plaque titration. The test compares the ability of two mutants to grow in mixed, relative to single, infections under nonpermissive conditions. Specifically, cells are first infected with two different virus mutants at high moi so that all cells are co-infected with both mutants, and infected cells are incubated under nonpermissive conditions where neither mutant alone can replicate, for an interval sufficient to achieve maximal virus yield. Single high-moi infections under nonpermissive conditions are performed as controls. Virus is then harvested, yields are quantified by plaque titration under both permissive and nonpermissive conditions, and a complementation index (CI) is calculated according to the following formula:

$$\frac{\text{yield } (A + B)_p - \text{yield } (A + B)_{np}}{\text{yield } (A)_p + \text{yield } (B)_p} = \text{CI},$$

where A and B represent individual virus mutants and the subscripts p and np represent the conditions, permissive or nonpermissive, under which the virus yields were plaque-titrated. Because both mutant and wild-type viruses will be counted in plaque titrations done at the permissive temperature, the first term in the numerator, yield $(A + B)_p$, measures the yield of all viruses, both mutant and wild type, from the initial high-moi mixed infections done under nonpermissive conditions. The second term in the numerator, yield $(A + B)_{np}$, measures the yield of wild-type viruses, mostly recombinants, from the high-moi mixed infections done under nonpermissive conditions, because only wild-type viruses will be counted in plaque titrations done at the nonpermissive temperature. Subtraction of the wild-type viruses from the total viruses leaves a count of only the mutant viruses in the numerator. The denominator measures the ability of each of the mutants to grow in single high-moi infections done initially under nonpermissive conditions.

If the two mutants, A and B, are in different virus genes, then in the mixed infection done under nonpermissive conditions mutant A can contribute wild-type B gene product and mutant B can contribute wild-type A gene product. Thus, the mutants can help or complement each other, resulting in a high yield of mutant virus in the mixed infection compared to the single infections, and a CI significantly greater than 1. If the two mutants A and B affect the same gene, then the wild-type gene product will be lacking in the mixed infection. In this case, the yield from the mixed infection will be equivalent to the yield from the single infections, and the CI should not exceed 1. In practice, because of error in plaque assays and from other sources, mixed infections with mutants in the same viral gene will often yield complementation indices of slightly greater than 1, and the practical cutoff must be determined empirically for a given viral system.

An example of complementation analysis for several mutants of Sindbis virus is shown in Table 6. Close examination of these data demonstrates both the utility and the vagaries of complementation analysis. For example, *ts*21, *ts*19, and *ts*17 clearly form a complementation group, as they are all noncomplementing with each other, and they complement all other mutants with the exception of *ts*24. The *ts*24 mutant is retained in group A because it is clearly noncomplementing with two other group A mutants, despite relatively high complementation indices with *ts*19 and *ts*17. The *ts*6 mutant is unusual in that it yields, for unknown reasons, relatively high complementation indices with all other mutants. The complementation pattern observed with *ts*11 is erratic; it was originally assigned to an independent group, then to group A, and finally to an independent group called A' to indicate uncertainty in the assignment (76).

Complementation Group	Mutant	Complementation level in mixed infection with: ts21	ts19	ts17	ts4	ts24	ts11	ts6	ts2	ts5	ts18	ts23	ts28

TABLE 6. *Complementation between* ts *mutants of Sindbis virus*

Qualitative complementation tests have also been devised for use with both bacterial and mammalian viruses (7,11,96). These qualitative tests are much easier to perform than quantitative tests and in practice just as reliable. In general, these tests are designed so that bacterial lawns or eukaryotic cell monolayers are infected either singly or with two viruses under nonpermissive conditions and at relatively low moi. The moi must be high enough so that numerous cells are doubly infected in the mixed infection, but low enough so that most cells are uninfected and a lawn or monolayer is maintained. Complementing mutant pairs produce plaques or cleared areas under nonpermissive conditions, whereas noncomplementing mutant pairs do not. An example of a qualitative complementation test is shown in Fig. 10. A disadvantage of the qualitative test is that it theoretically does not discriminate between complementation and recombination, but in practice this deficiency has not been a problem.

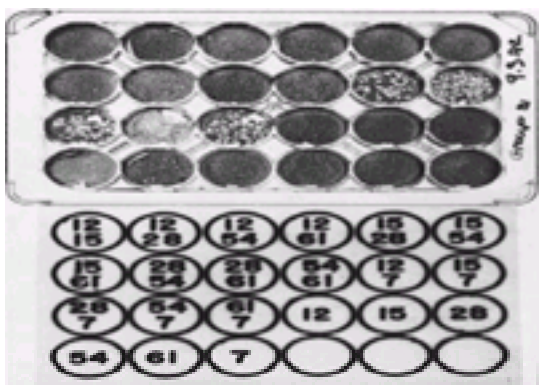

FIG. 10. Qualitative complementation test. This test was done to confirm that five different vaccinia virus temperature-sensitive mutants, *ts*12, *ts*15, *ts*28, *ts*54, and *ts*61, all reside in the same complementation group. Monolayers of the African green monkey kidney cell line BSC40 grown in a 24-well dish were infected at very low moi (0.03 pfu/cell) with individual mutants or mutant pairs. The dish was incubated at a nonpermissive temperature (40°C) for 3 days and stained with crystal violet. The stained dish is shown at the *top*, and a key to the infections is shown at the *bottom*. Mixed infections in the first 10 wells represent all possible pairwise combinations of the five candidate temperature-sensitive mutants, and the absence of plaques in these wells confirms that they all reside in a single complementation group. As a control, each mutant was also tested with another temperature-sensitive mutant, *ts*7, which was known to be in a different complementation group. The presence of plaques in each of the mixed infections containing *ts*7 represents positive complementation and confirms the validity of the test. Each mutant was tested in a single infection as an additional control. (From ref. 12, with permission.)

Complementation analysis has been of tremendous benefit in sorting mutants in most but not all viral systems. A notable exception is poliovirus, where complementation between temperature-sensitive mutants *in vivo* is not observed. The lack

of complementation in picornaviruses may be related to the unique mechanism of viral gene expression, in which all protein products are produced from a polyprotein precursor by proteolytic cleavage. If individual temperature-sensitive mutants affect structure, synthesis, or cleavage of the polyprotein precursor, they may behave as if they all belong to a single complementation group, even though they may map to different protein end products.

As a concept, complementation impacts broadly on virology and is not limited simply to the grouping of conditionally lethal mutants into genes. For example, the growth of engineered host-range deletion mutants in essential virus genes, discussed previously, relies on complementation of the missing viral function by an engineered cell line that expresses the wild-type viral gene product. In addition, the accumulation of defective virus genomes at high-multiplicity passage, also discussed previously, results from a complementing helper function provided by wild-type virus.

Recombination and Reassortment

Recombination describes a process by which nucleic acid sequences from two genotypically different parental viruses are exchanged so that the progeny contain sequences derived from both parents. In viral systems, there exist three distinct mechanisms of recombination, dictated by the structures of the viral genomes. For DNA viruses, recombination occurs by the physical breakage and rejoining of parental DNA molecules through regions of sequence homology, in a fashion similar or identical to the same process in bacteria or higher organisms. Of the RNA viruses containing nonsegmented genomes, only picornaviruses, coronaviruses, togaviruses, and retroviruses display efficient recombination, which is thought to occur during replication via “copy choice”—namely, switching templates during replication so that the newly synthesized genome contains sequences from two different parental molecules (39,48,54,55). For RNA viruses containing segmented genomes, recombination occurs through reassortment of individual parental genome segments into progeny viruses. Historically, recombination has been used to construct genetic maps of virus mutants and to construct novel virus genotypes. Although recombination mapping has been largely replaced by physical mapping techniques such as marker rescue, a technical knowledge of recombination mapping can contribute to an appreciation of the complexity of genetic interactions between viruses.

The methods used to determine recombination frequencies are the same regardless of genome structure or mechanism of recombination. Like complementation, the quantitative test to determine recombination frequency between two mutants, called a two-factor cross, is a two-step procedure, but in this case co-infections are first done under conditions permissive to recombination, and then the fraction of recombinants relative to the total virus yield is quantitatively assessed by plaque titration. Specifically, cells are first infected with two different virus mutants at high moi so that all cells are co-infected with both mutants, and infected cells are incubated under permissive conditions so that both mutants have maximal opportunity for interaction, for an interval sufficient to achieve maximal virus yield. Single high-moi infections under permissive conditions are performed as controls. Virus is then harvested, yields are quantified by plaque titration under both permissive and nonpermissive conditions, and a recombination frequency is calculated according to the followng formula:

$$\frac{\text{yield } (A + B)_{np} - \text{yield } (A)_{np} - \text{yield } (B)_{np}}{\text{yield } (A + B)_{p}} \times 2 \times 100\% = \text{RF},$$

where A and B represent individual virus mutants and the subscripts p and np represent the conditions, permissive or nonpermissive, under which the virus yields were plaque-titrated. The first term in the numerator, yield $(A + B)_{np}$, quantifies wild-type virus emerging from the mixed infection, including both recombinants and revertants, because only wild-type virus will grow in the plaque assay done under nonpermissive conditions. The second and third terms in the numerator, yield $(A)_{np}$ and yield $(B)_{np}$, quantify wild-type virus emerging from the control single infections, providing a measure of reversion in each of the two mutants. Subtraction of the revertants from the total yield of wild-type virus leaves a measure of recombinants only in the numerator. The denominator, yield $(A + B)_{p}$, quantifies the total virus yield from the mixed infection including both wild-type and mutant virus, as all input virus types will grow in the plaque assay done under permissive conditions. The quotient is multiplied by a factor of 2 to account for unscored progeny representing the reciprocal of the wild-type recombinants, namely double mutants, and converted to a percent.

Recombination mapping in DNA viruses relies on the assumption that the frequency of recombination between two genetic markers is proportional to the distance between the two markers. For several DNA viruses, observed recombination frequencies comprise a continuous range from less than 1% up to a theoretical maximum of 50%, allowing the construction of linear genetic maps (32).

In viruses with segmented genomes, recombination between markers on the same segment is extremely rare, but reassortment of segments is extremely efficient, so that recombination is an all-or-none phenomenon, with markers on the same segment displaying no recombination, and markers on different segments displaying very high levels of recombination (82). For these reasons, genetic exchange in segmented RNA viruses is commonly called reassortment rather than recombination. Reassortment analysis for segmented viruses is useful for determining whether two mutants map to the same genome segment, but it cannot be used to determine the order of markers on a given segment. Mutants can be mapped to individual RNA segments by performing intertypic crosses between virus types that differ in the electrophoretic mobility of each RNA segment. Specifically, if crosses are performed between a wild-type virus of one type and a mutant virus of another type and numerous wild-type progeny analyzed, one segment bearing the wild-type allele will be conserved among all the progeny, while all other segments will display reassortment (82).

Marker Rescue

Marker rescue is a physical mapping technique that measures directly whether a given virus mutation maps within a specific subfragment of a virus genome. Use of marker rescue is confined to DNA viruses in which homologous recombination takes place, but it has been of enormous value in these systems. The application of the technique varies somewhat depending on the virus system under study, but the general principles are the same. Specifically, full-length

mutant viral genomic DNA plus a wild-type DNA genomic subfragment, usually a cloned DNA molecule, are introduced into cells under conditions permissive for recombination and for wild-type virus replication. For viruses that contain infectious DNA—for example, herpesviruses (95), adenoviruses (36), and polyomaviruses (58,71)—the mutant genomic DNA and the wild-type genomic subfragment may be co-transfected into cells. For viruses containing noninfectious genomic DNA—for example, poxviruses (99)—the mutant DNA must be introduced into cells by infection with the mutant virus, and this is followed by transfection with the wild-type DNA subfragment. In either case, the protocol allows for homologous recombination between the mutant genome and the wild-type DNA subfragment. If the wild-type DNA subfragment contains the wild-type allele for the mutation, the recombination can exchange the wild type for the mutant sequence in the mutant genome, creating wild-type virus. Conversely, if the wild-type fragment does not contain the wild-type allele for the mutation, no wild-type virus, above a background of revertants, will be created in the experiment.

The presence of wild-type virus can be assayed using either a two-step or a one-step protocol. In the two-step protocol, depending on the nature of the mutation being rescued, infected and/or transfected cells are incubated under permissive conditions to facilitate recombination and replication, or under nonpermissive conditions to select for wild-type recombinants; then wild-type virus yields are quantified by plaque titration under nonpermissive conditions. In the one-step protocol, the infection and/or transfection is done so that only a small fraction of the cells in a monolayer are infected, and cells are then incubated under nonpermissive conditions so that wild-type virus formed during a successful rescue will form plaques on the monolayer (99). In short, regardless of the precise method used, conversion, or rescue, of mutant virus to wild type with a given wild-type DNA fragment means that the mutation maps within that fragment. Initial marker rescue mapping experiments may be facilitated by the use of a few large but overlapping wild-type DNA fragments, and fine mapping may be accomplished with fragments as small as a few hundred nucleotides. Marker rescue mapping has completely replaced recombination mapping as a method for mapping DNA virus mutants, and precise genetic maps of several DNA viruses have now been constructed.

Reverse Genetics

Prior to the advent of recombinant DNA and DNA sequencing technologies, classical genetic analysis, namely random isolation and characterization of virus mutants, was one of the few effective methods for identifying, mapping, and characterizing virus genes, and it was the only method for obtaining virus mutants. With the current ready availability of genomic sequences for virtually all the prototypical members of each virus family and a versatile package of genetic engineering tools, the experimental landscape has changed completely. One can now conduct a genetic analysis with a reasonably complete foreknowledge of the genetic structure of the virus, focus attention on individual genes of interest, and deliberately engineer mutations in genes to study their function. Termed reverse genetics, this process has come to dominate the genetic analysis of viruses.

Reverse genetic analysis involves two distinct considerations: strategies for construction of cloned mutations and strategies for incorporation of mutations into viral genomes. The principles governing these strategies are highly dependent on the structure of a given viral genome and the strategy of virus replication, and thus they vary in the extreme. However, a few general principles can be identified and are discussed later.

Incorporation of Mutations into Viral Genomes

The methods used for incorporation of mutations into viral genomes depend on several features of the individual virus under consideration, including genome size, whether the nucleic acid is infectious, and whether the genome is RNA or DNA. For DNA or RNA viruses with relatively small genomes and for which the nucleic acid is infectious, incorporation of a given mutation into the viral genome is a relatively straightforward matter of cloning the desired mutation in a full-length genomic clone in a prokaryotic vector, then transfecting cells with the mutant nucleic acid. For examples, engineered mutations have been constructed in both picornaviruses (18) and polyomaviruses (1) using full-length genomes.

For DNA viruses that are either too large or too complex to be easily manipulated as a full-length genomic clone, or that contain genomes that are not infectious as nucleic acids, incorporation of mutations into the viral genome requires homologous recombination catalyzed in infected and/or transfected cells, in a fashion virtually identical to marker rescue protocols described previously. For example, *in vivo* recombination has been used very successfully to construct numerous engineered mutations in both vaccinia virus (75) and herpes simplex virus (107).

For RNA viruses whose genomic nucleic acid is not infectious and for which homologous recombination is not an option, the protocols for incorporation of mutations into the genome become more complex and tailored to the particulars of replication of individual viruses. For example, construction of engineered mutations in rhabdoviruses requires construction of a full-length genomic clone which contains the mutation, and which can be transcribed from a bacteriophage T7 promoter. The mutant viral genome is activated by cotransferation with T7 promoter-driven plasmids encoding all required rhabdovirus replication proteins into cells infected with a recombinant vaccinia virus expressing T7 RNA polymerase (84). Similarly, construction of influenza virus recombinants requires co-transfection of multiple plasmids encoding the mutant RNA segment and several influenza replication proteins, and co-infection with a helper virus (81).

The methods used for isolation of the desired mutant virus depend on the nature of the mutation being constructed, and on the method of incorporation into the virus genome. In situations not requiring *in vivo* homologous recombination between cloned mutant DNA and wild-type virus, only the mutant allele of the target gene is present in the construction, all virus recovered from the construction will be mutant, and no selection or screen for mutants is required. This situation applies, for example, to construction of mutations in papovaviruses, picornaviruses, or rhabdoviruses, as described previously. In situations when *in vivo* homologous recombination is used to incorporate the cloned mutation into a wild-type genome, for example in poxviruses or herpesviruses, both mutant and wild-type viruses emerge from the mutant construction protocol, and thus a screen or selection is required to identify the mutant of interest. For mutations in nonessential genes, this may be a relatively straightforward matter of inserting into the target gene a color marker such as beta-galactosidase to facilitate a screen (107), or inserting a dominant selectable marker such as *E. coli* guanine

phosphoribosyltransferase (25), to facilitate a selection. For conditionally lethal phenotypes such as temperature sensitivity, although techniques exist that enrich for recombinant viruses, mutant isolation ultimately relies on a screen of individual mutants for differential growth under permissive and nonpermissive conditions.

Construction of Cloned Mutations

Construction of cloned mutations for use in virology is problematic only if the gene in question is essential, necessitating isolation of a conditionally lethal mutation. For genes that are nonessential, construction of a cloned mutation is a simple matter of engineering a null mutation, for example a deletion, insertion, or nonsense mutation, into the cloned gene sequence. Three basic types of engineered conditionally lethal mutations are currently in use: host-range deletion mutants that rely on the availability of a complementing host cell, temperature-sensitive mutants constructed by clustered charge-to-alanine scanning, and artificially induced gene regulation. For host-range deletion mutants, the primary problem is construction of a host cell that expresses the target gene in a fashion appropriate for complementation of a null mutant in the virus. Once a cell line has been isolated, construction of the cloned mutation in the virus gene follows the same principles governing construction of a null mutation in a nonessential gene. The fundamental problem in creating temperature-sensitive mutations is that it is currently impossible to predict from primary amino acid sequence or even from three-dimensional protein structure what type of mutation will render a protein temperature sensitive. This difficulty has been partially overcome with the use of clustered charge-to-alanine scanning mutagenesis, in which clusters of three or more charged residues in the primary amino acid sequence of a protein are all changed to alanine (105). In theory, charge clusters are likely to reside on the surface of the protein, where they may facilitate protein–protein interactions, and neutralization of the charge by replacement with alanine may weaken such interactions without seriously disrupting the three-dimensional conformation of the protein. In practice, as much as 30% of clustered charge-to-alanine scanning mutants prove to be temperature sensitive *in vivo*, and this mutagenesis technique has been successfully used to construct temperature-sensitive mutants of both picornaviruses and poxviruses (18,42). Last, conditionally lethal mutants have been constructed in poxviruses by placing essential genes under lactose operator–repressor control in the viral genome (85).

Viral Interference, Defective Interfering Particles

Interference refers generally to a phenomenon whereby infection by one virus results in inhibition of replication of another virus. Several distinct types of interference have been described (28), including direct heterologous interference, interferon-mediated heterologous interference, and defective interfering (DI) particle–mediated homologous interference. Direct heterologous interference describes a negative interaction between viruses of two different types, even different families, wherein viral gene products or alterations in the intracellular environment induced by one virus disrupt replication of another virus. The incompatibility of heterologous virus infections is not surprising, given the intricate interplay of virus and host functions in an infection, and the enormous variety of intracellular changes induced by different viruses. In interferon-mediated heterologous interference, discussed in detail in Chapter 12, infection by one virus induces interferon synthesis by the infected cell, and the interferon in turn induces an antiviral state in neighboring uninfected cells. DI particle–mediated homologous interference has been of particular interest to geneticists because of insights into the mechanisms of virus replication provided by defective interfering particles.

Defective interfering particle–mediated homologous interference was first described by von Magnus (103), who noted that serial undiluted passage of influenza virus resulted in a dramatic decrease in infectious titer, whereas the number of particles remained constant. Essentially the same phenomenon was subsequently observed in a wide variety of RNA and DNA animal viruses, and in both plant and bacterial viruses (49). The mechanism of interference in each case is similar: Virus stocks accumulate DI particles, which are virus particles that contain genomes that are grossly altered genetically, usually by significant deletion of essential functions, but that nevertheless retain critical replication origins and packaging signals, allowing for amplification and packaging in co-infections with complementing wild-type “helper” virus. DI particles usually display a replication advantage relative to wild-type virus, resulting from increases in the copy number or efficiency of replication origins. DI particles actively inhibit replication of wild-type virus, presumably by competing for limiting essential replication factors. Study of DI particles has provided significant insight into the viral replication, in particular structure and function of replication origins.

CHAPTER 3 Principles of Virus Structure

Stephen C. Harrison

Virus particles have evolved to transfer genetic material between cells and to encode information sufficient to ensure their own continued propagation. They are, in effect, extracellular organelles. They contain most or all of the molecular machinery necessary for efficient and specific packaging of viral genomes, escape from an infected cell, survival of transfer to a new host cell, attachment, penetration, and initiation of a new replication cycle. In many cases, the molecular machinery works in part by subverting more elaborate elements of the host cell apparatus for carrying out related processes. The principles of virus structure thus arise from the requirements imposed by the functions just outlined on the evolution of viral molecular architecture.

What are these requirements? One of the simplest and most general is the formation of a closed shell to protect viral nucleic acid during its passage from one cell to another. A second is one of genetic economy: the information necessary to specify the structural proteins must not exhaust the coding capacity of the viral genome. A third is the embodiment of specific strategies for exit and entry. The principles of protein folding and assembly, the sources of specificity in protein–protein interactions, and the possibilities for triggered conformational changes have determined what sorts of structures are observed. Indeed, much of our appreciation of these principles and possibilities has come from the study of viruses because they are among the simplest and most accessible of macromolecular machines.

Viruses come in many shapes and sizes. The broadest distinction is between the so-called enveloped and nonenveloped viruses, that is, those that contain or do not contain, respectively, a lipid-bilayer membrane. Most enveloped viruses acquire their envelope by budding through a membrane of the host cell into some extracytoplasmic compartment—either through the plasma membrane itself or through a membrane of the endoplasmic reticulum (ER) or Golgi apparatus. This last step in viral assembly is thus also an important part of the mechanism by which the virus escapes from an infected cell. Enveloped viruses then enter another host cell by fusion of their membrane with a membrane of the cell being infected. Again, this can be either the plasma membrane or the membrane of an internal compartment, such as an endosome. Nonenveloped viruses generally escape by lysis of the cell in which they have propagated, and their mechanism of entry is still incompletely understood.

Further categorization of virus structures depends on details of their molecular organization. The progress made recently in understanding viral architecture in atomic detail now allows us a glimpse of underlying similarities across various families of viruses, and the final section of this chapter attempts to develop some of those categories. We need first, however, to outline how virus structures are studied and to introduce the language needed to describe them. Integrated into this introduction is a synopsis of the principles of virus assembly and a discussion of how observed structural similarities relate to functional homologies in viral entry.

HOW VIRUS STRUCTURES ARE STUDIED

Electron microscopy is the most useful way to determine the general morphology of a virus particle. For examining infected cells and larger, isolated particles, the traditional thin-sectioning methods are used. The thickness of a section and the coarseness of staining methods limit resolution to about 50 to 75 Å, even in the best cases. (*Resolution* means the approximate minimal size of a substructure that can be detected or separated in an image from its neighbor. Recall that one atomic diameter is 2–3 Å; an a-helix, 10 Å; and a DNA double helix, 20 Å.) Negative staining, with uranyl acetate, potassium phosphotungstate, or related electron-dense compounds, gives somewhat more detailed images of isolated and purified virus particles. Viruses embedded in negative stain are often relatively well preserved. The electron beam destroys the particle itself very rapidly, but it leaves the dense “cast” of stain undamaged for much longer. If the particle is fully covered by the negative stain, the image contains contrast from both the upper and the lower surface of the particle, and visual interpretation of finer aspects of the image can be difficult (34).

Recently, methods for preserving viruses and other macromolecular assemblies by rapid freezing to liquid nitrogen or liquid helium temperatures have permitted visualization of electron-scattering contrast from the structures in the particle itself and not just from the cast created by a surrounding of negative stain (3). Moreover, quantitative methods for image analysis, originally developed for studying negatively stained particles, have been applied effectively to such images (3,34). Thus, a three-dimensional reconstruction of the electron-scattering density in a hepatitis B virus capsid has been computed to 7 Å resolution, permitting a tracing of the polypeptide chain later verified by x-ray crystallography at much higher resolution (14,115). An advantage of such cryoelectron microscopy is that regular images can be selected from a heterogeneous field, allowing study of unstable or relatively impure preparations. A gallery of cryoelectron microscopy

images is shown in Figure 1.

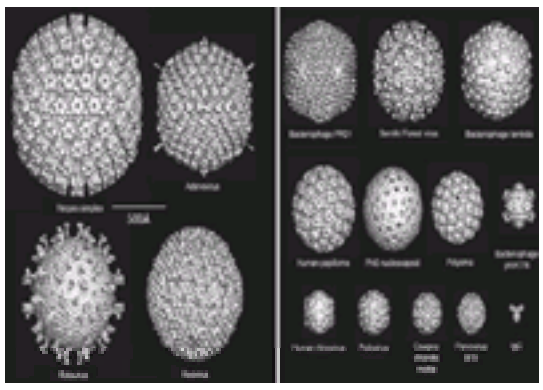

FIG. 1. A gallery of image reconstructions from cryoelectron microscopy of icosahedrally symmetric virus particles. The images illustrate the variety of sizes and specializations, even in these highly regular structures. The particles are labeled; the herpes simplex image is the nucleocapsid only. The image of an immunoglobulin molecule (IgG) is included on the same scale as the virus images, for direct comparison. The scale bar corresponds to 500 Å. (Modified from ref. 3, with permission.)

The detail obtained from even the most elegant of electron microscopy methods still falls short of what is required to understand molecular interactions. A higher-resolution picture can be obtained by x-ray diffraction methods, if single crystals of the relevant structure can be prepared. It has been known since the 1930s that simple plant viruses, such as tomato bushy stunt virus (TBSV), can be crystallized (8), and the first x-ray studies of such crystals were carried out as early as 1938 (11). Crystallization of poliovirus and other important animal viruses showed that the approach could be extended to human pathogens (95). The first complete high-resolution structure of a crystalline virus was obtained from TBSV in 1978 (61), and since then, the structures of a number of animal, plant, and insect pathogens have been determined. Only very regular structures can form single crystals; to study the molecular details of larger and more complex virus particles, it is necessary to dissect them into well-defined subunits or substructures. This dissection was originally done with proteases, by disassembly, or by isolation of substructures from infected cells. For example, the structure of the influenza virus hemagglutinin (114)—the first viral glycoprotein for which atomic details were visualized—was obtained from crystals of protein cleaved from the surface of purified virions (113); the structure of the adenovirus hexon was obtained from excess unassembled protein derived from adenovirus-infected cells (86). Recently, this dissection has more commonly been carried out using recombinant expression (e.g., of a fragment of gp120 from human immunodeficiency virus type 1 [HIV-1]) (65).

VIRUSES AS MOLECULAR PACKAGES

The simplest sort of package is a shell that can assemble spontaneously from a single component. The observation that certain viruses, particularly tobacco mosaic virus (TMV), assemble *in vitro* from dissociated components led Crick and Watson (33) to propose that virus shells would be highly symmetric objects. The arguments behind this proposal were simple: genetic efficiency requires that the viral coat be composed of many identical subunits, and experimentally observed self-assembly requires that the interactions among these subunits be specific and well defined. Identical subunits with specific interactions in general produce symmetric structures.

What is meant by *symmetric*? The rigorous definition of symmetry involves an operation, such as a rotation, that brings an object into self-coincidence. For example, if the ring of three commas in Figure 2 is rotated by 120 or 240 degrees, it will not be possible to recognize that a rotation has occurred (assuming that the commas are truly indistinguishable). The full symmetry of an object is defined by the collection of such operations that apply to it. In the case of protein assemblies, these operations can be rotations, translations, or combinations of the two. A symmetry axis that includes rotation by 180 degrees is called a *twofold axis* or a *dyad*; one with a 120-degree rotation (and, of course, a 240-degree rotation as well) is called a *threefold axis*; and so forth. Note the distinction between shape and symmetry: the *shape* of an object refers to the geometry of its outline, whereas its *symmetry* refers to the operations that describe it. The set of commas in Figure 2 has threefold symmetry; so does an equilateral triangle, the beer-company symbol with interlocked rings, and countless other objects with unrelated shapes.

FIG. 2. Three commas, arranged with threefold symmetry. The threefold rotation axis passes through the solid triangle in the center of the diagram.

Closed shells composed of identical subunits that interact through conserved, specific interfaces and that have a more or less spherical outline can have one of only three symmetries: the symmetry of the regular tetrahedron, the cube, or the regular icosahedron. These shells accommodate 12, 24, or 60 subunits, respectively. The icosahedral shells are obviously the most efficient of the three designs: they use the largest number of subunits to make a container of a given size, and hence they use subunits of the smallest size and the smallest coding requirement. Indeed, many of the viruses of interest to medical virologists contain at least some element with an icosahedrally symmetric shell, and the tetrahedral and cubic symmetries have not appeared in any normal virus assembly. We therefore describe icosahedral symmetry in some detail. Again, note the distinction between icosahedral symmetry and icosahedral shape. Not all objects with icosahedral symmetry have even the vague outline of an icosahedron; conversely, painting a single asymmetric object, like a comma, on each face of an icosahedron, rather than three such objects related by a threefold axis, would destroy the symmetry of the decorated object but would not affect its shape.

Icosahedral Shells

Icosahedral Symmetry

The diagram in Figure 3 shows the operations that belong to an icosahedrally symmetric object. They are a collection of twofold, threefold, and fivefold rotation axes. Placement of a single, asymmetric object on a surface governed by this symmetry leads to the generation of 59 others, when the various rotations are applied. One such object, one sixtieth of the total shell, can therefore be designated as an *icosahedral asymmetric unit,* the fundamental piece of structure from which all the rest can be produced by the operations of icosahedral symmetry. With a typical, compact protein domain of 250 to 300 amino acid residues, close to the upper limit for most single protein domains, what sort of container can we construct? Suppose that the protein is so constructed that 60 copies fit together into a 30 Å thick shell with no significant gaps. The cavity within that shell will then have a radius of about 80 Å, which can contain a 3-kb piece of single-stranded DNA or RNA (ssDNA or ssRNA, respectively), tightly condensed. A few, very simple virus particles indeed conform to this description. The parvoviruses (see Chapter 69) contain a 5.3-kb ssDNA genome, and their shells contain 60 copies of a protein of about 520 residues (Fig. 4). The capsid protein therefore uses up about one third of the genome. (*Capsid,* from the Latin *capsa,* for box, is used to describe the protein shell that directly packages DNA or RNA; *nucleocapsid* is sometimes used to refer to the shell plus its nucleic acid contents.) Likewise, the satellite of tobacco necrosis virus (STNV) contains 60 copies of a 195-residue subunit and a 1120 ssRNA genome, of which over half is used for the coat protein (68). As the name implies, however, STNV is actually a defective virus, and it requires tobacco necrosis virus co-infection to propagate.

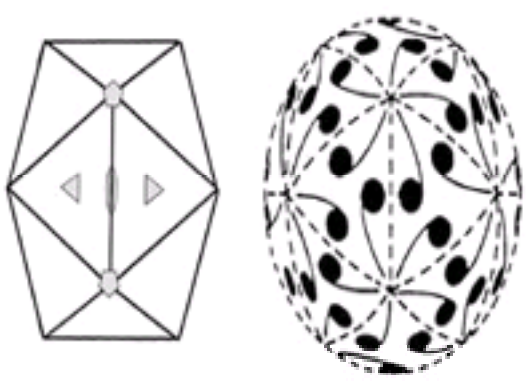

FIG. 3. *Left:* Outline of an icosahedron, showing some of the symmetry axes. Fivefold axes (*vertices*) are represented by pentagons; threefold axes (*faces*) by triangles; twofold axes (*edges*) by ovals. *Right:* 60 commas, distributed with icosahedral symmetry on the surface of a sphere. The *dashed lines* correspond to the edges of an icosahedron, projected onto the spherical surface.

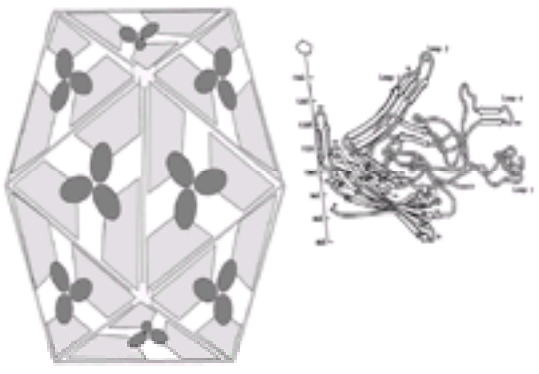

FIG. 4. *Left:* Diagram of the packing of 60 protein subunits in the shell of a parvovirus. The *trapezoids* represent a jelly-roll b-barrel domain (see Fig. 5) that forms the core of each subunit, and the *ovals* represent loops, emanating from the jelly-roll domain, which form contacts about the threefold axes. *Right:* Ribbon diagram of the folded subunit of canine parvovirus, viewed perpendicular to the fivefold and twofold axes, that is, as if viewing from the “southeast” the subunit that is just to the lower right of center in the larger packing diagram. The position and orientation of a fivefold axis, with respect to the subunit, are shown by the line with a fivefold symbol at its end. The jelly-roll b-barrel is at the *lower left* of this ribbon diagram, and the loops extend into the page toward the *upper right.* (From ref. 101, with permission.)

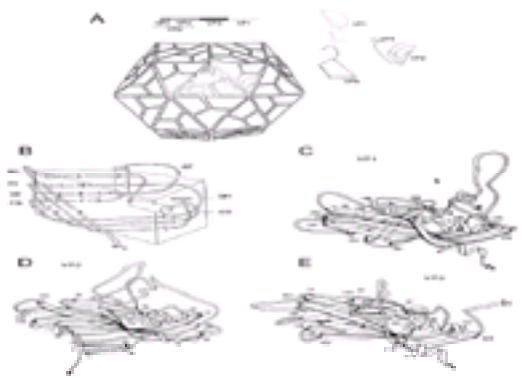

FIG. 5. Organization of the protein shell of picornaviruses. **A:** Subunit packing. *Upper left:* The order of domains in the precursor polypeptide chain. The cleavages between VP0 and VP3 and between VPP3 and VP1 are performed by a viral protease; the cleavage of VP0 to VP2 and VP4 is autolytic. Each subunit contains a jelly-roll b-barrel (*trapezoidal solid*), with highly variable loops and long N- and C-terminal extensions (*curved lines*). Two protomers (VP1, VP2, VP3, and V4) are shown in more detail in the center of the diagram. Distinct line qualities are used for each type of subunit. The diagram on the right is an "exploded view" of the right-hand protomer in the packing diagram. **B:** Schematic diagram of the folding of a polypeptide chain into a jelly-roll b-barrel. The strands are lettered in the order of their sequence in the chain. Strands B, I, D, and G form one sheet; C, H, E, and F, the other. The interstrand loops are designated BC, CD, etc. In picornaviruses and T=3 plant viruses, there are usually a-helices in the positions, shown as a cylinders. **C** to **E:** Ribbon diagrams of the jelly-roll cores of VP1 to VP3 of poliovirus. The numerals show residue numbers in each chain. Note how the loops give each subunit distinct characteristics. There is no evident sequence similarity, despite the similarity of fold. The small, curved arrow in C points to the entrance of a hydrophobic channel in the b-barrel, where various antipicornaviral drugs bind, blocking one or more steps in viral entry.

There are various ways in which viruses have evolved to produce larger icosahedral shells and thus to package larger genomes. The simplest is just to use several different subunits, each of "garden-variety" size, to make up one icosahedral asymmetric unit. The picornaviruses (e.g., polioviruses, rhinoviruses) have 60 copies of three distinct proteins, VP1, VP2, and VP3, each of between 230 and 300 amino acid residues, as well as 60 copies of a small internal peptide, VP4 (Fig. 5; see Chapter 23). The shell has a cavity about 95 Å in diameter, which contains an RNA genome of 7.5 to 8 kb. The picornaviruses thus expend about one third of their genome to encode the structural proteins of the virion. (*Virion* is used interchangeably with *complete virus particle.*) We note here two other important features of picornavirus molecular architecture. First, the folded structures of VP1, VP2, and VP3 are all based on the same kernel—a domain known as a *jelly-roll b-barrel* (see Fig. 5). This is the same fold that is found in the single subunits of the parvoviruses and of STNV. It is a module particularly well suited to the formation of closed, spherical shells, because of its blocklike, trapezoidal outline, but its prevalence among viral subunits may be evidence of a deeper evolutionary relationship. A second noteworthy feature of picornavirus design is the use of armlike extensions of the subunits for tying together the assembled particle (see Fig. 5). The importance of scaffold-like intertwining of subunit arms was first discovered in the simple plant viruses (61). In effect, folding of part of the subunit and assembly of the shell are concerted processes.

Quasi-Equivalence

A conceptually more complex, but evolutionarily simpler and more economical, way to build a shell of more than 60 average-sized subunits was described by Caspar and Klug in 1961 (23). It is illustrated by the diagram of 180 commas in Figure 6. The commas have similar interactions (head to head in pairs; neck to neck in rings of three; tail to tail in rings of five or six), but they fall into three sets, designated *A, B,* and *C.* If the commas are taken to represent proteins, the conformational differences between A and B positions, for example, involve the differences between rings of five and rings of six, for contacts involving the parts of the proteins symbolized by the tails. Caspar and Klug (23) postulated that protein subunits might have the sort of flexibility or capacity for conformational switching needed to accommodate in this way, and that viruses with more than 60 chemically and genetically identical subunits might exhibit the sort of near equivalence seen in the A, B, and C conformers in the comma illustration. Caspar and King (23) called this sort of local distortability, which might conserve the specificity and character of protein contacts, "quasi-equivalence."

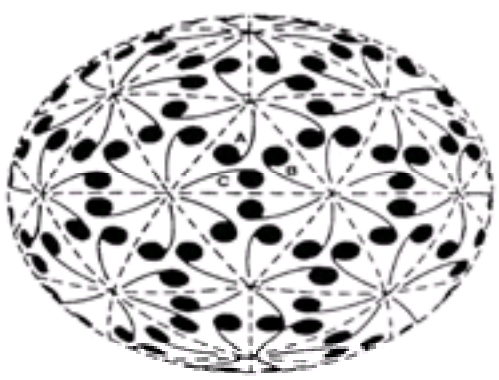

FIG. 6. Quasi-equivalent arrangement of 180 commas, in a T=3 icosahedral surface lattice on a sphere. Compare Figure 3 (*right*), a T=1 arrangement of 60 commas with icosahedral axes oriented similarly.

Quasi-equivalent designs are exemplified by a number of plant and animal viruses, such as TBSV (61) and Norwalk virus (78), as illustrated in Figure 7, Figure 8 and Figure 9. In TBSV and Norwalk virus, there are 180 genetically and chemically identical subunits that compose the capsid. The subunits are actually larger than those of the picornaviruses, but most of the extra size comes from a second, projecting domain that serves functions other than the construction of a closed shell. The size of the *shell domain* (S domain) in both cases is just about 200 residues, and the folded structure of the domain is again a jelly-roll b-barrel. The important feature of the packing of these 180 S domains is illustrated by the TBSV diagram in Figure 8. The contents of an icosahedral asymmetric unit can be described as three chemically identical subunits, with somewhat different conformations. These conformers are denoted A, B, and C, echoing the designation of commas in Figure 6. The differences among the conformers reside principally in an ordered or disordered conformation for part of the N-terminal arm and in the angle of the hinge between the S domain and the *projecting domain* (P domain). The A and B conformations are nearly identical, with disordered arms and similar hinge angles. The C conformation has an ordered arm and a different hinge angle from A and B. The ordered arms extend along the base of the S domain and intertwine with two others around the icosahedral threefold axis. Thus, the whole collection of 60 C-subunit arms forms a coherent inner scaffold.

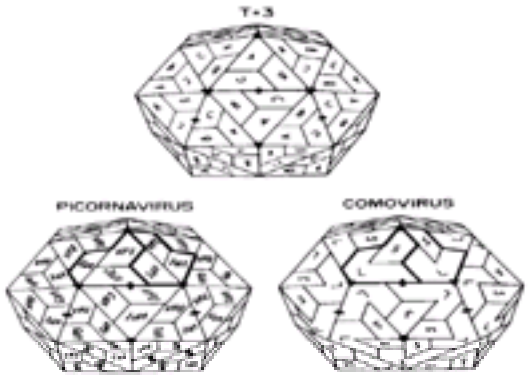

FIG. 7. Comparison of the packing of the jelly-roll b-barrel domains in T=3 plant and insect viruses; vertebrate picornaviruses; and plant comoviruses. In T=3 structures, the A, B and C subunits are chemically identical. In picornaviruses, VP1, VP2, and VP3 are different, but similar in the way the polypeptide chains folds (see Fig. 5). In comoviruses, the large subunit contains two b-barrel domains, in positions corresponding respectively to C and B in T=3 structures or to VP2 and VP3 in picornaviruses, and the small subunit contains one such domain, in a position corresponding to A or VP1. The diagrams are oriented (with respect to the icosahedral axes) like in Fig. 3 and Fig. 5**A**, but tilted slightly upward. The trapezoidal outlines represent subunits; the lettering or numbering on the subunits is oriented to show the rotational relationships among them. The small, solid symbols represent symmetry axes as defined in Figure 3. The heavy outlines in the lower two diagrams surround two protomers, related to each other by the fivefold axes toward the top of the diagrams. In Figure 5**A**, these are the protomers for which the N-terminal extensions of the subunits and VP4 are shown. The protomer on the right in the picornavirus diagram is the one shown in the “exploded” view on the upper right of Figure 5**A**. (Courtesy of J. Johnson.)

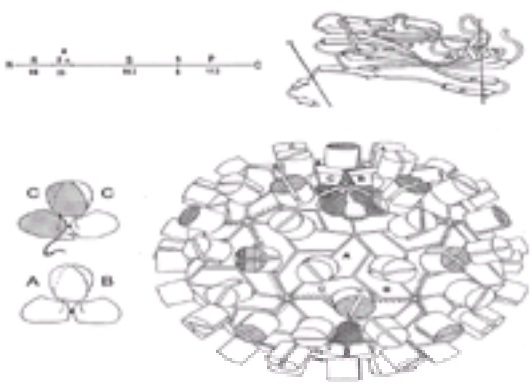

FIG. 8. Molecular architecture of tomato bushy stunt virus (TBSV), illustrating some of the principles of domain organization and quasi-equivalent interaction described in the text. TBSV is an icosahedrally symmetric, RNA-containing particle with 180 identical subunits. The 40-kd coat protein is organized into four regions: a positively charged, N-terminal R-segment; a connecting arm (*a*), and two compactly folded domains—*S* (shell) and *P* (projecting). There is a hinge (*h*) between the S and P domains. The relationship of the domains and connecting segments to the sequence (N- to C-terminus) is shown at the *upper left.* A ribbon diagram of the S domain is shown in the *upper right,* in an orientation corresponding to the similar diagrams in Figure 4 and Figure 5. Note how closely related are the folds of the b-barrels in all the subunits illustrated in these figures. The R segment of TBSV is probably irregularly folded in the particle interior; it interacts with viral RNA. By analogy with work on alfalfa mosaic virus (see text), a short piece of the R segment might be recognized by the RNA packaging signal, but this interaction has not been defined for TBSV. The arm is folded against the S domain on 60 of the subunits (those in positions symmetrically related to *C*), but it extends inward in a more disordered way on the remaining 120 (positions equivalent to *A* and *B*). The folded arms form an internal framework (*dashed lines* in full-particle diagram), with three arms meeting and interdigitating at each of the icosahedral threefold positions (cutaway in full-particle diagram). The shell can be considered an assembly of 90 dimers—30 C/C dimers, with ordered arms and rather little local curvature and 60 A/B dimers, with disordered arms and significant local curvature (*lower left*). The ordered framework of arms forces the bases of the S domains apart, whereas along the line that bisects an A/B dimer (the line that joins a fivefold to an icosahedral threefold), the bases of the S domains come together. The detailed side-chain interactions along the fulcrum of this contact remain essentially unchanged, however. Note that the interdomain hinges are essentially passive followers, so that the pair-wise clustered P domains simply project out along the strict and local twofold axes, and the weak interdomain contacts within a subunit do not significantly influence their

orientation.

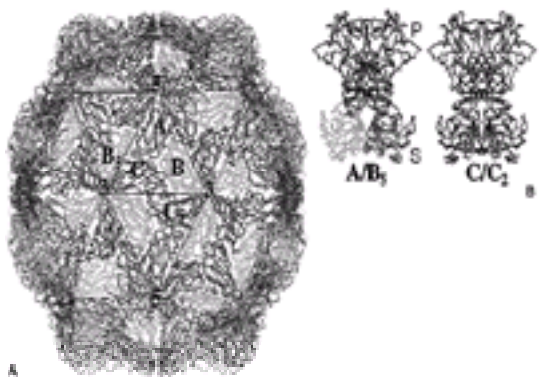

FIG. 9. Molecular architecture of the capsid of Norwalk virus, a human pathogen with a T=3 structure. The subunit arrangement resembles that in TBSV (see Fig. 8). There is a shell (*S*) domain with a jelly-roll b-barrel fold and a protruding (*P*) domain. The packing of S domains is shown in **A**. The P domain in Norwalk virus does not resemble the P domain in TBSV—it is larger, and it has two distinct subdomains—but it also forms strong dimer contacts. By comparing the side-view images of A/B and C/C dimers in part **B** of this figure with those in the lower left of Figure 8, the reader can see that the basic packing principle is similar in the two particles: the A/B contact generates curvature, whereas the C/C contact is relatively flat. The fulcrum around which the S-domain contact rotates in Norwalk virus is somewhat closer to the inward-facing margin of the domain than it is in TBSV. (From ref. 78, with permission.)

How equivalent or nonequivalent are the actual intersubunit contacts in TBSV or in other examples of quasi-equivalent designs? Most of the interfaces are quite conserved, with very modest local distortions that do not significantly change the way individual amino acid side chains contact each other. The interfaces between conformers that do exhibit noteworthy differences are those that include the ordered C-conformer arms in one of their quasi-equivalent locations. Even at these interfaces, however, where a clear switching mechanism takes place, many side-chain contacts are conserved around the “fulcrum” of the differences created by C-arm insertion (see Fig. 8).

The ways of subdividing an icosahedral shell, to create quasi-equivalent subunit packing as in TBSV and Norwalk virus, were enumerated by Caspar and Klug (23). Only certain multiples of 60 subunits can be accommodated in this way; they are given by the formula $T=h^2 + hk + k^2$, where *h* and *k* are any integer or zero. The multiple T is known as the *triangulation number* because, as illustrated by comparison of the 60- and 180-comma structures in Figure 3 and Figure 6, it corresponds to subtriangulations of an icosahedral net on the surface of a sphere. Such nets are known as *surface lattices,* and they are another way of describing the symmetry of a closed-shell arrangement of building blocks. If an icosahedrally symmetric structure is imagined as a folded-up hexagonal net (Fig. 10), 12 uniformly spaced sixfold vertices are transformed into fivefold vertices. The intervening twofold, threefold, and sixfold symmetry axes of the flat net are transformed either into quasi-twofold, quasi-threefold, and quasi-sixfold axes of the icosahedral net (i.e., approximate symmetry axes that apply only locally to the subunits in the immediate neighborhood) or, in some cases, into strict icosahedral twofolds or threefold axes (see Fig. 10). A number of the designs predicted by the Caspar and Klug concepts have been found among various viruses of vertebrates, insects, and plants (see Fig. 1; see also ref. 3).

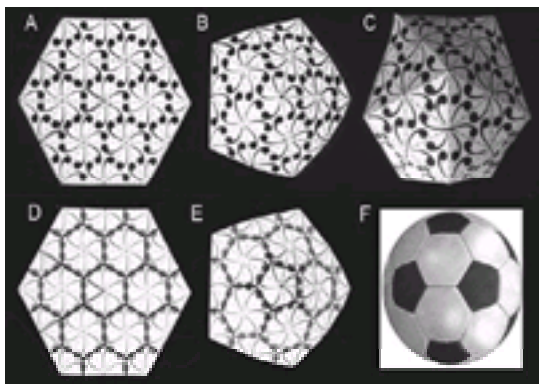

FIG. 10. A: Portion of a hexagonal lattice. Six triangular cells of the lattice meet at each lattice point, and each triangular cell contains three “subunits” (*commas*). Thus, there is a sixfold symmetry axis at each lattice point, a threefold symmetry axis at the center of each triangle, and a twofold axis at the midpoint of each edge. Imagine that the lattice extends indefinitely in all directions. **B:** Curvature can be introduced by transforming one of the sixfold positions into a fivefold (*center*). A 60-degree “pie slice” has been removed from the object in **A** by cutting along the heavy dotted lines, and the cut edges have been joined to generate the curved lattice shown here. **C:** If further cuts are made at regular intervals in an extended lattice, such as the one in **A**, and the edges joined as in **B**, a closed solid can be produced. In the case of the icosahedral solid shown here, vertices of the lattice separated by two cell edges have been transformed into fivefold axes, whereas the intervening lattice points have been left as local sixfold axes, producing a T=4 (h=2, k=0) structure. Notice that the local sixfold axes are actually only approximately sixfold in character; they correspond strictly to the twofold axes of the icosahedral object. **D:** Lines joining the centers of the triangular cells in **A** create a pattern of hexagons. **E:** When a sixfold is transformed into a fivefold, a hexagon becomes a pentagon. **F:** If second nearest-neighbor lattice points are all transformed into pentagons, a “soccer ball” figure results. This is a T=3 structure. A description of the lattice as a network of hexagons and pentagons is complementary to its description as a network of triangles. The representations in Figure 3 and Figure 6 use triangles. The representations in Figure 11 and Figure 12

use hexagons and pentagons. One representation for a given structure can easily be derived from the other.

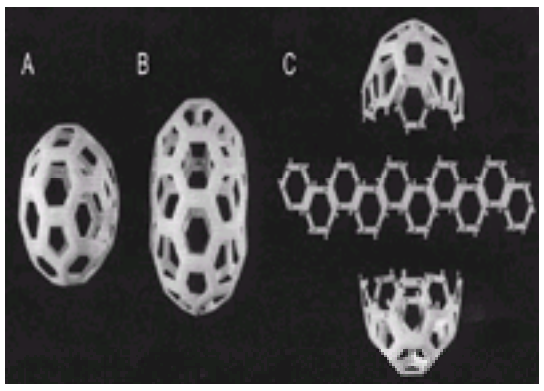

FIG. 11. A: Schematic representation of a T=3 lattice. Compare the soccer ball in Figure 10**F**. In this figure, the lattice is oriented so that there are pentagons at the north and south poles. Altogether, there are 12 pentagons and 20 hexagons (180 subunits) in a T=3 assembly. **B:** Schematic representation of the lattice describing phage f29. There are 12 pentagons and 30 hexagons (240 subunits). Again, there are pentagons at the poles of the structure. **C:** The f29 lattice can be derived by cutting the T=3 structure into two hemispheres, each with a pentagon at its pole, and adding a band of 10 hexagons around the equator. (From ref. 112, with permission.)

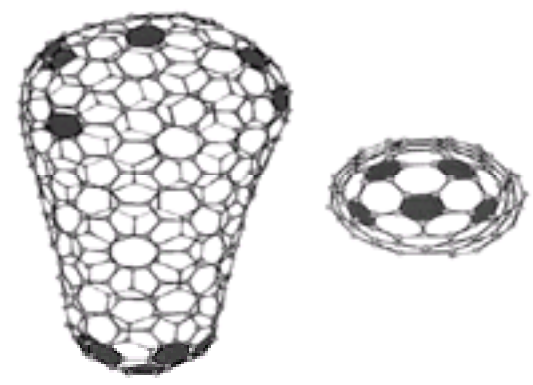

FIG. 12. *Left:* a conelike lattice of hexagons and pentagons, representing the rearranged ("mature") capsid of human immunodeficiency virus type 1. There are seven pentagons in the upper curved surface and five in the lower one. Thus, the upper surface contains a bit more than a full hemisphere and the lower surface, a bit less. *Right:* View from below, showing the five-pentagon surface. Addition of one more pentagon would turn it into a T=3 hemisphere. (From ref. 50, with permission.)

The external appearance of the virus particles in Figure 1 do not in all cases immediately reveal the underlying quasi-equivalent design. At high enough resolution, they will do so, of course, but as seen in the electron microscope at moderate resolution, they reveal variously disposed "bumps" rather than individual protein subunits. The bumps usually correspond to projecting parts of subunits, clustered around local symmetry axes. The 90 bumps in a three-dimensional reconstruction from electron micrographs of negatively stained TBSV, for example, correspond to pair-wise clustered P domains of the protein subunit, projecting at the 30 strict twofold and 60 quasi-twofold positions. In a frequently found arrangement, the intersubunit contacts are particularly tight and prominent around fivefold and quasi-sixfold axes in the surface lattice, as in the images of the herpesvirus capsid, bacteriophage P2, and cowpea chlorotic mottle virus (CCMV) in Figure 1 (*hexamer-pentamer clustering*). In low-resolution electron micrographs, such as those taken of negatively stained particles, the structure of CCMV (see Fig. 1) would simply have 32 smooth bumps, rather than obviously subdivided hexamers and pentamers. In general, hexamer-pentamer clustering produces 10 (T – 1) + 12 bumps in an icosahedral lattice with triangulation number T. Before the molecular principles of virus structure were fully understood, these bumps were called *capsomeres* (meaning the structural units of the capsid). This word is sometimes still used when referring to apparent morphologic units on the surface of a virus shell, but it is best reserved for cases in which all capsomeres are the same and hence represent a defined oligomer, as in the pentameric units of papovaviruses (see later).

Some noteworthy variations on subtriangulated icosahedral designs are nonetheless in keeping with the basic Caspar-Klug notion of quasi-equivalence, namely, that once a stable and specific protein interface has evolved, structures requiring deviations from simple designs generally make use of the possibility for flexing the contact, rather than developing a completely different specificity within the same surface of the folded subunit. One such variation is found in elongated structures with hemi-icosahedral caps (Fig. 11). Near the poles of these caps, the shell looks like a normal icosahedral design. As the lattice approaches the equator, however, the regular interspersion of fivefold and quasi-sixfold axes gives way to sixfold axes only, so that there is a tubular region around the middle of the particle. The tubular region can be of varying extent; in extreme cases, it can be much longer than the caps themselves. A further variation on this theme is found in the shells formed by the CA fragment of the lentivirus Gag protein. Conical structures seen within HIV-1 particles have been shown to be based on the sort of arrangement shown in Figure 12, where one cap has more than six fivefold axes and the other has less, so that the diameters of the two caps are different (50). (Note that

if there are only sixfold and fivefold vertices in a closed surface lattice, there will always be exactly 12 of the latter.)

A key issue in assemblies with quasi-equivalent contacts, like those just illustrated, is positional regulation. Of the different quasi-equivalent interactions, what determines, for any given site, which state is actually present? Consider for definiteness the T=3 design exemplified by TBSV (see Fig. 8). Structures like this one are known to assemble from dimers of the protein subunit. We can think of the dimer as having two states: the A-B state, characterized by unfolded arms and one position for the interdomain hinge, and the C-C state, characterized by folded arms and another position for the interdomain hinge. Experiments show that assembly proceeds by addition of dimers to a growing shell and that the curvature of the growing shell is always nearly correct (94) (Fig. 13). That is, when a dimer adds to a shell, it adopts the correct state, and the characteristics of the site at which the dimer adds determine that state. Assembly mechanisms of this kind depend on getting started correctly—having a correct initial nucleus—and on addition of defined "assembly units." In the case of TBSV, the initial nucleus probably includes an RNA packaging signal, and the assembly unit is the subunit dimer.

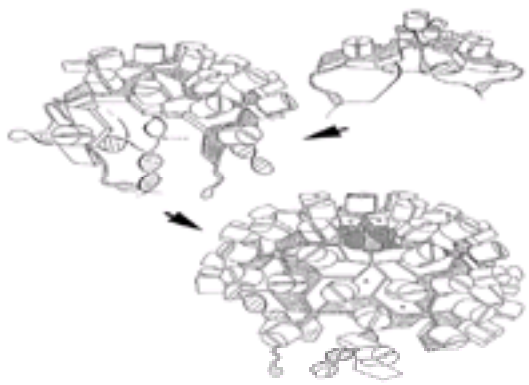

FIG. 13. Model for assembly of a T=3 virus shell (derived from work on turnip crinkle virus; see ref. 94). The key steps are: specific initiation, propagation by addition of a defined assembly unit, and closure. In the case of most T=3 structures that have been studied, the assembly unit is a dimer of the subunit. The initiation structure is shown as a trimer of dimers, nucleated by interaction with a packaging signal on the RNA. All the dimers adopt the C/C (ordered arm) conformation (see Fig. 8). An alternative model, probably not ruled out by the data, would be a pentamer of dimers, all in the A/B conformation (disordered arms), also nucleated by the packaging signal. In either case, the key characteristic of each addition step is that the conformation of the assembly unit that associates with the growing shell is uniquely determined by the nature of the site at which it adds. In the model shown here, the first addition to the trimer of C/C dimers is necessarily an A/B dimer because the interdigitated arms prevent further ordered arms around that threefold, and the assembly unit that slips in must necessarily leave its arms in a disordered state.

More Complex Icosahedral Shells

Pentameric Assembly Units in Papovaviruses

A number of icosahedral shells have structures in which the individual subunits are not in roughly equivalent positions with respect to their neighbors. In papovaviruses, 72 pentamers of the major capsid protein form the viral shell (82). The pentamers are centered on the vertices of a T=7 icosahedral surface lattice (Fig. 14), but of these, only 12 can be on fivefold positions, and the remainder are six-coordinated. That is, 60 of the 72 pentamers are "fivefold pegs in sixfold holes." In the case of the polyomaviruses (such as SV40 and murine polyoma), each subunit has an extended, C-terminal arm that issues from the body of the pentamer and invades a subunit in a neighboring pentamer (67). Thus, each subunit donates and accepts an arm. The interactions made by the arms are essentially invariant: they fit the same way into every target subunit. The essential variability lies in the way an arm bridges from one pentamer to the next, in other words, in the flexibility of the arm as it passes across the boundary between the pentamer from which it emanates and the pentamer into which it inserts. The folded part of the subunit is a jelly-roll b-barrel, just as in the RNA viruses with quasi-equivalent designs, but the long axis of the domain is oriented essentially radially, rather than tangentially, in the shell.

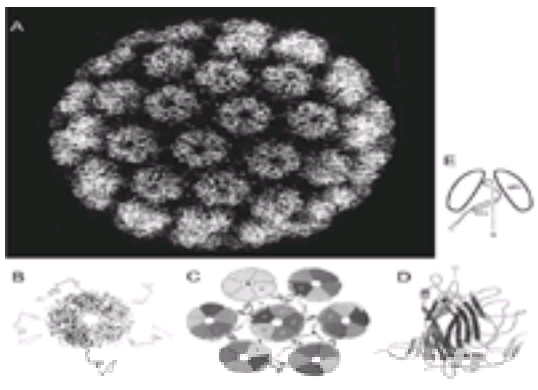

FIG. 14. Organization of the polyomaviruses (67). **A:** Overview of the particle, showing the packing of VP1 pentamers. The diagram is based on a molecular graphics representation in which the polypeptide chain of each subunit is shown as a folded line. The pentamers are all centered on lattice points of a T=7 icosahedral surface lattice. Only 12 of those lattice points are five-coordinated, however; the remaining 60 are six-coordinated. The orientation of the particle corresponds to that of the icosahedron in Figure 3; note the five-coordinated pentamers toward the top and bottom of the image, along the central vertical axis. The intervening pentamers are six-coordinated. **B:** A six-coordinated VP1

pentamer, “extracted” from the model in **A.** The extended carboxyl-terminal arms are shown in the conformations they adopt in the assembled particle; in the free pentamer, they are disordered and flexible. **C:** Pattern of interchange of arms in the virion. The arms “invade” neighboring pentamers, to link the structure together. The body of a pentamer is shown as a five-petalled flower; the arms are cylinders (a-helices) and lines. The *small open circles* mark Ca^{2+} sites. The central pentamer in this diagram corresponds to the one just to the upper right of center in **A. D:** The subunit, viewed normal to the pentamer axis. Strands are represented as *ribbons;* helices, as *cylinders;* loops as *narrow tubes.* The two sheets of the b-barrel domain are in different *dark shades;* the carboxyl-terminal arms are pale; the amino-terminal arms are somewhat darker. The complete carboxyl-terminal arm seen here actually emanates from a subunit in another pentamer; only the initial, a-helical segment of the arm from this subunit is shown because it then extends out of the page. Note how the amino-terminal segment clamps the invading arm in place. The small ball represents the site of a Ca^{2+} ion. **E:** Interaction of VP2 (or VP3) with VP1. The VP1 pentamer is shown in cross-sectional “side” view, with the outside of the virion at the top and the inside at the bottom. The C-terminal part of VP2 (identical with the C-terminal part of VP3) inserts from within the virion, into the conical hollow in the pentamer (4,25).

The assembly unit of the papovavirus shell is a pentamer (91), and just as the assembly mechanism for a T=3 shell described previously involves a unique nucleation event, followed by successive addition of individual dimers, so the likely mechanism for assembly of the papovavirus shell involves a specific initiation step followed by successive addition of pentamers. A scheme can be drawn by which the nature of a site for pentamer addition, at the growing edge of the shell, determines where the C-terminal arms of the new pentamer will insert (96). A clear advantage of the papovavirus design is that there is a single type of preformed assembly unit: the pentamer.

Scaffold Proteins in Phage and Herpesvirus Capsid Assembly

Structures with hexamers and pentamers of the same protein species cannot assemble by simple addition of a single kind of assembly unit, and they consequently require a substantially more intricate assembly mechanism. For example, genuine T=7 structures do exist, with 12 pentamers and 60 hexamers made of the same subunit. The heads of bacteriophages, such as lambda and P22, are examples of such designs (79). Unlike the papovaviruses, however, they cannot be put together from a unique kind of subassembly. Indeed, their assembly pathway is quite complex, involving formation of a precursor particle (the procapsid) with participation of an internal scaffold protein, which is degraded or recycled before insertion of the viral DNA (22). Herpesvirus capsids (see Fig. 1), which have T=16 shells with 12 pentamers and 150 hexamers of the major capsid protein (VP5 in the case of herpes simplex virus type 1 [HSV-1]), also assemble around a scaffold, which is degraded before insertion of the DNA genome (see Chapter 72).

Trimeric Assembly Units, Chemically Distinct Pentons, and “Cement” Proteins in Adenoviruses

Adenoviruses (Fig. 15) exhibit a combination of nonequivalent and quasi-equivalent interactions (98). They have 12 “pentons” on the fivefold positions, and 240 “hexons” on the sixfold positions of a T=25 icoshedral lattice. The pentons are pentamers of the penton-base protein, with an inserted, trimeric fiber (105). The hexons are actually trimers, not hexamers, of the hexon protein, and each face of the icosahedron is triangulated into a net with local threefold (rather than sixfold) symmetry. Within a face, the hexons make essentially equivalent interactions with each other, but at the edges, there are completely different hexon–hexon contacts (see Fig. 15). Additional proteins are needed to cement the hexons in place in the adenovirus shell and to anchor the pentons (47,99). The high-resolution structure of the hexon (Fig. 16) shows that each subunit contains two similar jelly-roll b-barrel domains, so that the threefold symmetric hexon does have a pseudo-sixfold (86). Just as one can imagine taking one subunit of a T=3 quasi-equivalent shell and generating three related but distinct subunits by gene duplication and divergence (e.g., going from a TBSV-like design to a picornavirus-like design), so too can one imagine taking a subunit from a true, quasi-equivalent, T=25 lattice and generating the adenovirus-like structure by gene duplication without separation of the two polypeptide chains.

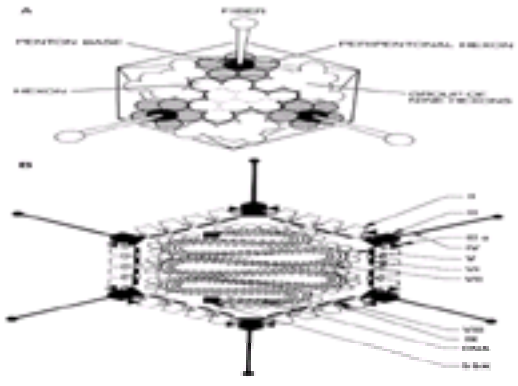

FIG. 15. A: Diagram of the adenovirus particle, showing the location of major protein subassemblies. The nine hexons drawn as a group and the “peripentonal” hexons are trimers of the same polypeptide; they are distinguished only by their location in the structure. (Illustration by John Mack. From ref. 16, with permission.) **B:** Cross-section showing the probable location of the principal polypeptide components and the viral DNA. The assignment for proteins other than II (hexon), III (penton base), and IV (penton fiber) is based on studies of step-wise dissociation and on difference cryoelectron microscopy. (Redrawn from ref. 39, with permission.)

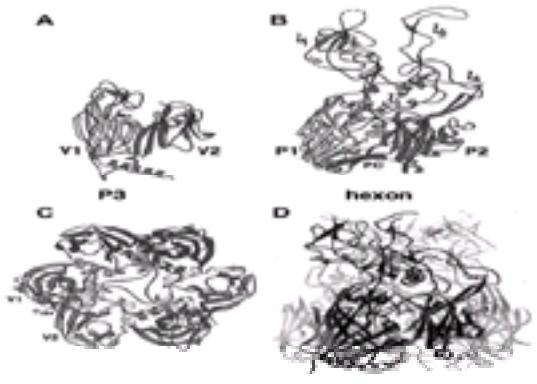

FIG. 16. Comparison of the adenovirus hexon structure and the P3 outer-shell protein from bacteriophage PRD1. **A** and **B:** The polypeptide chains of P3 and adenovirus hexon. The direction of view is perpendicular to the threefold axis. The two b-barrel domains are shown in *gray*; the loops between strands in each domain and between domains are shown in a *lighter shade.* Note that these domains are oriented so that their b-strands would run radially in the virus particle, as in the polyomaviruses, rather than tangentially, as in the picornaviruses. Except for the much more restricted loops of the "tower," P3 closely resembles hexon. **C:** Top view of the PRD1 P3 trimer, showing its pseudo-hexagonal outline. The adenovirus hexon would have, near its base, a very similar outline; this is the part of the trimer that interacts with others in the lattice of the virion shell (compare Fig. 15A). **D:** Side view of the adenovirus hexon trimer. The black subunit, in the foreground, is in the same orientation as the single subunit in **A.** The loops of the individual chains fold extensively with each other. These loops would probably not be ordered in a monomeric subunit, and it is likely that subunit folding and trimer assembly occur coordinately. (**A** to **C** redrawn from ref. 10, with permission; **D** courtesy of R. Burnett.)

Multishelled Architecture of Double-Stranded RNA Viruses

Double-stranded RNA viruses also exhibit both nonequivalent and quasi-equivalent interactions, but in separate protein shells. The core of bluetongue virus, for example, has an inner shell, made of 120 copies of a protein known as VP3, and an outer shell, made of 780 copies of VP7 (57). There are two totally distinct environments for VP3, because 2 is not a permitted triangulation number (Fig. 17). The amino acid side chains on the lateral surfaces of VP3 have different partners, depending on the interface in which they lie. The distortion of the subunit itself, when the two environments are compared, is quite small. By contrast, the VP7 shell has a classic, T=13, quasi-equivalent design. The contacts between VP7 trimers resemble each other closely. Intershell contacts are obviously highly variable because there is no match between the triangulation of the two shells. It is likely that addition of VP7 nucleates at threefold positions, where there is a match in symmetry of the two layers; these strong intershell contacts can then initiate lateral propagation of the VP7 lattice by addition of further trimers.

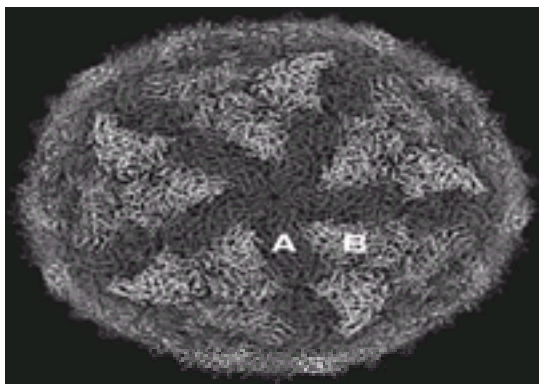

FIG. 17. A structure with 120 identical subunits: the principal shell of the inner capsid particle (core) from reovirus (83). The 60 dark copies of the protein l1 (one of which is labeled *A*) and the 60 lighter copies (*B*) have different interactions within the shell. For example, the "tips" of five A subunits contact each other around a fivefold axis, whereas the corresponding surfaces of B subunits touch different parts of A subunits. Thus, the same molecular surface makes two quite different, yet specific, interactions. A similar arrangement of the protein VP3 is found in the core of bluetongue virus (57).

Rearrangements in Icosahedral Lattices

Icosahedral surface lattices can undergo rearrangements, which preserve the overall symmetry of the structure but change the pattern of specific intersubunit contacts. There is often an accompanying change in the diameter of the shell. The T=3 plant viruses expand, in most cases reversibly, when the calcium cations that stabilize a particular set of subunit interfaces are removed (87) (Fig. 18). This swelling is believed to be the first step in disassembly. Plant viruses are injected by their vectors directly into the cytoplasm of the recipient cell, where they are exposed to a low Ca^{2+} environment. A similar, but transient, expansion occurs when poliovirus binds its receptor (9). The double-stranded DNA (dsDNA) bacteriophages insert their genomic DNA into a preformed "prohead," and the outer shell of the prohead generally expands as its subunits shift around to form the mature structure (22). Herpesviruses likewise package DNA into a procapsid, which undergoes structural changes in the process, but without a change in diameter (100).

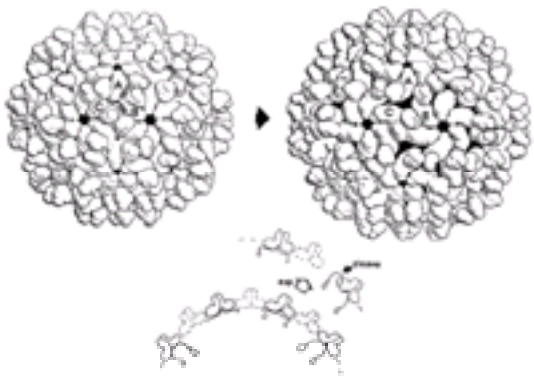

FIG. 18. Expansion of TBSV. The mature, compact particle (*upper left*) expands when Ca^{2+} ions (*small circles*) are removed. The expanded form (*upper right*) is reached by a smooth transition, in which many of the intersubunit contacts are conserved. The contacts that included the ions in the compact state have separated substantially, creating a fenestrated shell. As diagrammed in the lower part of the figure, the arms of A and B subunits, which do not participate in the inner scaffold (see Fig. 8), can loop out through the fenestrations, becoming susceptible to cleavage by proteases.

Symmetry Mismatches

P>The papovavirus structures have already provided us with one example of mismatched symmetry—what we called a "fivefold peg in a sixfold hole." A somewhat different example is the way these same pentamers bind the internal proteins, VP2 and VP3 (4,25). These proteins are the same, except for an about 100-residue N-terminal extension unique to VP2. Each VP1 pentamer binds one internal protein, through interaction with residues near the common C-terminus (see Fig. 14**E**). In the virus particle, all five symmetry-related registers of the VP1-VP2/3 interaction occur, so that the internal protein projecting inward from a given VP1 pentamer adopts one of five equally likely orientations. A similar rotational randomness is likely to characterize the adenovirus fiber, which is a trimeric molecule anchored in a pentameric base (see Fig. 15). Symmetry mismatch appears to be used in rotary motors, such as those that package DNA or RNA in phage heads, to subdivide a full rotation into discrete steps.

Helical Tubes

Isometric virus structures occur much more frequently than tubular ones, perhaps because of the inherently greater efficiency of nucleic acid packaging within a quasi-spherical cavity. There are, however, a number of well-known and widely studied helical and filamentous viruses, and the nucleocapsids (protein-coated nucleic acid) of many enveloped, negative-strand RNA viruses are helical arrays, which coil within the virion and uncoil when released.

Helical structures are organized around a single axis (the *helix axis*). They can be described by the number of units per turn, *u* (not necessarily integral), and the axial rise per unit, *p.* (Axial rise is the increment in "height" along the helix axis between one unit and the next.) The pitch of the helix, *P,* defined as the distance along the helix axis corresponding to exactly one turn, is equal to the product of *u* and *p.* Helical structures can have a rotation axis coincident with the helix axis (e.g., the T4 phage tail, with a sixfold axis) or an array of twofold axes perpendicular to the helix axis (as in DNA). The diagram of TMV in Figure 19 illustrates that a structure with helical symmetry (in this case, having u = 16 $^1/_3$, p = 1.4 Å, and P = 23 Å) can also be described by reference to a surface lattice—the network connecting equivalent units in the curved surface. The lattice lines correspond to different helical paths, as shown in the figure and described in more detail in the caption.

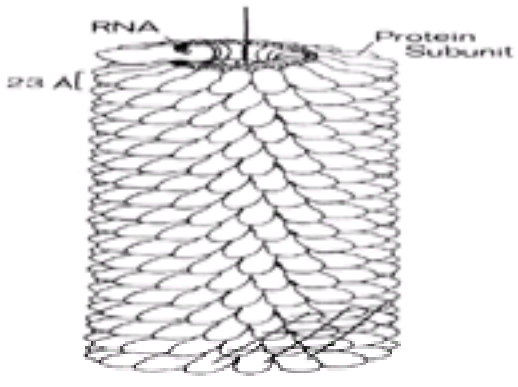

FIG. 19. The helical structure of tobacco mosaic virus (TMV). There are 161/3 subunits per turn of the helix, which has a 23 Å pitch. Three RNA nucleotides fit into a groove on each subunit. There is an about 30 Å diameter hollow along the axis. The surface lattice (four "unit cells") is indicated in the lower part of the figure.

In TMV, and probably in the nucleocapsids of negative-stranded RNA viruses like influenza and vesicular stomatitis virus (VSV), the RNA winds in a helical path that follows the protein. That is, the tubular package does not simply contain the RNA, it co-incorporates it. There are exactly three nucleotides per subunit in TMV, and they fit into a defined groove between the helically arrayed proteins. By contrast, the protein coat of a filamentous, ssDNA phage, such as M13, forms a sleeve that surrounds and constrains the closed, circular genome, without there being a specific way in which each subunit "sees" one or more nucleotides (51). Thus, there can be a non-integral ratio of nucleotides to protein monomers.

Genome Packaging

Incorporation of viral nucleic acid must be specific but independent of most of its base sequence. Therefore, viral genomes often contain a *packaging signal*—a short sequence or set of sequences that directs encapsidation. Recognition of the packaging signal depends on the nature of the genome and on the complexity of the assembly mechanism. The coats of simple viruses usually assemble around the genomes, and in these cases, there is likely to be a direct interaction between genome and capsid protein. More complex viruses sometimes insert nucleic acid into a preformed shell, and genome recognition is a property of the packaging system. If replication and packaging are closely coupled in some way, there may be no requirement for a specific packaging signal at all, as may be true of the picornaviruses.

In positive-stranded RNA viruses, no definite overall secondary or tertiary fold is needed for the genomic RNA, aside from the restriction that it fit within the shell. This restriction is actually quite severe, and the RNA is generally packed very tightly, approximating the density of RNA in crystals (e.g., of tRNA). Even random-sequence ssRNA contains about 60% to 70% of its nucleotides in base-paired stems (55), and to fit efficiently within the interior of a capsid, these RNA stems must pack tangentially, many in contact with the inward-facing surface of the shell. Such packing can be achieved by assembly around the RNA, without defined capsid–RNA interactions. In some viruses, segments of partially ordered RNA appear, packing into shallow grooves on the inner capsid surface (27,42). The ordered structures of these segments may result simply from the shape of the groove and the possible structures that a tightly packed polynucleotide chain can adopt. There do not appear to be any base-specific contacts in these ordered segments.

Recognition of RNA packaging signals has been analyzed in detail in a few cases. In RNA phage such as MS2 and R17, the packaging signal folds into a stem-loop structure (Fig. 20**A**), recognized by a dimer of the coat protein (the assembly unit for this T=3 particle) (20,103,104). Bases of the loop in the packaging signal and a looped-out base in the stem fit into a groove on the inward-facing surface of the subunit dimer, and conserved bases make defined protein contacts. The MS2 subunit has a structure unrelated to those of nonenveloped positive-stranded RNA viruses of eukaryotes, many of which recognize their genomic RNA, not through a groove-like site on the protein, but rather through a flexibly extended, positively charged protein arm, often at the N-terminus. In the case of alfalfa mosaic virus, the arm may fit against a recognition structure formed by the folded RNA packaging signal (2). In a sense, the RNA “recognizes” the packaging signal, rather than the other way around. A similar recognition principle determines the specificity of interactions between the Tat protein of HIV-1 and its cognate site, TAR, on the HIV-1 RNA (80), as well as of those between HIV-1 Rev and its cognate site, the RRE (6). It may also apply to the way the positively charged, N-terminal arm of alphavirus capsid proteins direct specific RNA packaging.

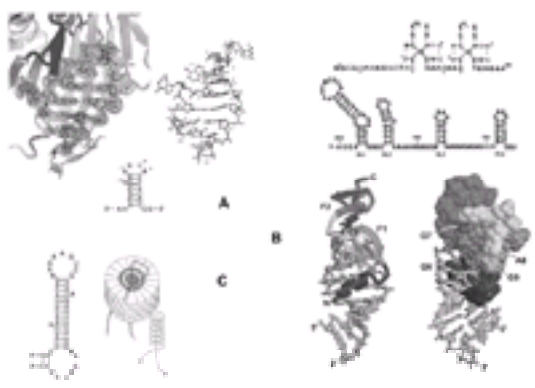

FIG. 20. RNA virus packaging signals. **A:** Recognition of the bacteriophage MS2 packaging sequence (a stem-loop structure, with a sequence shown in the lower part of the figure) by a dimer of the coat protein. The stem-loop fits into a hollow on the inward-facing surface of the protein (*upper left*); three bases in the loop and a looped-out base in the stem are critical for specific recognition; the stem structure presents them to the protein in correct spatial orientation (*upper right*). (Redrawn from ref. 104, with permission.) **B:** Recognition of the human immunodeficiency virus type 1 packaging sequence by the dual “zinc knuckle” element in the NC protein. The amino acid sequence of this 55-residue element is shown at the *top,* using single-letter notation. The nucleotide sequence of the packaging signal (“psi sequence”) in the genomic RNA is shown in the *middle.* Note that it contains four distinct stem-loops. The two zinc knuckles (F1 and F2) fold around the loop at the tip of stem-loop 3 (SL3), and a segment N-terminal to the first Zn knuckle forms an a-helix in the widened major groove of the RNA. The NC peptide itself is ordered only within each Zn-liganding fold (about 16 residues each), and the two knuckles are flexibly linked. The structure of SL3 thus imposes additional structure on the peptide, including the N-terminal helix. (Redrawn from ref. 35, with permission). **C:** Assembly of TMV from an assembly origin that lies just upstream of the coat-protein coding sequence at the 3' end of the genome (17,117). The sequence and likely secondary structure of the assembly origin are shown on the left. The location of this origin, roughly 500 nucleotides from the 3' end of the RNA, implies that the 5' end of the RNA runs back along the axis of the assembling particle, as shown on the right.

Retroviral packaging signals, known as *psi* sequences, are recognized by the nucleocapsid (NC) domain of the Gag protein. The HIV-1 psi element has a stem-loop structure that associates with two “zinc-knuckle” modules in HIV-1 NC (35) (see Fig. 20**B**). The two zinc modules are flexibly linked in unbound NC, but they adopt a defined, three-dimensional organization in complex with the RNA. Thus, the structure of the RNA imparts additional order to the protein element with which it binds.

Helical structures must unwind any base-paired stems of an RNA genome in order to package it. For example, TMV assembly begins at an internal origin sequence, about 1 kb from the 3' end of the genome (102,117). A 75-base

sequence containing a presumptive stem-loop structure is sufficient to initiate specific encapsidation (see Fig. 20**C**), which proceeds by a mechanism that requires the 5' end of the RNA to be drawn through a channel along the axis of the assembling particle (17). This process may be described as an assembly-driven helicase. In negative-stranded RNA viruses such as influenza, the sequences that determine encapsidation by the nucleocapsid protein are probably in the conserved termini of the genome segments (see Chapter 46).

The mechanism of overall condensation of a viral genome may be distinct from the specific recognition just discussed. If there is no regular, repeated interaction between coat protein and nucleic acid, there are various strategies for neutralizing the net negative charge on the nucleic acid. Those icosahedral viruses with inwardly projecting, positively charged arms use most of these arms for nonspecific interactions with RNA and only one or a few for specific recognition. In the picornaviruses, polyamines are incorporated to achieve charge neutralization. Double-stranded DNA viruses use either cellular histone to condense the viral chromosome (polyomaviruses) or basic, virally encoded proteins (adenoviruses). The dsDNA bacteriophages and the herpesviruses “pump” DNA into a capsid precursor, using adenosine triphosphate hydrolysis to drive condensation. The most efficient packing of a double-stranded genome within a hollow shell can be achieved by uniform coiling of the dsDNA or dsRNA, such that in cross-section, adjacent segments are hexagonally arrayed (37,54). DNA is packed this way in herpesviruses and in phage heads (Fig. 21**A**), as is dsRNA in reoviruses and their relatives (83). Reoviruses have segmented genomes, and each segment may form an independent coil (see Fig. 21**B**).

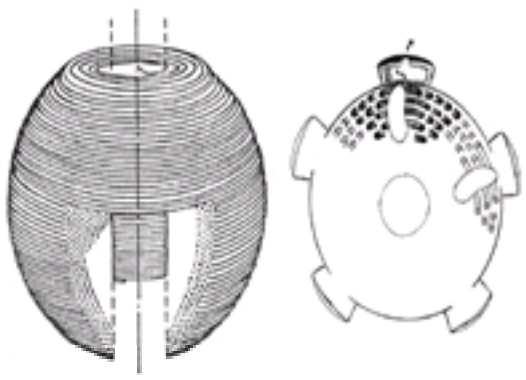

FIG. 21. Packing of double-stranded nucleic acid in virions. **A:** Uniform coiling of DNA within the head of bacteriophage lambda and its relatives (37). The DNA is introduced into a prohead by the action of an adenosine triphosphate–driven rotary motor. In the filled, mature phage head, adjacent, parallel segments of DNA form a local hexagonal packing (*cutaway view toward the bottom of the drawing.*) **B:** Model for coiling of double-stranded RNA (dsRNA) genomic segments within the core of reovirus and other dsRNA viruses (54,83). The negative strand for each segment is generated by the polymerase (*oval outline*), after core assembly in which are packaged one each of the positive-stranded segments. Each genomic segment must be transcribed multiple times, probably by the polymerase around which it is coiled. The transcript exits through a pore along the fivefold axis; in the case of orthoreoviruses, it passes through the chamber of a capping-enzyme complex (*hollow turrets*).

Viral Membranes

Budding

Most enveloped viruses (except for the large and very complex poxviruses) acquire their membrane, a lipid bilayer with associated proteins, by budding through an appropriate cellular membrane—the plasma membrane in many cases, the ER, Golgi apparatus, or nuclear membrane in others (Fig. 22). Using the cell's compartmentalization mechanisms, these viruses direct the insertion of their surface glycoproteins into the relevant membrane of the cell. Budding is driven either by interactions between cytoplasmic tails of the glycoproteins and assembling or preassembled internal structures, by lateral interactions between glycoprotein subunits, or by a combination of both. In some cases, assembly of an internal structure on the cytoplasmic face of the membrane is sufficient to drive budding, even if glycoproteins are lacking. Pinching off from the cell surface, or into the lumen of the ER or Golgi apparatus, appears not to need a cellular activity; assembly of viral components provides the force needed to distort the membrane bilayer. The lipids in the resulting bilayer derive from the cell, whereas the proteins are virally encoded. To a first approximation, the incorporated lipids represent a sample of those in the membrane through which the virus budded, but the significance of potential detailed specificities in lipid incorporation are still poorly understood. Viruses that emerge through the plasma membrane contain phospholipid and cholesterol in characteristic proportions, whereas those that emerge into the lumen of the ER contain almost no cholesterol. Cholesterol tends to increase the thickness of a bilayer, by restricting free rotation around single bonds in the fatty acid chains of adjacent phospholipids (81). The lengths of a-helical transmembrane segments in viral glycoproteins vary accordingly: from about 26 residues in influenza (which buds at the cell surface) to 18 to 20 residues in yellow fever (which buds into the ER).

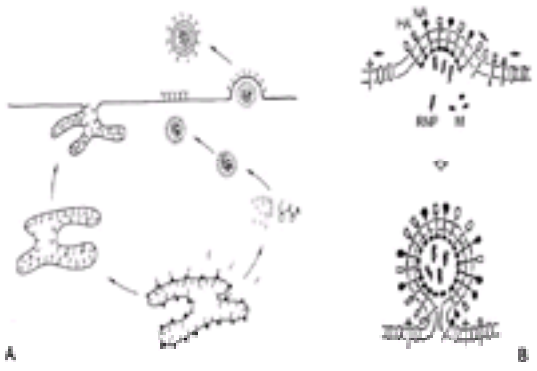

FIG. 22. Budding of enveloped viruses. **A:** Diagram of alphavirus biosynthesis and assembly. The viral structural proteins are synthesized as a polyprotein from a single message. The core protein, a serine protease that acts only on its own polypeptide chain, cleaves itself from the precursor at an early stage. The ribosomes and nascent viral polyprotein then associate with endoplasmic reticulum membranes to complete synthesis of the glycoproteins, which are exported to the cell surface by the standard constitutive route through the Golgi compartments. Core protein and RNA assemble to form nucleocapsids, which associate with glycoprotein patches and initiate budding. **B:** Influenza virus budding. Nucleocapsid protein (N), matrix protein (M), and glycoproteins (HA, NA) are synthesized from independent messages. Glycoproteins arrive at the cell surface by the usual route. Budding is a coassembly at the cell surface of the glycoproteins with M and with RNP segments. Host cell proteins are excluded (*arrows*).

Figure 22 illustrates features of the budding process in two examples—an alphavirus (Sindbis) and an orthomyxovirus (influenza). The structure of the nucleocapsid varies with virus type. It is a compact, spherical particle in the alphavirus; a filamentous, helical nucleocapsid in paramyxoviruses and rhabdoviruses; and a multisegmented helical nucleocapsid in the orthomyxoviruses. The viral glycoproteins are anchored in the cellular membrane by a transmembrane hydrophobic segment (in some cases, a hydrophobic hairpin), and there is a small cytoplasmic domain. In alphaviruses (see Fig. 22**A**), a core particle (nucleocapsid) assembles independently in the cytoplasm. Interactions between the core and the cytoplasmic tail of the glycoproteins then determine the location of budding. Lateral interactions of the glycoproteins also appear to assist the budding process. In orthomyxoviruses such as influenza (see Fig. 22**B**), an M (matrix) protein associates with the nucleocapsid segments and with the underside of the membrane, presumably by interaction with the cytoplasmic domains of the glycoproteins. M organizes both the glycoproteins and the nucleocapsids. Budding then proceeds by coassembly of structures on both surfaces of the membrane. The two patterns of budding shown in Figure 22 are not fundamentally different; rather, they depend on the relative strength of core–core, envelope–envelope, and core–envelope contacts. In at least one case, a mutation has been shown to convert budding from one mode to the other (85). Absolute specificity is sometimes violated in viral budding, leading to cases of phenotypic mixing, in which, for example, SV5 glycoproteins can be found in the membrane of VSV. In retroviruses (Fig. 23), cleavage of core proteins after budding leads to major internal rearrangements.

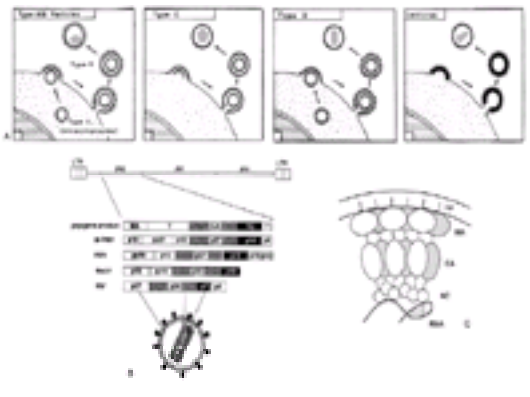

FIG. 23. Assembly and budding of retroviruses. **A:** Diagrammatic representation of the organization of retroviruses of different apparent morphologies in thin section. (Redrawn from ref. 12, with permission.) In at least one case, mutations in *gag* can change the budding pattern from that of type D to that of type C, that is, from preassembly of a core in the cytoplasm to coassembly of core and envelope at the membrane. **B:** Organization of the *gag* region of a retroviral genome and its relationship to the organization of an “immature” (unprocessed Gag precursor) and “mature” (proteolytically processed Gag) virion. *Top:* overall arrangement of genomic information. *Middle:* The subunit products of cleavage of the Gag precursor and their specific names in the case of Mason-Pfizer monkey virus (M-PMV), a type D particle, Rous sarcoma virus (RSV), a type A/B particle, murine leukemia virus (MuLV), a type C particle, and human immunodeficiency virus (HIV), a lentivirus. *Bottom:* Representation of an HIV particle, showing locations of MA, CA, and NC proteins (Redrawn from ref. 64, with permission). **C:** Diagram of the organization of the HIV Gag precursor. The MA domain is myristoylated at its N-terminus, facilitating its association with the membrane. It forms a trimer. The CA domain dimerizes, through its carboxyl-terminal subdomain. This combination of trimer and dimer formation may help drive extended lateral association and budding.

The simplest enveloped virus particles—those of the alphaviruses and the flaviviruses—are icosahedrally symmetric. In these positive-stranded RNA viruses, one-to-one interactions between the envelope glycoprotein and the nucleocapsid subunit appear to ensure coherence between external and internal structures (28,106) (Fig. 24; see Fig. 22**A**). The larger, negative-stranded RNA bunyaviruses also have an icosahedrally symmetric envelope (a T=12 lattice), but their internal structures are probably not icosahedrally organized (108), and the outer lattice is the major determinant of symmetry and stability. The rhabdoviruses have a helically organized shaft with a (probably hemi-icosahedral) cap at one

end. The orthomyxoviruses, like influenza A, bud out as variable elongated structures with no overall symmetry, although there is probably considerable local order. Retrovirus particles also do not appear to have a global symmetry. The fluid character of a lipid bilayer means that the virus can form a closed structure without a perfect surface lattice. Defects in a protein layer that would produce unacceptable holes in a nonenveloped virus are tolerable if the barrier protecting the genome is a lipid membrane rather than a protein shell.

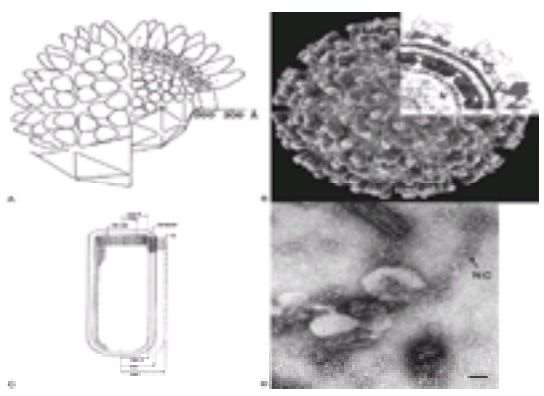

FIG. 24. Organization of two types of enveloped viruses. **A:** Diagram of an alphavirus particle (Sindbis). The pear-shaped objects represent the ectodomains of E1 and E2, closely associated as heterodimers and further clustered into trimers in the T=4 icosahedral lattice that describes the surface organization (107). There are 240 E1:E2 heterdimers in the complete particle. Hydrophobic transmembrane segments of E1 and E2 penetrate the lipid bilayer. A 33-residue internal domain on E1 mediates interactions with the core. The core also has a T=4 icosahedral structure (28). **B:** Reconstruction of the closely related Semliki Forest virus particle from cryoelectron microscopy at 10 Å resolution. Most of the figure shows a surface rendering; the *upper right-hand quadrant* shows a thin cross-section, with a scale to show radius (in angstoms), for comparison with the diagram in **A**. (Redrawn from ref. 69, with permission.) **C:** Diagram of the vesicular stomatitis virus (VSV) particle, showing the relationship of nucleocapsid (N), matrix protein (M), and glycoprotein (G) to the lipid bilayer. The scale of this diagram is about half that of the diagram in **A**, but the VSV genome is only slightly larger than that of Sindbis. The Sindbis RNA, which collapses into stem-loop structures in the interior of the core, is therefore markedly more condensed than the VSV RNA, which winds as an extended strand along the helical nucleocapsid. **D:** Electron micrograph of disrupted VSV, showing partially disassembled "cores." The hollow tubes are helically coiled nucleocapsid (*NC*), fixed into a rigid structure by interaction with M, which has probably dissociated from the more loosely coiled NC (e.g., *upper right*). Paramyxovirus nucleocapsids have a rather similar appearance, after release from disrupted particles.

Internal Structures

As Figure 22, Figure 23 and Figure 24 suggest, the proteins on the internal side of viral envelopes are significantly more varied in design than those in the outer shells of nonenveloped viruses, where most of the known outershell protein structures contain jelly-roll b-barrel domains. The alphaviruses have subverted a serine protease to serve as the principal domain of the capsid subunit (C) (29). The protease is functional in the single step required to cleave C from the nascent polyprotein of these positive-stranded RNA viruses. The core, sealed within the bilayer, can afford to be fenestrated. The hexamer and pentamer clusters of the protease domains do not contact each other, and coherence of the T=4 icosahedral lattice is maintained by interacting N-terminal arms. Thus, these positively charged arms, like those of TBSV (see Fig. 8), appear to knit the core together as well as to recognize and neutralize RNA. The hepatitis B capsid is also an open, almost lattice-like, structure, formed by a largely a-helical subunit that can assemble into either T=3 or T=4 shells (14). The retroviral Gag precursor is usually anchored by an N-terminal myristoyl group to the membrane bilayer, and successive domains are separated by cleavage into radially organized layers (see Fig. 23 and Chapter 57). The structures of the various domains from HIV-1 Gag have been determined (44), as have those of certain domains from a few other retroviruses.

Most viral envelope proteins are so-called type I membrane proteins, with a single transmembrane a-helix linking the ectodomain and the cytoplasmic tail. The transmembrane helices have been resolved in a recent cryoelectron microscopy study of Semliki Forest virus (69). In some positive-stranded RNA viruses, like the flaviviruses, where structural proteins are derived from a polyprotein precursor, the anchor may be an a-helical hairpin that traverses the membrane twice (24). Contacts between the cytoplasmic tails of viral envelope glycoproteins and target sites on the underlying core of matrix subunits generally determine specificity of envelope protein incorporation. These interactions usually involve a short segment of envelope polypeptide, fitting against a site on the internal protein (13,66,75). Individual interactions are weak, and bilayer disruption by nonionic detergents readily dissociates them. But the cooperativity imparted by lateral contacts, both within the core or matrix and within the outersurface layer, is strong, and the ensemble of cooperative, weak interactions drives budding.

Surface Proteins

The proteins on the surface of an enveloped virus must carry out at least two functions: receptor (and co-receptor) binding and fusion. In addition, there may be a receptor-destroying enzyme (e.g., the influenza-virus neuraminidase or the coronavirus esterase), to promote viral release. The membrane of influenza A contains a fourth activity: a proton channel that assists uncoating and transcriptase activation (M2). In some cases (e.g., rhabdoviruses and retroviruses), the receptor-binding and fusion activities are combined in a single protein; in others (e.g., paramyxoviruses), there are two distinct proteins to carry out these functions. A trimeric, coiled-coil fusion-protein structure, found in a wide range of enveloped viruses, is described later under Membrane Fusion.

Viral Entry into Cells

Receptor Binding

There are no simple generalizations about virus receptors and how they bind with viral surfaces (see Fig. 24). We note two broad issues here. The first is that most viruses have evolved a mechanism to avoid "getting stuck" at the cell surface when emerging from an infected cell. Many viruses simply bind weakly to their receptors and thus can dissociate in a reasonable time. The virulence of polyomavirus in mice is inversely related to viral affinity for its sialoglycoconjugate receptor (Fig. 25**A**), demonstrating that spread in the animal host, rather than entry into cells, is the principal correlate of pathogenesis (7). Like polyoma, influenza virus recognizes a sialic acid–containing carbohydrate for cell attachment (77) (see Fig. 25**B**). A receptor-destroying enzyme (neuraminidase) is present on the surface of the virion; its activity allows release of newly assembled virions from the cell surface through which they have budded (76). The neuraminidase is thus required for effective spread of the virus, and the enzyme is the target of antiinfluenza drugs, developed in part by exploiting knowledge of the neuraminidase structure (109). HIV-1 has several mechanisms for down-regulating its receptor (CD4) after infection, both to avoid envelope–receptor interactions within the secretory pathway and to facilitate viral release after budding (see Chapter 59). The second broad issue is that some viruses require a cascade of at least two distinct receptors, in order to enter efficiently. One receptor is required for initial cell attachment and a second for triggering fusion or penetration. The former may be a quite broadly distributed molecule, like sialic acid or other glycans (heparan sulfate for HSV-1), or it may be a quite specific protein, like the adenovirus receptor, CAR, or the HIV-1 receptor, CD4 (see Fig. 25**C**). The latter is often called a *co-receptor,* for example, the chemokine receptors for HIV-1. In the case of HIV-1, CD4 primes the envelope glycoprotein to bind the co-receptor, which in turn induces fusion activation. An obligate order of this sort may turn out to be relatively common.

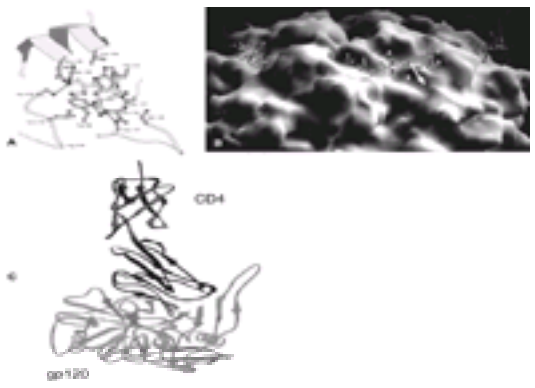

FIG. 25. Virus–receptor interactions. **A:** Influenza virus recognizes the terminal sialic acid on cell surface glycoconjugates, both glycoproteins and glycolipids. The sialic acid–binding site, shown here, lies on the outward-facing tip of the haemagglutinin protein, indicated by a *star* in Figure 26**B** (110). Polypeptide chain segments adjacent to the bound sugar are shown as "*worms*" and as a *helix.* Side chains of residues that contact the sialic acid are shown explicitly. *Dashed lines* indicate hydrogen bonds. **B:** Polyomavirus binds glycans with structures such as sialic acid–a-2,3-Gal-b-1,4-GlcNac, as shown in this view of the outer surface of a VP1 pentamer (compare Fig. 14) (97). The sialic acid fits into a specificity pocket, and the shallow groove that receives the rest of the carbohydrate moiety is complementary to the shape imparted by its particular glycosidic linkages. Pocket 1 receives the terminal sialic acid; pocket 2, the galactose and *N*-acetyl glucosamine; pocket 3 can receive an additional sialic acid, in a-2,6 linkage to the glucosamine. The pockets for sialic acid are structurally unrelated to the influenza sialic acid site. The affinity for an individual receptor group is very low (about 1 mmolar). The virus can probably bind glycan that is attached to any cell surface glycoprotein; the position and direction of the protein linkage is shown by the arrow. **C:** The complex of the core of the human immunodeficiency virus type 1 receptor–binding domain, gp120, with the receptor, CD4 (65). A key phenylalanine on CD4 fits into a hydrophobic pocket on gp120 (*center*).

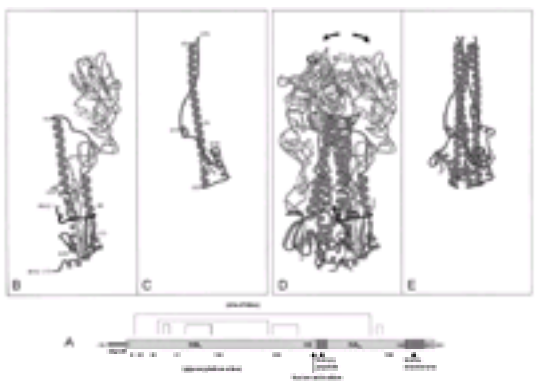

FIG. 26. Influenza-virus haemagglutinin (*HA*). **A:** Schematic representation of the primary structure of the 1968 Hong Kong virus HA, showing the ectodomain, HA_1 + HA_2(1–185), the transmembrane anchor (HA_2 185–211), and the cytoplasmic domain (HA_2 212–221). The cleavage site between HA_1 and HA_2 is labeled *fusion activation.* The secretion signal sequence (removed by signalase), S-S bridges, carbohydrate (CHO) attachment sites, and fusion peptide (N-terminus of HA_2) are shown. The uncleaved precursor is known as HA_0. **B** to **E:** The folded structure of HA and its rearrangement when exposed to low pH. **B:** The HA monomer: HA_1 is *light;* HA_2 is *dark;* the fusion peptide is *black.* Residue numbers in HA_2 are shown at several key positions to assist in visualizing the conformational change that occurs on fusion activation. The receptor-binding pocket in the b-barrel "top" domain of HA_1 is indicated with a *star* (compare Fig. 25**A**). The viral membrane would be at the bottom of this part of the figure. The transmembrane and cytoplasmic segments are not shown. **C:** The HA_2 monomer in the fusion-active form. A short segment of HA_1 (*white*) remains bound

to the rearranged HA_2 in this structure. Note the dramatic conformational change, in which residues 40 to 105 become a continuous a-helix. The introduction of a kink at residue 105 also causes the "bottom" part of the molecule to turn upward, so that the N- and C-termini of the fragment are next to each other. Thus, the fusion peptide, extending from the N-terminus, and the transmembrane segment, extending from the C-terminus, would be spatially adjacent after the full conformational change. **D:** The HA trimer. The subunit toward the right in this illustration is viewed in essentially the same orientation as the monomer in **B.** HA_2 is shaded. Exposure to low pH initiates a conformational change, causing the "top" domains of HA_1 to move apart (*arrows at top of diagram*). **E:** The rearranged HA_2 trimer. Imagine the tops of HA_1 to have spread to either side, and the three HA_2 monomers to have undergone rearrangement to the conformation shown in **C**. (Courtesy of F. Hughson, modified.)

An Irreversible Step Between Assembly and Entry

Assembly of TMV protein and RNA into infectious particles was among the key observations that triggered thinking about viral symmetry. *In vitro* self-assembly of components from the mature virion into complete infectious particles is, however, an exceptional characteristic of the simplest plant and bacterial RNA viruses. A far more general property of virus assembly pathways is a modification, often a simple proteolytic cleavage, that "primes" the particle for large-scale, irreversible events accompanying entry. Loss of a scaffolding protein is a particularly extreme example of such a modification. Picornaviruses such as polio assemble from VP0, VP1, and VP3, but autolytic cleavage of VP0 into VP4 (an internal peptide) and VP2 accompanies assembly (see Chapter 23). When receptor binding triggers expansion of the viral shell, exit of VP4 renders the rearrangement irreversible (9). The receptor acts as a catalyst to lower the energy barrier to an irreversible reorganization. The function of this reorganization is viral entry, and the triggering mechanism has evolved to occur only in an appropriate location. Reoviruses have an outer protein, s3, that caps the penetration protein, µ1 (36). Proteolytic removal of s3 is required to render the particle competent to attach and penetrate (see Chapter 52). There is, in addition, an essential autolytic cleavage of µ1 (73). The hemagglutinin (HA) of influenza virus folds in the ER into a stable, trimeric structure. Cleavage of one peptide bond in HA by the protease, furin, in a compartment late in the secretory pathway, primes the protein to undergo a dramatic, low-pH triggered rearrangement (Fig. 26), which mediates fusion of viral and target cell membranes. In effect, cleavage renders the virion form of HA metastable, but the barrier to rearrangement is so great at neutral pH that no conformational change occurs. Proton binding in the low pH environment of the endosome removes this barrier and triggers a refolding of the HA protein. Protons have the role taken in other cases by a second receptor (e.g., the chemokine receptors for HIV-1). The expression "spring loaded" has been used to describe the state of HA at neutral pH after cleavage to HA1 and HA2 (21). "Jack-in-the-box" might be a comparable image for poliovirus after cleavage of VP0.

Membrane Fusion

The rearrangement of influenza virus HA, shown in Figure 26, has two essential features that also characterize a number of other viral fusion proteins. The first is ejection of a previously protected hydrophobic *fusion peptide,* which is at the N-terminus of HA2 in the case of influenza. The second is a folding back of the fusion protein (HA_2) so that the N-terminus (the fusion peptide) and the C-terminus (the viral membrane anchor) are brought together (92,111). Assuming that the fusion peptide inserts into the target membrane, as generally believed, a possible intermediate state, for which there is indirect evidence in the case of HIV-1 gp41, would be an extended structure with the fusion peptide buried in one membrane and the anchor in the other (Fig. 27). Folding back of this *prefusion intermediate* would bring the two membranes into apposition. As sketched in Figure 27, a ring of rearranged fusion proteins might be required to surround and induce a *fusion pore.* What further molecular events, if any, are needed to cause the two bilayers to fuse remains an important open question.

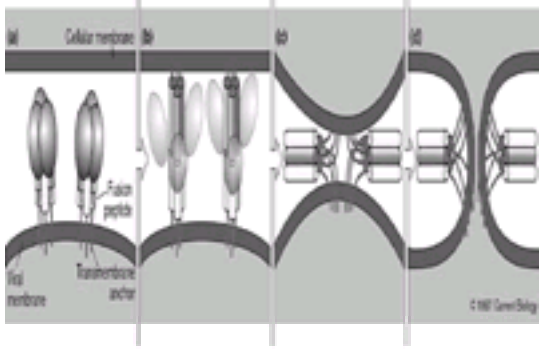

FIG. 27. Fusion. Schematic diagram of membrane fusion, as catalyzed by viral fusion proteins such as influenza virus hemagglutinin (HA). **A:** Neutral pH conformation of HA trimers in the viral membrane (compare Fig. 25D). The fusion peptides are buried. **B:** Initial conformation change triggered by low pH. The receptor-binding domains of HA_1 (ellipsoids) have separated from each other and from the HA_2 stems (although in influenza, they remain attached by a disulfide bond; in retroviruses, the corresponding SU fragment dissociates). The fusion peptides have been thrust by the conformational change into the membrane of the cell to be infected. **C:** The HA_2 stem folds back to form a chain-reversed structure, as seen in Fig. 26**C** and Fig. 26**E**. The fusion peptide and the transmembrane anchor of HA are brought together by the folding back. Because the former lies in the cell membrane and the latter in the viral membrane, the two membranes are forced to approach each other. As suggested by the diagram, more than one HA trimer is needed to form an effective fusion structure. **D:** Putative fusion pore, formed by local rearrangement of the two apposed bilayers. (Adapted from ref. 63, with permission).

The influenza HA is a trimer, organized by a central a-helical coiled-coil (114) (see Fig. 25**A**). HA_1 forms a globular domain at the “top” of the molecule, with a binding pocket for the receptor, sialic acid (110). Binding of protons at low pH leads initially to dissociation of the three HA_1 “heads” from their docked positions (but not to complete dissociation from HA_2, owing to disulfide links between HA_1 and HA_2) (52). This first step liberates HA_2 to undergo the rearrangement shown in Figure 26. The product of this conformational change (see Fig. 25**B**) is a quite simple structure: there is a three-chain, a-helical, coiled-coil inner core, surrounded by three outer-layer helices, derived from the part of each HA_2 chain that immediately precedes the transmembrane anchor (15). The fusion proteins of paramyxoviruses, retroviruses, and filoviruses have all been shown to form similar structures, after triggering by fusion-inducing signals (93).

Are rodlike structures the only way in which molecular fold-back can bring about close approach of two membranes? Apparently not, because the flaviviruses have quite a different structure for their fusion protein, as exemplified by the E protein from tick-borne encephalitis virus (84). In that case, the fusion peptide is an internal loop, and the protein is a platelike rather than a rodlike molecule. Moreover, the E protein itself does not undergo cleavage; rather, proteolytic processing of a second protein, PrM, is the step that primes the virion for a low-pH triggered conformational rearrangement (58). E and M (the truncated product, derived from PrM by removal of most of its ectodomain) form an icosahedral array on the surface of the virus particle, and the fusion-inducing step involves a concerted reorganization of this array (41). The alphaviruses and rhabdoviruses also have fusion proteins with internal loops as their putative fusion peptides (see Chapter 29 and Chapter 38).

Penetration of Nonenveloped Viruses

Nonenveloped viruses must breach a membrane to access the cytoplasm or nucleus of a cell, but unlike their enveloped cousins, they cannot do so by membrane fusion. The molecular mechanism by which a nonenveloped virus particle, bound at the surface of a cell or taken up into an endosome, translocates itself (or its genome) across the intervening lipid bilayer is not fully understood. In general, it appears that binding of a receptor or co-receptor induces a conformational change in the virion and that a consequent exposure of previously buried hydrophobic elements is important for penetration. In several cases, at least one of the exposed hydrophobic elements is an N-terminal myristoyl group: on VP4 in picornaviruses (30), on VP2 in polyomaviruses (90), and on µ1 in reoviruses (74). Myristoyl groups target proteins to membranes, and it is logical to suppose that exposure of the myristoylated protein leads it to associate with membranes and ultimately to contribute to penetration.

One class of models for nonenveloped virus penetration invokes formation of a pore, through which the viral genome is drawn into the cell; another class of models postulates a more extensive, transient disruption of the cell membrane (or of the endosome) in order to admit the virion (in altered form) into the cytoplasm. In the case of adenoviruses, uptake into an endosome and subsequent endosomal disruption have been reported (43,56). The subviral particle admitted to the cytoplasm lacks pentons, as a result of events triggered by receptor and co-receptor binding; this partially stripped virion subsequently disassembles in association with a nuclear pore. The dsRNA viruses must likewise insert an intact, roughly 700 Å diameter inner capsid particle (the *core* in the case of reoviruses; the *double-layered particle* in the case of rotaviruses) into the cytoplasm. Indeed, this particle never uncoats because it contains the enzymes necessary for mRNA synthesis and modification (see Chapter 52 and Chapter 54). In the case of picornaviruses, receptor binding triggers a rearrangement or destabilization of the virion, exposing the myristoylated VP4 as well as a hydrophobic N-terminal segment of VP1 (45,53,59,60,71). Formation of a pore in the endosomal membrane, through which the RNA passes, has been proposed. Such a model requires a mechanism by which secondary structural elements in the RNA are melted out to make translocation possible but for which candidate helicases have not been demonstrated. One possibility would be a ribosome, by analogy with an uncoating mechanism established (*in vitro*) for certain positive-stranded RNA plant viruses. With those viruses, exposure of the 5' end of the RNA (e.g., through expansion of the virion induced by intracellular ionic conditions) leads to association of ribosomes with the still largely packaged RNA genome, and progress of the ribosome along the message-sense genome appears to generate uncoating (114). A similar mechanism could, in principle, draw RNA through a membrane pore as well as through an opening in the viral shell. An alternative picture for picornavirus penetration involves membrane disruption (a “large” pore), either by the altered particle plus VP4 or by the dissociated components; RNA unwinding is not required in this model.

STRUCTURE-BASED CATEGORIES OF VIRAL DESIGNS

A particularly noteworthy consequence of the proliferation of high-resolution structural information about viruses is the frequent discovery of totally unexpected relationships. This sort of surprise came early, when the determination of the structure of southern bean mosaic virus (SBMV) revealed that it closely resembled TBSV (1). Equally striking was the relationship between the picornaviruses and the T=3 plant viruses (62,89). Even the development of sensitive sequence alignment methods has failed to predict structural homologies that are obvious once high-resolution three-dimensional images are available. Thus, the number of strategies that evolution has found, for carrying out the functions that are embodied in virions, is smaller than one might have imagined. In the sections that follow, we attempt to group certain viruses or viral substructures, not by replication strategy or host range, but rather by three-dimensional organization and its functional consequences. The available structural information is by no means sufficient to make a full catalog, but there is reason to believe that in the future, newly determined structures are quite likely to look like something we have already seen in another, perhaps superficially unrelated, virus particle.

Simple, Icosahedrally Symmetric Capsids with Jelly-Roll b-Barrel Subunits

Small, Nonenveloped, Positive-Stranded RNA Viruses

The comparison in Figure 7 shows that picornaviruses and T=3 plant viruses have closely related architectural features, based on 180 jelly-roll b-barrels. Variant packing of the same sort of domain yield T=1 and T=4 structures, such as those found in STNV and in nodaviruses, respectively. Common features in addition to the shell domains themselves are the

formation of an internal network of amino-terminal arms and (in the T=3 and T=4 structures) a specific switching mechanism to ensure accurate assembly. When this switching mechanism is disturbed (e.g., through cleavage of the amino-terminal arms), the same subunit that makes a T=3 structure can instead make a T=1 structure (94). Although the shells have a similar basic architecture, the loops between framework elements of the jelly-roll b-barrel vary enormously from one virus to another. These variations give rise to differences in receptor interactions, antigenic characteristics, and particle stability. The RNA bacteriophages have a T=3 icosahedral shell, but with a very different subunit architecture (104).

Parvoviruses

Parvoviruses have T=1 icoshedral shells (101). The subunit has a standard jelly-roll framework, but substantial insertions into the interstrand loops increase the volume of the capsid it forms. The jelly-roll cores pack neatly around the fivefold and twofold axes, roughly as in the T=1 variants of T=3 structures, but a very large (more than 200-residue) segment between strands G and H makes expanded contacts between threefold related monomers (see Fig. 4). The ssDNA phage fX174 has a shell in which subunits with a jelly-roll framework (protein F) interact very roughly, as in parvoviruses (70). Twelve pentamers of a distinct, jelly-roll subunit (protein G) decorate the surface: the protein G pentamers resemble the polyomavirus VP1 capsomeres in the packing of their subunits. Because there may be a restricted number of ways to organize jelly-roll structures into icosahedral shells, these similarities may not imply close evolutionary relationships.

Double-Stranded DNA Viruses

Papovaviruses

As described earlier (see Fig. 14), the assembly unit of the polyomaviruses and papillomaviruses is a pentamer of the major capsid protein (VP1 in polyomaviruses; L1 in papillomaviruses). The axes of the 72 pentamers that form the viral shell align with the vertices of a T=7 icosahedral lattice, but they do not conform to its symmetry because even the six-coordinated vertices have pentamers of the protein (82). The subunits have jelly-roll b-barrels as a framework, with relatively elaborate loops facing outward (26,67). Both the polyomaviruses and papillomaviruses have an internal protein (VP2/VP3 and L2, respectively). VP2 is probably required for penetration; L2 may have a similar function.

Adenoviruses

The architecture of adenoviruses is based on a shell of hexons, centered at the six-coordinated vertices of a T=25 icosahedral surface lattice. The hexons are trimers with an approximate internal repeat, making them pseudo-hexamers (see Fig. 16). The same fold has been discovered in the principal outershell subunit, P3, of bacteriophage PRD1 (10). The phage protein looks like a “stripped-down” version of the hexon: it lacks the elaborate projecting loops that form the principal antigenic structures in the adenovirus protein. This striking relationship between an animal-virus structural protein and a phage structural protein is evidently more than a simple convergence, but how viruses have made the presumed evolutionary jump is not clear. Phage PRD1 has a separate penton-base subunit and a penton fiber, just like adenoviruses, but it also has a lipid membrane just beneath the outer, adenovirus-like, pseudo T=25 lattice (10). Thus, the common shell can clearly be combined with different internal structures, depending on strategies for assembly, entry, and uncoating.

Herpesvirus Capsids

Herpesviruses are enveloped particles, but the capsid is an independently assembling entity that has many of the characteristics of a nonenveloped particle (100,116). The high-resolution structure of the principal herpesvirus capsid protein has yet to be determined. Moderate-resolution studies of capsid structure and assembly, using electron cryomicroscopy, show that the hexamers and pentamers of the major capsid protein are held together at local threefold positions by a heterotrimeric “triplex” complex, which may serve a function analogous to the cement proteins in adenoviruses. Assembly of the herpesvirus capsid by way of a scaffold-containing procapsid regulates morphogenesis at a different level (72).

Double-Stranded RNA Viruses

All dsRNA viruses of the *Reoviridae* family have a common design for the 120-subunit shell that serves as the major framework of the particle (57,83). The 120- to 140-kd protein that forms this shell—known as l1 in reoviruses, VP2 in rotaviruses, VP3 in orbiviruses, and so forth—has the shape of a flattened teardrop. Five copies radiate from a fivefold axis, like petals of a gently cupped flower, and five further copies insert between them. This decamer may also be the assembly unit. Certain other components (an RNA polymerase or helicase; capping enzymes) are associated with each fivefold, and it is logical to suppose that they are incorporated as part of a 12-decamer assembly mechanism (see Chapter 52). The outer layers of protein, which surround the common framework, differ significantly from one genus of this family to another. Of the nine genera, four have pentameric “turrets” that project outward from each fivefold axis of the framework shell. The structure of the reovirus core (83) shows that the turrets are hollow cylinders, with the active sites of the capping enzymes facing their inner cavity. The mRNA is capped as it is exported through these structures. Members of the other five genera contain a protein with the various capping activities inside the framework shell; it is likely that the capping protein is associated directly with the polymerase. The outermost layers of the dsRNA viruses are specialized for their specific routes of assembly and entry, and the proteins in this layer appear to be the least conserved from one genus to another.

There are three other families of dsRNA viruses, including ones that infect lower eukaryotes as well as the enveloped f6 phage of *Pseudomonas syringae*. Image reconstructions from electron cryomicroscopy of exemplars of each of these families demonstrate structural features in common with *Reoviridae* (3). The fungal and bacterial viruses both have a principal shell with 120 subunits. Thus, it is possible that the designs of all dsRNA viruses, even those of bacteria, are

based on a similar framework.

Enveloped Positive-Stranded RNA Viruses

The alphaviruses and flaviviruses are T=4 and (probably) T=3 icosahedral assemblies, respectively (41,107). There is at present no structural information for pestiviruses or for hepatitis C. The various proteins derive from a single polyprotein; in the alphaviruses, the core and the envelope have the same T=4 surface lattice, as expected from a uniform stoichiometry. Parallels between alphaviruses and flaviviruses are only hinted at by structures currently known. The flavivirus envelope proteins are PrM and E, found in that order in the polyprotein. PrM is a “chaperone” subunit: cleavage of PrM exposes E for low-pH triggered rearrangement. The corresponding envelope proteins in alphaviruses are PE2 and E1; cleavage of PE2 to E2 and E3 (E3 is lost in some cases, not in others) primes E1 for a fusion transition. Appreciation of detailed structural parallels, if any, between flavivirus E and alphavirus E1 must await the crystal structure of the latter (F. Rey, in progress). The flavivirus receptor-binding domain is on E; the alphavirus receptor-binding protein is E2. Transfer of this function from the fusion subunit to the chaperone subunit may parallel the association of receptor binding and fusion on one protein in orthomyxoviruses and the separation of these functions in paramyxoviruses.

Enveloped Viruses with Trimeric, a-Helical, Coiled-Coil Fusion Proteins

A Fundamental Fusion Module

The envelopes of orthomyxoviruses, paramyxoviruses, filoviruses and retroviruses all contain a glycoprotein with a fundamental fusion module, into which may be inserted domains that carry out other functions. Using the HA of influenza virus A as a model (see Fig. 26), the fusion module comprises HA_2 plus the very beginning and the very end of HA_1. The HA_1 N- and C-terminal segments are part of the folded structure of the fusion module in its precursor state; they do not contribute to the rearranged structure that forms after triggering by exposure to low pH. The organization of the hemagglutinin-esterase-fusion (HEF) protein of influenza C (and of coronaviruses) is particularly revealing (88) (Fig. 28). This protein has three activities: receptor (9- *O*-acetylsialic acid) binding (H), receptor hydrolysis (E), and fusion (F). The receptor-binding domain (homologous to the receptor-binding domain in HA from influenza A) is inserted into a surface loop on the esterase domain (homologous to other acetyl hydrolases), which is in turn inserted into the basic fusion apparatus as just defined. Structures have been determined of fusion-module fragments (in the posttriggering state) from members of all four groups of viruses listed previously. They reveal variants of a conserved, trimeric unit (Fig. 29). Although the precursor state (before triggering) is known only for HA of influenza A and HEF of influenza C, it is plausible to suggest that similar final (posttriggering) structures might in all cases be derived from similar initial (pretriggering) structures.

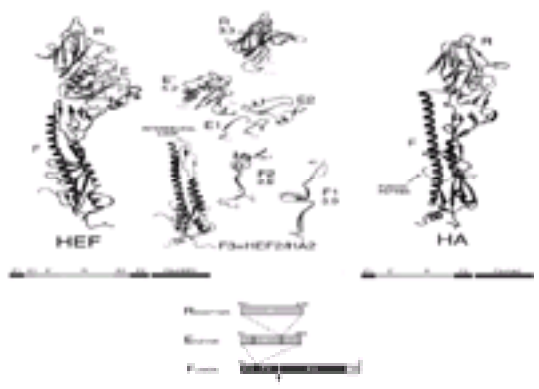

FIG. 28. Comparison of the fusion proteins from influenza C (*HEF*—haemagglutinin-esterase-fusion protein) and influenza A (*HA*) reveals a common core fusion module (*F*), into which evolution appears to have inserted the enzymatic domain (*E*) that catalyzes cleavage of the receptor (in influenza C) and then a receptor-binding domain (*R*). Parts of the E domain have been deleted in the HA of influenza A, leaving R as the only functional part of the insert. (Influenza A has a separate receptor-destroying enzyme, the neuraminidase.) The pattern of insertions is shown in the diagram at the *bottom* of the figure. The core F module thus comprises a segment F1, N-terminal to the insertion point for E (and R), and a segment F2-F3, C-terminal to this point. The fusion-activating cleavage separates F2 from F3 (*arrow in bottom diagram*). F3 is thus known as HEF_2 or HA_2 in influenza C and A, respectively. After triggering by low pH, F3 rearranges. *Top left: Ribbon diagram of one subunit of the HEF trimer from influenza C.* Top right: Similar diagram of a subunit of the HA trimer from influenza A. Compare the view of the HA subunit in Figure 26**B**. Beneath each ribbon diagram is a *bar,* showing the arrangement of segments in the polypeptide chain, *shaded* to correspond to the shading in the ribbon diagram. In the *top center* are ribbon diagrams of the various segments, with their conformations in HEF and HA superimposed. (From ref. 92, with permission; see also ref. 87).

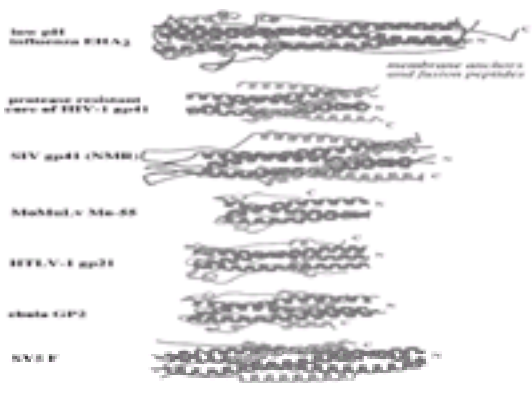

FIG. 29. The core fusion modules from influenza virus (HA_2), human immunodeficiency virus type 1 (HIV-1) and simian immunodeficiency virus (SIV; gp41), Moloney murine leukemia virus (TM), human T-cell lymphotropic virus type 1 (HTLV-1; gp21), Ebola virus (GP2), and SV5 (F), all rearrange after triggering to form related structures. There is a central coiled-coil, formed by three copies of the polypeptide chain segment that immediately follows the fusion peptide, and an outer layer of three helices, formed by the polypeptide chain segments that immediately precede the transmembrane anchor. The fusion peptides and membrane anchors are thus brought together (on the right-hand side of the figure). The fold-back regions on the left have various sizes and characteristics, and they have been deleted in most of the structures actually determined. Note that in all cases, the structures shown here correspond to the "F3" segment of a fusion protein, as defined in Figure 28. (From ref. 92), with permission.)

Diverse receptor-binding domains can evidently be inserted into the common fusion module. The sialic acid–binding domain of influenza virus HA (110) (see Fig. 25**B**), the CD4 and chemokine receptor–binding domain of HIV-1 (65) (see Fig. 25**C**), and the arginine transporter–binding domain of Moloney murine-leukemia virus (40) have unrelated structures. Moreover, some viruses have an additional membrane protein to carry out a function not incorporated into the fusion protein itself. The neuraminidase of influenza A and B, a tetramer with a globular "head" borne on a flexible, extended stalk (32), is unrelated to the esterase domain in the HEF of influenza C (88). The outer surfaces of the larger enveloped viruses can thus exhibit considerable combinatorial variability.

Internal Structures of Large, Enveloped Viruses

Enveloped viruses that share the conserved coiled-coil fusion module can have unrelated internal structures. For example, the Gag proteins of retroviruses and the matrix (M) and nucleocapsid (N) proteins of orthomyxoviruses and paramyxoviruses are completely dissimilar. From the limited structural data available, the following groupings can be discerned.

Retroviral Gag Proteins

When retroviruses bud, the internal protein (Gag) is in the form of a precursor (see Fig. 23). The key domains of this precursor are MA (matrix), CA (capsid), and NC (nucleocapsid); some retroviruses have additional fragments. MA, which trimerizes (probably already before cleavage of the precursor), associates with the inner face of the bilayer. Except in avian retroviruses, it bears an N-terminal myristoyl group, which helps anchor it to the membrane. MA from HIV-1 and from human T-cell lymphotropic virus type II (HTLV-II) have similar structures (31). In HIV-1, MA forms regions of hexagonal lattice, but it does not appear to make a regular icosahedral shell (46). Cleavage of the Gag precursor, subsequent to budding, leads to significant internal rearrangements. In this process, CA assembles into a defined, internal capsid that encloses the two packaged copies of the RNA genome and the associated NC domains. The morphology of the capsid, as seen in the electron microscope, appears to differ from one type of retrovirus to another; a detailed picture is available only for HIV-1 (48,49 and 50). Nonetheless, clear structural similarities among CA proteins from HIV-1, HTLV-I, and Rocus sarcoma virus (19) suggest that the fundamental assembly scheme is likely to be similar in all cases. The NC domain contains one or two (depending on the virus) zinc knuckle domains—small, folded modules stabilized by a Zn^{2+} ion (see Chapter 57). These structures recognize the specific viral packaging signal (see Fig. 20**B**), but they also interact nonspecifically with other segments of genomic RNA (35).

Nucleocapsids and Matrix Proteins of Negative-Stranded RNA Viruses

The genomes of negative-stranded RNA viruses are associated with the viral nucleocapsid protein (N), which remains bound even during transcription. The N proteins of myxoviruses, paramyxoviruses, filoviruses, and rhabdoviruses have similar molecular masses (about 50 kd), and apparent N-protein sequence similarities have been reported among members of the last three of these viral families (5). The ribonucleoprotein complex of Sendai virus has been analyzed by electron microscopy (38). Its most condensed form is a stiff, helical rod, with a pitch of 53 Å and about 13.1 NP subunits per left-handed turn. RNA and protein are wound together, and there appear to be exactly six nucleotides per subunit (18,38). The total length of the rod is 1.1 μm (11,000 ÅÅ); its outer diameter is about 200 Å, and there is a 50 Å diameter hollow core. This form is clearly too stiff and too long to fit into the roughly spherical virions, of about 1000 Å diameter, and indeed much more flexible rods can be seen, corresponding to various degrees of uncoiling of the helix just described (38). The stiff rod could, in principle, represent a transcriptionally active state, if the polymerase were to wind its way down the central hollow and if the bases of the encapsidated RNA were to face inward. Alternatively, it may simply be an intermediate between initial assembly and viral budding.

The VSV ribonucleoprotein complex (RNP) contains eight to nine nucleotides per N-protein subunit. Association with the matrix protein (M) imparts a fixed, tightly coiled structure to the RNP, and this assembly also gives the virion its elongated, bullet-like shape. The dimensions of the viral core are shown in Figure 24**C**. It has a much larger diameter than the paramyxovirus RNP rod just described. The rigid form of the VSV RNP–M complex can be produced either by recombinant coexpression of N and M (which presumably leads to assembly on cellular RNA) or by disassembly of virions. Removal of M produces a far more loosely and flexibly coiled form of the RNP: images from electron microscopy resemble a released spring (Fig. 24**D**). M also mediates incorporation of the envelope glycoprotein (G). Its location with respect to the RNP coil has not, however, been determined unambiguously. Thus, although the structural information currently available hints strongly at parallels between paramyxoviruses and rhabdoviruses, the details remain to be determined.

CHAPTER 4 Virus Entry and Uncoating

John A. T. Young

IDENTIFICATION AND CHARACTERIZATION OF VIRAL RECEPTORS AND CORECEPTORS

The first step of viral infection requires the binding of viral attachment proteins to specific cell surface receptors and, in some cases, also to coreceptors. Following binding, viruses penetrate a cellular membrane, delivering the viral genome into the host cell cytoplasm. Viral genomes enter cells either as naked nucleic acid molecules, as is seen with a number of plus-strand RNA viruses, or instead as nucleoprotein complexes as with minus-strand RNA viruses, retroviruses, and DNA viruses. Coincident with, or immediately following, their entry into the cell, virions undergo *uncoating* events involving the step-wise disassembly of viral components, leading to genome replication.

This chapter will review some aspects of our current understanding of viral entry and uncoating mechanisms.

Viral Receptors and Coreceptors

Because of their critical involvement in the early steps of infection, viral receptors and coreceptors are major determinants of viral tropism. Viral receptors are defined as cell surface factors that bind directly to native virions and include proteins such as the CD4 receptor for the human and simian immunodeficiency viruses (HIV and SIV, respectively) (130) and polio virus receptor (PVR) for polioviruses (141). In addition to primary binding receptors, some viruses also interact with secondary receptors (coreceptors) that can bind either to native virions or instead to altered forms of virions that are produced as a result of the primary binding step. Viral coreceptors include a variety of CC and CXC chemokine receptors for different strains of HIV and SIV (19), the HveA, HveB, and HveC mediators of herpesvirus entry (82,143,213), and specific integrins used by adenoviruses (222).

Genetic and Receptor-Interference Approaches to Understand Viral Receptors

Genetic and viral receptor-interference studies have been used widely to characterize the nature of virus–receptor interactions. A classical genetic approach is to mate together two parental individuals, one that expresses candidate receptors and the other that does not. The individual progeny of these crosses are then analyzed for their susceptibility to viral infection. These studies can establish the existence of one or more putative viral receptor genes, can determine whether such genes are autosomal or sex-linked, may reveal functionally distinct alleles of these genes, and will establish whether susceptibility to infection is a dominant or a recessive trait.

A second genetic approach involves mapping a putative receptor gene to a specific chromosomal location by analyzing panels of somatic cell hybrids formed between donor cells that express receptors and recipient cells that do not. The chromosomal location of a putative receptor gene can then be deduced by identifying donor cell–derived genomic DNA fragments that are shared between independent somatic cell hybrids that display the appropriate receptor activity. This approach led to the mapping of the putative receptor genes for polytropic and xenotropic murine leukemia viruses (MLVs) and for measles virus, to specific portions of chromosomes 1 from mice and humans, respectively (63,101).

Receptor-interference studies can classify viruses into different receptor usage groups and can indicate whether virus infection abrogates expression of a putative receptor. One approach is based on the principle that cells infected by a given virus are often resistant to superinfection by other viruses that use the same receptor. By contrast, the infected cells remain fully susceptible to infection by viruses that use distinct cellular receptors (Fig. 1A). This technique led to the classification of retroviruses into several distinct receptor usage groups (190).

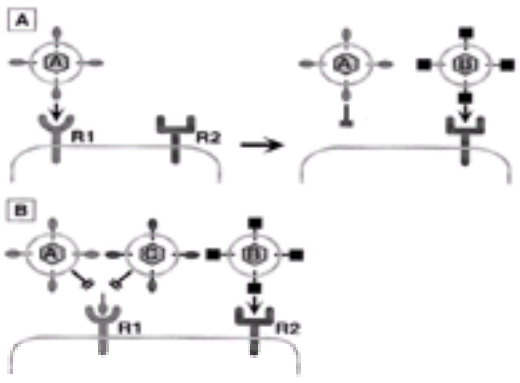

FIG. 1. Viral receptor interference. **Panel A:** Following infection. The cellular receptors for virus type A and virus type B are designated as R1 and R2, respectively. Following infection, expression of the type A viral attachment protein may interfere with the function of R1, leading to a specific block to superinfection by other type A viruses. **Panel B:** Mediated by a soluble viral attachment protein. In this example, type A viruses and type C viruses share the R1 receptor. A soluble form of the type A viral attachment protein may block infection by types A and C viruses, but it will have no effect on the type B virus–R2 interaction.

Although most viruses that establish receptor-interference are thought to do so by forming a complex between newly synthesized viral attachment proteins and the cellular receptor, in most cases the cellular compartment where this occurs is not known. However, in the case of HIV-1, the viral envelope protein (Env) can form a complex with CD4 within the endoplasmic reticulum (ER) and thus interfere with the transport of the receptor to the cell surface (46). HIV-1 encodes two accessory proteins, Vpu and Nef, that also contribute to receptor down-regulation: Vpu causes the ubiquitin-dependent proteolysis of ER-retained CD4 proteins by a mechanism that involves the cellular proteins beta TrCp and Skp1p (132), and Nef seems to serve as an adaptor protein that can target cell surface CD4 for endocytic uptake through clathrin-coated pits (153). Although the Env, Vpu, and Nef proteins of HIV-1 are each capable of reducing cell surface levels of CD4, maximal receptor down-modulation occurs when all three proteins are expressed (37).

A second receptor-interference method used to define viral receptor usage groups relies on the ability of a soluble viral attachment protein to block infection by other viruses that share the same receptor (Fig. 1B). This technique was employed using soluble adenovirus-type 2 (Ad-2) fiber protein to indicate that Ad-2, Ad-5, and Coxsackie B viruses interact with a common receptor (127,160). This notion was later confirmed when the Coxsackie and adenovirus receptor (CAR) that is shared by these viruses was identified (15,203).

Identification of Viral Receptors

Protein Receptors

Various techniques have been employed to identify viral receptors and coreceptors, including the use of specific monoclonal antibodies raised against cell surface proteins, gene and/or cDNA transfer strategies, the virus overlay protein blot assay, and screening the functions of cell surface proteins that are highly related to known viral receptors (Table 1).

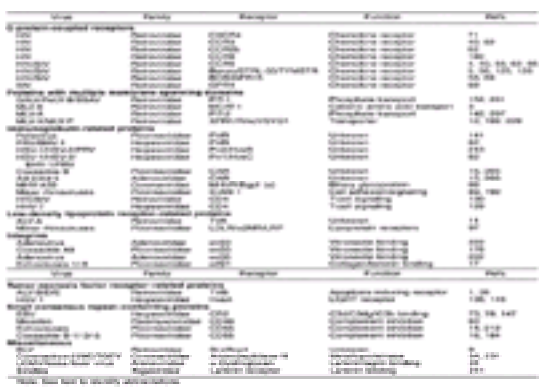

TABLE 1. *Protein viral receptors and coreceptors*

Monoclonal antibodies that bind to specific cell surface proteins and block viral infection have been used extensively to identify viral receptors. Receptors identified by this approach include CD4 for HIV-1 (48,119,130), intercellular adhesion molecule (ICAM)-1 for the major subgroups of rhinoviruses (89,192), MHVR/Bgp1(a) for mouse hepatitis virus A59 (68), a2b1 integrin for echoviruses 1 and 8 (17), CAR for coxsackie B viruses, and adenoviruses (15,203), CD46 for measles virus (63), CR2 for Epstein-Barr virus (73,78,147), CD55 for different subtypes of echoviruses and coxsackie B viruses (14,16,212), aminopeptidase N for human coronavirus-229E and transmissible gastroenteritis virus (54,231), and the high-affinity laminin receptor for Sindbis virus (211). Antibodies specific for the avb3 and avb5 integrins were also used to demonstrate that these cell surface factors can facilitate a post-binding step of adenovirus entry (222).

Gene-transfer and cDNA-transfer methods have been used to clone viral receptor and coreceptor genes. These approaches involve preparing genomic DNA libraries or cDNA libraries from donor cells that express a viral receptor and then introducing these molecules into a recipient cell type that lacks the receptor. Transduced cells that express the

receptor are then identified either (a) because they become susceptible to viral infection or to virus-induced cell–cell fusion, or (b) because they acquire an ability to bind to a viral attachment protein. The viral receptor gene/cDNA can then be directly cloned from these cells.

Viral receptors and coreceptors that were identified by gene/cDNA transfer include PVR for polioviruses (141), PiT-1 for gibbon ape leukemia viruses/subgroup B feline leukemia viruses/simian sarcoma-associated viruses (152), ATRC1/MCAT-1 for ecotropic MLV (3), TVA and TVB for subgroups A, B, and D avian leukosis virus (ALV) (11,26,232), PiT-2 for amphotropic MLVs (142), CXCR4 for X4-tropic strains of HIV-1 (71), and HveA and HveB/Prr2 (poliovirus receptor-related protein 2) for herpes simplex viruses (HSV) (143,213). The use of retroviral cDNA libraries has greatly accelerated the pace of discovering new viral receptors, because putative receptor cDNA molecules can be directly isolated from transduced cells by polymerase chain reaction (PCR) amplification using oligonucleotide primers that are derived from the flanking sequences of the retroviral vector (12,56,168,199,229).

Several viral receptors, including low-density lipoprotein receptor (LDLR)-related receptor proteins for minor subgroups of rhinovirus (97) and a-dystroglycan for lymphocytic choriomeningitis virus and lassa fever virus (31), have been identified using the virus overlay protein blot assay. This assay relies on virion binding to receptors that have been immobilized on a membrane following SDS-polyacrylamide gel electrophoresis.

In some cases, receptors for specific viruses have been identified by testing the activities of either known viral receptors or highly related proteins. For example, the fact that HSV-1 and HSV-2 use Prr2/HveB as a mediator of viral entry led to the finding that these viruses can also use the highly related Prr1 protein for entry (82). Similarly, the identification of the CXCR4/fusin a-chemokine receptor for T-cell tropic strains of HIV (71), coupled with the observation that entry of macrophage-tropic (M-tropic) strains of HIV can be blocked specifically by certain b (CC)-chemokines (43), led to the remarkable discovery that a number of CXC and CC chemokine receptors can serve as coreceptors for different strains of HIV and SIV (5,39,40,55,56,62,65,69,125,126,180).

Carbohydrate Receptors

Certain viruses have evolved to use carbohydrate receptors that are expressed as components of cell surface glycoproteins or glycolipids (Table 2). Because these receptors are generally expressed on cell types from a number of different species, viruses that use carbohydrate receptors tend to have a broad host range.

Virus	Family	Receptor	Refs.
Influenza A	Orthomyxoviridae	Sialic acid-containing oligosaccharides	158
Sendai	Paramyxoviridae	Sialic acid-containing oligosaccharides	93, 133
Reovirus-3	Reoviridae	Sialic acid-containing oligosaccharides	7
Murine polyomavirus	Papovaviridae	Sialic acid-containing oligosaccharides	80
Canine parvovirus	Parvoviridae	Sialic acid-containing oligosaccharides	80
Influenza C	Orthomyxoviridae	9-O-acetylsialic acid	10
Human/bovine coronaviruses	Coronaviridae	N-acetyl-9-O-acetylsialic acid	209
HIV	Retroviridae	Galactosyl ceramide	92
HSV	Herpesviridae	Heparan sulfate	128
Human CMV	Herpesviridae	Heparan sulfate	45

HIV, human immunodeficiency virus; HSV, herpes simplex virus; CMV, cytomegalovirus.

TABLE 2. *Carbohydrate viral receptors*

Carbohydrate receptors can be identified by determining whether the treatment of cells with carbohydrate-destroying enzymes impacts virus binding and infection. Neuraminidase treatment was used to implicate sialic acid–bearing oligosaccharides as receptors for influenza A virus (158), Sendai virus (133), reovirus type 3 (7), porcine rotavirus (177), murine polyomavirus (80), and canine parvovirus (10). Furthermore, virus binding was restored by adding back sialic acid residues to asialylated membranes, confirming the role of this carbohydrate in virus attachment (18,80,93,158,177,198). Similar studies performed using heparinase- and/or heparitinase-treated cells indicated that HSV-1 and human cytomegalovirus (CMV) bind to cell surface heparan sulfate molecules, a result that was confirmed when these viruses failed to attach to cells deficient in heparan sulfate proteoglycan synthesis (45,227).

Carbohydrate-containing receptors have also been implicated using specific monoclonal antibodies that block viral attachment. An antibody that recognizes galactosyl ceramide (GalCer) specifically blocked HIV infection of certain cell types, suggesting that this glycolipid may act as an alternative viral receptor (92). Indeed, GalCer can bind with a high affinity to the HIV-1 Env protein (92,128).

Antibody-Dependent Enhancement of Viral Entry

In addition to classical receptor/coreceptor-dependent mechanisms of entry, viruses may also enter cells when they become complexed with subneutralizing amounts of virus-specific antibodies. Virus–antibody complexes can then be taken up into cells following their binding to immunoglobulin receptors expressed on the cell surface. This type of antibody-dependent enhancement (ADE) of viral infection has been observed through cellular Fc receptors with dengue virus (52), West Nile virus (32,159), influenza A viruses (202), and HIV-1 and HIV-2 (99,137,200). This effect is also seen with Epstein-Barr virus (EBV) that is complexed with polymeric immunoglobulin A (pIgA) specific for the viral gp340 protein, raising the interesting possibility that this pathway of EBV infection may be important at mucosal surfaces of the body where this virus persists and where pIgA is produced (186). The existence of these alternative viral entry pathways indicates that in the absence of a robust immune response that generates high titers of neutralizing antibodies, viruses may be able to bypass their normal requirements for receptors and coreceptors for cell entry, potentially expanding their

in vivo cell-type tropism.

THE ROLE OF ENDOCYTOSIS IN VIRAL ENTRY

After binding viral receptors and/or coreceptors, there are at least two major mechanisms of viral entry that can be distinguished by their requirement for a low pH environment. The pH-independent mechanism of viral entry is proposed to occur at neutral pH, involving viral entry either directly at the plasma membrane or instead from within endosomal compartments following endocytosis of virus–receptor complexes (Fig. 2) (Table 3). By contrast, the pH-dependent mechanism involves the trafficking of virus–receptor complexes to endosomes with an acidic lumenal pH, where the high concentration of protons serves to facilitate viral entry. These distinct mechanisms of viral entry have been distinguished by testing the effect on viral infectivity of treating cells with agents that act to neutralize acidic endosomal compartments such as lysosomotropic agents, carboxylic ionophores, and v-type H^+/ATPase inhibitors such as bafilomycin A1.

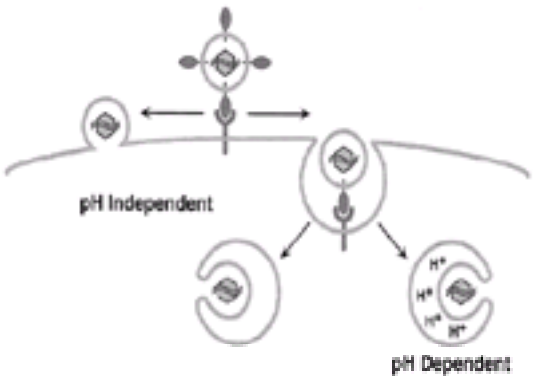

FIG. 2. The pH-independent and pH-dependent mechanisms of viral entry.

pH-Dependent	pH-Independent
Influenza A virus	Retroviruses
Semliki Forest virus	Herpes simplex viruses
Vesicular stomatitis virus	Vaccinia virus
Reoviruses	Rotaviruses
Adenovirus	Paramyxoviruses

TABLE 3. *Examples of pH-Dependent and pH-Independent viruses*

There are two major endocytic pathways that lead to virus uptake from the cell surface, one that is clathrin dependent and the other that is clathrin independent. Electron microscopy has proved useful for uncovering which of these pathways is used by a specific virus—for example, this approach provided strong evidence that influenza A virus enters cells through clathrin-coated pits (135). However, a caveat in using this approach is that RNA viruses usually have a high particle-to-infectivity ratio, so there can be no guarantee that a virus that is imaged represents one that is truly infectious. Therefore, a more definitive approach is to assess the impact on virus infection of expressing dominant negative inhibitors that block cellular endocytic pathways.

Two such inhibitors have been tested for their impact on viral entry, dominant negative forms of the cellular guanosine triphosphatase (GTPase) dynamin and of caveolin. Dynamins constitute a large protein family with at least 27 distinct protein isoforms that are encoded by three separate cellular genes (Dyn1 to Dyn3) (138,182). These proteins are proposed to be “pinchases,” or mechanoenzymes, that can constrict and sever membrane tubules into discrete membrane vesicles (138). Expression of a dominant-negative, GTPase-defective form of Dyn1 inhibits endocytosis through clathrin-coated pits as well as from caveolae, which are microdomains of the plasma membrane that are rich in cholesterol and glycosphingolipids (138,182). The dominant-negative Dyn1 protein blocks the entry of Semliki Forest virus, Sindbis virus, influenza virus, human rhinovirus 14, and adenovirus, indicating that each of these viruses uses a dynamin-dependent pathway for viral entry (58,178,210). By contrast, poliovirus and Moloney murine leukemia virus are apparently unaffected by the expression of this mutant protein, indicating that these viruses use a dynamin-independent mechanism of entry (58,121). A dominant-negative form of caveolin that prevents endocytosis through caveolae has been used to implicate these plasma membrane microdomains as the major sites of SV40 uptake into cells (100,150,157,179).

Factors That Influence Receptor Choice

A comparison of known viral receptors and coreceptors reveals that members of a given virus family have evolved to use a variety of different cell surface factors for viral entry. For example, a cell surface glycolipid, multiple membrane-spanning transporter proteins, and proteins that are members of the immunoglobulin, LDLR, and tumor necrosis factor receptor (TNFR) superfamilies are used as retroviral receptors (see Table 1 and Table 2). Similarly, different picornaviral receptors include immunoglobulin-related proteins, an LDLR-related protein, integrins, and small

consensus repeat–containing proteins that regulate complement activation (see Table 1).

Despite this heterogeneity of viral receptor usage, it is striking that several distinct viruses use precisely the same receptor. Two herpesviruses, pseudorabies virus and bovine herpes virus-type 1, can use the same cellular receptor as poliovirus, a picornavirus (see Table 1). Also, CD4 is a receptor used by retroviruses and by a herpesvirus, whereas CAR and avb3 integrin are used by picornaviruses and adenoviruses (see Table 1).

This apparent convergence of receptor usage may simply be a coincidence. However, it seems much more likely that viruses have evolved to recognize receptors that have properties that are particularly well suited for mediating viral entry. Although these factors remain largely unknown, it intuitively seems that one important property would be the close proximity of the viral attachment site to the host cell membrane. Indeed, by varying the distance between the measles virus attachment site on the CD46 receptor and the host cell membrane, it has been possible to uncouple virus binding from entry (27). An additional factor that could influence receptor choice is the localization of that protein within specific microdomains of the plasma membrane and the subsequent membrane trafficking of that protein after virus binding—for example, SV40 binding leads to a clustering of the major histocompatibility complex (MHC) class I molecule receptors in caveolae, which represent the site of virus uptake into the cell (150,157).

Another factor that can influence receptor choice is the presence of receptor-associated signal transduction pathways that may facilitate steps of viral replication either during or after viral entry. Endocytosis of adenoviruses is stimulated by a signal transduction pathway linked to the integrin coreceptor that activates phosphoinositide-3-OH kinase (PI3K) and cellular Rho GTPases to stimulate the necessary rearrangements of the actin cytoskeleton (123,196). The actin cytoskeleton is also implicated as playing a critical role in the entry mechanisms used by other viruses such as HIV (103) and MLV (117). The interaction between the EBV gp350/220 protein and the CR2 receptor also activates a receptor-associated protein phosphorylation pathway that is important for the early steps of EBV replication (41,174). Similarly, the interaction of the CMV gB protein with an as yet unidentified receptor activates the interferon-responsive pathway, which may provide an optimal cellular environment for the subsequent transcription of viral genes (24).

Receptor interference, which is often observed after virus infection, may represent another selective force on viral receptor usage. For those viruses that assemble and bud at the plasma membrane, this block to cell surface receptor expression is presumably necessary to allow the efficient release of nascent viral particles. The fact that HIV-1 has evolved three separate mechanisms to interfere with cell surface CD4 expression (37) underscores the importance of receptor down-regulation for viral replication.

As discussed, receptor interference can prevent viral receptor expression on the cell surface because newly synthesized receptors and viral attachment proteins can form a complex that is retained within the cell. It therefore follows that the expression level of a given cellular factor may dictate whether it can be used as a viral receptor. Those factors that are expressed at a low level will presumably be more easily titrated out by viral attachment proteins than are factors that are expressed at a higher level.

Receptor interference may also prevent that cellular receptor from interacting with its cognate ligand and thus abrogate the normal receptor function. If the ligand–receptor pair in question plays a critical role in host defenses against virus infection, then this mechanism of interfering with receptor function may provide an additional level of selection on receptor choice. Indeed, this may explain why subgroups B, D, and E of ALV use TVB, a TNFR-related death receptor, as a viral receptor. TVB is most closely related to the human TRAIL (TNF-related apoptosis-inducing ligand) receptors, TRAIL-R1 (or DR4), and TRAIL-R2 (or DR5). TRAIL and its receptors have been implicated in the induction of apoptosis in cell populations infected with several distinct classes of viruses including HIV-1, human CMV, and adenoviruses (113,183,225). Therefore, certain subgroups of ALV may have evolved to use the TVB receptor, at least in part, because after the establishment of receptor interference, the infected cells may be protected against cell death induced by the cognate ligand (26).

ENVELOPED VIRUS ENTRY

Enveloped viruses have a lipid bilayer, or envelope, that surrounds their nucleocapsids. Therefore, the entry of these viruses into cells requires the fusion of viral and cellular membranes by a process that is driven by viral glycoproteins located on the virus surface.

The Influenza A Virus Paradigm and Related Viral Fusion Proteins

The mechanism of virus–cell membrane fusion is best understood in the case of the influenza A virus hemagglutinin (HA) protein. HA is synthesized as a precursor glycoprotein (HA_0) that is assembled into homotrimers within the lumen of the host cell endoplasmic reticulum prior to its export to the cell surface. During its biosynthesis, HA_0 is proteolytically cleaved into two mature subunits, HA_1 and HA_2. This trimer of HA_1/HA_2 heterodimers exists as a metastable trimer on the viral surface (33). HA_1 contains the sialic acid receptor binding site of the viral glycoprotein, and HA_2 contains two hydrophobic regions that are important for the complete fusion of virus and cell membranes, an N-terminal fusion peptide, and a membrane anchor located near the C-terminal end.

Following receptor binding, influenza viruses are endocytosed via clathrin-coated pits and then trafficked to acidic endosomes. The acidic lumenal environment of these endosomal compartments then activates irreversible conformational changes in HA that promote membrane fusion. These structural alterations can be detected as an increased susceptibility of the protein to cleavage by specific proteases such as trypsin and proteinase K (59,163). Also, these structural changes can be detected using conformation-specific antibodies to monitor the appearance and disappearance of certain epitopes of HA. For example, the fusion peptide region of HA_2, which is found buried at the trimer interface in the native HA structure, becomes rapidly exposed following low pH treatment, leading either to aggregation of the viral protein or to its attachment to membranes (59,115,187,219). By contrast, an epitope located at

the interface between two HA_1 subunits in the native trimer is lost following this treatment, indicating that the HA_1 subunits must be dissociated from each other during the fusion reaction (115,219). Indeed, when intermonomer disulfide bonds were introduced into HA_1 subunits to prevent their dissociation from each other, this led to a specific block to the fusion activity of the viral glycoprotein (84,114).

During low pH–induced activation, the HA trimer is converted from its metastable state to one in which HA_2 adopts a highly stable trimeric structure. During this conversion, the hydrophobic fusion peptide regions of HA_2 are predicted to be displayed at the tip of a long, triple-stranded, a-helical coiled coil region that forms the core of the structurally altered viral glycoprotein (29,33,34). X-ray crystal structures of the native form of HA_2, as well as of an apparent postfusion form of this glycoprotein, are described in Chapter 3 and will not be discussed in detail here.

The exposed fusion peptide regions of HA_2 are critical for the membrane fusion reaction and have been proposed to bind directly to target membranes (Fig. 3). The importance of these regions for membrane fusion has been demonstrated using mutant viruses bearing amino acid replacements within this hydrophobic region. Although these altered viral glycoproteins can still bind to sialic acid receptors and are capable of undergoing the characteristic low pH–induced structural changes, their membrane fusion activities are abrogated (51,83,193). In addition, experiments performed with liposomes containing radiolabeled photoreactive lipids have demonstrated that the fusion peptide region is the only domain of HA_2 that becomes associated with a target lipid bilayer following the low pH activation (66).

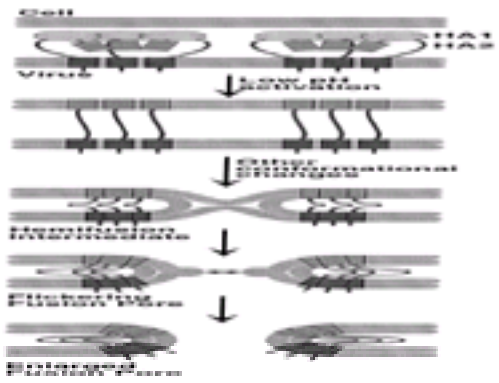

FIG. 3. A model for influenza A virus hemagglutinin (HA) protein–mediated membrane fusion.

It is thought that, following attachment of the HA_2 fusion peptides to the target membrane, this protein undergoes additional rearrangements, bringing the viral and target lipid bilayers into close apposition (see Fig. 3). These rearrangements are thought to lead initially to mixing of lipids between the outer leaflets of membranes, a process known as hemifusion, leading to the formation of a hemifusion diaphragm (see Fig. 3). This step is then followed by the formation of a small fusion pore that flickers open and closed before becoming fully dilated (191). It has been suggested that at least three and perhaps six HA trimers are needed to form the fusion pore (22,50), although a single HA trimer is capable of perturbing membranes (106).

During the membrane fusion reaction, the HA_2 protein is proposed to assume a hairpin-like structure in which the fusion peptide domains and the transmembrane domains of HA_2 become localized in the same lipid bilayer (see Fig. 3). Several independent lines of evidence support this hypothesis. First, in the absence of a suitable target membrane, low pH treatment inactivates virions because the newly exposed fusion peptide domains become inserted in the viral membrane—that is, in the same membrane as the membrane-spanning domain (215,218). Second, the x-ray structure of the low pH form of the core of HA_2 has revealed that the C-terminal end of this protein has an inverted orientation relative to its N-terminal end, and that in fact the N- and C-termini can combine, generating an N-cap structure (38). Whatever the precise mechanism is that leads to membrane fusion, it is clear that the transmembrane region of HA_2 is critical for this process because a glycosylphosphatidylinositol-linked form of HA is capable only of mediating hemifusion (115). It has been proposed that the membrane-anchor region of the HA_2 region might facilitate the complete fusion reaction by imposing a positive curvature on the inner leaflets of the hemifusion diaphragm (139).

Despite the large body of information that is available regarding HA-mediated membrane fusion, there are still several important unanswered questions about this process: (a) What are the precise step-wise structural changes that convert the native HA protein from its metastable form on the virion to the postfusogenic state? (b) At what step during the fusion reaction does the HA_2 hairpin structure form? (c) How many HA trimers are needed to form an active fusion pore and mediate the hemifusion and the fusion reactions? (d) What is the precise role of the transmembrane region of HA_2?

Structural analyses have revealed that the basic architecture of the HA membrane fusion machine is shared by the glycoproteins of a number of other enveloped viruses, including retroviruses, filoviruses, and paramyxoviruses. These glycoproteins include the transmembrane proteins of Mo-MLV (70), HIV (35,217), and SIV (30); the GP2 protein of Ebola virus (131,216); and the F_1 protein of SV5 (8). Like HA_2, each of these viral glycoproteins is the C-terminal cleavage product of a precursor envelope glycoprotein, and each contains a hydrophobic fusion peptide located near the N-terminal end and a single membrane-spanning anchor region located near the C-terminal end. Each of these viral glycoproteins can fold into a rodlike structure similar to that of activated HA_2, with the fusion peptide regions located at the tip of a central, triple-stranded, a-helical coiled, coil. Also, in some of these glycoproteins, three antiparallel helices are packed against the central, triple-stranded coil, coil domain, providing additional support for the idea that the fusion peptide and transmembrane regions of these glycoproteins become located in the same lipid bilayer at a late stage

during membrane fusion (8,30,35,131,216,217).

In addition to the structural similarities observed between retroviral transmembrane and influenza virus HA_2 proteins, there is also biochemical evidence that, like HA, retroviral Env proteins must undergo conformational changes leading to viral entry. However, as most retroviruses are thought to enter cells by a pH-independent mechanism, it is presumed that fusion-activating conformational changes in Env are induced upon receptor/coreceptor binding. Consistent with this hypothesis, CD4-binding can induce conformational changes in the HIV-1 surface protein (SU) that, in lab-adapted viral strains, causes dissociation of the surface protein from the transmembrane protein, increases the exposure of certain antibody epitopes of Env, increases the susceptibility of the viral glycoprotein to protease cleavage, and leads to exposure of the coreceptor binding site of SU (173,181,206,226,228). CD4 and coreceptor interactions also lead to exposure of hydrophobic determinants of HIV Env proteins as measured using a fluorescent probe that binds specifically to hydrophobic groups (108). Additional evidence for receptor-induced structural changes in retroviral glycoproteins has been obtained for a soluble ALV-A Env protein that is induced to undergo structural changes leading to fusion-peptide exposure and to stable liposome binding following its interaction with the TVA receptor (49,96).

Other Types of Viral Fusion Proteins

Although the core structural elements of the membrane fusion machinery described for the influenza HA protein are shared by many viruses, other enveloped viruses use fusion proteins with different architectures to enter cells. For example, the G protein of the rhabdovirus vesicular stomatitis virus (VSV) is a homotrimer of a single protein subunit with an internal hydrophobic fusion peptide region (79,220,233) that becomes labeled by hydrophobic photoactivatable probes under conditions that stimulate viral fusion (67). However, unlike HA, which irreversibly associates with target membranes following low pH-induced activation, VSV-G reversibly associates with these membranes, implying that it is less stably associated with target bilayers (156).

Another type of viral fusion protein is represented by the E protein of the tick-borne encephalitis virus (TBE), a flavivirus that contains two transmembrane segments and has a putative internal fusion peptide (171). The E protein of TBE exists as a dimer that is parallel to the membrane on the virus surface but is converted to a trimer that is active for membrane fusion when incubated under low pH conditions needed for membrane fusion (6,171).

Alphaviruses have yet another type of viral glycoprotein complex. Semliki Forest virus has three envelope proteins: E1 and E2, which are both type 1 membrane glycoproteins, and E3, which is an extrinsic protein. These proteins assemble as E1/E2/E3 heterotrimers. At low pH, the viral glycoprotein complex undergoes conformational changes leading to the formation of a stable E1 homotrimer that mediates membrane fusion (72,94).

More complex viral fusion machines are seen with the herpesviruses. Usually, five glycoproteins of HSV-1 are required for viral entry: gB and gC, which bind to cell surface heparan sulfate molecules; gD, which interacts with herpesvirus entry mediators such as HveA (143); and the gH/gL heterodimer, which participates in membrane fusion (166). Additionally, viral glycoproteins such as the gE/gI complex and gM can facilitate viral spread into certain cell types by interacting with receptors that are expressed at cell–cell junctions (166).

Regulating Viral Fusion Proteins

The membrane fusion activities of viral glycoproteins need to be tightly regulated to prevent their premature activation during viral protein synthesis and assembly. As described, the fusion activities of viral glycoproteins can be controlled by receptor/coreceptor interactions and by exposure to a suitable, low pH–containing environment. A number of viral glycoproteins are also regulated by proteolytic cleavage of their extracellular domains, which converts an energetically stable precursor glycoprotein to a metastable form that is then capable of being triggered for membrane fusion. This form of regulation is seen with the glycoproteins of orthomyxoviruses, paramyxoviruses, and retroviruses (95).

Amino acid residues located within the transmembrane and cytoplasmic tail domains of viral glycoproteins can also regulate their fusogenic activity. For example, the Env proteins of Mason Pfizer monkey virus and Mo-MLV become competent for fusion following viral protease-mediated cleavage at a specific site in their cytoplasmic tail domains (25,165,170). As retroviral proteases become activated at a late stage of viral replication that is coincident with, and/or occurs shortly after, virus budding, this form of regulation ensures that the viral glycoproteins are not prematurely activated within the virus producer cell. Specific mutations introduced into the transmembrane domain of VSV-G or into the transmembrane region or cytoplasmic tail domains of influenza virus HA, have also been shown to selectively block complete membrane fusion without affecting hemifusion (42,140). However, how these residues act to regulate membrane fusion remains to be determined.

Another mode of regulating viral fusion protein activity is seen with paramyxoviruses. For most of these viruses, with the exception of SV5, the fusogenic activity of the F protein is tightly regulated by its association with the homologous hemagglutinin (HN) protein that is responsible for receptor binding. Therefore, the fusion activation of paramyxoviral F proteins generally involves homotypic HN-F interactions following receptor binding (57,195,230). The coordinated action of separate viral attachment and fusion proteins presumably evolved to ensure that the fusion protein would become activated only following viral attachment to an appropriate target cell surface.

NONENVELOPED VIRUS ENTRY

Nonenveloped virus entry into cells involves either the formation of proteinaceous pores in a host cell membrane, as has been suggested for picornaviruses, or processes that disrupt the integrity of a cellular membrane, as seems to be the case for adenoviruses and reoviruses. A common feature of each of these viral entry mechanisms is the orchestrated disassembly of the virion leading to loss of specific capsid proteins and to the interaction of the viral particle with a host cell membrane.

It has been proposed that the positive-stranded RNA genome of picornaviruses enters cells through a proteinaceous core composed of viral proteins. Mature picornaviral virions contain a single copy of plus-stranded genomic RNA and 60 copies each of four viral proteins, VP1, VP2, VP3, and VP4. The VP1 proteins of poliovirus and of rhinovirus contain a deep surface depression, or canyon, located at each fivefold axis of symmetry. This canyon represents the site of receptor interaction on the viral surface (154,164).

During poliovirus entry, the viral particle undergoes a series of structural changes at the cell surface that are predicted to lead to the transfer of the viral RNA genome into the host cell cytoplasm to begin replication. The first change detected is the conversion of mature virions sedimenting as 160S particles to those that sediment at 135S (223). This alteration involves the loss of VP4, which is located within the virion interior, and the buried hydrophobic N-terminus of VP1 is translocated to the virion surface to mediate membrane binding (164,223). Thus, as for a number of enveloped viruses, exposure of hydrophobic viral protein surfaces is a critical event and required for poliovirus entry. A second similarity between polioviruses and the enveloped viruses discussed earlier is that poliovirus virions seem to exist in a metastable state and are converted to more highly stable forms during the process of viral entry (223). At physiologic temperatures, poliovirus is a conformationally dynamic entity, with VP4 and the N-terminal end of VP1 being transiently and reversibly exposed on the virus surface by a so-called breathing mechanism, even in the absence of a target cell (124). Reversible conformational changes in viral capsids have also been noted with rhinovirus (122), and with the nodavirus Flock House virus (23).

The data implicating 135S particles as obligatory intermediates during poliovirus entry are compelling. Receptor binding converts native virions to 135S particles, a result that indicates that the receptor alone may be capable of triggering the first steps of viral uncoating (164,223). However, it is still not clear whether the 135S particles are obligatory intermediates during poliovirus entry or instead are simply dead-end products. In support of their importance, 135S particles are infectious, albeit at much reduced levels compared to mature virions (47). Arguing against their importance, cold-adapted poliovirus mutants seem to enter cells without the need to generate 135S particles (64). These disparate findings might be rationalized if 135S particles are short-lived only in the case of cold-adapted viral strains (223). Additional experimentation is needed to validate the role of the 135S particles during poliovirus entry.

The next stage in poliovirus entry is predicted to involve the conversion of the 135S particle to an 80S form that is devoid of RNA and that probably represents the empty protein capsid (91,204). Furthermore, it has been proposed that an amphipathic helix located at the exposed amino-terminus of VP1, and the N-terminal myristic acid group of the extruded VP4 protein might participate in the formation of protein channels in host cell membranes that could allow translocation of the poliovirus genomic RNA into the cytoplasm (13,91,204). However, it is not yet clear exactly how the viral RNA exits from the virion (13).

Adenovirus is predicted to enter cells by perturbing the integrity of cellular endosomal membranes, thus allowing viral nucleoprotein complexes access to the host cell cytoplasm. Adenovirus is a nonenveloped DNA virus that contains 11 different types of protein, including 12 complexes of penton base, each with an associated fiber protein. Following the binding of the viral fiber protein to the CAR receptor, the viral penton base interacts with specific host cell integrins. Following virus uptake into the host cell by receptor-mediated endocytosis, adenoviruses enter the cytoplasm after the pH-dependent lysis of endosomes, a step that is facilitated by the penton base–integrin interaction (221). Coincident with endosomal lysis, the viral nucleocapsid begins to disassemble with the fiber, penton base, and viral IIIa proteins being shed from the viral particles (88).

Reoviruses are also proposed to enter cells by perturbing a cellular membrane after being trafficked to a low-pH endosomal compartment. However, in contrast to the situation with adenoviruses where low pH is proposed to play a direct role in the membrane perturbation event, the role of low pH in the case of reoviruses is to activate cellular cysteine proteases that cleave the viral outer capsid proteins s3 and µ1/µ1C, giving rise to infectious subviral particles (ISVPs). ISVPs are then capable of infecting cells in a pH-independent manner. It has been suggested that removal of the s3 protein of reoviruses may lead to conformational changes in µ1/µ1C that in turn lead to membrane perturbation (105).

VIRAL UNCOATING

The events that immediately follow viral penetration into the host cell, but precede replication of the viral genome, are commonly referred to as uncoating. These events may be intrinsically coupled with those leading to cellular membrane penetration, as in the case of picornaviruses, which must simply introduce their plus-stranded RNA genome into the host cell cytoplasm for replication to proceed. Other viruses, however, introduce viral nucleoprotein complexes into the cell, and for these viruses a series of disassembly steps that occur after virus entry are required for successful uncoating.

Most RNA viruses are replicated in the host cell cytoplasm, presumably because their replication via the associated RNA-dependent RNA polymerase does not usually require activities provided by the host cell nucleus. By contrast, most DNA viruses, retroviruses, hepadnaviruses, and other RNA viruses such as the orthomyxovirus influenza A virus must access the host cell nucleus for replication to proceed. These viruses require nuclear functions involved in cellular DNA and RNA synthesis as well as in RNA processing. These viruses must traverse the physical barrier imposed by the nuclear envelope in addition to that imposed by the plasma/endosomal membrane.

The nuclear envelope consists of a double membrane, within which are embedded nuclear pore complexes (NPCs) made up of more than 50 different types of nucleoporins that regulate the transport of macromolecules into and out of the nucleus (86). Active transport of proteins and of nucleoprotein complexes through the NPC is mediated by specific transport signals designated as nuclear localization signals (NLSs). The NLS is recognized by importin-a, an NLS receptor, which in turn binds to importin-b, a transport receptor that facilitates binding to, and translocation through, the NPC (86). The importin-a and -b subunits are then exported—shuttled—back to the cytoplasm in a complex with the GTP-bound form of the cellular GTPase Ran (RanGTP) (86). The GTPase activity of Ran becomes activated in the cytoplasm by RanGAP1, giving rise to RanGDP, an event that leads to release of the importin subunits so that they can

engage in a new round of nuclear import. RanGDP is then returned to the nucleus where a guanine nucleotide exchange factor (RCC1) acts to regenerate RanGTP for a new round of nuclear export. It has been proposed that the GTP hydrolysis that is associated with the establishment of the nucleocytoplasmic gradient of RanGTP is the driving force for cellular nuclear import and export pathways (86).

Influenza A viruses and lentiviruses such as HIV-1 seem to employ several distinct NLSs on viral core proteins for efficient targeting of viral nucleoprotein complexes to the host cell nucleus. Influenza A viruses contain eight single-stranded negative-sense RNA segments that encode viral proteins. Within the virion, these segments are found as viral ribonucleoprotein complexes (vRNPs) containing the nucleoprotein NP and the viral polymerase complex, and these vRNPs are associated in turn with the viral M1 protein. An essential step of influenza virus uncoating is the dissociation of M1 from the vRNPs. M1 dissociation occurs under low pH conditions when the virus is trafficked to acidic endosomal compartments, and it results from the translocation of protons through the M2 ion channel located on the virus surface (28,134,161). Thus, this critical step of viral uncoating is linked both spatially and temporally within the cell to that of HA-mediated membrane fusion. Following M1 dissociation, the viral RNPs are trafficked to the host cell nucleus to begin replication by a mechanism that presumably involves nuclear localization signals contained on each of the NP and polymerase proteins (2,107,148,149,214). The NLS of the NP protein has been found to interact with an importin-a/b complex (155).

Lentiviral preintegration complexes (PICs) consist of viral DNA, the matrix protein (MA), nucleocapsid (NC), reverse transcriptase (RT), integrase (IN), and the Vpr accessory protein (194). These viruses differ from most other retroviruses in that they are able to infect nondividing cell types such as macrophages, and thus their entry into the host cell nucleus is not dependent on nuclear envelope breakdown. Several distinct nuclear-targeting signals have been found associated with HIV-1 core proteins. The Vpr protein, which is associated with viral PICs, is an importin-b-like protein that can bind importin-a and is proposed to target the viral core particles to nuclear pores where it interacts with nucleoporins to facilitate viral translocation into the nucleus (77,162,208). Additional nuclear localization signals have been described in the viral integrase protein that mediate interactions with importins (81), as well as in the viral MA protein, although the existence of this latter signal has been the subject of much controversy (76,169).

Posttranslational modifications of viral proteins may regulate their nuclear uptake, as has been seen with the hepatitis B virus core protein, where the NLS is exposed to interact with an importin-a/b complex after protein phosphorylation (110). It has been proposed that this phosphorylation step involves protein kinase C molecules assembled into hepatitis B viral capsids (110). Also, the nuclear transport of HIV-1 PICs can be regulated by the phosphorylation status of the viral MA protein, which is a substrate for the virion-associated mitogen-activated protein kinase (ERK/MAPK) (104).

Viruses have evolved to use components of the host cell cytoskeleton to facilitate their intracellular trafficking to sites of virus replication, as exemplified by adenovirus and by the herpesvirus HSV-1. Intracellular adenoviral complexes are translocated to the NPC through their association with the minus-end-directed microtubule motor complex of dynein and dynactin (197). Adenovirus capsids then dissociate at the NPC so that viral DNA and protein VII can enter the nucleus to begin genome replication (87).

Following HSV-1 entry at the plasma membrane and dissociation of the viral tegument proteins, the capsids associate with dynein, which is proposed to traffic these complexes toward NPCs (189). Once docked at the NPC, HSV-1 DNA is delivered into the host cell nucleus, leaving the empty capsid behind (189). Transport along microtubules probably represents an important event during HSV-1 infection of neuronal cells, where the viral capsids have to travel some distance from the site of virus entry to the nucleus.

INHIBITORS OF VIRAL ENTRY

Specific inhibitors of viral entry have been useful reagents for studying the basic mechanisms of this first step of viral replication and represent attractive antiviral agents because their action does not require that they be taken up into cells. Several different classes of viral entry inhibitor have been described, including neutralizing antibodies, soluble receptors, peptide inhibitors, small molecules, and ligand-based inhibitors that bind to target viral receptors or coreceptors (Fig. 4).

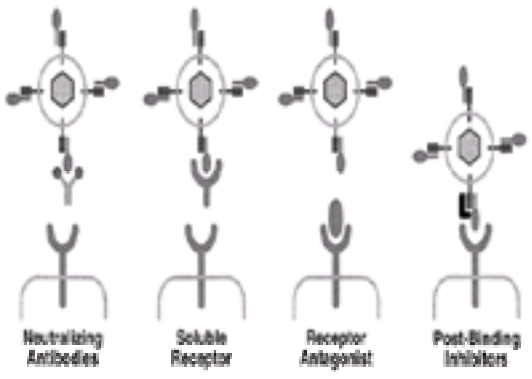

FIG. 4. Inhibitors of viral entry.

Neutralizing Antibodies

One of the ways by which the host organism can restrict viral entry into cells is to produce neutralizing antibodies that bind to and inhibit the function of viral attachment and fusion proteins. These antibodies can block infection by binding directly to the receptor-interaction site located on viral proteins, as has been seen with human rhinovirus 14 (36) and with

influenza virus HA (20). Alternatively, these antibodies can block infection by binding to an epitope that is located outside of the receptor-binding site, where they sterically hinder the receptor association (75). Neutralizing antibodies that block viral association with coreceptors by binding to receptor-induced epitopes located on viral proteins have also been described in the case of HIV-1 (120,228).

Soluble Receptors

Soluble proteins composed of the extracellular domains of viral receptors have been used as reagents to block viral infection. Examples of such soluble receptors include PVR for polioviruses (111,112), ICAM-1 for rhinoviruses (90), and CD4 for HIV-1 (53,74,102,188,205). These agents act by binding to, and occluding, the receptor-binding site of the viral attachment protein. In addition, some soluble viral receptors are capable of triggering a series of conformational changes in virion proteins that are similar to those that occur normally during viral entry and that lead to virus inactivation (85,90).

Although soluble receptors might appear to be suitable antiviral reagents, their efficacy as viral entry inhibitors has been compromised by the fact that independent viral isolates are differentially sensitive to their action. For example, although lab-adapted, T-cell tropic strains of HIV-1 are highly sensitive to soluble CD4-inhibition, primary viral isolates are not (118). An additional problem with the use of soluble receptor–based inhibitors is that viruses that are resistant to the action of these reagents are readily obtained because of the selective pressures they impose on replication. For example, a variety of different soluble receptor–resistant (srr) mutants of poliovirus evolved in the presence of a soluble PVR protein, and most of these viral variants had a reduced binding affinity for receptor and had altered responses to receptor-mediated structural changes (44,112).

Peptide Inhibitors

Different classes of small peptide–based inhibitor have been used to block viral infection. Some peptide inhibitors used are derived from the viral interaction site of a viral receptor. These inhibitors act presumably by binding to the viral interaction site on a viral attachment protein, thus preventing its interaction with cell surface receptors. For example, an oxidized 19–amino acid peptide containing viral interaction determinants of TVA is an effective inhibitor of subgroup A ALV entry (234).

Other classes of peptide inhibitor act to block steps of viral entry subsequent to virus–receptor interactions. For example, peptides derived from two separate a-helical regions of the HIV-1 transmembrane protein that are predicted to interact with each other during the membrane fusion reaction, as described previously, are potent inhibitors of a postbinding step during entry. Presumably, either these inhibitors block the formation of the central coiled coil of the transmembrane protein trimer, or they block the contacts that are formed between this central trimer and the outer-layer a-helices of the transmembrane protein (35,217,224). Peptides corresponding to similar regions of other viral fusion proteins are also effective viral entry inhibitors—for example, in the case of paramyxovirus F_1 proteins (109,167). These inhibitors have been used to define an intermediate “lipid-mixing only” step in the viral fusion reaction, where hemifusion has apparently occurred but complete membrane fusion has not (109,145).

This class of peptide inhibitor has already shown some promise in the clinic, at least when administered at a high dose to HIV-infected individuals (116). However, as with soluble receptors, it seems that one problem that will be encountered with these reagents is the evolution of inhibitor-resistant viral strains with mutations that interfere with inhibitor binding and/or function (172).

Another class of peptide inhibitor that acts to block virus infection after receptor binding are those that antagonize the function of viral coreceptors. For example, the T22 and ALX40-4C peptides that are antagonists of CXCR4 can inhibit entry of T-cell-tropic HIV-1 (61,146).

Small-Molecule Inhibitors

Small-molecule inhibitors of viral entry include the drug amantadine hydrochloride, which was instrumental in revealing the ion channel activity of the influenza A virus M2 protein that is essential for the low pH–induced dissociation of M1 from viral RNPs during viral entry (28,161). Other small-molecule inhibitors act by binding to and inactivating viral proteins that are necessary for entry—for example, the compound WIN 52084 acts to block viral entry when located in a hydrophobic pocket that is located in the canyon floor of the VP1 protein. It does so by preventing dynamic conformational changes in the viral capsid that are necessary for infectivity (122). Also, small-molecule inhibitors of influenza A virus entry have been described that act either by blocking the necessary conformational changes in HA or by prematurely activating these changes (98). Other classes of small molecules have been described that are antagonists of viral receptors and/or coreceptors. These molecules include the bicyclam AMD3100 antagonist of CXCR4 function, which prevents entry of T-cell-tropic strains of HIV into cells (60).

Ligand-Based Inhibitors

In some cases, it has been possible to block viral entry using naturally occurring ligands or ligand derivatives that bind to viral receptors and coreceptors, thus interfering with viral entry. Examples of naturally occurring ligands used as viral inhibitors are the a-chemokine SDF-1, and the b-chemokines RANTES, MIP-1a, and MIP-1b that block viral entry by binding to the HIV coreceptors CXCR4 and CCR5, respectively (4,21,40,43,55,65,151). An example of a chemically modified form of one of these ligands that can still block viral entry without potentiating the normal function of the receptor is amino-oxypentane (AOP)-RANTES (185). However, selection of viral variants that resist inhibition may restrict the utility of this approach, in this case by selecting for viruses that use other HIV coreceptors (144).

CONCLUDING REMARKS

Over the course of the last decade, much has been learned about how virus–receptor interactions lead to viral entry. The exact mechanisms of viral entry into cells are beginning to be revealed through the combined use of biochemical, genetic, and structural analyses of specific viral proteins or whole virions. Also, a number of different cell surface proteins and carbohydrates that serve as viral receptors have been identified and their viral binding determinants defined. The challenge that lies ahead is to understand the step-wise series of events leading to viral entry that occur after virus binding to receptors/coreceptors, and in the presence of other activators such as low pH conditions.

The mechanisms of viral uncoating are also beginning to be understood. Future research in this area should provide valuable new information about this important step of viral replication. It will undoubtedly shed new insights into how viruses exploit host cell processes for their own ends, and it will, we can hope, provide a new set of targets for the development of antiviral strategies.

CHAPTER 5 Replication Strategies of RNA Viruses

L. Andrew Ball

INTRODUCTION

Replication of genetic information is the single most distinctive characteristic of living organisms, and nowhere in the biosphere is this process accomplished with greater economy and apparent simplicity than among the RNA viruses. To achieve the expression, replication, and spread of their genes, different families of RNA viruses have evolved diverse genetic strategies and life cycles that exploit the biology and biochemistry of their hosts in many different ways. Because the global environments in which viruses replicate and evolve are dictated largely by their hosts, understanding virus replication also illuminates host biology at the molecular, cellular, organismal, and population levels. Each infection represents an encounter between the genetic program of a virus and that of its host, and the ensuing interplay reflects the current status of their ongoing co-evolution. The details not only enrich our understanding of the biosphere in general and virus–host relationships in particular, but also create opportunities for the rational development of antiviral drugs and for domesticating viruses as expression vectors, live attenuated vaccines, and pesticides. This chapter presents an overview of the replication strategies of the major families of RNA viruses that infect animals, attempting wherever possible to identify the general principles that guide and constrain RNA virus replication and evolution. Most of the references cite review articles where citations of the primary literature can be found.

Unique Pathways and Enzymes

RNA viruses are the only organisms known to use RNA as their genetic material. They accomplish this by replicating their genomes through one of two unique biochemical pathways: either RNA-dependent RNA synthesis (RNA replication) or, among the retroviruses, RNA-dependent DNA synthesis (reverse transcription) followed by DNA replication and transcription. Both these pathways require enzyme activities that are not usually found in uninfected host cells and must therefore be encoded in the viral genome and expressed during infection. Furthermore, in some families of RNA-containing viruses, these unique synthetic processes are required right at the start of the infectious cycle. This necessitates copackaging of the corresponding polymerase and other associated enzymes with the viral genome during the assembly of virus particles in preparation for the next round of infection.

Whatever the structure and replication strategy of their genomes, all viruses must express their genes as functional mRNAs early in infection to direct the cell's translational machinery to make viral proteins. The various genetic strategies used by RNA viruses can therefore be organized into a simple conceptual framework centered around viral mRNA (Fig. 1). By convention, mRNA is defined as positive sense and its complement as negative sense. The pathways leading from genome to message vary widely among the different virus families and form the basis of viral taxonomy. Their variety suggests that RNA viruses either had several different origins or that they have diverged expansively since their most recent common ancestors. Although it is generally believed that viruses originated from cellular organisms, it remains possible that some RNA virus components are descended directly from a primordial RNA or ribonucleoprotein world, which may have predated the emergence of DNA and cells.

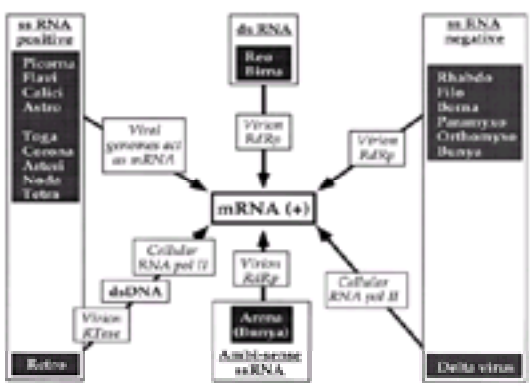

FIG. 1. Pathways of primary mRNA synthesis by RNA viruses of animals. How RNA viruses produce mRNA at the start of infection depends on the nature of the viral genome.

RNA Replication is Error Prone

The polymerases that catalyze RNA replication and reverse transcription have minimal proof-reading activities. As a result, their error rates are about 10 thousand times higher than those encountered during DNA replication, and they approximate the reciprocal of the number of nucleotides in the viral genome (10,19,32). This means that the genome of any individual RNA virus particle will contain an average of one or more mutations from the consensus wild-type sequence for that virus species. This simple fact has far-reaching consequences for the biology and evolution of RNA viruses, because it means that an RNA virus population does not represent a homogenous clone—either in nature or in the laboratory—but rather a molecular swarm of related nucleotide sequences clustered in sequence space around a master consensus sequence (14). This molecular swarm or “quasi-species” provides a fertile source of phenotypic variants that can respond rapidly to changing selection pressures by shifting its composition. As a consequence, RNA viruses can evolve up to one million times faster than can DNA-based organisms (10,14).

Their rapid rates of evolution are not without cost to RNA viruses, however, because high polymerase error rates impose upper limits on genome size. The combination of replicative error rate and genome size defines an “error threshold” above which a virus cannot maintain even the sequence integrity of its quasi-species (14). As a result, few RNA virus genomes contain more than 30 kilobases (kb), and most have between 5 kb and 15 kb. RNA genomes of this size are poised just below their error thresholds, and whereas their genetic diversity inevitably wastes individual progeny that may carry lethal mutations, the cost is offset by the potential for rapid evolutionary response.

Subcellular Sites of Genome Replication

Whereas most DNA viruses of eukaryotes (apart from the poxviruses) replicate their genomes in the nucleus, most RNA viruses replicate in the cytoplasm. However, in addition to the retroviruses, which integrate DNA copies of their genomes into cellular chromosomes, other notable exceptions to this generalization are the orthomyxo- and bornaviruses whose linear negative-sense RNA genomes replicate in the nucleus. The circular RNA genome of hepatitis delta virus, like the viroids of plants, also replicates in the nucleus (Table 1). Each site of replication presents distinct opportunities and challenges in terms of which cellular components and pathways are available to be parasitized, and how the synthesis and trafficking of viral proteins, genome replication, virion assembly, and the release of progeny can be coordinated. For example, RNA splicing occurs only in the nucleus, so this way to access multiple open reading frames in a single transcript can be used only by the retro-, orthomyxo-, and bornaviruses that transcribe there. It is interesting that the paramyxoviruses, which replicate in the cytoplasm, have instead evolved a transcriptional editing mechanism that achieves the same result (8).

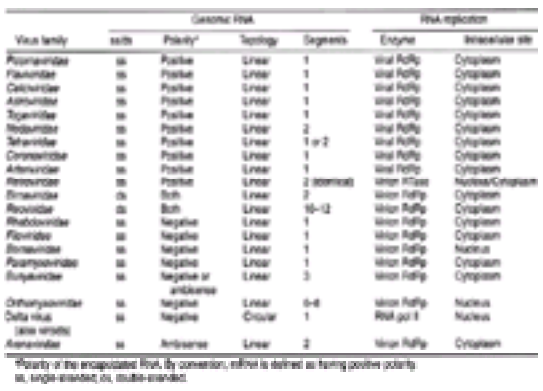

TABLE 1. *Families of RNA-containing viruses that infect animals*

Levels of Segmentation: Genes, mRNAs, and Proteins

Another distinctive feature of eukaryotic cells—besides their partitioning into nuclear and cytoplasmic compartments—has a profound influence on the biology of their viruses. On most mRNAs, eukaryotic ribosomes require a methylated cap structure at the 5' end that plays a critical role in signaling the initiation of protein synthesis. As a result, eukaryotes generally obey the rule “one mRNA, one polypeptide chain,” and with very few exceptions, each message operates as a single translational unit. Similarly, viral RNA-dependent RNA polymerases (RdRp's) generally appear somewhat limited in their ability to access internal initiation sites on RNA templates, and this creates the problem of how an RNA virus can derive several separate protein products from a single genome. Through evolution, different RNA virus families have found three solutions: fragmentation at the level of proteins, mRNAs, or genes, with some viruses using more than one level. For example, RNA viruses in the picorna-, toga-, flavi-, and retrovirus families rely on extensive proteolytic processing of polyprotein precursors to derive their final protein products (13). Others (in the corona-, arteri-, rhabdo-, and paramyxo-virus families, among others) depend on complex transcriptional mechanisms to produce several different monocistronic mRNAs from a single RNA template (8,26,39). Still others (in the reo-, orthomyxo-, bunya-, and arenavirus families, among others) have solved the problem by fragmenting their genomes and assembling virions that contain multiple genome segments, each often representing a single gene (see Table 1) (15,40,45). Among plant viruses, such RNA genome segments are often packaged into separate virions, necessitating co-infection by several virus

particles to transmit infectivity (50), but the genome segments of animal viruses are usually copackaged. In contrast, DNA viruses seldom use either genome segmentation or polyprotein processing. This is likely due to the relative ease with which monocistronic mRNAs can be transcribed from internal promoter sites on double-stranded (ds) DNA and the use of differential splicing of nuclear transcripts to express promoter-distal open reading frames.

STRUCTURES AND ORGANIZATION OF VIRAL RNA GENOMES

Unlike cellular genomes, which uniformly consist of dsDNA, viral RNA genomes provide examples of almost every structural variation imaginable. As shown in Table 1, different families of RNA viruses have genomes that consist of either ds or single-stranded (ss) RNA; of either positive, negative, or mixed (ambi-sense) polarity; of either linear or circular topology; and of either single or multiple RNA segments. Each of these variations has consequences for the pathways of genome replication, viral gene expression, and virion assembly.

Single- and Double-Stranded RNA Genomes

Although all RNA genomes replicate through conventional Watson–Crick base-pairing between complementary template and daughter strands, different RNA virus families encapsidate and transmit different molecular stages of the RNA replication cycle. Families of ssRNA viruses outnumber families of dsRNA viruses by almost 10 to one, roughly the inverse of the ratio found among DNA viruses. In view of the greater stability of ds nucleic acids of both types, this difference calls for an explanation. Two possibilities seem plausible: first, dsRNA viruses must somehow circumvent the translational suppression resulting from the coexistence of equimolar amounts of antisense RNAs. How the dsRNA reoviruses solve this problem is described in Chapter 52. Second, dsRNA is widely recognized by the cells of higher eukaryotes as a signal for the induction of defense mechanisms that act to suppress viral replication, such as the interferon system in vertebrates (27; also see Chapter 12) and gene silencing in plants (30). These two effects probably suffice to explain the relative scarcity of dsRNA viruses.

For these same reasons, it is important even for ssRNA viruses to limit the accumulation of replicative intermediates that contain regions of dsRNA, and the strategies to ensure this differ between positive- and negative-strand viruses. All positive-strand RNA viruses synthesize disproportionately low levels of negative-sense RNA—typically 1% to 5% of the levels of positive-sense RNA—and thereby minimize the potential for dsRNA accumulation. Conversely, negative-strand viruses, which need substantial amounts of both positive- and negative-sense RNAs to use as messages and progeny genomes, respectively, usually prevent them from annealing to one another by keeping the genomic RNA covered with a viral nucleocapsid protein (7,39).

Positive- and Negative-Sense RNA Genomes

The differences between positive- and negative-strand RNA viruses extend beyond the polarity of the RNA assembled into virions. Positive-sense RNA genomes exchange their virion proteins for ribosomes and cellular RNA-binding proteins at the start of infection. Once synthesized and assembled, the virus-specified RdRp and other nonstructural proteins replace the ribosomes to accomplish RNA replication. Virion structural proteins are reacquired during the assembly of viral progeny. In contrast, negative-sense RNA genomes and their antigenomic complements remain associated with their nucleocapsid proteins both within virus particles and throughout the viral replication cycle, even during RNA replication. These fundamentally different adaptations can be attributed to the fact that whereas positive-sense genomes must satisfy criteria for translation that are dictated by the host cell, negative-sense genomes and antigenomes must satisfy only the template requirements of the virus-specified RdRp because they are replicated but never translated. Although it remains unclear how polymerases can copy protein-coated RNA templates, the mechanism was surely refined during the coevolution of negative-strand viral nucleocapsids and their RdRp's relatively free from cellular constraints. Double-stranded RNA genomes are intermediate between these extremes: the parental genome segments remain sequestered in subviral particles, whereas positive-sense precursors to the progeny dsRNAs are initially unencapsidated. These distinctions most likely reflect significant differences in the structures of the viral RdRp–template complexes and in the molecular mechanisms of replication of positive, negative, and dsRNA genomes.

Linear and Circular RNA Genomes

RNA replication not only requires an acceptable error rate, as discussed earlier, but also must avoid the systematic deletion or addition of nucleotides. Genome termini are particularly troublesome in this respect, which has been dubbed “the end problem.” For DNA replication, the end problem is exacerbated by the fact that DNA polymerases cannot initiate daughter strands and must therefore depend on primers, which creates the additional complication of how to replicate the primer-binding site(s). Among several known solutions, the most economical and widespread in nature is to eliminate the ends by covalently circularizing the DNA, as in prokaryotic genomes.

Unlike DNA polymerases, most RNA polymerases do not require primers, so RNA genomes are less susceptible to the end problem. Accordingly, most RNA virus genomes are linear molecules. Covalently closed circular RNAs are found only in hepatitis delta virus in animals (see Table 1), and among the viroids and some other subviral RNA pathogens that infect plants (9,24). Nevertheless, the termini of linear RNAs are especially vulnerable to degradation, and their replication is likely to be particularly error prone. Consequently, every family of RNA viruses has features designed to preserve the termini of the genome. For example, many positive-strand RNA genomes carry the 5'-caps and 3'-poly(A) tracts that protect the termini of eukaryotic mRNAs against degradation, and similar roles are likely played by the Vpg protein that is covalently bound to the 5' end of picornavirus RNAs (36), and by the stable RNA secondary structures found at the 3' ends of flavivirus and other genomes. The 3' ends of many plant virus RNAs form cloverleaf structures that resemble tRNAs so closely that they are recognized by cellular tRNA charging and modifying enzymes (12). In addition to playing protective roles, terminal modifications of positive-sense RNAs also may serve to bring their ends together by binding to interacting cellular proteins such as the poly(A)-binding protein and cap-binding complex, thereby forming noncovalent functionally circular complexes that may promote repetitive translation by ribosomes and repetitive

replication by RdRp's.

Unlike the genomes of positive-sense RNA viruses, negative- and ambisense RNA genomes rarely carry covalent terminal modifications. Instead, these RNAs routinely show some degree of terminal sequence complementarity, which is thought to stabilize the viral nucleocapsid in a panhandle structure and promote RNA replication, perhaps by rendering the template functionally circular, as described for positive-strand RNAs (see Chapter 38, Chapter 41, and Chapter 46). Terminal complementarity also may enable the RNA ends to act as telomeres for one another, with the 5' end serving as a template to restore nucleotides eroded from the 3' end.

In other solutions to the end problem, there is evidence that some ambisense arenaviruses may be able to tolerate a substantial level of sequence variation at the termini of their genomic RNAs, presumably by locating all necessary cis-acting signals internally, well away from the RNA termini (41; also see Chapter 50). Retroviral genomes conversely are terminally redundant, and have direct repeats of between 12 and 235 nucleotides at each end that maintain and restore the integrity of the termini during reverse transcription and virus replication (28; also see Chapter 57).

Segmented and Nonsegmented RNA Genomes

Although genome segmentation facilitates the production of multiple gene products in eukaryotic cells, it also means that the various genome segments must each contain appropriate cis-acting signals to mediate their expression, replication, and assembly into virions. In some virus families with segmented genomes (such as the orthomyxo-viruses and some reoviruses), these signals comprise conserved sequences at the RNA termini, but in others (such as the bipartite noda- and tetraviruses), significant sequence conservation between the segments is undetectable. In these cases, the specificity of RNA replication and assembly is presumably determined by conserved RNA secondary or tertiary structures. However, the mechanisms that coordinate the replication and packaging of multiple genome segments remain poorly understood for any eukaryotic virus.

Evidently the evolutionary barrier between viruses with segmented and nonsegmented RNA genomes is readily traversed, because both genome types occur in members of the alphavirus-like supergroup, a taxonomic cluster based on phylogenetic comparisons of viral nonstructural protein sequences (23). Indeed, among the tetraviruses, segmented and nonsegmented genomes can be found even within the same family (31). Furthermore, the genomes of some toga- and rhabdoviruses, which are naturally nonsegmented, have been experimentally divided in two without destroying viral infectivity, thus confirming the flexibility of RNA virus genomes in this regard. Nevertheless, genome segmentation has major effects on the biology of a virus, because individual segments can often reassort between dissimilar strains in co-infected cells, enabling segmented genome viruses to make substantial evolutionary leaps by horizontal gene transfer. This mechanism underlies the antigenic shifts that produce new pandemic strains of the orthomyxo-virus influenza (see Chapter 47).

Cis-Acting Signals and Specificity

Replication and packaging of viral RNAs display striking specificity; both processes unerringly pick the correct viral molecules from among thousands of cellular RNAs that may be much more abundant. This is generally attributed to the presence of cis-acting signals that selectively channel the viral RNAs into replication and assembly complexes, but in most RNA virus genomes, these signals remain to be clearly identified. Those that have been characterized mostly comprise not linear nucleotide sequences but RNA secondary structures such as bulged stem-loops, tRNA-like cloverleaves, and pseudoknots, which are thought to create distinctive three-dimensional molecular shapes that interact specifically with viral enzymes and structural proteins (11). However, although high-resolution structures have been determined for some RdRp's, reverse transcriptases, and several viral capsids, our understanding of the molecular basis of specificity in RNA replication and virus assembly is limited by our scant knowledge of the three-dimensional structures of the viral RNA and its cis-acting signals. Not infrequently, the structural basis of RNA selectivity during replication and assembly has proved elusive, perhaps because the specificity determinants can be redundant, dispersed, or global properties of the viral genome. Furthermore, in both RNA replication and assembly, specific initiation is followed by less specific RNA–protein interactions that propagate the reactions. The transitions between these different stages are largely unexplored, and much remains to be learned concerning the recognition of cis-acting RNA signals and how they promulgate RNA replication and virus assembly.

Satellite RNAs and Defective RNA Genomes

Occasionally RNA molecules arise that are neither independently infectious nor essential for infectivity but nevertheless contain cis-acting signals that promote their own replication and/or packaging by the proteins encoded by another virus. Such satellite RNAs are parasitic on the parent virus and can modulate its replication and virulence (46). Among the RNA viruses of animals, a prime example is hepatitis delta virus, which packages its genome in virion proteins encoded by the hepadnavirus hepatitis B, and can severely exacerbate its pathogenicity (24; also see Chapter 88). Dependence of an RNA satellite on a DNA virus parent is unusual; more commonly, satellite RNAs are replicated and encapsidated by the proteins of an RNA virus parent with which they share at least some sequence homology. In some instances, satellite RNAs encode their own distinct capsid proteins, or proteins required for RNA replication (as in the case of hepatitis delta virus), but in others, they are translationally silent. Satellite RNAs are much more common among the viruses of plants than in those of animals (see Chapter 19), perhaps because the transmission of animal viruses between hosts generally involves narrower bottlenecks, which select against the spread of satellites.

In contrast to the transmission of viral infection between hosts, the spread of infection within a single animal usually involves successive episodes of localized virus replication, which resemble the conditions of plaque formation and serial high-multiplicity passage in cell culture. These conditions favor the generation and amplification of defective viral RNAs, which can arise from simple deletions of viral genes as well as from more complex genome rearrangements that occur during RNA replication. Like satellite RNAs, defective RNAs parasitize the parent virus and usually interfere with its replication, but because they also depend on it for their own survival, they typically establish a fluctuating coexistence

(46). Most families of animal RNA viruses readily generate defective interfering (DI) RNAs in cell culture, but their influence on viral disease and evolution is less well understood.

EXPRESSION AND REPLICATION OF RNA VIRUS GENOMES

Variety of RNA Virus Genome Strategies

The type of RNA genome largely determines whether the first step of macromolecular synthesis is translation, transcription, or RNA replication. Viruses with positive-sense ssRNA genomes (except the retroviruses) deliver their genomic RNAs directly to cellular ribosomes and begin the infectious cycle with translation (Fig. 2 and Fig. 3). Accordingly, these genomic RNAs are infectious even when completely deproteinized, as was first shown for tobacco mosaic virus RNA in classic work that helped to establish that genes were composed of nucleic acids rather than proteins (17). Positive-sense RNA viruses fall into two groups: those that produce subgenomic mRNAs and those that do not. For viruses in the latter group (like the picorna- and flaviviruses), genomic RNA directs the synthesis of a single polyprotein precursor to both the structural and nonstructural viral proteins, which are therefore produced in equimolar amounts (see Fig. 2). After cleavage by proteases contained within the polyprotein itself, the nonstructural proteins catalyze RNA replication to produce progeny genomes that assemble with the processed structural proteins to form progeny virus particles. For positive-sense viruses in the other group, which include the astro-, calici-, toga-, corona-, and arteriviruses (see Fig. 3), genomic RNA directs the synthesis of a precursor to only the nonstructural proteins, which include the viral RdRp. This enzyme then transcribes one or more subgenomic mRNAs that encode the structural proteins. Their greater transcriptional complexity allows these viruses to produce their proteins in dissimilar amounts.

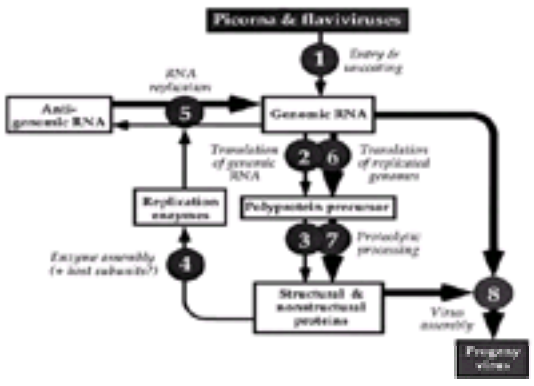

FIG. 2. Replication scheme of positive-strand RNA viruses that make no subgenomic mRNAs. After entry and uncoating (*step 1*), genomic RNA is used directly as the mRNA for both nonstructural and structural proteins (*steps 2 and 3*). The nonstructural proteins catalyze RNA replication via the synthesis of antigenomic RNA (*steps 4 and 5*). Replication produces more genomic RNA for further translation of viral proteins (*steps 6 and 7*) and for assembly with the structural proteins to produce progeny virus particles (*step 8*). For further details, see Chapter 23 and Chapter 32. In this and the figures that follow, *arrow thickness* denotes the relative magnitude of the reactions.

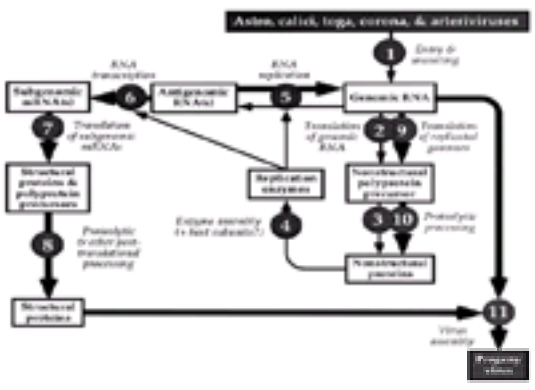

FIG. 3. Replication scheme of positive-strand RNA viruses that make one or more subgenomic mRNAs. After entry and uncoating (*step 1*), genomic RNA is used directly as the mRNA for nonstructural proteins that include the viral RNA-dependent RNA polymerases (RdRp's) (*steps 2 and 3*). The RdRp catalyzes RNA replication through the synthesis of full-length antigenomic RNA (*steps 4 and 5*). It also transcribes one or more subgenomic mRNAs (*step 6*), which direct synthesis of the viral structural proteins (*steps 7 and 8*). Replicated genomes are translated to produce more nonstructural proteins (*steps 9 and 10*), and assembled with structural proteins into progeny virus particles (*step 11*). Note that the corona- and arteriviruses (Chapter 35 and Chapter 37) synthesize their subgenomic mRNAs by a very different mechanism from that used by the toga-, astro-, and caliciviruses (Chapter 27, Chapter 28 and Chapter 29).

Viral genomes that consist of negative- or ambisense ssRNA or of dsRNA are not infectious by themselves because they must begin the infectious cycle by transcribing viral mRNAs, and uninfected cells do not contain an appropriate RdRp. Except in the case of hepatitis delta virus, this reaction is catalyzed by enzymes that are carried into cells by the infecting virions, which transcribe individual mRNAs for the viral proteins (Fig. 4, Fig. 5 and Fig. 6). For negative- and ambisense RNA viruses, the viral RdRp and newly synthesized nucleocapsid protein mediate RNA replication to produce antigenomic nucleocapsids (7,35). Although they are positive sense, antigenomes do not direct protein synthesis but instead are used exclusively as templates for RNA synthesis. For dsRNA viruses, individual mRNAs are transcribed from genome segments that remain enclosed in subviral particles (see Fig. 6). These ssRNAs and their translation products

reassemble into progeny subviral particles, where the synthesis of negative-strand RNAs then recreates the dsRNA genome segments (40,45,47). Uniquely among animal viruses, the genome of hepatitis delta virus, which is a negative-sense circular ssRNA, is transcribed and replicated by the cell's DNA-dependent RNA polymerase II in an uncharacteristic RNA-templated reaction (24; also see Chapter 88). Finally, retroviruses begin their infectious cycles by replicating their ssRNA genomes into dsDNA proviruses by using reverse transcriptase, an RNA/DNA-dependent DNA polymerase that is carried by the infecting virion (28). After integration into a host chromosome, proviral DNA is transcribed by cellular RNA polymerase II to produce unspliced and spliced viral mRNAs that direct viral protein synthesis (Fig. 7).

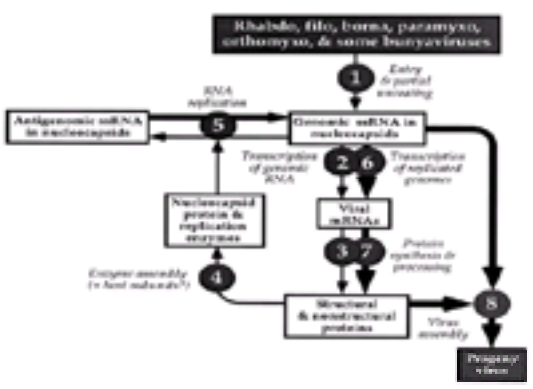

FIG. 4. Replication scheme of negative-strand RNA viruses. After entry and partial uncoating (*step 1*), encapsidated viral RNAs are transcribed by the nucleocapsid-associated RNA-dependent RNA polymerases (RdRp's) to produce mRNAs (*step 2*) for the viral proteins (*step 3*). These catalyze RNA replication through the synthesis of antigenomic nucleocapsids (*steps 4 and 5*). Replication produces more genomic nucleocapsids for further transcription (*step 6*) and translation (*step 7*) of viral genes, and for assembly with the structural proteins to produce progeny virus particles (*step 8*). Orthomyxo- and bornaviruses transcribe and replicate in the nucleus, and some of their mRNAs are spliced (Chapter 46 and Chapter 51). The other virus families listed replicate in the cytoplasm and avoid splicing (Chapter 38, Chapter 40, Chapter 41 and Chapter 48). Some bunyavirus genomes are negative sense and some are ambisense (Chapter 48 and Chapter 49; see Fig. 5).

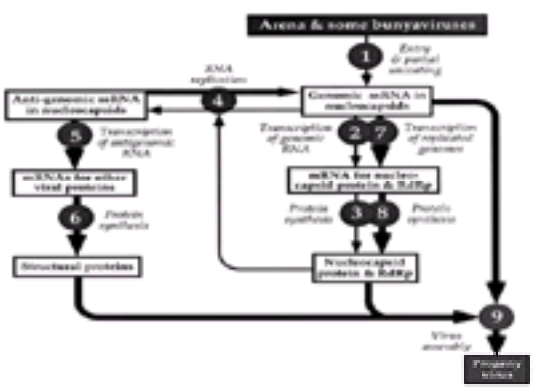

FIG. 5. Replication scheme of ambisense RNA viruses. After entry and partial uncoating (*step 1*), encapsidated viral RNAs are partially transcribed by the nucleocapsid-associated RNA-dependent RNA polymerases (RdRp's) to produce mRNAs (*step 2*) for the nucleocapsid protein and RdRp (*step 3*). These catalyze RNA replication through the synthesis of antigenomic nucleocapsids (*step 4*), which serve both as templates for transcription of mRNAs (*step 5*) for the other viral proteins (*step 6*), and for the production of more genomic nucleocapsids. Replicated genomic nucleocapsids serve as templates for transcription (*step 7*) and translation (*step 8*) of viral genes, and for assembly with the structural proteins to produce progeny virus particles (*step 9*). Some bunyavirus genomes are ambisense and some are negative sense (see Fig. 4). For further details, see Chapter 48 and Chapter 57.

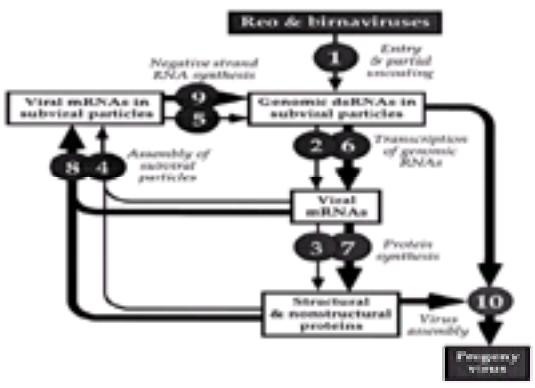

FIG. 6. Replication scheme of double-strand RNA viruses. After entry and partial uncoating (*step 1*), dsRNA segments within subviral cores are transcribed by the core-associated RNA-dependent RNA polymerases (RdRp's) to produce mRNAs (*step 2*) for the viral proteins (*step 3*). These form subviral particles around the mRNAs (*step 4*), which are then copied to produce genomic dsRNAs (*step 5*). Progeny subviral particles contribute to viral gene expression (*steps 6 and 7*) and replication (*steps 8 and 9*), and assemble with outer shell structural proteins to form progeny virus particles (*step 10*). For further details, see Chapter 52, Chapter 54, and Chapter 56.

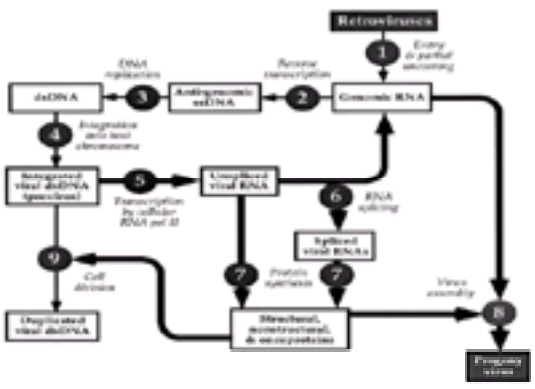

FIG. 7. Replication scheme of retroviruses. After entry and partial uncoating (*step 1*), genomic RNA is copied to dsDNA by reverse transcriptase (*steps 2 and 3*) and covalently integrated into cellular DNA in the nucleus by DNA integrase (*step 4*). Both enzymes are present in the viral core. The integrated viral genome (or provirus) is transcribed by cellular RNA polymerase II (*step 5*) to produce viral RNA transcripts that function both as precursors to mRNAs for the viral proteins (*steps 6 and 7*) and for assembly into progeny virus particles (*step 8*). For further details, see Chapter 58.

Regulation of Gene Expression

DNA viruses typically express different sets of genes before and after DNA replication, predominantly making catalytic amounts of nonstructural proteins during the prereplicative or early phase of infection, and stoichiometric amounts of structural proteins later, after DNA replication has amplified the gene copy-number. In contrast, most RNA viruses show little differentiation between the pre- and postreplicative phases of the infectious cycle, expressing their genes at roughly the same relative levels throughout infection. In cases like the toga- and influenza viruses, in which some temporal modulation of gene expression does occur, the differences are subtle and are accomplished mostly at the transcriptional level through modulation of mRNA levels.

However, posttranscriptional controls and countermeasures dominate the struggle between eukaryotic cells and viruses for the supremacy of gene expression. Apart from the retroviruses, RNA viruses generally inhibit host protein synthesis either directly or indirectly, and some specific mechanisms have been elucidated. For example, influenza virus blocks the splicing and nuclear export of cellular mRNAs, whereas polio- and rhinoviruses degrade mRNA cap-binding protein, but some other viruses monopolize translation simply by flooding the cell with highly efficient mRNAs (1). To counteract virus infection, some cells have evolved antiviral defense mechanisms such as gene silencing in plants and the interferon system in vertebrates, which intervene posttranscriptionally to degrade viral mRNAs and inhibit their translation (27,30; also see Chapter 12). In response, many viruses have acquired mechanisms to neutralize or evade these cellular defenses in ways that provide valuable insights into virus–host coevolution (1). Because retroviruses integrate DNA copies of their genomes into cellular chromosomes, their replication depends on the survival and proliferation of the host cell. Many retroviruses therefore express oncogenes that override cell-cycle controls and drive infected cells to divide (28).

Structural and Nonstructural Proteins

By definition, virus-specified structural proteins are incorporated into virus particles, whereas nonstructural proteins are found only in infected cells. However, negative-, ambisense, and dsRNA viruses assemble their RdRp's and associated enzymes into progeny virions and therefore encode predominantly or exclusively structural proteins. In addition to the polymerase, virus-encoded enzymes often include one or more proteases, an RNA helicase, guanylyl- and methyl-transferases, poly(A) polymerase, sometimes a nuclease, and in the case of the retroviruses, a DNA integrase. However, for several RNA viruses, the evidence that these enzymes are virally encoded is only circumstantial or is based on inconclusive sequence homologies.

The proteases process the primary translation products of which they are a part by cleaving them at highly specific target sequences, and in some picornavirus-infected cells, they also selectively inhibit host cell protein synthesis by cleavage of the cellular cap-binding protein (13). Particularly among the larger RNA viruses, RNA helicases may be required to disrupt inter- or intramolecular base-pairing during RNA synthesis, although some RdRp's are capable of melting RNA duplexes without help (21). Guanylyl- and methyltransferases construct the 5'-caps found on the mRNAs of almost all eukaryotic RNA viruses (42), except for the picornaviruses, which are uncapped, and the orthomyxo- and bunyaviruses, which steal the caps from cellular mRNAs by means of a cap-specific endonuclease (3,15,37). At their 3' ends, most animal virus mRNAs carry untemplated poly(A) tails, although 3' tRNA-like structures are common among plant RNA viruses (12,50). Polyadenylation is usually ascribed to a stuttering side-reaction of the viral RdRp rather than to a separate poly(A) polymerase, as in poxviruses, although the enzymology of the reaction remains to be clearly defined (38).

Comparisons among the amino acid sequences of viral RdRp's establish clear phylogenetic relationships that also reflect other differences in viral genome structures and strategies (23). Moreover, the x-ray crystal structures of the polio- and hepatitis C virus RdRp's (4,18) show unmistakable resemblances not only to one another but also to those of reverse transcriptases, as well as DNA-dependent RNA and DNA polymerases. Although the overall levels of amino acid sequence homology among these diverse polymerases are statistically insignificant, RdRp's share many of the characteristic polymerase motifs that occupy critical positions in the three-dimensional architecture of the polymerase active site (20,34). Taken together, the structural homologies of their RdRp's firmly anchor the RNA viruses to the rest of

the biosphere, and suggest that despite their diversity, these viruses radiated from common ancestors that probably escaped from cellular origins to establish a transmissible parasitic existence (see Chapter 13).

Host-Cell Proteins

Proteins provided by the host undoubtedly play essential roles in RNA virus replication, although different cellular proteins have been implicated in different virus systems (25,44). The clearest example comes from the RNA replicase enzymes of the RNA bacteriophages Qb and MS2, which, in addition to the single phage-specified polypeptide that provides the polymerase active site, contain four cell-specified subunits: the *Escherichia coli* ribosomal protein S1, two translation elongation factors (EF-Tu and EF-Ts), and a strand-specific RNA-binding protein, host factor-1 (2). In view of the similarity of their host components, the distinct specificities of the Qb and MS2 replicases for their cognate RNA templates must be determined by their unique viral subunits. The unexpected recruitment of translation factors to assist RNA replication—despite the evident differences between these two processes—may reflect underlying biochemical similarities in the RNA–protein interactions that are involved. Whether it also reflects a common evolutionary origin for translation and RNA replication is speculative, but the possibility is supported by the discovery that peptide bond synthesis is catalyzed by RNA.

Translation factors also have been implicated in RNA replication in some viruses of eukaryotes. For example, a subunit of the initiation factor eIF-3 binds to brome mosaic virus RdRp and increases its activity, and several other host proteins bind to the termini of some viral RNAs in infected cells. Among these are poly(A)- and polypyrimidine tract-binding proteins, calreticulin, and the snRNA-binding proteins Ro and La (5,29). Although it is often difficult to distinguish fortuitous interactions from those that play functional roles, the development of cell-free systems and recombinant strains of yeast that support the complete replication of certain viral RNAs promises clarification from biochemical and genetic studies, respectively (5).

Host-Cell Membranes

Unlike phage replicases, the RdRp's of eukaryotic viruses are invariably found associated with some type of supramolecular assembly: host-cell membranes for positive-sense RNA viruses, nucleocapsids for negative-sense RNA viruses, and subviral particles for dsRNA viruses. In general, the intracellular membranes of cells infected with positive-sense RNA viruses undergo proliferation and redistribution to form anchor sites for the viral RNA replication complexes. When these complexes are released from membranes during purification, they generally lose the ability to catalyze true RNA replication, although they often retain the more limited ability to copy an RNA template into its complement. In the case of the nodavirus flock house virus, true RNA replicase activity was restored to partially purified RdRp by adding glycerophospholipids to the cell-free extract (49), reinforcing the idea that membrane organization and dynamics play central roles in positive-sense RNA replication. The same conclusion is indicated by the inhibition of poliovirus RNA replication by brefeldin A, which interferes with intracellular membrane trafficking (5). Although the specific role of membranes is unclear, it is thought that they may expedite replication complex assembly by reducing the dimensionality of the process, and perhaps also segregate the RNA products from their templates.

Mechanisms of Replication and Transcription

The simplest mechanism of RNA replication is that used by hepatitis delta virus, in which rolling-circle synthesis by RNA polymerase II makes multimeric RNAs of both positive and negative polarity. Cis-acting ribozymes then cleave linear RNA monomers from these concatamers and covalently circularize them to produce mature antigenomes and genomes, respectively (24). Although this simple mechanism is shared by several viroids and other subviral RNA pathogens of plants (9), delta virus is the only animal RNA pathogen known to replicate by a rolling-circle mechanism. Far more commonly, ssRNA genomes are replicated through the synthesis of complementary RNA monomers produced by successive rounds of strand-displacement during end-to-end copying of linear templates (5). However, both ends of the RNA are generally required for template activity, suggesting that even linear RNAs may function as if they were circular, perhaps to facilitate reiterative replication and to hinder erosion of the termini.

The relative levels of genomic and antigenomic RNAs are regulated in different ways in different virus families. In the case of Qb, negative-strand synthesis is limited by the requirement for an additional host subunit that is not needed for the synthesis of positive-sense RNA (2). In some other systems, it appears that different cis-acting RNA signals are largely responsible for determining the relative template activities of the complementary strands, although it is possible that different host factors are involved here, too. For the togavirus Sindbis, negative-sense RNA is synthesized only by a transient version of the RdRp, an intermediate in the proteolytic processing pathway of the viral nonstructural proteins (43). As infection proceeds, the increased viral protease cleaves this intermediate and thereby switches the template specificity of the RdRp to the synthesis of positive-sense RNA (see Chapter 29).

Unlike the enzymes that replicate DNA, which usually require primers, most RdRp's can initiate RNA synthesis *de novo.* However, there are exceptions: picornavirus RdRp's use a small viral protein (Vpg), which is first covalently uridylated and then used as a primer for all viral RNA synthesis (36). In another mechanism of priming, the enzymes encoded by orthomyxo- and bunyaviruses cleave short capped oligonucleotides from host mRNAs and use them to prime transcription, although for replication, they initiate RNA synthesis *de novo* (37). Arenavirus RdRp's also initiate replication *de novo,* but they start at the penultimate nucleotide of the template and then realign the nascent strand and use it to prime replication of the entire genome, including the 3' nucleotide (16; also see Chapter 50). The ability of some plant virus RdRp's to restore several nucleotides to the 3' ends of their templates suggests that additional novel mechanisms of initiation await discovery (22).

Viral RdRp's also sometimes catalyze unorthodox reactions during RNA chain elongation. For example, some paramyxovirus polymerases edit selected transcripts internally by specifically inserting one or more nontemplated nucleotides, thereby allowing ribosomes access to additional open reading frames and expanding the coding potential of the viral genome (8). Somewhat similarly, negative-strand RNA virus RdRp's generally polyadenylate their transcripts by

stuttering on short runs of U residues in the template (38). Finally, almost all RdRp's occasionally switch templates during replication, thereby producing recombinant progeny molecules that, as satellite or DI RNAs, can influence both the course of infection and the evolution of the virus (6,33,48).

SUMMARY AND PERSPECTIVES

The many different genome strategies of RNA viruses furnish a wealth of unique biochemical pathways found nowhere else in the biosphere. As our understanding deepens, we can look forward to new opportunities for the development of antiviral agents that specifically target these pathways, like the successful antiretroviral protease inhibitors, for example. Furthermore, it is now possible to recover infectivity from cDNA clones of many RNA viruses and thus to manipulate their genotypes and phenotypes in systematic and deliberate ways. This technology has far-reaching potential for the creation of novel reagents, including recombinant vaccines, biopesticides, targeted cytolytic agents, and vectors for gene therapy. Both as foes and friends of mankind, RNA viruses have an interesting and exciting future.

CHAPTER 6 Replication Strategies of DNA Viruses

Daniel DiMaio and Donald M. Coen

All viruses, whether they contain RNA or DNA genomes, adsorb to cell membranes, enter cells, uncoat, express their genes, replicate their genomes, assemble new virions, and exit from cells. These activities entail interactions with the host cell that range from simple binding to cellular receptors to complex modulation of host processes. In addition, DNA viruses carry out some steps that RNA viruses do not. For most DNA viruses, these steps include transport of virion DNA into the nucleus, initiation of transcription from this DNA and induction of transcription of additional viral genes, preparation of the cell for viral DNA replication, replication of the DNA genome, resolution and packaging of DNA into virions, and egress from the nucleus. In addition, many DNA viruses have evolved interesting mechanisms to evade host defenses, and many DNA viruses can cause tumors in animals. The intimate relationship between viruses and their host cells dictates that viruses exploit key cellular regulatory systems and usurp important cellular processes to carry out successful infection. Thus, studies of various aspects of DNA virus replication have provided fundamental new insights into important cellular processes including gene expression, DNA replication, and cell-cycle control.

This chapter reviews most of the steps just listed that are specific to DNA viruses. Nuclear entry and egress (which are not employed by poxviruses) are discussed in Chapter 7, and virus assembly and packaging of DNA per se are discussed in Chapter 8. Because of space constraints, this review cannot be comprehensive. A limited—and necessarily subjective and arbitrary—set of examples from various mammalian viruses is presented to illustrate unifying themes and interesting exceptions.

TRANSCRIPTION OF VIRAL DNA

Each mammalian cell contains about 6×10^9 base pairs of DNA and $>10^4$ active promoters. This presents a considerable challenge for viral DNA to compete effectively in recruiting the cellular transcriptional machinery to viral promoters. Moreover, once recruited, the machinery must generate viral transcripts efficiently. To meet this challenge, DNA viruses have adopted strategies to permit efficient initiation of transcription at one or more specific promoters on viral DNA shortly after it enters the nucleus. These promoters drive the transcription of what are frequently termed immediate early genes.

Enhancers

To recruit the transcriptional machinery to immediate early viral promoters and activate transcription, many DNA viruses contain enhancers—*cis*-acting regulatory sequences that, unlike promoters, can activate transcription from thousands of base pairs (bps) upstream or downstream of the transcriptional start site. This defining feature of enhancers emphasizes the competitive advantage they confer on viral promoters. Indeed, the high activity of the cytomegalovirus immediate early enhancer/promoter accounts for the popularity of its use in expression vectors. Although cellular genes frequently contain enhancers, the first enhancer to be recognized was that of the papovavirus SV40 (3,30,56). The SV40 enhancer consists of two tandem repeats of 72 bp, which contain binding sites for at least six different transcription factors, including multiple binding sites for certain factors. Although it is possible to create a synthetic enhancer by multimerizing a binding site for a single transcription factor, the multiplicity of factors and binding sites characteristic of natural enhancers appears to be required for optimal enhancer function.

Many enhancers also contain binding sites for “architectural” proteins, which do not necessarily have transcriptional activation functions on their own but rather promote the stereospecific, three-dimensional assembly of enhancer-protein complexes (“enhanceosomes”) (9). These nucleoprotein complexes can then activate transcription by interactions with the RNA polymerase II transcriptional machinery with considerable potency and specificity (29,72,73). Indeed, subtle sequence changes in papovavirus enhancers can drastically affect their function in different cell types (39).

Virion Transcription Factors

In addition to enhancers, some DNA viruses encode proteins that are packaged into virions, enter the cell with the viral DNA, and then facilitate transcription of immediate early genes. An extreme example of this is provided by poxviruses, which replicate in the cytoplasm and make no use of the cellular transcription machinery. Rather, as described in Chapter 84, poxviruses encode and package in virions their own RNA polymerases, capping and polyadenylation enzymes, and

transcription factors. Upon entry into the cell and uncoating, the viral transcription machinery becomes active and synthesizes viral immediate early transcripts.

A more general example is the herpes simplex virus (HSV) transactivator VP16 (also known as aTIF) (58,72,74). HSV VP16 is synthesized late in infection and is packaged into the portion of the virion known as tegument, which lies between the capsid and the envelope. Upon entry of HSV into cells, VP16 is transported to the nucleus and forms a complex with at least two cellular proteins—Oct-1, which is a transcription factor that recognizes an eight-bp DNA sequence, and HCF-1. This tripartite complex binds to specific DNA sequences with the consensus TAATGARAT (R = purine) upstream of HSV immediate early genes, with much of the DNA binding specificity and affinity provided by Oct-1. The complex then serves as a strong activator of transcription. Much of the activation is due to the C-terminal “activation domain” of VP16. This domain, when linked to virtually any sequence-specific DNA-binding domain that binds upstream of a TATA-box element of a promoter, can activate transcription in any eukaryote. Indeed, VP16 has served as a paradigmatic transcriptional activator. The VP16 activation domain can interact with many different proteins in the cellular transcriptional machinery, and it remains controversial as to whether any one protein is most important for its transcriptional activity. Indeed, the ability of VP16 to interact with more than one protein may account for the strength of its activation domain, given the evidence that this domain functions to recruit the transcriptional machinery to promoters rather than to stimulate the activity of any particular transcription protein (e.g., 41). Regardless, in the absence of an intact VP16 activation domain, the expression of HSV immediate early genes and viral replication is greatly impaired (1,64).

Stimulation of Gene Expression by Viral Immediate Early Proteins

As infection proceeds, DNA viruses typically express their genes in a highly ordered sequence. Although expression of viral genomes can be regulated posttranscriptionally, major control is exerted at the level of transcription. Viral immediate early genes generally encode proteins that stimulate expression of viral genes that are expressed subsequently during infection (the early and late genes). This enables early and late promoters, which usually lack enhancers or binding sites for transcription complexes such as those formed by virion proteins like VP16, to compete effectively with cellular promoters for the transcriptional machinery. Expression of some viral genes (e.g., papillomavirus late genes) is restricted to cells in a particular state of differentiation. Tissue-specific expression of essential cellular transcription factors may underlie this restriction. It should also be noted that several viruses also encode proteins that repress expression of certain viral genes at particular times in the virus life cycle. In addition, many viruses affect cellular gene expression. This can entail the induction and repression of specific genes, as well as a more nonspecific shut-off of cellular gene expression. The latter topic is considered in Chapter 7.

There appear to be many mechanisms by which viral immediate early proteins function. Certain of these proteins, such as the Epstein-Barr virus (EBV) BZLF1 protein (also known as Zta or Zebra), can behave like cellular transcription factors in that they bind to specific sequences upstream of genes and activate transcription (66). Other immediate early proteins increase the activity of cellular sequence-specific transcription factors. For example, the adenovirus E1A protein displaces members of the transcription factor E2F family from inhibitory retinoblastoma (Rb) family proteins. This increases transcription of adenovirus early genes that contain E2F binding sites (44) [and also has important consequences on cellular transcription and, indirectly, on viral and cellular DNA replication (see later)]. Other immediate early proteins, such as HSV ICP4, appear to stimulate transcription by direct interaction with the transcriptional machinery without binding to specific DNA sequences in the target promoter (31,36), while still others, like HSV ICP27, appear to stimulate viral gene expression by both transcriptional and posttranscriptional mechanisms (38,51,65). The net result of the activities of these viral proteins is that cells devote most of their gene expression machinery to production of viral gene products.

PREPARING THE CELL FOR VIRAL DNA REPLICATION

Viral Effects on Cell Cycle Progression

During productive viral infection, many DNA viruses carry out prodigious feats of DNA replication, in which a single viral genome gives rise to up to 100,000 or more genome copies in the course of a few days. This requires the action of many proteins, including DNA binding proteins and polymerases, as well as an abundant supply of nucleotides. Replication of some DNA viruses occurs only in cells that are naturally replicating their own DNA, thereby providing the necessary cellular environment for viral DNA replication. Many other DNA viruses also rely largely on the cellular DNA replication machinery, but these viruses encode proteins that induce cells to enter the necessary replicative state. Finally, some of the largest DNA viruses make limited use of the cellular replication machinery but rather encode viral versions of many of the necessary proteins.

The parvoviruses are among the simplest DNA viruses and contain single-stranded linear genomes. Parvoviruses can undergo DNA replication and carry out their full infectious cycle only in cells undergoing cellular DNA replication—that is, only in cells in the S-phase of the cell cycle (70,79). In fact, viral gene expression is not activated until after the cells enter S phase and the incoming DNA genome is converted into a double-stranded form suitable as a template for transcription (15). However, unlike certain other viruses that require cells to be actively replicating cellular DNA, parvoviruses are unable to induce the cells to enter S-phase, and thus they can carry out successful infection only if they encounter cells already committed to DNA synthesis. Some parvoviruses, notably adeno-associated virus (AAV), have even more stringent requirements and can replicate only if helper adenoviruses or herpesviruses provide viral gene products that permit parvovirus gene expression and DNA replication (7,62). Certain forms of cellular stress, such as DNA damage, can also induce a cellular state compatible with AAV DNA replication (62,83,84).

Many other DNA viruses induce cells to enter the replicative state required for viral DNA replication. For these viruses, viral DNA replication is the result of collaboration between cellular replication proteins and viral proteins that have direct roles in replication, such as initiator proteins that localize the replication apparatus to the viral replication origin. These DNA viruses generally induce cells to enter this essential replicative state by encoding proteins that participate in specific

protein–protein interactions with key cellular regulatory molecules, and some of these viral proteins have molecular chaperone activity that enables them to assemble these protein complexes (4,8,67). Often, these interactions lead to the neutralization of cellular tumor suppressor proteins such as p53 and members of the Rb protein family, whereas in other cases, these interactions result in the activation of cellular growth-stimulatory signal transduction pathways, which may indirectly inhibit Rb activity (Table 1).

Neutralization of tumor suppressor function
Direct effects on retinoblastoma expression or activity
Stimulation of cyclin-dependent kinase activity
Activation of growth-promoting signal transduction pathways
Receptor tyrosine kinase pathways
Intracellular signal transduction pathways

TABLE 1. *Mobilization of the host cell replication machinery by DNA Viruses*

The viral proteins that induce the replicative state commonly inactivate Rb family members p105 ^{Rb}, p107, and p130 (13). Rb inactivation relieves repression and releases E2F transcription factors to stimulate expression of numerous cellular proteins required for S-phase, including DNA polymerase a, thymidine kinase, ribonucleotide reductase, and thymidylate synthase (Fig. 1) (17,20,34). Some viral proteins, such as adenovirus E1A and human papillomavirus (HPV) E7, directly bind Rb proteins and inhibit Rb function, thereby activating E2F (2,27,81). Other viral proteins regulate the activity of cyclin-dependent kinases (cdks), which catalyze the phosphorylation of Rb, resulting in release of active E2F and transcription of E2F-regulated genes. Viral proteins that indirectly influence Rb activity in this way include herpesviruses-encoded cyclins that bind and activate cdks (40) and a variety of proteins that impair the expression or activity of proteins that inhibit cdk activity. For example, adenovirus E1B 55K and E4orf6 protein and HPV E6 inhibit the activity of p53, a transcriptional activator (24,61,80). Several viral proteins target the p53 coactivator CBP/p300. Abrogation of p53 function results in decreased expression of the p53-responsive gene encoding the cdk inhibitor p21, thus stimulating cdk activity. Similarly, adenovirus E1A binds the related cdk inhibitor p27, neutralizing its effects (50). SV40 large T antigen is a particularly versatile protein that not only binds and inactivates both Rb and p53 (19,45,49) but also carries out several functions directly required for viral DNA replication (see later) as well as essential roles in other aspects of the virus life cycle. Another mechanism is employed by polyomavirus middle T antigen and bovine papillomavirus E5 protein, which activate growth factor receptor signaling cascades and presumably induce expression of the cyclin D regulatory subunit of the cdks, thereby stimulating cdk activity and Rb phosphorylation (22,23,59). Certain herpesvirus and hepadnavirus proteins also appear to stimulate signal transduction cascades by activating intracellular signal transduction proteins such as NFkB, p21 ^{ras}, and pp60$^{c\text{-}src}$ (23). Although poxviruses encode growth factor homologs, these do not appear essential for viral DNA replication; rather, they are involved in various aspects of viral pathogenesis (6).

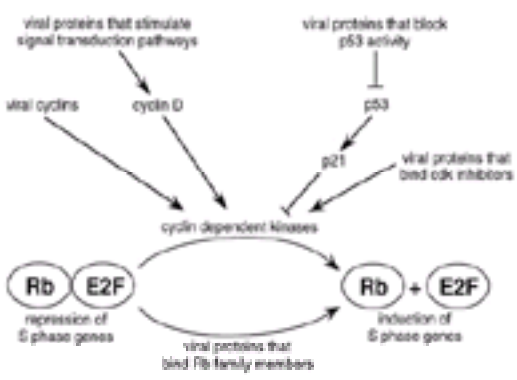

FIG. 1. Inactivation of retinoblastoma family members and activation of E2F by DNA tumor viruses. Viral proteins can cause the release of E2F family transcriptional activators from Rb-E2F repressor complexes by stimulating the activity of cyclin-dependent kinases or by binding directly to Rb family members. See text for details and examples.

Not surprisingly, induction of a panel of cellular DNA replication proteins has profound consequences on the host cell, which is often induced to undergo DNA replication and proliferation as a by-product of this mobilization of the cellular replication machinery. When this proliferative signal is sustained and tolerated, for example in nonpermissive cells that are unable to support viral DNA replication, the cells may undergo stable growth transformation, a topic covered in detail in Chapter 10. Thus, not only do many DNA viruses induce quiescent cells to reenter the cell cycle, but they also transform cells in culture and cause tumors in animals. Viewed in this light, the ability of many DNA tumor viruses to induce transformation is not a feature of normal viral replication but rather an aberrant cellular response to the need of the virus to generate the proper cellular milieu for viral DNA replication. In accord with this view, the parvoviruses, which as noted previously lack the ability to stimulate cellular DNA replication, are one of the few DNA virus groups that do not transform cells. However, the relationship between the ability of viruses to stimulate cellular DNA synthesis and to transform cells is not simple. For example, some herpesviruses stimulate DNA synthesis, others do not, and still others

actually inhibit cell proliferation. Such large viruses, with their large coding capacity, are able to create the proper environment for viral DNA replication without relying on mobilization of the cellular replication machinery.

The cell cycle normally is tightly regulated to prevent excess proliferation and ensure that each step in the cycle is successfully completed before the next step begins. When the cell cycle is disrupted, as is the case when unscheduled cellular DNA synthesis occurs, cells often initiate a suicidal response called *apoptosis*, or programmed cell death. Apoptosis is characterized by specific morphologic changes and biochemical events, including the activation of caspase proteases and the degradation of cellular DNA, and it is regulated by components of the cell cycle machinery. For example, E2F1 can stimulate apoptosis, and p53 appears to play a central role in mediating apoptosis in response to diverse stimuli. Because viruses often target these same cell cycle components, viral proteins can induce or inhibit apoptosis. In fact, DNA virus infection and the DNA synthesis response it elicits often induces host cell apoptosis. Because apoptosis and the resulting premature cell death can curtail virus production, viruses have evolved numerous mechanisms to inhibit apoptosis, including the neutralization of p53 function. Therefore, transformation by some viruses requires the seemingly antagonistic action of two or more viral proteins. For example, adenovirus E1A stimulates both proliferation and apoptosis, in part by inactivating Rb proteins and releasing active E2F1. Stable transformation ensues only if viral E1B gene products prevent E1A-induced apoptosis by interfering with p53 function or by acting downstream of p53 in the apoptotic pathway (18,60). By neutralizing p53, HPV E6 may block a similar apoptotic activity of E7. These relationships suggest that some viral oncogenes have evolved to thwart antiviral host defenses, such as apoptosis or interferon induction, by interfering with cellular pathways that mediate these defense mechanisms (54).

Whether viral oncogenes primarily function to generate the milieu for viral DNA replication or to counteract host defense mechanisms, the fundamental strategy is the same: The virus has evolved proteins that influence intracellular processes to allow vegetative viral replication, and the ability of these proteins to induce cell transformation and tumorigenesis is an unintended consequence of the underlying cellular biochemistry. The papillomaviruses are unusual in that benign tumor formation is an integral part of the virus life cycle. However, even for these viruses, carcinogenic progression is not a normal feature of the virus life cycle but rather a response to defective viruses with deregulated oncogene expression.

Provision of Nucleotides for DNA Replication

As described, parvoviruses require cells to be in S-phase to replicate, and papovaviruses and adenoviruses stimulate cells to enter S-phase. The requirement for S-phase is, in part, a requirement for cells to supply deoxynucleoside triphosphates (dNTPs) for DNA synthesis. Via effects on Rb and E2F family members, papovaviruses and adenoviruses induce the synthesis of enzymes such as ribonucleotide reductase that are required to generate sufficient dNTPs for viral DNA replication (Fig. 2). In contrast, herpesviruses and poxviruses are able to replicate in resting cells. One reason that these viruses can circumvent the requirement for S-phase is that they encode enzymes for dNTP synthesis, both of the *de novo* pathway (e.g., ribonucleotide reductase) and the salvage pathway (e.g., thymidine kinase) (see Fig. 2). In the case of HSV and varicella zoster virus, viral-encoded thymidine kinases provide Achilles heels for antiviral chemotherapy because these viral enzymes phosphorylate nucleoside analogs such as acyclovir more efficiently than do cellular enzymes. Following conversion by cellular enzymes to their triphosphate form, these dNTP analogs selectively impair viral DNA replication (37).

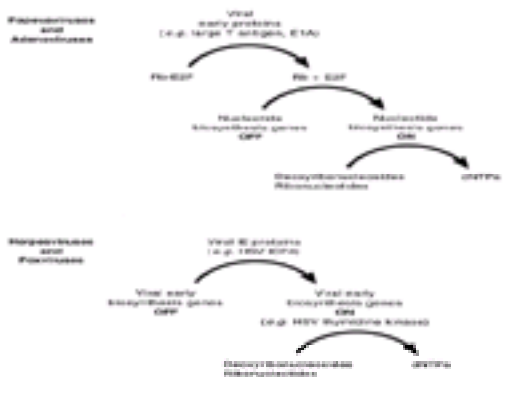

FIG. 2. Mechanisms of provision of nucleotides for DNA replication. **Top:** Papovaviruses and adenoviruses encode viral proteins such as SV40 large T antigen and the adenovirus E1A protein, which displace members of the E2F family of transcriptional activators from the retinoblastoma protein (Rb), as indicated in Fig. 1. The E2F transcription factors are then free to induce expression of numerous cellular genes required for DNA replication, including those that encode proteins that catalyze the formation of deoxyribonucleoside triphosphates (dNTPs) from deoxynucleosides or ribonucleotides. **Bottom:** Herpesviruses and poxviruses encode viral immediate early (IE) proteins such as herpes simplex virus (HSV) ICP4, which induce expression of viral enzymes involved in deoxyribonucleotide biosynthesis, such as HSV thymidine kinase.

VIRAL DNA REPLICATION

Initiation of Viral DNA Replication

Replication of DNA virus genomes generally initiates at specific sites called origins. Unlike most cellular origins, which are active once and only once per cell cycle, a viral replication origin can fire many times during a single replication cycle. Replication proceeds away from the origin either by utilizing classic replication forks with lagging and leading strand synthesis or by displacement synthesis with leading strand synthesis only. Viruses have evolved a number of strategies to assemble the replication apparatus at the origin and initiate DNA synthesis at the correct position. Most commonly, a viral early protein binds directly and specifically to the double-stranded DNA that comprises the origin and

recruits the cellular replication machinery to this site. Other viral genomes have a 3' end base-paired to a template strand that can be extended by polymerase, whereas in some cases unusual protein-priming strategies are used. Despite the diversity of initiation mechanisms, a common theme is the use of specific protein–protein interactions to recruit essential viral and cellular replication proteins to participate in replication initiation.

The role of the SV40 large T antigen in origin-dependent viral DNA replication has been particularly well studied (21,32,48). Large T antigen is the only SV40 protein required for viral DNA replication. It binds tightly and specifically to the SV40 origin, a short segment of viral DNA shown by numerous studies to be the necessary and sufficient *cis*-acting element for initiation of bidirectional viral DNA replication in permissive monkey cells. Elegant genetic studies established that the binding of large T antigen to the origin is required for replication (63). In the presence of ATP, hexameric complexes of large T antigen bind specifically to the origin and carry out several functions essential for replication initiation (Fig. 3). Large T antigen induces local DNA distortion and melting at AT-rich sequences within the origin. Large T antigen then associates with the cellular replication protein A (RPA), a single-stranded DNA binding protein, thereby permitting extensive DNA unwinding catalyzed by the intrinsic ATP-dependent helicase activity of large T antigen (52). DNA polymerase a-primase binds directly to the origin-bound large T antigen, and this replicative polymerase synthesizes short RNA sequences that serve as primers for viral DNA synthesis. The importance of the interaction between large T antigen and DNA polymerase a-primase is highlighted by the finding that the inability of viral DNA to replicate in nonpermissive cells is the result of the inability of large T antigen to recognize DNA polymerase a-primase from these cells (6,25,28,68). The molecular chaperone activity of large T antigen may play an important role in assembling the protein complexes necessary for initiation of replication.

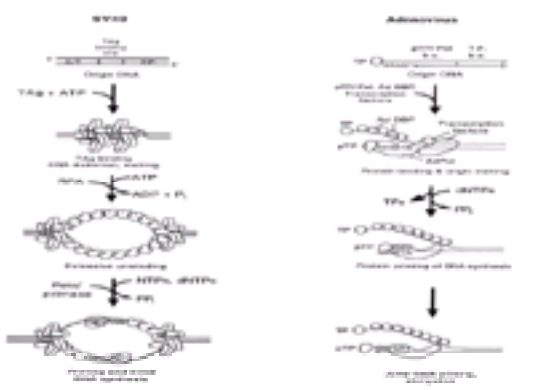

FIG. 3. Two mechanisms of initiation of DNA replication.
Left: A model for initiation of SV40 DNA synthesis. The *top panel* shows the SV40 origin with a binding site for SV40 large T antigen (TAg) flanked by a highly AT-rich sequence (A/T) and a modestly AT-rich sequence known as the early palindrome (E.P.). In the presence of ATP, two TAg hexamers form on the TAg binding site, leading to distortion and melting of the AT-rich sequences. Then, in the presence of the cellular heterotrimeric single-stranded DNA binding protein, replication protein A (RPA), TAg extensively unwinds origin DNA, a reaction driven by ATP hydrolysis. The four-subunit cellular DNA polymerase a/primase (Pola/primase) then binds to each single strand and catalyzes the incorporation of nucleoside triphosphates (NTPs) into RNA primers on each strand (*zigzag line*). The DNA polymerase catalyzes the incorporation of deoxynucleoside triphosphates (dNTPs), extending the RNA primers into newly synthesized strands of DNA. Pola/primase is then replaced at the primer terminus by replication factor C and subsequently the DNA polymerase d complex (not shown; see Fig. 4 for subsequent steps).
Right: A model for initiation of adenovirus DNA synthesis. The *top panel* shows the adenovirus terminal protein TP bound to the 5' end of an adenovirus origin of DNA synthesis at a terminus of adenovirus DNA. Near the end of the DNA is a binding site for the preterminal protein (pTP)-adenovirus DNA polymerase (Pol) complex (pTP/Pol b.s.) and an adjacent binding site for cellular transcription factors (T.F. b.s.). These transcription factors interact with Pol such that pTP/Pol binds to the template strand (sequence 5'-ATGATG-3'OH) with a serine side chain in pTP placed opposite the G, four bases from the 3' end of the viral DNA. This interaction is abetted by the adenovirus single-stranded DNA binding protein (Ad DBP), shown coating the TP-bound strand, thereby favoring the melting of origin sequences. Pol then adds a C to the serine hydroxyl moiety in the pTP protein primer and extends that C two bases in a template-dependent fashion, synthesizing the sequence CAT. The pTP/Pol bound to the newly synthesized CAT sequence then “jumps-back” to the very end of the template strand, and the CAT serves as a primer for elongation of the rest of the daughter DNA strand (see Fig. 4).

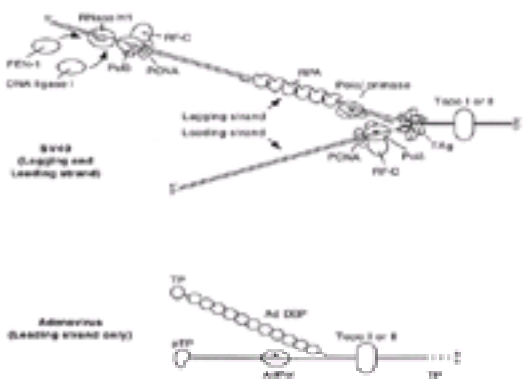

FIG. 4. Contrasting sets of proteins at the replication fork.
Top: A replication fork during SV40 DNA replication. The replication fork is shown as a branched DNA molecule, with 5' and 3' ends indicated. On the right, downstream of the replication fork, either a type I or a type II topoisomerase (Topo I or II) releases supercoiling generated during DNA synthesis. At the replication fork, a hexamer of SV40 large T antigen (TAg), the only viral protein present, serves as a helicase, unwinding DNA in front of the DNA synthetic machinery. The leading strand for DNA synthesis is shown as the bottom of the two branches with the two-subunit DNA polymerase d

(Pold) bound to the processivity factor, proliferating cell nuclear antigen (PCNA; this is trimeric, but it is shown as a ring around the DNA). The heteropentameric replication factor-C (RF-C) is drawn as a large oval bound to Pold and PCNA. RF-C loads the PCNA ring onto DNA, which is then recognized by Pold. The Pold complex synthesizes DNA in a continuous fashion, starting from the RNA–DNA primers laid down by DNA polymerasea/primase at the SV40 origin (see Fig. 3). The lagging strand for DNA synthesis is shown as the top of the two branches. Closest to the replication fork is the four-subunit DNA polymerase a/primase (Pola/primase). The primase subunit lays down RNA primers (*zigzag line*) on the lagging strand, and the DNA polymerase extends the RNA into newly synthesized DNA (*straight line*). To the left of the Pola/primase is replication protein A (RPA), coating single-stranded DNA ahead of Pola/primase. To the left of the RPA is a stretch of RNA–DNA primer previously synthesized by Pola/primase. The Pold/PCNA/RF-C complex, having assembled at the primer terminus, is drawn as extending the DNA strand. Farther to the left, a previously synthesized RNA primer is being digested by RNase H1. The nuclease FEN-1 (also known as MF-1) will remove the last ribonucleotide of the RNA primer. After the Pold complex finishes extending the DNA strand, DNA ligase I will ligate together the two Okazaki fragments. Although events on the leading and lagging strands are shown as occurring separately, there is evidence that they are coordinated within a large macromolecular complex.
Bottom: A replication fork during adenovirus DNA synthesis. The replication fork is shown as a branched DNA molecule. On the *right*, downstream of the replication fork, supercoiling generated during DNA synthesis is released by type I or type II topoisomerase, the only cellular protein present. The top branch is a single strand of parental viral DNA displaced during DNA synthesis, coated with the adenovirus single-stranded DNA binding protein (Ad DBP) and with the 5' end bound to terminal protein (TP). The double-stranded bottom branch is made up of a parental template strand and a newly synthesized strand whose 5' end is bound to preterminal protein (pTP) and whose 3' end is being extended by the adenovirus DNA polymerase. This enzyme synthesizes DNA in a continuous fashion starting from the pTP protein primer, as described in Fig. 3. Events at the adenovirus replication fork are much simpler than those at the SV40 replication fork, largely because there is no lagging strand synthesis.

Similar initiation strategies are used by other viruses with double-stranded origins. However, unlike SV40, in which all the required viral replication functions are contained within a single viral protein, other viruses are not so parsimonious. For example, the papillomaviruses encode two proteins, E1 and E2, required in *trans* for efficient viral DNA replication in rodent fibroblasts (75). The E1 protein appears to be the major viral replication protein, and, like large T antigen, is an ATP-dependent helicase. Both the E1 and E2 proteins bind to specific DNA sequences in the origin region, and they bind to each other (53). The presence of the E2 protein in the complex facilitates the specific, high-affinity binding of E1 to the origin. Moreover, both the E1 and E2 proteins participate in specific protein–protein interactions that localize cellular replication proteins such as DNA polymerase a-primase and RPA to the origin. The presence of more than one viral protein at the origin raises the possibility that different combinatorial multimeric protein complexes may play distinct roles in different phases of the virus life cycle, such as stable maintenance of plasmids at a low copy number during latent infection versus rapid amplification of viral DNA during vegetative DNA replication. Origins also often contain binding sites for cellular transcription factors, which may facilitate replication, perhaps by altering chromatin structure or by recruiting replication proteins. Some of the large DNA viruses, including HSV, have multiple specific origins (55,76). Unlike the case of the polyomaviruses and papillomaviruses, the detailed mechanics of origin recognition and initiation of replication have not been completely worked out for the larger DNA viruses, in part because of the lack of suitable *in vitro* DNA replication systems for these viruses. Indeed, the development and analysis of *in vitro* replication systems for small viral genomes has led to the identification of essential cellular replication proteins and to many important insights into the mechanism of cellular DNA replication (see later) (11,42,48).

The linear DNA packaged by a number of viruses has base-paired 3' ends that are extended as the initial steps in viral DNA replication. In the case of parvoviruses, these base-paired primer-template structures are formed by complicated stem-loop structures occurring at the ends of the viral genome that is otherwise single-stranded (15). These 3' ends are extended by cellular DNA polymerase in a reaction that does not appear to require viral proteins. The resulting double-stranded DNA replication intermediates are then nicked at specific sites by viral NS or Rep proteins to generate primers for ongoing DNA synthesis. Cellular DNA binding proteins collaborate with the viral proteins to ensure efficient nicking. These viral proteins also presumably play an important role in recruiting cellular replication proteins, including DNA polymerase, to these sites. The ends of the linear poxvirus genomes are imperfectly base-paired hairpin loops. Recent evidence indicates that these ends can serve as the sites of replication initiation in the cytoplasm, but the details of initiation of this virus group are obscure (26). Indeed, it is not known whether poxviruses encode all essential origin recognition and replication proteins, or whether the cell also makes a contribution.

The most unusual strategy for initiating viral DNA replication is the use of proteins as primers. The adenoviruses are the prototype viruses that use this strategy (33). Adenovirus DNA replication origins are located at inverted repeats at both ends of the linear double-stranded viral genome. The 5' end of each DNA strand contained within the virus particle is covalently linked to a virally encoded protein (the terminal protein). Immediately adjacent to the terminal protein are specific DNA sequences that comprise a core origin and an auxiliary region that binds cellular transcription factors. Viral DNA synthesis is initiated when a complex of the adenovirus DNA polymerase and the precursor to the terminal protein (preterminal protein, pTP) binds to the origin and melts the origin region in conjunction with a virally encoded single-stranded DNA binding protein (see Fig. 3). The binding of viral proteins to the origin may be assisted by transcription factors bound to the auxiliary sequences and by the bound terminal protein, although these proteins are not absolutely required. The adenovirus polymerase then adds nucleotides directly to pTP by a remarkable template-dependent mechanism that entails a “jump back” so that the first bases added correspond to the sequence of the 5' ends of the genome (12,43). The DNA 3'hydroxyl group of the pTP–oligonucleotide complex is then extended by viral DNA polymerase (see next section).

Provision and Action of Proteins That Act at the Replication Fork

Once viral DNA replication is initiated, the elongation phase of DNA synthesis proceeds via the concerted action of multiple proteins at replication forks. At replication forks in most organisms, one strand (the leading strand) is replicated

by simple 5'-3' extension in a continuous manner. Because the other strand (the lagging strand) must also be synthesized 5'-3', it is replicated discontinuously, by repeated synthesis and joining of short Okazaki fragments. Table 2 lists proteins that act at replication forks, and their functions.

Replication protein	Function
DNA Polymerase	Elongate DNA chains
Polymerase-accessory proteins (e.g., PCNA)	Stimulate polymerase, increase processivity
ss DNA binding protein	Remove hairpins, etc., especially on lagging strand
Primase	Lay down RNA primers on lagging strand
RNases	Remove RNA primers
Ligase	Seal nicks, especially on lagging strand
Helicase	Unwind DNA at fork
Topoisomerase	Remove superhelicity ahead of fork

PCNA, proliferating cell nuclear antigen.

TABLE 2. *Proteins that act at replication forks*

DNA viruses employ different strategies to provide these proteins. For the most part, small DNA viruses use cellular proteins at the replication fork. The best understood of these viruses is SV40 where the replication proteins involved were identified following the development of a cell-free system for replicating SV40 DNA *in vitro* (48) (Fig. 4). Subsequent work led to the purification of 10 proteins that are sufficient to catalyze the replication of SV40 DNA *in vitro* (32,77,78). Nine cellular activities were purified: DNA polymerase a, which is mainly responsible for initiating DNA synthesis at the origin and during lagging strand synthesis; primase, which is associated with DNA polymerase a and primes DNA synthesis at the origin and during the synthesis of Okazaki fragments; DNA polymerase d, which is mainly responsible for leading-strand synthesis and for completing synthesis of Okazaki fragments; proliferating cell nuclear antigen (PCNA), which binds to DNA polymerase d and forms a ring around DNA, thereby increasing polymerase processivity; replication factor-C, which loads the PCNA ring onto DNA and stimulates polymerase d; RPA, a single-stranded DNA binding protein; RNase H, which removes all but one ribonucleotide of the RNA primer; FEN-1 (also known as MF-1), an exonuclease that removes the remaining ribonucleotide; DNA ligase I, which ligates together Okazaki fragments; and either topoisomerase I or topoisomerase II to remove superhelicity during synthesis. Although it is difficult to demonstrate that these cellular proteins perform these functions during SV40 replication in living cells, the importance of their homologs for chromosomal DNA replication in yeast supports this idea. SV40 large T antigen, the only required viral protein, provides the requisite helicase function at the replication fork, in addition to the origin-binding and unwinding activities during initiation alluded to previously.

Other viruses provide almost all of the replication fork proteins. The elongation phase of adenovirus DNA replication *in vitro* requires only the single subunit adenovirus DNA polymerase; the adenovirus single-stranded DNA binding protein, which can increase the processivity of the polymerase; and either cellular topoisomerase I or II (57) (see Fig. 4). This remarkable simplicity is due in part to the unusual nature of adenovirus DNA replication, which does not entail lagging-strand synthesis (see later). Larger DNA viruses provide more activities still. For example, herpesviruses each encode a DNA polymerase, a processivity factor, a primase–helicase complex, and a single-stranded DNA binding protein (10). It is not known whether herpesviruses or poxviruses, whose full complement of virally encoded replication proteins has probably not yet been identified, require cellular proteins at all for synthesis of viral DNA.

STRATEGIES TO ENSURE COMPLETE REPLICATION, GENOME RESOLUTION, AND PACKAGING

It is critical for all organisms to replicate their entire genome. In most organisms, this problem is exacerbated by the semidiscontinuous nature of DNA replication, in which replication of the lagging strand requires laying down a primer; thus, one strand of a linear double-stranded DNA is never completed (the end-replication problem). Eukaryotic cells have overcome this problem by the use of telomeres. DNA viruses utilize several alternate strategies to solve the end-replication problem, which also inform their strategies for resolution of replicating DNA into daughter molecules and their packaging into virions.

Papovaviruses avoid the end-replication problem by being endless—that is, they are circular. Bidirectional replication generates complete circular daughter DNA molecules that are then resolved via the action of topoisomerase II (21). In the virion and in the cell nucleus, papovavirus DNA, like cellular DNA, is wound around nucleosomes, which are disrupted during replication. Daughter DNA molecules then reassemble into nucleosomes that are mixtures of “old” and “new” histones (82); thus, daughter minichromosomes are generated that are the substrates for packaging into new virions.

For other DNA viruses, virion DNA is not a simple double-stranded circle and is not wound around nucleosomes. Herpesvirus DNA is linear in the virion but circularizes when it enters cells. However, instead of generating circular daughter molecules, replication evidently generates long, concatameric molecules via rolling circle and perhaps recombinational mechanisms (10). To regenerate linear progeny DNA molecules with the correct ends, viral proteins cleave the viral DNA at specific sequences during packaging into capsids.

Adenoviruses, poxviruses, and parvoviruses, all with linear genomes, solve the end-replication problem in very different ways from papovaviruses and herpesviruses. Following initiation at one end of the adenovirus genome by protein priming (see earlier), DNA is extended from the protein primer continuously to the other end of the genome, displacing the preexisting parental strand intact (46). The displaced parental single-stranded DNA is replicated after its self-complementary inverted termini anneal, reconstructing a double-stranded origin, which is recognized by the initiation proteins (see earlier), leading to synthesis of another parental-daughter duplex. Thus, each parental duplex can be

replicated semiconservatively. The linear daughter DNAs are substrates for packaging into adenovirus virions, and pTP is cleaved to generate terminal protein. Poxviruses have linear genomes with sealed hairpin ends, so they are effectively circular single-stranded DNAs. They evidently also replicate via leading-strand synthesis only, involving the generation of concatameric, double-stranded genomes that are resolved into unit-length daughter molecules by cleavage at specific DNA sequences by viral proteins. Parvoviruses utilize similar mechanisms involving leading-strand synthesis to generate double-stranded replicative intermediates, but mature unit-length, single-stranded daughter DNA molecules are displaced during the final stages of DNA synthesis (71). These stages of parvovirus and poxvirus replication require complicated genome gymnastics that are described in Chapter 69 and Chapter 84.

HEPADNAVIRUSES: A RUBE GOLDBERG STRATEGY OF VIRAL DNA REPLICATION

Hepadnaviruses have a particularly complicated replication scheme, described in Chapter 86, that incorporates several of the features already outlined here and defies simple categorization. The viral genome in extracellular virus particles is a circular, largely double-stranded DNA molecule that contains a single-stranded gap. In a step similar to that used by parvoviruses, the 3' end of the shorter strand is extended to generate the fully double-stranded circular genome as the first step in viral DNA replication. With the aid of a viral enhancer, cellular RNA polymerase II then transcribes the nuclear double-stranded DNA genome from a specific promoter to generate a terminally redundant linear RNA pregenome that is packaged into immature virus particles. The single-stranded pregenome is later replicated to generate the mature, gapped virion DNA by virion reverse transcriptase (69), which utilizes several mechanisms including protein-priming similar to that employed by adenovirus, template jumping similar to that employed by retroviruses, and scavenging of RNA primers from degraded pregenomic viral RNA. Although this mechanism of genome replication may appear cumbersome, it evidently serves the needs of hepadnaviruses very well, as they often establish persistent infections that last for decades.

EVASION OF HOST DEFENSES AND LATENCY

Cells mount stout defenses against viral infection. Infection can induce the synthesis of interferons, which initiate a complex series of antiviral responses that inhibit virus replication. Cells can also respond to virus infection by undergoing apoptosis. If apoptosis occurs early during the virus life cycle, virus replication is terminated by the premature demise of the host cell, limiting virus yield. (Later in the life cycle, some viruses actively stimulate apoptosis, which might facilitate virus release and dissemination.) Finally, organisms can mount effective immune and inflammatory responses that prevent virus infection or lead to clearance of the virus or of virally infected cells. Spurred on by their evolutionary need to replicate and spread, viruses have evolved a number of mechanisms to overcome these defenses. The study of viral proteins that interfere with the cellular defense machinery is providing new insights into important cellular processes, such as immune recognition and apoptosis, and these viral proteins are being used as tools to identify and characterize key cellular proteins involved in these processes. Details of the interaction of host defense systems and viruses can be found in Chapter 7, Chapter 11, and Chapter 12, and in the chapters on specific viral groups.

Latent Infection

An effective mechanism of evading host defenses is for a virus to withdraw into a latent state in which the viral DNA is present at a low copy number, few viral proteins are expressed, and the cellular defenses are not mobilized. At some later time, perhaps when conditions are more conducive to virus replication, the virus can reenter the lytic, vegetative cycle. Herpesviruses commonly employ this strategy. A striking example is the latency involving varicella zoster virus, a herpesvirus that causes chicken pox during childhood but commonly sets up a latent infection in the neurons in dorsal root ganglia. When immunity has waned decades after the initial infection and acute disease, the virus can reinitiate lytic replication, resulting in lesions termed shingles in the body segment innervated by the affected dorsal root ganglion. The reactivated virus can even be transmitted to a new host.

In general, the mechanisms underlying establishment and release from latency are not well understood. EBV latency in B lymphocytes has been studied intensively (see Chapter 75), and its regulation exemplifies many of the principles discussed in this chapter. Upon infection of B cells, latency is established via an elaborate interplay of host and viral transcription factors acting at various viral promoters to activate or repress transcription. During latency, the viral genome is present in only a few extrachromosomal copies per cell, and the virus evades the immune system by expressing very few proteins, at least some of which are poor immunogens. In latently infected nondividing cells, viral proteins are not even required for replication of EBV DNA. In latently infected dividing cells, EBV DNA is replicated using a specific viral origin sequence and cellular replication proteins, and it is segregated properly to daughter cells by the action of the viral protein EBNA-1. At a low spontaneous rate, or at a high rate in response to certain stimuli such as chemical inducers, there is a dramatic induction of viral DNA synthesis utilizing a different replication origin and viral replication proteins. The viral protein Zta (or Zebra) appears to play the primary role in induction of EBV (16). This DNA-binding transcriptional activator induces the efficient expression of a variety of virus lytic cycle genes, including those required for high-level viral DNA replication. The molecular events responsible for activation of Zta during spontaneous and induced escape from latency are not known.

Smaller DNA viruses, such as papillomaviruses and some parvoviruses, also undergo latent infections. In the case of the papillomaviruses, the basal epithelial cells in virus-induced warts are latently infected: The viral genomes are present at low copy number, late gene products are not expressed, and no virus particles are produced. In the more differentiated cells of the same lesion, latency is disrupted and active viral replication and production of infectious virions takes place. The nature of the switch between latent and vegetative replication is obscure, but it appears to be tightly linked to the state of differentiation of the host cell. In latent parvovirus infection, the viral genome is integrated into the cellular DNA. Superinfection of these latently infected cells with helper adenoviruses or herpesviruses supplies factors required for reentry into vegetative parvovirus replication.

Transmission of Latent Viral Genomes to Daughter Cells

During latent infection, viral genomes must be faithfully segregated during cell division. Some latent viral genomes are integrated into the cellular DNA and are replicated and segregated passively during the appropriate stage of the cell cycle. This is the case for the nonautonomous parvovirus AAV, which in the absence of helper function stably integrates with high efficiency into a specific site in a cellular chromosome and remains latent until helper function is provided (14). Other latent viral genomes are often maintained as relatively low copy number plasmids. For these viruses, unequal segregation would lead to the loss of the viral DNA in some daughter cells. Bovine papillomavirus, which replicates as a nuclear plasmid in transformed rodent fibroblasts, has devised a clever strategy to achieve proper genome distribution during cell division (35,47). The viral E2 replication protein not only binds viral DNA but also associates with mitotic cellular chromosomes. The E2 protein thus tethers the viral DNA to the cell chromosomes as they undergo migration during mitosis and cytokinesis, and the viral DNA hitchhikes a ride into the daughter cells. The EBV protein EBNA1 may carry out a similar function during viral genome segregation during latency. In this fashion, the viruses take advantage of the elaborate cellular machinery that ensures proper chromosome segregation during cell division.

SUMMARY AND PERSPECTIVES

Viruses have evolved many different strategies to effect their replication. The diverse strategies employed for each step in replication are summarized in Table 3. Despite this diversity, there are remarkable similarities in how rather different viruses execute specific steps in their replication. For example, replication of the smallest (parvovirus) and that of the largest (poxvirus) viral DNAs appear to employ similar “rolling hairpin” mechanisms. These similarities presumably reflect the ability of viruses to identify and exploit or interfere with conserved cellular processes to carry out the essential steps of the virus life cycle: viral gene expression, genome replication, evasion of host defenses, and production of progeny virions. Viruses thus continue to be unique and powerful tools to elucidate these fundamental cellular processes. Unfortunately, many intricate and interesting mechanisms utilized by DNA viruses are not outlined in this brief chapter. Some of these mechanisms are described in the chapters on the various viruses in this volume; others remain to be uncovered.

Step	Strategy	Viruses
Initiation of transcription	Strong enhancer(s) Virion protein(s)	Papovaviruses, adenoviruses, hepadnaviruses Herpesviruses, poxviruses
Stimulation of subsequent viral gene expression	Viral-encoded transactivators	All
Modulation of cell cycle	Inactivation of tumor suppressors Stimulation of signal transduction pathways	Papovaviruses, adenoviruses Some papovaviruses, some herpesviruses
Provision of deoxynucleoside triphosphates	Stimulation of cell enzymes Synthesis of viral enzymes	Papovaviruses, adenoviruses Herpesviruses, poxviruses
Initiation of DNA synthesis	Internal origin-recognition proteins Protein-primers plus sequence recognition Preexisting or newly formed primers	Papovaviruses, some herpesviruses Adenoviruses, hepadnaviruses Parvoviruses, poxviruses, hepadnaviruses, some herpesviruses (?)
Provision of replication fork proteins	Mainly cellular proteins Mainly viral proteins	Parvoviruses, papovaviruses Adenoviruses, herpesviruses, poxviruses, hepadnaviruses
Genome completion and resolution	Circles to circles Circles to linear RNAs to circles Linears to linears Linears to circles to linears Hairpins to concatemers to hairpins	Papovaviruses Hepadnaviruses Adenoviruses Herpesviruses Parvoviruses, poxviruses
Evasion of host defenses	Interference with host defense systems Latent infections	Adenoviruses, papovaviruses, poxviruses, herpesviruses Some parvoviruses, some papovaviruses (including papillomaviruses), herpesviruses

CHAPTER 7 Virus–Host Cell Interactions

David M. Knipe, Charles E. Samuel, and Peter Palese

By definition, viruses are unable to replicate on their own but must enter a host cell and use the host-cell macromolecular machinery and energy supplies to replicate. Thus, in many ways the study of viral replication is a study of the interactions of viruses with their host cells. The study of virus–host cell interactions has impacted several areas of biology and biomedical science. First, investigation of the mechanisms by which viruses replicate in, alter, or take over their host cells has often led to insight into basic cell biologic and molecular biologic mechanisms. Viruses often target critical regulatory events in the host cell; thus, knowledge of the processes subverted by viruses has often highlighted cellular regulatory mechanisms.

Second, during their replication within cells, viruses exploit host-cell molecules and processes at the expense of the host cell, which may result in cell injury or death. These injurious effects of viral replication in cells are one of the basic causes of viral disease. Therefore, precise knowledge of the pathogenic mechanisms by which viruses replicate in specific tissues, spread, and cause disease must come, in part, from studies of the intracellular replication of the virus. Over the past 45 years, increasing understanding of the mechanisms of viral replication has emerged from biochemical and cell biologic studies of virus replication in cultured cells. Investigators of viral pathogenesis have recently attempted to define the molecular events occurring in different cell types during the series of stages that define viral pathogenesis within a host organism.

Third, the definition of antiviral strategies requires knowledge of the replicative mechanisms of viruses and the identification of replicative steps that involve virus-specific processes and not host-cell processes.

This chapter will focus on the interactions of viruses with an individual host cell. Chapter 9 discusses the events that lead to (a) spread of a virus from one cell to another within a host organism, (b) induction of disease, and (c) spread within the environment. Virus infection of a cell can lead to any of several possible outcomes. First, a nonproductive infection can occur in which viral replication is blocked, and the host cell may or may not survive. After the nonproductive infection, the viral genome may be lost from the cell. Alternatively, the viral genetic information may become integrated as DNA in the cellular genome or may persist as episomal DNA in these surviving cells. If the growth properties of the cell are altered to make it oncogenic, this would constitute an oncogenic transformation event (see Chapter 10). The virus may become dormant with limited or no viral gene expression, and a latent infection is established (see Chapter 9). Second, a productive viral infection may result in which the host cell dies and lyses. Third, the cell may survive and continue to produce virus at a low level, resulting in a chronic infection (see Chapter 9).

Which of these possible scenarios is realized is determined by the nature of the interactions between the virus and the

host-cell constituents. For example, a nonproductive infection may result if a host-cell component necessary for viral replication is not present. One of the main goals of this chapter is to describe the types of interactions between virus-encoded macromolecules and the host cell, which may define the ultimate outcome of a virus infection. This chapter will examine (a) the molecular and cell biologic events that allow viral replication, (b) the ways in which viruses modify their host cells to promote their own replication, and (c) the kinds of mechanisms that may have evolved in cells to prevent virus infection. The types of experimental approaches used to obtain evidence for specific virus–host interactions will also be discussed.

The study of virus–cell interactions really started with the growth of viruses in cultured cells (83). Although infection of host organisms had given some indication of cell death resulting from viral infection, there was little clear evidence of other effects of viruses on the host cell before the infection of cultured cells and the identification of cytopathic effect (CPE) of viruses on cells (82). The elucidation of viral replication strategies in the 1950s and 1960s provided the broad outlines of virus replication. More recently, better probes for nucleic acids and proteins have allowed more precise descriptions of the molecular events of viral replication in a host cell. The techniques of molecular genetics and cell biology have begun to define the specific host-cell molecules and cellular compartments with which virus-encoded molecules interact.

In addition to classifying virus–host cell interactions in terms of the final outcome of the infection, virus–cell interactions can also be described in molecular terms with regard to individual replication events. For example, the effects of viruses on the host cell may be mediated by addition or substitution of a virus-specific macromolecule into a cellular complex or structure. Alternatively, the virus may mediate a covalent or noncovalent modification of a host-cell molecule. Virus infection may cause a disassembly or rearrangement of a host-cell complex or structure, or virus infection may lead to the assembly of a new infected cell–specific complex or structure in the infected cell. After defining these molecular interactions, the challenge for us as virologists is to relate this molecular information back to the biology of the virus in the host cell and ultimately the host organism.

CYTOPATHIC EFFECTS OF VIRUS INFECTION

One of the classic ways of detecting virus replication in cells was the observation of changes in cell structure, or CPEs, resulting from virus infection (Fig. 1, Fig. 2 and Fig. 3, and see Fig. 1 in Chapter 18). Some of the most common effects of viral infection are morphologic changes such as (a) cell rounding and detachment from the substrate (see Fig. 1), (b) cell lysis, (c) syncytium formation (see Fig. 2), and (d) inclusion body formation (see Fig. 3). The occurrence of cell morphologic changes resulting from CPE has even led to classification schemes for viruses. In 1954, Enders (1982) proposed classifying viruses into the following groups: (a) those causing cellular degeneration; (b) those causing formation of inclusion bodies and cell degeneration; and (c) those causing formation of multinucleated cells or syncytial masses and degeneration, with or without inclusion bodies. However, as described in Chapter 2, other classification schemes based on virion and genome structure and modes of replication have provided much better ways of classifying viruses.

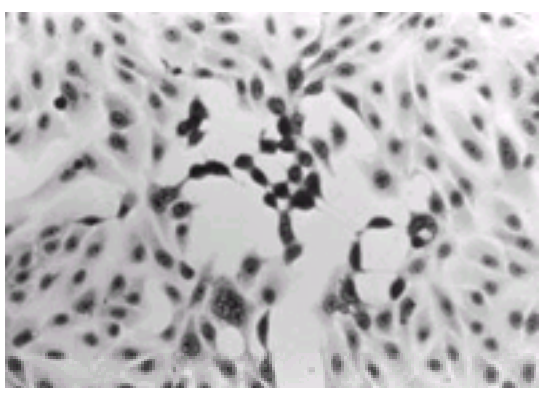

FIG. 1. Cytopathic effect (CPE) resulting from virus infection. The center portion of the figure shows monkey (Vero) cells rounding up and detaching from the substrate after infection with Herpes simplex virus 1 (HSV-1). A normal monolayer of cells is visible around the focus of CPE. The cells were fixed with methanol and stained with Giemsa stain. Micrograph courtesy of M. Kosz-Vnenchak.

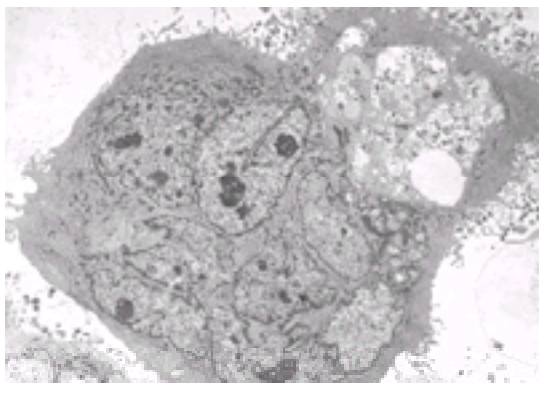

FIG. 2. A syncytium formed by human immunodeficiency virus (HIV) infection of T cells. Electron micrograph courtesy of J. Sodroski.

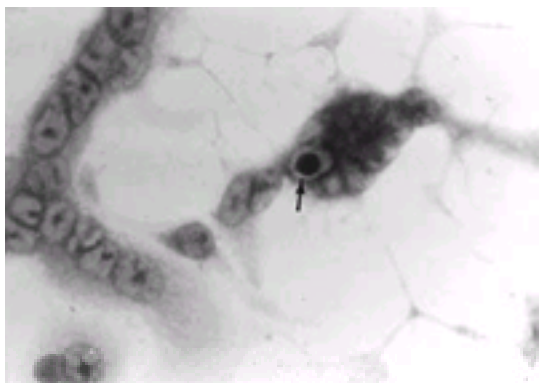

FIG. 3. Inclusion body formation in infected cells. The *arrow* indicates an intranuclear eosinophilic inclusion in a cell infected with HSV-1. The inclusion is surrounded by a clear halo. The cells were stained with hematoxylin and eosin. Micrograph courtesy of M. Kosz-Vnenchak.

The CPE of viruses on cells has also been called cell injury. These terms tend to emphasize the pathology of the host cell; however, from a virologist's point of view, we will see that many of the host-cell alterations by virus infection can now be explained as changes in the host cell that permit necessary steps in viral replication. Thus, many of the CPEs or cell injuries are secondary effects of the virus doing what it needs to do to replicate and are not simply toxic effects of viral gene products on the host cell. Some viral gene products cause toxic effects to the host with no apparent purpose, but as we learn more about the precise mechanisms of virus–cell interactions, many of these effects will likely be explained as aspects of essential steps in viral replication. For example, an adenovirus virion component was shown more than 30 years ago to cause monolayer cells to detach from the culture substrate (87,257), and this was later shown to be caused by the penton base protein (32,328,353). This remained an unexplained toxic effect until it was observed that the penton base protein binds to a_v integrins during adenovirus internalization (368). Thus, penton base protein causes cell detachment by binding through RGD sequences to cell-surface integrins, thereby displacing vitronectin from the integrins. The interaction of vitronectin and integrins is involved in cell attachment and spreading on the culture substrate.

A number of reviews and monographs have examined the various aspects of cytopathology resulting from virus infection (96,175,304). The reader is referred to these sources for detailed discussion and references on these topics. Determining the primary cause of death of a cell resulting from viral infection can be a complex and difficult issue because of the numerous events occurring within the infected cell. It is also apparent now that there are at least two general pathways for cell death: necrosis and apoptosis (programmed cell death). Necrosis involves the death of a cell as a result of physical damage or toxic agents. During necrosis, there is disruption of the mitochondria, swelling of the cell, disruption of organized structure, and lysis. Apoptosis involves cell death in situations controlled by physiologic stimuli during development and hormonal signaling in response to DNA damage. During apoptosis, there is DNA condensation and fragmentation, cell shrinkage, and membrane blebbing. Cell death due to viral infection could result from either mechanism in that viruses may have toxic effects on the host cell, activate programmed cell death pathways, or both.

USE OF HOST CELL MOLECULES AND PROCESSES FOR VIRAL ENTRY

Viruses must enter the host cell to replicate. Therefore, they must cross the cell plasma membrane to gain access to the cellular synthetic machinery in the cytoplasm and, in some cases, the nucleus of the host cell. Virus entry into the host cell has been divided into two events: (a) binding to cell-surface receptors and (b) penetration of the plasma membrane, or entry. These processes are described in detail in Chapter 4; thus, the purpose of this discussion is only to highlight the aspects of the host cell that are utilized during virus entry. Virus particles serve to protect the viral genome during spread from cell to cell or from one host to the next. The lipid envelope and the protein capsid act to protect the genome from nucleolytic attack or chemical reaction in the extracellular environment. As the virus enters a new host cell, these components must be removed to allow the viral genome to be replicated. Thus, viruses have evolved to have a stable, protective particle that can be readily disassembled in a new host cell. For the enveloped virus, cell entry by fusion serves two functions, a means to cross the plasma membrane barrier and a means to remove its outer coat, the envelope.

Viruses utilize a wide variety of cell-surface molecules as their receptors in that they can use protein molecules, carbohydrates, or glycolipids for their initial attachment to cells. Additional molecules or coreceptors may be involved in the fusion event between the viral envelope and the cellular plasma membrane. After binding to its surface receptor, a virus must cross the plasma membrane to replicate. Two general pathways have been defined for virus entry: (a) surface fusion between the viral lipid envelope and the cell plasma membrane and (b) receptor-mediated endocytosis (Fig. 4). Enveloped viruses can gain entry to the cytoplasm by fusion of their lipid envelope with the plasma membrane or endosomal membrane, whereas nonenveloped viruses must use alternative strategies to cross the membrane.

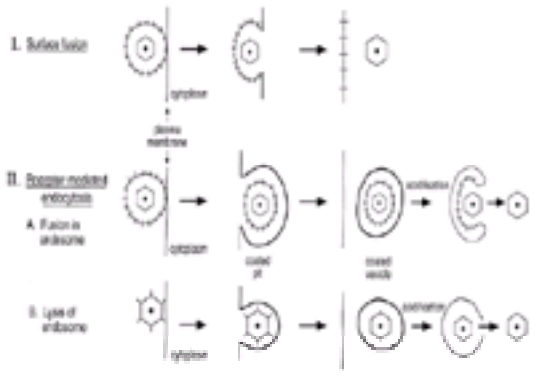

FIG. 4. Pathways for viral entry of the host cell.

Fusion at the surface involves the cellular plasma membrane (see Fig. 4, panel I), and uptake into the cell by endocytosis involves normal endocytotic mechanisms for uptake of molecules into vesicles within cells (see Fig. 4, panel IIA). Cellular proton pumps lower the pH in the endocytotic vesicles, activating membrane fusion between the viral and cellular membranes or activating enzymes that lyse the vesicle (see Fig. 4).

Based on these entry processes, virus–host interactions can be divided into at least seven strategies (Fig. 5). This classification depends on whether the viruses are enveloped or nonenveloped, and in which cell compartment replication and virus assembly or budding takes place. In the case of poliovirus (PV) (see Fig. 5, line 1), the native virion binds to the specific PV receptor and undergoes a receptor-mediated conformational change. The altered (A) particles, which appear to have lost an internal viral protein (VP4), form a pore in the endosome structure, thereby releasing the viral RNA into the cytoplasm. Certain members of the picornavirus group (but not PV) and other nonenveloped RNA viruses, including reovirus, have been shown to require the acidification of endosomes (119).

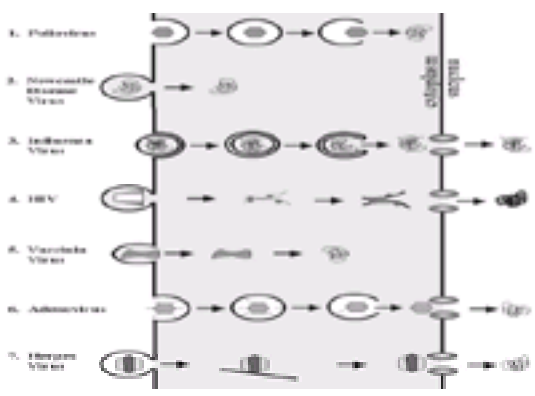

FIG. 5. Entry mechanisms for different classes of viruses. Nonenveloped RNA viruses such as poliovirus (*line 1*) and DNA viruses such as adenovirus (*line 6*) enter the cell by endocytosis at the cytoplasmic membrane. Enveloped RNA or DNA viruses can enter the cell by fusion at the cell membrane [Newcastle disease virus (*line 2*), HIV (*line 4*), vaccinia (*line 5*), and herpes (*line 7*) viruses] or by endocytosis and subsequent fusion of the viral and vesicular membranes [influenza virus (*line 3*)]. Viral replication may ensue in the cytoplasm (*lines 1, 2, 5*), or viral genomes are transported through the nuclear pore into the nucleus (*lines 3, 4, 6, and 7*), where they are replicated. For the sake of clarity, not all viral proteins implicated in entry are shown. Line 7 depicts only one of the two possible routes of HIV egress described in the text.

Even more complex is the entry of adenovirus, another nonenveloped virus (see Fig. 5, line 6). Following attachment to the cell and internalization, the virus undergoes a series of changes in which the viral protein interactions of the capsid are broken down. The acidification of the endosome is a required step in entry as well as the activity of the viral protease (120).

Many enveloped viruses, including paramyxoviruses such as Newcastle disease virus and the Sendai and parainfluenza viruses, fuse directly with the cytoplasmic membrane at neutral pH (see Fig. 5, line 2). For all of these viruses, the first step involves the binding of HN to its sialic acid receptor, which may cause HN to undergo a conformational change. This in turn triggers a conformational change in the F protein, which expresses the fusion peptide and allows it to embed in and perturb the cell membrane. This ultimately leads to the fusion of the cell and viral lipid bilayer (187,363).

A similar mechanism is postulated to mediate entry of retroviruses, including human immunodeficiency virus (HIV) (see Fig. 5, line 4). One of the differences between paramyxoviruses and retroviruses is that the cell binding and fusion activities of the latter are present in the same viral glycoprotein rather than in two different proteins. Also, the entry of HIV has an added degree of complexity in its requirement of coreceptors, which is a defining factor in the fusion process of HIV and target cells (19).

In contrast to the fusion at plasma membranes observed for many enveloped viruses, influenza viruses undergo an acid pH–mediated membrane fusion and entry process (see Fig. 5, line 3). Following binding to sialic acid on the cell surface via the hemagglutinin, the virus–receptor complex is endocytosed and the acidified environment of the endosome triggers a conformational rearrangement of the viral surface protein. The fusion reaction facilitated by the influenza virus hemagglutinin is one of the best characterized processes in virology and it has helped to provide a detailed

understanding of viral entry mechanisms (363).

To promote the release of the influenza viral ribonucleoprotein (vRNP) into the cytoplasm and to conclude the uncoating process, protons in the acidic endosome are pumped into the interior of the virus (see Fig. 5, line 3). The M2 protein in the influenza virion envelope serves as a proton channel (263,332) that exposes the nucleocapsid to low pH conditions, resulting in a conformational change in the M1 protein and its irreversible dissociation from the nucleocapsids (38,210). The antiviral drugs amantadine and rimantadine can block this ion channel and thereby interfere with uncoating of influenza A viruses (but not influenza B viruses).

The alphaherpesviruses make initial contact with the cell by low-affinity binding to glycosaminoglycans (i.e., heparan sulfates; see Fig. 5, line 7). Subsequent interactions with membrane coreceptors facilitate fusion of the viral membrane and the plasma membrane and subsequent entry. In the cytoplasm, the capsid structures undergo a microtubule-mediated transport to the nuclear pore complex (NPC) (322).

TARGETING OF VIRAL GENOMES TO INTRACELLULAR SITES FOR TRANSCRIPTION AND/OR REPLICATION

Once the viral nucleocapsid has gained entry to the cytoplasm, it needs to be targeted to the intracellular site where transcription and/or replication of the viral genome can take place. For most DNA viruses, the viral genome must localize into the nucleus, usually through the nuclear pores. The reverse transcription product of the retrovirus genome also must be transported into the nucleus. In general, trafficking of viral genomes into the cell nucleus involves normal cellular pathways, and, as described later, optimal replication may require targeting to specific sites within the nucleus. In contrast, the poxvirus DNA genome and most RNA virus genomes replicate in the cytoplasm. As we will see, some of these viruses replicate their genome at specific sites within the cytoplasm.

Transport of Viral Genomes into the Cell Nucleus

The cellular mechanisms for transport of macromolecules across the double membranous nuclear envelope involve the recognition of a nuclear localization signal (NLS) on the protein by cellular proteins called importins. This complex then binds to fibrils extending from the NPC and moves to the NPC. Translocation through the nuclear pore involves a complex of the Ran GTP-binding protein and p10 or NTF2.

Most viral nucleocapsids are too large to move through the nuclear pores, so alternative macromolecular complexes containing the viral genome must move through them. Retroviruses, except the lentiviruses, cannot enter the nucleus until mitosis, when the nuclear membrane is disassembled. In contrast, the lentiviruses have an additional gene product, Vpr, that is reported to promote the nuclear entry of the preintegration complex (140). Vpr may interact with importin a (karyopherin a) and the NPC, thus acting as an importin itself (357). Other viral determinants have also been described as contributing to the nuclear uptake of the lentivirus DNA genome. Specifically, the NLSs of the matrix (MA) (95) and of the integrase protein (IN) of HIV-1 (104) have been implicated in the uptake of DNA into the nucleus. However, the significance and contribution of these proteins to the import of HIV DNA into the nucleus remain in debate (98). In fact, HIV-1 nuclear import was recently described as dependent on a cis-acting determinant on the DNA itself. A three-stranded DNA structure, the central DNA flap, was reported to be crucial for nuclear import of the HIV-1 preintegration complex (383).

Influenza virus is unique among RNA viruses in that its RNPs must localize into the nucleus because its transcriptase uses the 5' ends of cellular messenger RNAs (mRNAs) as primers for transcription of the genomic RNAs. The viral RNPs then enter the nucleus through the nuclear pores. All four protein components of the vRNPs (NP, PB1, PB2, and PA) have NLSs and could drive the RNPs into the nucleus (65,243,244,319,360). Nevertheless, the transport of the vRNP depends primarily on the NLSs present in the NP protein. It has been demonstrated that NP binds to the NPI-1 (karyopherin a protein), which then binds karyopherin b, resulting in a docking complex at the nuclear pore (Fig. 6). In studies with permeabilized cells, the influenza virus NP has been shown to be the crucial factor in allowing the import of the incoming RNP from the cytoplasm to the nucleus.

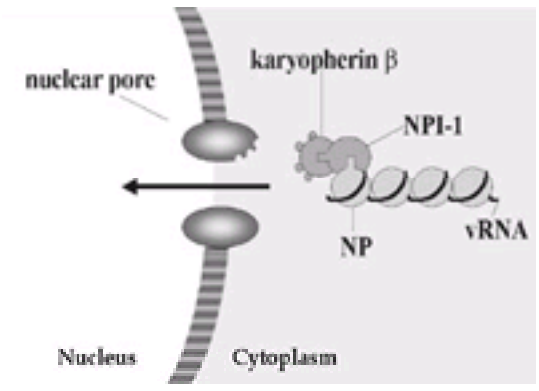

FIG. 6. Influenza viral ribonucleoprotein (RNP) import. Import of influenza viral RNPs is mediated by soluble cellular proteins NPI-1 (karyopherin a) and by karyopherin b. Interaction of the RNP complexes with these cellular factors is mediated by nuclear localization signals (NLSs) located on the viral nucleoprotein (NP). The NLS receptor consists of NPI-1, which binds to the NLS, and karyopherin b, which interacts directly with the proteins of the nuclear pore.

The DNA viruses uncoat their genomic DNA before it enters the nucleus through the nuclear pores. After adenovirus enters the cell by endocytosis and disruption of the endosome, it binds to microtubules that mediate movement to the

nuclear membrane. The adenovirus capsids then bind to the NPC (228), and the viral DNA is transferred into the nucleus in a process that requires metabolic energy (47). The capsid is disassembled during or soon after release of the DNA. Herpesvirus nucleocapsids bind to the dynein motor protein, which transports the nucleocapsid along microtubules to the microtubule-organizing center located near the nucleus (322). These nucleocapsids also bind to the NPC, and the DNA is transferred into the nucleus, but the empty capsid remains at the nuclear pore. Simian virus 40 (SV40) and polyoma viruses are both taken into the cell in endocytotic vesicles, and delivery of the virions from the vesicles to the cytoplasm, the endoplasmic reticulum, and the nucleus has been reported (123,165,217). The precise route of entry of the papovaviruses into the nucleus remains to be defined.

Once within the nucleus, viral DNAs appear to be targeted to specific sites for transcription and possibly initiation of replication. The genomic DNAs of herpes simplex virus (HSV), adenovirus, and SV40 localize to intranuclear sites at the periphery of nuclear domain 10 (ND10) structures, where immediate-early and early gene transcription takes place (155,216). HSV DNA replication proteins localize to these same sites, at which viral DNA synthesis then initiates (216,352). As viral DNA replication progresses, these punctate structures grow into the larger replication compartments in the infected cell nucleus (66). The mechanisms of targeting viral DNA and viral proteins within the cell nucleus remain to be defined, but these viral processes provide some of the best evidence for specific structural organization of the interior of the cell nucleus.

Targeting of Viral Genomes in the Cytoplasm

Much less is known about the localization of viral genomes to specific sites in the cytoplasm for replication. It has long been known that PV replicates on membranes in the cytoplasm (40,62), and other positive-strand RNA viruses also replicate on the cytoplasmic face of internal membranes (13,24,124,308,356,364). In contrast, other viruses such as vesicular stomatitis virus (VSV) and paramyxoviruses replicate on the cytoskeleton (128,131,142).

TAKING OVER THE CELLULAR TRANSCRIPTION MACHINERY

Viral mRNA is needed during replication of viruses to encode viral proteins for replication of the genomic nucleic acid and for virion assembly. In the case of positive-strand RNA viruses, genomic RNA can be used as mRNA directly, so synthesis of viral RNA need not precede initial rounds of translation. However, for negative-strand RNA viruses and DNA viruses, *de novo* synthesis of viral mRNA must occur. If the virion contains an RNA polymerase, then synthesis of viral mRNA may depend on cellular factors to only a limited extent. However, if the virus uses cellular polymerases to synthesize mRNA, specific mechanisms may have evolved to promote transcription of viral DNA or to shift the host-cell RNA polymerase to the transcription of viral DNA. Viruses may even encode a new transcription factor (29).

DNA viruses often exhibit two general phases of transcription during infection of the host cell. First, they must ensure efficient transcription of at least part of their DNA genome immediately upon entry into the cell, a process known as immediate-early or early gene transcription. This has been accomplished by packaging a new polymerase in the virion (poxviruses), packaging a transcriptional adaptor molecule in the virion (HSV), or having a strong transcriptional enhancer upstream from the promoter for the immediate-early genes (e.g., adenovirus, papovaviruses, and cytomegalovirus). Second, they must be capable of efficient transcription of the later viral genes, called early, delayed-early, and late genes. The strategy used by DNA viruses to achieve this last aim is to encode a trans-activator protein as an immediate-early or early viral gene product that activates later viral gene expression after the viral DNA template has increased in number. The following sections describe how viruses inhibit host-cell transcription and ensure efficient immediate-early transcription and later viral gene transcription.

The general process of transcription in eukaryotic cells can be described as follows: Preinitiation complexes are formed by the binding of the general transcription factors, primarily transcription factors II-D (TFII-D), TFII-B, and TFII-I, to the promoter, and this complex then positions RNA polymerase II (pol II) near the start site of transcription. The pol II molecules that initiate transcription are not phosphorylated on the C-terminal domain (CTD), which consists of 52 repeats of a heptapeptide sequence (YSPTSPT). Molecules bound to the CTD also interact with activators bound to the DNA, and these interactions increase the number of initiation events. The general transcription factor TFII-E is bound to pol II and binds TFII-H, which contains DNA helicases and the CDK-activating kinase. The helicase activities open the double-stranded DNA so that it can be transcribed by pol II, and the kinase activity phosphorylates the CTD, which destabilizes the binding of the mediators and activators. Elongation factors, which include capping enzymes, splicing factors, and polyadenylation machinery, can then bind to the CTD and promote elongation. Viruses target several of these steps to inhibit pol II transcription or to divert it to their own advantage.

Inhibition of Cellular Transcription

Infection with many viruses leads to an inhibition of transcription of cellular protein-coding genes by host RNA pol II. However, little is known about how DNA viruses cause an inhibition of host-cell transcription, except for possible competition for RNA pol II and cell transcription factors. For RNA viruses, which do not use host-cell RNA polymerases for their replication, the presumed advantage conferred by this inhibition would be to provide larger pools of ribonucleoside triphosphate pools for viral RNA synthesis. Possible mechanisms for inhibition of host transcription have been formulated for cells infected with the RNA viruses VSV and PV. VSV infection causes rapid inhibition of host RNA synthesis, and this inhibition requires transcription of the viral genome (213,362). Two viral components have been implicated in the process of RNA pol II inhibition. Earlier data suggested that the leader RNA—a short (approximately 50 nucleotides long) transcript synthesized from the 3' end of the virion genome—has this activity (125). However, Dunigan et al. (80) cast doubt on this interpretation because the kinetics of expression of the leader RNA in infected cells did not correlate with the timing of the shut off of host mRNA transcription. The second component of VSV that has been shown to inhibit host transcription is the M (matrix) protein (26). This activity of the M protein appears to be independent of that required for viral assembly at the cytoplasmic membrane (93). The inhibition of RNA pol II–dependent transcription by the VSV M protein is not cell-type specific. Although the mechanism by which the VSV M protein exerts its activity is not well defined, recent data suggest that the TFII-D is altered, resulting in an inhibition of host transcription (379). This

inactivation of TFII-D is probably not mediated through a direct protein–protein interaction, but rather through indirect effects of the VSV M protein in the nucleus. Yet another mechanism of modulation of TFII-D by viruses has been observed. Infection by PV results in the proteolytic cleavage of TATA-binding protein (TBP) through the viral protease 3C (53).

Transcription factor II-D is not unique in being a target for virus-mediated inhibition of transcription. Inhibition of host mRNA transcription may involve cleavage of capped host mRNAs through a viral polymerase complex. It appears that influenza viruses inhibit the expression of host genes at least in part through the viral activity of cap snatching, which is localized to the nucleus of infected cells (182). In addition, it has been reported that the influenza A virus NS1 protein targets the poly(A)-binding protein II (PAB-II) and the cleavage and polyadenylation specificity factor (CPSF) of the cellular 3'-end processing machinery (48,235). When both host activities are inhibited by the viral NS1 protein, this should result in a severe reduction of the level of functional host mRNA transcripts. Whether the induction of a proteolytic activity (301) in influenza virus-infected cells is a third major factor contributing to the remarkable ability of influenza viruses to shut off host transcription remains to be seen.

On the other hand, many RNA viruses—including negative-strand RNA viruses such as Sendai virus—do not appear to have an appreciable effect on host transcription. Although these viruses can cause cytopathic and cytolytic effects, they may do so by mechanisms that do not involve the inhibition of cellular transcription.

Mechanisms to Ensure High-Level Transcription upon Viral Entry

DNA viruses have several general mechanisms to promote efficient transcription of their DNA immediately after entry into cells, and many of these mechanisms involve some form of subversion of the host transcriptional apparatus.

Packaging a Virally Encoded RNA Polymerase in the Virion

Poxviruses contain a double-stranded DNA genome but replicate in the cytoplasm. These viruses have evolved their own transcriptional and DNA replication machinery, allowing these processes to occur in the cytoplasm, almost completely independent of the host cell nucleus. The poxvirus particle contains a virally encoded RNA polymerase (166) capable of transcribing about one half of the viral genome (30,250). The presence of the RNA polymerase in the virion ensures efficient transcription of the viral genome upon entry into the cell.

Packaging a Transcriptional Activator in the Virion

The best-known example of a virion trans-activator is the HSV virion protein 16 (VP16). HSV VP16 (also called aTIF or Vmw65) is assembled into the virion and, when introduced into the cell, becomes a part of a transcriptional activation complex that specifically stimulates viral immediate-early (a) gene expression (41,271). VP16 binds to host-cell proteins (221,272); specifically, it is thought to bind to at least one host factor, the HCF protein complex (180), and this complex binds to the transcription factor Oct-1 bound to DNA (112). One portion of VP16 binds to HCF and Oct-1, whereas another activates transcription (346) by binding to basal transcription factors. Thus, HSV provides for adequate transcription of its immediate-early genes by carrying in its virion a viral trans-activator that binds to a cellular protein, which in turn binds to specific DNA sequences located in immediate-early gene promoters, thereby stimulating transcription and causing increased transcriptional initiation on immediate-early viral gene promoters that contain this specific sequence.

Use of an Enhancer to Ensure High-Level Immediate Transcription

An alternative mechanism by which DNA viruses promote efficient transcription of viral genes immediately after infection is to have an enhancer sequence located upstream of these genes. Enhancers are blocks of DNA sequences containing multiple binding sites for transcription factors acting in synergy to promote high-level transcription from a nearby gene. They act in a position- and orientation-independent manner. Enhancers were, in fact, first identified in viral genomes (12,17). For example, the early transcriptional units of SV40 virus (12,17), polyoma virus (351), human papilloma virus (58), the adenovirus E1A transcriptional unit (139), and the human cytomegalovirus IE1/IE2 transcriptional unit (31,343) all contain enhancers. These enhancer sequences provide for utilization of multiple cellular transcription factors in the transcription of the earliest genes of these viruses immediately after infection.

Mechanisms for Activation of Later Viral Genes

Many DNA viruses encode trans-activators among their earliest gene products. The SV40 large T-antigen stimulates late transcription, both by promoting viral DNA replication and by binding to host-cell transcription factors (127). The adenovirus E1A, the HSV ICP4, and the papilloma virus E2 proteins all serve to stimulate later viral gene transcription by altering the activity of host-cell RNA pol II. The mechanism of trans-activation has been most extensively studied with the adenovirus E1A proteins (23,160). The E1A gene encodes two mRNAs, 13S and 12S, by differential splicing, and much of the trans-activation activity is caused by the 13S gene product. The E1A proteins increase the expression of pol II–transcribed genes (121,152,237) and pol III–transcribed genes (20,109,144). The promoter requirements for E1A trans-activation coincide with basal-level promoter elements (22,238). The E1A proteins do not bind to DNA specifically or efficiently, and there is now considerable evidence that E1A stimulates transcription through various effects on cellular transcription factors (191,316,374). The numerous specific effects of E1A are described in detail in Chapter 67, but the general mechanisms are relevant here. The E1A protein activates transcription by interacting with basal transcription factors, by interacting with activating proteins that bind to upstream promoter and enhancer elements, and by interacting with other regulatory or DNA-binding proteins. E1A protein binds directly to the TBP of TFII-D to activate transcription (145,192), and it also binds to p53 and Dr1 and relieves their repressive effects on transcription (146,179). E1A can also bind to TAF subunits of TFII-D and TFII-F (110,198,218).

E1A can activate transcription of certain genes by binding to the pRb protein, releasing E2F to activate transcription at its

cognate sites (8). E1A can also activate transcription by binding to ATF transcription factors, by binding to YY1 to relieve its repressive effects, and by binding to AP1 to activate transcription. E1A activates pol III transcription of the adenoviral VA genes by increasing the amount of the IIIC2a transcription factor.

Promotion of RNA Polymerase II Elongation on Viral Templates

Transcription of the HIV genome by pol II is very inefficient in the absence of prior viral gene expression. However, when the HIV Tat protein is expressed, it serves as a novel transcription activator in that it regulates elongation rather than initiation of transcription and acts by binding to the nascent transcript rather than to DNA (337). Pol II initiates transcription in the HIV long terminal repeat (LTR) promoter but synthesizes only short RNA products. Tat binds to a specific sequence called the trans-activation response (TAR) element on the nascent RNA molecule and promotes elongation of transcription. This is accomplished by Tat interacting with the cyclin subunit of the positive elongation factor b (P-TEFb) and with TAR. Tat also interacts with cyclin T1 and recruits the cyclin-dependent kinase 9, which phosphorylates the CTD of pol II. This phosphorylation activates pol II for elongation along the proviral genome. Thus, HIV Tat promotes transcription of the HIV genome by a novel mechanism, and elucidation of this mechanism has provided insight into the molecules regulating transcriptional elongation.

VIRUSES CAN REGULATE CELLULAR SIGNAL TRANSDUCTION PATHWAYS

Viruses often modify the host cell signal transduction pathways for their own benefit. The effect may be exerted by the binding of virions to a surface receptor on the cell surface, by a new protein encoded by modifying the activity of a cellular protein, or by a viral protein mimicking a cellular protein. For example, binding of human cytomegalovirus to the cell surface is believed to activate NF-kB (34), which would induce expression of cellular regulatory proteins, some of which would block the interferon response (386). Similarly, binding of Epstein-Barr virus to its receptor, CR2, activates B-cell signaling pathways (286). As a third example of this mechanism, binding of adenovirus to a_v integrins activates mitogen-activated protein (MAP) kinase signaling pathways (236). An example of a different mechanism is human herpesvirus 8, which is associated with Kaposi's sarcoma, encoding a protein, vIRF, that heterodimerizes with the host interferon regulatory factor, IRF-1, and blocks its action in interferon responses (see later).

TAKING OVER THE CELLULAR RNA PROCESSING AND TRANSPORT MACHINERY

RNA splicing and transport to the cytoplasm are cellular pathways often used by viruses for maturation of their mRNA from nucleus to cytoplasm. In fact, the first evidence for RNA splicing came when the adenovirus late mRNAs were mapped on the viral DNA by R-loop hybridization (21,51). These studies showed that adenoviral late mRNAs are encoded by noncontiguous portions of the genome. Splicing of the viral mRNA precursors is accomplished by cellular enzymes recognizing splice donor and acceptor sequences in the viral RNA. However, some viruses use the cellular splicing mechanisms but regulate the extent to which the full-length transcript is spliced. For example, influenza and retroviruses have transcripts that are infrequently spliced (see Chapter 46 and Chapter 57). In cells infected with influenza virus, the viral NS1 and M1 RNAs are spliced to yield the NS2/NEP and M2 mRNAs, respectively, at a frequency of 10% (186,188). Although splicing of the NS1 RNA is inefficient, formation of the spliceosome complex involving the snRNPs U1, U2, U4, U5, and U6 is efficient (2). Thus, the block seems to occur after formation of the spliceosome complex. The block may be mediated by the structure of the RNA itself or by a virus-encoded protein. This appears to be a situation in which virus infection determines the extent of splicing of one of the viral RNAs, thereby regulating the levels of one of its own gene products. The NS1 gene product has been postulated to be responsible for this regulatory event (181). However, a mutant influenza virus lacking the entire NS1 open reading frame (ORF) was shown to have normal levels of splicing of the viral mRNAs (106).

Adenovirus inhibits maturation of cellular mRNA at a different stage. In adenovirus-infected cells, cell transcripts are synthesized and processed but do not accumulate in the cytoplasm (15). The adenoviral E1B-55kD and E4-34kD proteins are required for inhibition of transport of cellular mRNA as well as for promotion of cytoplasmic accumulation of viral mRNA (7,130,262). The E1B and E4 proteins have been observed to localize within and around the nuclear inclusions where viral transcription is believed to occur (245). Thus, these proteins may redistribute a cellular factor involved in mRNA transport. This system may provide important insights into the regulation and specificity of mRNA transport.

A similar observation has been made in cells infected with HSV, in which transport and processing of host-cell RNA is inhibited (359). In HSV-infected cells, small nuclear ribonucleoprotein particles become aggregated (211), and this may be related to impaired transport or splicing. The HSV IE protein ICP27 or IE63 has been reported to be necessary and sufficient for this effect (133,134,259), possibly by affecting phosphorylation of SRP proteins. Only four of the more than 70 HSV genes contain introns. Thus, inhibition of host-cell splicing should contribute to host shutoff, but the mechanisms for specific retention of viral RNA splicing, if any exist, are unknown.

The regulation of RNA maturation may also provide a mechanism for temporal regulation of viral gene expression. HIV encodes several regulatory gene products from spliced mRNAs. One of these regulatory gene products, the *rev* gene product, stimulates the cytoplasmic accumulation of unspliced viral mRNAs that encode the viral structural proteins (90,173,207,294,323,341). The Rev protein seems to promote the export of newly synthesized viral transcripts to the cytoplasm so that the splicing pathway is avoided (208). The Rev protein enters the nucleus using a classic NLS and binds to the viral RNA via a Rev-responsive element (RRE) (61). The Rev-RNA complex is then recognized by the nuclear export machinery. Specifically, it appears that the nuclear export signal (NES) of rev binds to the CRM1 exportin (94), which in turn interacts with members of the nucleoporin family. The NES-mediated interaction of Rev with CRM1 is inhibited by the drug leptomycin B (371). Lentiviruses, including HIV and human T-cell lymphoma virus (HTLV)-1, have developed this mechanism of a viral protein (Rev and Rex, respectively) that binds to viral RNAs and chaperones them through the NPC.

Other retroviruses also transport unspliced or partially spliced viral mRNAs from the nucleus into the cytoplasm.

However, they do this by relying on a different mechanism. Many oncovirus RNAs possess so-called constitutive transport elements (CTEs), which interact directly with the cellular RNA export machinery without the mediation of a rev-like viral protein. Tang et al. (336) showed that a cellular RNA helicase A binds to the CTE from simian retrovirus (SRV)-1 and thus facilitates the export process. Similar CTE-like elements are found in all oncovirus RNAs, and they are thought to allow unspliced (or partially spliced) viral mRNAs to be effectively transported from the nucleus to the cytoplasm. Like the retroviruses, the hepatitis B viruses produce RNA transcripts in the nucleus that possess a cis-acting posttranscriptional regulatory element (PRE) that facilitates interactions with the nuclear export machinery (289).

Influenza viruses face yet another RNA maturation/transport problem. Not only does transcription of viral mRNAs occur in the nucleus, but also the entire genome of the virus replicates in infected cells. In fact, one incoming genome complement (consisting of eight RNA segments) may result in the amplification of up to 100,000 copies, which must then be transported out of the nucleus. The work of many groups now indicates that the newly amplified virion (v) RNAs are not in naked form in the nucleus but exist as complexes with the viral NP and the polymerase (P) proteins. In addition, the presence of the viral M1 protein appears to be necessary for the formation of mature nucleoplasmic vRNP structures destined for export into the cytoplasm (366). Finally, the influenza virus nuclear export protein (NEP) (formerly the NS2 protein), which had no previously assigned function, has been shown to facilitate the nuclear export of virion RNAs by acting as an adaptor between vRNP/M1 complexes and the nuclear export machinery of the cell. NEP interacts with cellular nucleoporins and CRM1 and can functionally replace the effector domain of the HIV-1 Rev protein. A functional domain on the NEP with characteristics of an NES was mapped: It mediates rapid nuclear export when cross-linked to a reporter protein. Microinjection of anti-NEP antibodies into infected cells inhibited nuclear export of vRNPs, suggesting that the Rev-like NEP mediates this process. In the model shown in Figure 7, NEP acts as a protein adaptor molecule bridging influenza vRNPs and the NPCs of infected cells. This novel export mechanism for genomic viral RNA differs from that mediated by Rev for HIV-1 RNA in that the influenza viral NEP does not interact directly with the virion RNA. Rather, the NEP functions as a chaperone for the newly formed influenza virus ribonucleoprotein complexes.

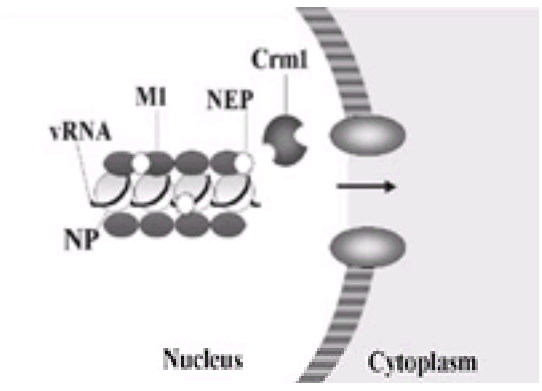

FIG. 7. Influenza viral ribonucleoprotein (RNP) nuclear export. The nuclear export of amplified influenza viral RNP complexes is mediated by the viral nuclear export protein (NEP). NEP interacts with a cellular export factor, Crm1, and with the viral RNPs via the viral matrix (M1) protein. By interacting with the cellular export machinery, NEP mediates the transport of the viral genome from the nucleus to the cytoplasm via the nuclear pore.

Influenza virus intervenes in and takes advantage of the host-cell mRNA maturation pathway in another novel way. Influenza mRNA transcription from the genomic RNA segments occurs in the host cell nucleus (141). Cellular nascent transcripts are cleaved by a virus-encoded endonuclease, and the 5' end of the host transcript is used as a primer for synthesis of viral mRNA from the viral genome (33,266). Thus, influenza virus transcriptional complexes subvert the host mRNA maturation pathway to obtain primer molecules for the viral transcriptional process, and then the virus most likely uses the cellular mRNA export machinery to transport its viral mRNAs out of the nucleus.

TAKING OVER THE TRANSLATIONAL MACHINERY: STRATEGIES FOR OPTIMIZATION OF VIRAL PROTEIN SYNTHESIS AND ANTAGONISM OF CELLULAR PROTEIN SYNTHESIS

Animal viruses utilize the host translational machinery for production of their own proteins. The biochemical pathway of mRNA translation in animal cells is summarized in Figure 8. Several strategies are utilized by viruses to optimize their own protein synthesis, and to antagonize cellular protein synthesis, by altering the host translational machinery. For some virus–cell combinations, the efficiency of mRNA translation (that is, the amount of protein produced per unit of mRNA) varies during the infective process. Multiple biochemical mechanisms account for the translational control observed in virus-infected cells. Many, but not all, are operative at the initiation phase of mRNA translation, the phase generally believed to be rate-limiting.

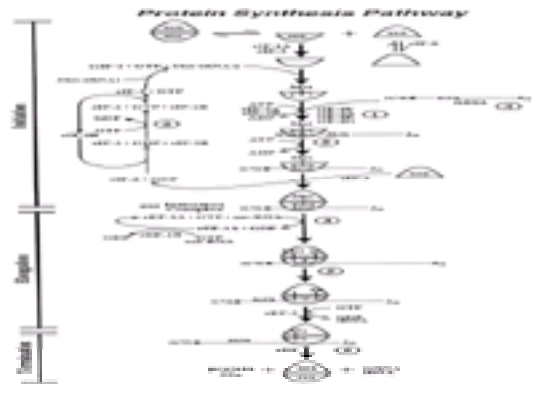

FIG. 8. The cellular protein synthesis pathway and examples of the modification of the process by viruses. **1:** Modification of eIF-4F initiation factor function involved in recruitment of the 40S subunit to mRNA. Picornaviral 2A protease catalyzes cleavage of the eIF-4G component of the eIF-4F complex and also the poly A binding protein; phosphorylation of the eIF-4E component is decreased in cells infected with adenovirus, influenza virus, and encephalomyocarditis virus. **2:** Modification of eIF-2 initiation factor function involved in binding of tRNA to the 40S subunit. Phosphorylation of the a subunit of eIF-2 is antagonized by several viral RNAs (including adenovirus VA1 and Epstein-Barr virus EBER) and proteins [including reovirus s3, vaccinia E3L and K3L, hepatitis C virus NS5A and E2, influenza virus NS1, and Herpes simplex virus (HSV) g34.5 and Us11]. **3:** Elongation factor function is altered in cells infected with human immunodeficiency virus, HSV, and vesicular stomatitis virus. **4:** Host-cell mRNA is degraded in cells infected with HSV, influenza virus, and poxvirus. **5:** Unconventional strategies used for viral protein synthesis include leaky scanning and ribosome shunting during initiation, frameshifting during elongation, and suppression of termination.

Two steps of translation regulated during initiation are the recruitment of the small (40S) ribosomal subunit to mRNA, and the binding of the initiator transfer RNA (met-tRNAi) to the 40S subunit. Most cellular and viral mRNAs found in animal cells possess a 5'-terminal cap [7mG(5')ppp(5')N] structure and a 3'-terminal poly A tail (224,258,293). The 5'-cap and 3'-poly A tail act synergistically to enhance 40S ribosomal subunit recruitment to mRNA during the initiation phase of translation (258,293). Initiation factor eIF-2 functions in a complex with GTP and met-tRNAi to deliver the initiator transfer RNA to the 40S ribosomal subunit (224). The 40S small ribosomal subunit is recruited to the mRNA 5'-cap structure by protein synthesis initiation factor eIF-4F in a process that requires ATP. The eIF-4F is composed of three subunits: eIF-4A (which is an RNA-dependent ATPase), eIF-4E (which interacts directly with the cap structure), and eIF-4G (formerly known as p220). The eIF-4G factor appears to function as a scaffold, binding several initiation factors during the assembly of the mRNA-ribosome initiation complex including eIF-3, -4A, and -4E, as well as the poly(A)-binding protein PABP (224,227,258).

Modification of Initiation Factor Function Involved in Recruitment of the 40S Ribosomal Subunit to mRNA

For many members of the *Picornaviridae* family, infection leads to a rapid and efficient inhibition of cellular protein synthesis. One of the best-characterized examples of the selective shutoff of host cell translation in infected cells is provided by poliovirus. Cellular protein synthesis is drastically reduced within about 1 to 2 h after PV infection (256). PV and other picornavirus mRNAs lack the 5'-cap structure (14,293). Their translation initiation occurs by a cap-independent mechanism, in which the 40S subunit binds directly to an internal ribosome entry site (IRES) located in the 5'-UTR region of the picornavirus RNA (158,255,347). Translation of 5'-capped cellular mRNAs is inhibited at the initiation step in picornavirus-infected cells because of proteolytic inactivation of the eIF-4G subunit of the cap binding protein complex eIF-4F (14). Two functional homologs of the eIF-4G factor have been identified, eIF-4GI and eIF-4GII. Both eIF-4GI and -4GII are cleaved in PV-infected (117) and rhinovirus-infected (333) cells. The cleavage of eIF-4GII coincides with the shutoff of host protein synthesis and, at least for PV and HRV-14, this eIF-4GII cleavage appears to be the rate-limiting step in the shutoff process. The molecular basis for the differential susceptibility of eIF-4GI and -4GII to proteolytic degradation, and the physiologic significance of the differential sensitivity in the context of the virus–host interaction, are not yet fully resolved. In addition, whether this cleavage pattern is general for all picornavirus infections is not yet clearly established. The picornaviral 2A proteases ($2A^{pro}$) catalyze the cleavage of eIF-4GI and II (189). However, eIF-4G is not the only target of picornavirus $2A^{pro}$. For example, Coxsackie virus $2A^{pro}$ also catalyzes the cleavage of PABP (170). This may represent an additional mechanism for shutoff of host protein synthesis in picornavirus-infected cells. The eIF-4G subunit binds PABP and functions in poly(A)-dependent translation (258). Thus, the possibility of a synergistic reduction in host protein synthesis arises in picornavirus-infected cells by cleavage of two different factors by viral 2A proteases, eIF-4G and PABP, that interact during the process of initiation of translation to synergistically enhance 40S ribosomal subunit recruitment to mRNAs.

In group A rotavirus-infected cells, the nonstructural viral protein NSP3A appears to play an important role in the efficient expression of viral proteins by disruption of cellular eIF-4G factor function. NSP3A is bound to the 3' end of viral mRNAs. NSP3A also interacts *in vivo* with the initiation factor eIF-4GI, an association that evicts the cellular PABP from eIF-4GI (264). The translation of the viral mRNA, which is not polyadenylated, thus is enhanced at the expense of the translation of the cellular polyadenylated mRNA by the action of NSP3A. Despite binding on the same site on eIF-4GI, the PABP and NSP3 do not have strong sequence similarities even in their respective eIF-4GI binding domains.

Phosphorylation of the mRNA 5'-cap binding protein eIF-4E correlates with increased translation rates (115,171). Initiation factor eIF-4G recruits MAP kinase–activated protein kinase Mnk1 to phosphorylate eIF-4E (361). The extent of eIF-4E phosphorylation is often decreased in virus-infected cells, including cells infected with adenovirus, influenza virus, PV and, encephalomyocarditis (EMC) virus, but not with Semliki Forest virus or reovirus (172). For example, in adenovirus-infected cells, the vast majority (>95%) of the eIF-4E factor is dephosphorylated. A late adenovirus gene function impairs the phosphorylation of eIF-4E, an effect that coincides with the inhibition of cell protein synthesis. Presumably, the relative amounts of eIF-4E required for efficient translation of the viral and cellular mRNAs differ, possibly because of differences in relative structures among the RNAs. The function of eIF-4E is also regulated through binding to a family of translational repressor proteins designated as 4E-BPs. Binding of 4E-BPs to eIF-4E depends on the phosphorylation status of 4E-BP; thus, the 4E-BPs act in their unphosphorylated form as inhibitors of eIF-4E function. Dephosphorylation of 4E-BP1 following infection with picornaviruses such as PV and EMC virus has been observed, and in the case of EMC virus, the time course of 4E-BP dephosphorylation generally coincides with the shutoff of host protein synthesis (115). Thus, both 4E-BP1 dephosphorylation and eIF-4GII cleavage may contribute to picornavirus-mediated shutoff of host protein synthesis.

Influenza virus infection results in a dramatic shutoff of cellular protein synthesis. This shutoff is concomitant with the selective translation of viral mRNAs, mediated in part by the cellular RNA-binding protein GRSF-1, a positive-acting

translation regulatory factor that binds to specific G-rich sequences within the 5'-UTR region of influenza virus mRNA (251). Influenza virus mRNAs contain the cellular 5'-cap structure and about a dozen nucleotides from host mRNA sequences at their 5' end and are translated by a 5' cap-dependent mechanism. The precise mechanism by which GRSF-1 enhances viral mRNA translation is not yet known, but it may involve interaction with eIF-4G, which is known to interact with the PABP. Dephosphorylation and inactivation of eIF-4E also plays a role in the shutoff of host cell translation in influenza virus–infected cells (115,172). Influenza virus mRNAs display a decreased requirement for eIF-4F relative to host mRNAs, thus allowing them to be translated in the presence of low levels of the cap-binding complex factor.

Modification of Initiation Factor Function Involved in Binding of Initiator Transfer RNA to the 40S Ribosomal Subunit

Initiation factor eIF-2 is composed of three subunits (a, b, and g). Phosphorylation of eIF-2a correlates with decreased translation rates and suppression of cell proliferation (55,298,334), and phosphorylation of the a subunit mediates an inhibition of translation. Among the protein kinases that phosphorylate eIF-2a is the RNA-dependent protein kinase PKR (298). PKR plays a central role in the regulation of protein synthesis in virus-infected cells (55,295,297,298). PKR possesses a double-stranded RNA binding domain that consists of two tandem copies of a conserved dsRNA-binding motif (dsRBM). Binding of structured RNAs of viral origin to the dsRBM motifs occurs in a sequence-independent fashion and leads to either activation or inhibition of kinase enzymatic activity. Following catalytic activation by an RNA-dependent intermolecular autophosphorylation, PKR then catalyzes the phosphorylation of eIF-2a at serine residue 51. This modification of eIF-2a leads to an inhibition of protein synthesis, because it blocks the eIF-2B catalyzed guanine nucleotide exchange reaction of eIF-2:GDP (55,298).

During virus infection, PKR may become activated by viral RNA molecules and then in some cases later inhibited, thereby reversing any PKR kinase–mediated translational block that had been established. The mechanism by which PKR-catalyzed phosphorylation of eIF-2 is antagonized differs among viruses and can involve either RNA or protein modulators. The best-characterized viral RNA inhibitor of PKR is the adenovirus virus–associated VAI RNA (214). VAI RNA is produced in large amounts at late times after infection, and it subsequently impairs activation of PKR and phosphorylation of eIF-2a (214,215). Viral mutants that lack functional VAI RNA multiply poorly because of the dominant effect of virus-specific RNAs that activate PKR, thereby causing an inhibition of late viral protein synthesis. Adenovirus VAI RNA is bound by the dsRBMs of PKR, the same motifs that also bind activator RNAs (219). Modulation of eIF-2a phosphorylation is the primary function of viral VAI RNA, at least in cell culture, because substitution of serine 51 with alanine not only eliminates the phosphorylation site on the eIF-2a substrate but functionally complements the deletion of VA from the virus genome. Epstein-Barr virus–encoded RNAs (EBER), which functionally can substitute for adenovirus VAI RNA *in vivo*, also inhibit PKR activation (55).

The fundamental importance of PKR in the modulation of the translational pattern in virus-infected cells is further demonstrated by the large number of viruses that encode proteins that affect PKR function and subsequently the biochemical activity of initiation factor eIF-2 (102,215,298). The s3 major capsid protein of reovirus was among the first animal virus proteins identified that antagonize PKR function by sequestering activator dsRNAs (299). The preferential translation of reovirus mRNAs and the inhibition of cellular protein synthesis appear to be mediated in part by a s3-dependent mechanism that depends on both the subcellular localization of s3 (303) and the interaction of s3 with µ1c, the other major outer capsid protein of reovirions (380). Proteolytic cleavage of s3 results in enhanced dsRNA binding activity (299), but the association of s3 with µ1c eliminates dsRNA-binding activity and the ability to antagonize PKR function and stimulate protein synthesis (380). Reovirus mRNAs also can activate PKR. For example, the poorly translated S1 mRNA that encodes the minor capsid protein s1 is an efficient activator of PKR, whereas the efficiently translated S4 mRNA that encodes s3 is a poor PKR activator (298,299).

In influenza virus–infected cells, changes in the translational machinery mediated by down-regulation of PKR occur by two different strategies. One involves the viral nonstructural RNA-binding protein NS1 (102,137) and the other involves the activation of the stress-related cellular P58 ^{IPK} inhibitor of PKR (223). NS1, an abundant protein in influenza virus–infected cells, performs several regulatory functions during the viral infective cycle including regulation of synthesis, transport, splicing, and translation of mRNAs. NS1 prevents activation of PKR by binding to dsRNA activators. Temperature-sensitive mutant influenza A viruses with an RNA-binding defective NS1 protein cannot block activation of PKR in infected cells. These ts mutant virus strains exhibit temperature sensitivity in virus protein synthesis at the translational level, in a manner that correlates with increased activation of PKR and phosphorylation of eIF-2a. P58 ^{IPK}, a constitutively expressed cellular protein, inhibits PKR activity through direct protein–protein interaction with PKR. Influenza virus infection activates P58 ^{IPK} by promoting dissociation from its negative regulator, heat-shock protein 40; thus, cellular P58^{IPK} is believed to be targeted with hsp70 to PKR, thereby inhibiting kinase function in influenza virus–infected cells (223). The baculovirus PK2 gene product also inhibits PKR by a dimerization mechanism. Baculovirus PK2 protein is a truncated viral kinase that forms a heteromeric complex with the cellular PKR, thereby blocking kinase autophosphorylation and eIF-2a phosphorylation. Insect cells infected with wild-type baculovirus, but not PK2-deleted virus, exhibit reduced phosphorylation and increased translational activity (72).

Hepatitis C (HCV) and vaccinia viruses provide examples of animal viruses that encode multiple proteins that act synergistically to disrupt PKR function. Two HCV-encoded proteins, the nonstructural protein NS5A (101) and the envelope protein E2 (338), have been reported to prevent activation of PKR. NS5A of HCV interacts with a region of the PKR catalytic domain that also serves as a dimerization domain, thereby disrupting PKR dimerization and PKR-mediated eIF-2a phosphorylation (101). The HCV envelope protein E2 also appears to bind to and inhibit PKR (338). Interestingly, E2 contains a sequence identical to the phosphorylation sites of the PKR kinase and the eIF-2a substrate, but the contribution of E2 as a potential pseudosubstrate to the antagonism of PKR in natural infections is unknown, given the different subcellular localizations expected for PKR and this portion of E2. Inhibition of PKR by the NS5A and E2 proteins of HCV may facilitate survival and proliferation of the infected host, ultimately leading to HCV-associated hepatocellular carcinoma (342).

Vaccinia virus also encodes two gene products, E3L and K3L, that stimulate translation through inhibition of the PKR kinase (55,298). E3L and K3L function by different mechanisms. The viral E3L protein is a dsRNA binding protein that both sequesters dsRNA activators of PKR (314) and interacts directly with the eIF-2a substrate-binding region of PKR (309), thereby down-regulating PKR autoactivation and eIF-2a phosphorylation. The vaccinia K3L protein is a virus-encoded homolog of the eIF-2a substrate. The K3L pseudosubstrate inhibits PKR-catalyzed phosphorylation of eIF-2a (167).

TAR, a highly structured RNA leader element located at the 5' end of all HIV transcripts, activates the PKR kinase (55,206). HIV uses two proteins to counter this TAR-mediated activation of PKR. PKR function is down-regulated by the cellular TAR-RNA binding protein TRBP, which forms an inactive heterodimer with PKR (16), and by the viral trans-activating Tat protein, which inhibits autophosphorylation of PKR and competes with eIF-2 (35). HIV Tat protein also activates transcription factor NF-kB through a process that requires the function of the PKR kinase (69). The relative roles during the HIV infective process of the negative (35) and positive (69) effects of Tat protein on PKR kinase activity are not yet fully resolved.

In HSV-infected cells, the viral g34.5 protein affects phosphatase function, thereby blocking the shutoff of protein synthesis mediated by activated PKR. In the absence of the g34.5 gene, eIF-2a is phosphorylated and protein synthesis is impaired beginning at about 5 hours after infection; however, in the presence of g34.5, protein synthesis continues even though PKR is activated. The g34.5 protein binds to the protein phosphatase 1a and redirects it to dephosphorylate eIF-2aP (138). The HSV U_s11 protein can substitute for the g34.5 protein if it is present early in infection before PKR is activated. U_s11 protein blocks the shutoff of protein synthesis by binding to PKR and blocking the subsequent phosphorylation of eIF-2a (43).

Modification of Elongation Factor Function in Virus-Infected Cells

Viral proteins also interact with the translation elongation factors eEF-1A (formerly known as EF-1a) and eEF-1B (52,64,168,169,376). Factor eEF-1A is the protein synthesis elongation factor involved in the delivery of aminoacylated transfer RNAs to the ribosome A site as an eEF-1A:GTP:aa-tRNA ternary complex during the process of polypeptide chain elongation (see Fig. 8). The matrix MA protein and the $Pr55^{gag}$ polyprotein of HIV-1 both interact with eEF-1A (52). This interaction appears selective, as eEF-1A does not associate with nonlentiviral MA proteins. RNA, possibly the eEF-1A:aminoacyl-tRNA complex, is involved in the eEF-1A interaction with MA/Gag. The interaction between eEF-1A and MA/Gag leads to an inhibition of translation (52). Elongation factor eEF-1B catalyzes the exchange of GDP for GTP on the eEF-1A factor. The second coding exon of the HIV-1 Tat protein interacts with the d subunit of eIF-1B and specifically inhibits cellular translation, without significantly affecting the efficiency of viral translation (376). Interaction of viral proteins with eEF-1 delineates a possible mechanism for HIV-1–mediated modulation of host translation.

In addition to the functions that translation elongation factors play during the process of protein synthesis, the eEF-1B factor also is implicated as a component of the RNA replication complex of VSV (64). Purified VS virions include packaged eEF-1B, which interacts with the L protein of VSV to give an active viral RNA polymerase, in striking similarity to earlier observations made with Qb RNA phage where the bacterial homolog of eEF-1B is involved in viral RNA replication. The eEF-1A factor has been shown to bind RNA genomes of some viruses, for example West Nile virus genomic RNA (28) and tRNA-like structures from plant viral RNAs (113), and, like eEF-1B, it may play a role in RNA replication.

Degradation of Cellular mRNA in Virus-Infected Cells

Degradation of the host mRNA following virus infection provides an additional mechanism to modulate the utilization of ribosomes and factors of the translational machinery for preferential translation of viral mRNAs and also to delay the host response to infection. For example, following infection with HSV, influenza virus, or poxvirus, inhibition of cellular translation occurs and a decrease in intact host-cell mRNA is observed (92,153,242,282). For viruses such as these that have a lytic life cycle, an overall reduction in the level of cellular mRNAs, together with high rates of transcription of a comparatively small number of viral genes, creates an environment where highly abundant viral mRNAs can effectively out-compete relatively more scarce cellular mRNAs for the translational machinery.

An important question concerns the origin of the nuclease(s) that catalyze the degradation of cellular mRNAs in infected cells. Probably the earliest HSV gene that plays a significant role in abating or delaying the host response to infection through degradation of mRNA is U_L41, which encodes a protein that is introduced into the cell in virions at the time of infection (278). Although the HSV virion host shutoff (vhs) activity of the U_L41 protein reduces the synthesis of host proteins by causing the destruction of mRNA, it apparently does so in a nonspecific manner, as the half-lives of both host and viral mRNAs are reduced by the U_L41 protein (185,246,382). U_L41 has the biochemical properties of an RNase, but it has not been unequivocally resolved whether U_L41 alone possesses ribonucleolytic activity or whether an accessory component is required. Interestingly, the U_L41 function of HSV-2 strains generally leads to shutoff of the host more rapidly and completely than that seen with HSV-1 strains (88,91). Because there is no apparent discrimination between host and viral mRNA in the degradative process, in addition to providing a means for inhibiting host translation, it is conceivable that the U_L41 viral function promotes the shutoff of immediate-early and early gene expression in the HSV lytic cycle.

Another cellular RNA degradation pathway that can be activated by viral infection, which is also up-regulated by interferons, is the 2-5A system. Interferon treatment of cells induces a family of RNA-dependent 2'-5' oligoadenylate synthetases (279,297,315). These enzymes synthesize novel 2'-5'-phosphodiester-linked oligoadenylates (2-5A) that function to activate an endoribonuclease, designated as RNase L. The 2-5A dependent RNase L degrades single-stranded RNAs by preferentially cleaving uridylate-rich sequences. Although RNase L is constitutively present in most types of mammalian cells, because the 2-5A effector of the nuclease is unstable, the effects of 2-5A are transient.

Among the small structured viral RNAs that can activate 2-5A synthetase are the EBER-1 RNA of Epstein-Barr virus, the VAI RNA of adenovirus, and the TAR RNA of HIV-1 (71,206,310).

Unconventional Translational Strategies Used for Viral Protein Production

Most viral mRNAs found in the cytoplasm of infected cells possess the following five features: (a) a 5'-terminal cap structure; (b) a 5'-untranslated sequence; (c) an ORF that typically begins with an AUG codon and ends with an UAA, UAG, or UGA codon; (d) a 3'-untranslated sequence; and (e) a poly A tail. Following attachment of the small ribosomal subunit at or near the 5' end of the mRNA and identification of the functional AUG initiation codon by the scanning 40S subunit, the host translational machinery reads the single ORF of the mature viral mRNA to produce a single protein product (178). In addition to this conventional strategy, viruses also utilize a number of other strategies in specific instances to optimize the production of their protein products, strategies that include leaky scanning, ribosome shunting, translational frameshifting, and suppression of termination, as well as posttranscriptional RNA editing to alter the expression of viral genetic information.

Leaky Scanning

Some animal virus families include members that encode functionally polycistronic mRNAs in which translation initiation occurs alternatively at one or more AUG initiation sites in the same mRNA (296). The efficiency of translational initiation at a given AUG codon is thought to be modulated in part by the position and context of the start codon. The leaky scanning model provides a conceptual framework for understanding the process of initiation of translation on those viral mRNAs that utilize more than one AUG codon for initiation (178). According to the model, 40S ribosomal subunits bind at or near the 5' end of the mRNA and advance linearly until an AUG codon in a favorable context is reached, at which point assembly of complete 80S ribosomes takes place and initiation of polypeptide chain synthesis begins. If the 5'-proximal AUG codon is in an optimal context with purines in the –3 and +4 positions relative to the A of the AUG, initiation is typically unique and efficient. If the context is suboptimal, initiation at that codon is inefficient, scanning is leaky, and consequently some of the 40S subunits bypass the first suboptimal AUG and begin initiation at a downstream AUG positioned in a more favorable context. Thus, leaky scanning provides a mechanism by which multiple viral proteins may be produced from a single mRNA.

For several of the polycistronic viral mRNAs, the AUG codon of the 5'-proximal upstream cistron is present in a suboptimal context, whereas the initiation codon of the internal downstream cistron is often, but not always, present in an optimal context (178,296). Thus, some of the scanning 40S ribosomal subunits would presumably “leak” past the suboptimal initiation site and begin translation at the downstream initiation site, which may occur either in the same or different ORF (296). The relative efficiency of utilization of the upstream and downstream initiation codons may be of possible regulatory importance, as certain polycistronic mRNAs appear to be organized so that the relative abundance of the proteins encoded by the different cistrons correlates with the relative strength of the initiation codon.

A number of animal virus genes encode mRNAs in which different in-frame AUG initiation sites are alternatively utilized to generate related forms of a protein that differ in their amino terminal sequences. This is exemplified by the SV40 late 19S mRNAs encoding capsid proteins VP2 and VP3. The less abundant VP2 capsid protein is synthesized from the 5'-proximal AUG, which is in a suboptimal context, and the more abundant VP3 capsid protein is synthesized from an in-frame downstream AUG codon in a more favorable context (307). About 70% of the scanning ribosomes are estimated to bypass the VP2 initiator AUG and instead initiate translation at the downstream VP3 translation start site. Several examples of polycistronic viral mRNAs exist in which two proteins are produced from different, overlapping reading frames, as exemplified by the reovirus S1 mRNA, which encodes the minor capsid protein s1 and the nonstructural protein s1ns, also known as s1S (296). The steady-state distribution of translating ribosomes on reovirus S1 mRNA is not uniform, and interactions may occur between ribosomes in different reading frames. Ribosome pausing occurs at sites of initiation and termination of translation, both for the simple S4 mRNA in which a single ORF is utilized to produce the major capsid protein s3 and for the more complex S1 mRNA, where two overlapping ORFs are utilized. For the polycistronic S1 mRNA, the rate-limiting initiation event at the downstream favorable AUG utilized for ORF2 initiation of s1ns synthesis leads to ribosome stacking and elongation arrest in the upstream s1 ORF1 that encodes the minor capsid attachment protein (78).

Ribosome Shunting

Ribosome shunting refers to the process by which intervening regions of an mRNA are bypassed without scanning by ribosomes during the translation process. Examples in which ribosome shunting or jumping occurs include animal cells infected with adenovirus (381) and papilloma virus (281) and plant cells infected with cauliflower mosaic virus (76). In the case of adenovirus late mRNAs that are preferentially translated during infection, ribosomes are recruited to the 5' end of the tripartite leader RNA and then are translocated to a downstream AUG codon without scanning the intervening sequences (381). The tripartite leader confers preferential translation by reducing the requirement for initiation factor eIF-4F, the rate-limiting cap binding complex. Adenovirus inhibits cell protein synthesis, in part, by inactivating eIF-4F. The tripartite leader directs both 5' linear scanning and ribosome jumping when eIF-4F is abundant, but it exclusively uses the jumping mechanism at late times after infection when the level of eIF-4E phosphorylation is reduced and eIF-4F function is impaired (381).

Translational Frameshifting

In addition to the conventional process of mRNA translation where a single ORF is read by an elongating ribosome, some retroviruses, coronaviruses, toroviruses, arteriviruses, and astroviruses exploit the ability of the host cell ribosomes to shift from one reading frame to another in response to signals programmed by the mRNA (36,89). The elongating ribosome typically slips backward by one nucleotide (–1), resulting in a change in reading frame. For many retroviruses, production of the polymerase gene products occurs following a –1 frameshift during translation. The *pol* gene partially overlaps and is in the –1 reading frame with respect to the upstream *gag* gene. As exemplified by Rous sarcoma virus

(157) and HIV (156), a small fraction of the ribosomes (about 5%) shift reading frames during translation to produce a Gag-Pol fusion protein, whereas the majority of ribosomes (about 95%) terminate at the end of the *gag* ORF. This provides a mechanism for viruses to synthesize, from a single mRNA, relatively large amounts of an upstream product (e.g., Gag structural proteins) compared to the downstream product (e.g., reverse transcriptase). Two cis-acting viral mRNA signals are involved in the process of –1 ribosome frameshifting: a slippery sequence where the ribosome changes reading frame, and a stimulatory structure located downstream (36,89). Pseudoknot structures involved in frameshifting of various retroviral RNAs and infectious bronchitis coronavirus RNA are believed to impose a thermodynamic barrier to elongating ribosomes, resulting in ribosome pausing, which increases the opportunity that ribosome-bound tRNAs will slip into the –1 reading frame at the slippery sequence because of specific interaction between the viral mRNA and host protein synthesizing machinery (49,233). Small amounts of HSV thymidine kinase enzyme can be produced by drug-resistant strains utilizing a translational recoding mechanism of +1 (or –2) frameshifting (147). Thus, this provides a general mechanism whereby specific viral RNA sequences cause ribosomal slippage so that small amounts of an essential viral protein can be synthesized.

Suppression of Translational Termination

The UAG, UGA, and UAA codons typically specify translation termination. However, termination can sometimes be leaky. Expression of limited amounts of a viral protein can be achieved by suppression of a stop codon, resulting in the synthesis of a carboxy-terminally extended protein. For certain retroviruses, as exemplified by murine leukemia viruses (MuLV), this is the mechanism used to express the *pol* gene as a Gag-Pol fusion protein by reading through the *gag* stop codon to produce viral reverse transcriptase (261). The amber UAG codon of MuLV is decoded as glutamine, thus allowing read-through to permit expression of downstream Pol ORF sequences at about 5% to 10% efficiency (4,261). Suppression of translational termination is also observed with some alphaviruses, as exemplified by Sindbis virus, where read-through of an opal UGA codon occurs to produce nsp4, a nonstructural protein required for viral RNA polymerase activity (195). No cases of read-through are yet known for UAA, a commonly used translation termination codon. Like frameshifting, the suppression of translational termination by ribosome read-through requires cis-acting sequences on the viral mRNA to interact with the host translational machinery to make the nonsense stop codon an inefficient terminator, and thus subject to read-through to allow the regulated expression of downstream viral ORFs (4,195).

Posttranscriptional RNA Editing

RNA editing is a posttranscriptional process by which RNA transcripts are covalently modified in a manner that potentially alters the function of the encoded product. Site-selective conversion of adenosine to inosine represents one such editing process, catalyzed by RNA-specific adenosine deaminases (ADAR). This A-to-I RNA editing modifies the expression of genetic information by changing codons, as inosine is read as guanine instead of adenine by ribosomes and polymerases. Two types of A-to-I editing processes have been described in viral RNAs. First, modifications characteristic of adenosine deamination are found at multiple sites, as exemplified by the extensive adenosine modifications present on the viral antisense RNA late in polyoma virus infection (183) and by the biased hypermutations observed in negative-stranded RNA virus genomes during lytic and persistent infections, as in the case of measles virus (44). Second, highly site-specific A-to-I modifications have also been identified at one or a few sites in certain viral and cellular RNA transcripts, as demonstrated by the editing of hepatitis delta virus (HDV) RNA (270) and pre-mRNAs encoding the glutamate GluR and 5HT-2c serotonin receptor channel subunits (200), respectively. Editing of these viral and cellular RNAs results in codon changes and thus mRNAs that encode protein products with altered functional activities. In the case of HDV infections, RNA editing plays an essential role in the production of two forms of hepatitis delta antigen (HDAg) from the same ORF. A-to-I editing at adenosine 1012 of HDV antigenomic RNA has the effect of converting an amber UAG termination codon to a UGG tryptophan codon in the mRNA (270), thereby extending the ORF. The two HDAg proteins encoded by the ORF have different functions in the viral life cycle. Small HDAg is required for RNA replication, and large HDAg, which inhibits replication, is required for packaging of viral RNA. Interestingly, the human ADAR gene is regulated by two promoters, one of which is interferon inducible and one of which is not inducible (111). The possible roles of RNA editing by ADAR in viral pathogenesis are numerous but so far have not yet been studied extensively.

NUCLEAR LOCALIZATION OF DNA REPLICATION AND ASSEMBLY PROTEINS

During viral infection, proteins encoded by certain viruses must localize from the cytoplasm into the nucleus to replicate viral genomes, to regulate viral transcription and RNA processing, and to assemble progeny viral capsids. In general, viral proteins use cellular machinery for localization through the nuclear pores into the nucleus (reviewed in ref. 366). In fact, the first NLS was identified as PKKKRKV in the SV40 large T-antigen (162). The importin a/b complex binds to this sequence and attaches to fibrils that extend to the nuclear pore. Once at the nuclear pore, the complex binds to the nucleoporins and the protein is transported into the nucleus. Some proteins, such as the SV40 large T-antigen, can localize to the nuclear compartment independently of other viral proteins and assemble into higher-order complexes after they enter the nucleus. Other proteins, such as the HSV helicase–primase complex (209) or capsid proteins (241,285), must assemble into a complex in the cytoplasm prior to localization into the nucleus.

TAKING OVER THE CELLULAR DNA REPLICATION MACHINERY

Inhibition of Host-Cell DNA Replication

Both RNA and DNA viruses cause the inhibition of host-cell DNA synthesis. There are several possible reasons for viral inhibition of cell DNA synthesis: (a) to provide precursors for viral DNA synthesis, (b) to provide host-cell structures and/or replication proteins for viral DNA synthesis, or (c) as a secondary effect of inhibiting cellular protein synthesis. The possible mechanisms by which virus infection might inhibit cellular DNA synthesis are discussed individually.

A Secondary Effect of Inhibiting Cell Protein Synthesis

There appears to be a small pool of an essential cell DNA replication protein (or proteins), as suggested by the decrease in rate of DNA chain growth seen within minutes after inhibition of protein synthesis (265,329). It has been proposed that some viruses, such as the herpesviruses, inhibit cellular DNA synthesis as a consequence of inhibiting cellular protein synthesis (164), and indeed, the two shutoff functions do map together on the HSV genome (91). HSV and adenovirus DNA synthesis do not require the limiting cellular factor, or the factor is not limiting in infected cells because their DNA synthesis continues independently of whether protein synthesis is ongoing or not (148,287).

Displacement of Cellular DNA from Its Normal Site of Replication

Herpesvirus infection has been variously reported to displace cellular DNA from the nuclear membrane (240) or to cause the displacement of cellular chromatin to the periphery of the nucleus (63,305). In either case, the cell DNA could be displaced from its normal site for replication because cell DNA synthesis has been reported to occur on the “nuclear cage” (220), or the nuclear matrix (18). The exposed sites on the nuclear matrix may provide a structural framework for viral DNA replication and late transcription (174).

Recruitment of Cell DNA Replication Proteins to Viral Structures

Several studies have shown that HSV infection leads to a redistribution of the host-cell DNA replication apparatus (66,369). This type of event could serve the dual function of providing cellular factors for viral DNA replication and inhibiting cell DNA synthesis, thereby reserving deoxynucleoside triphosphates for viral DNA synthesis.

Degradation of Cellular DNA

Infection by vaccinia virus leads rapidly to a marked inhibition of cell DNA synthesis. A virion-associated DNase enters the host cell nucleus and acts on single-stranded DNA (ssDNA) (267,268). This inhibition is mediated by the action of a virion component on the host cell.

Mechanisms by Which DNA Viruses Ensure the Availability of a DNA Replication Apparatus

DNA viruses need a replication apparatus for amplification of their genomic nucleic acid. Although the host-cell enzymes may be used for DNA replication, they may not always be available for use by the virus. Thus, several strategies have evolved to ensure the availability of DNA replication machinery. These range from encoding an entirely new replication apparatus to inducing host cell DNA synthesis to allow the virus to use the cellular machinery.

Viruses Can Encode a New Replication Apparatus

The poxviruses replicate entirely in the cytoplasm. Indeed, poxviral DNA synthesis can occur in enucleated cells. Therefore, they must encode all (or nearly all) of the proteins needed for replication of their DNA in the cytoplasm. Similarly, retrovirions contain an enzyme capable of copying the genomic RNA into DNA. This step is not possible in cells without the virion enzyme, because a cellular reverse transcriptase is not available to copy the viral RNA. For these viruses, DNA synthesis is usually not restricted in different cells, because the enzymes are virally encoded.

The herpesviruses encode several proteins that form a major part of the replication complex. For example, HSV encodes seven viral proteins required for and directly involved in viral DNA replication (46,373). In addition, HSV encodes several other enzymes involved in providing deoxynucleoside triphosphate precursors for viral DNA synthesis: thymidine kinase, ribonucleotide reductase, and dUTPase. HSV replicates in the resting neuron and has apparently evolved to encode these DNA replication proteins because they are expressed at low levels in resting neurons. Some cellular proteins may be involved in HSV DNA replication. Although the identity and role of specific cell proteins in HSV DNA replication have not been defined, the cellular DNA replication machinery is redistributed after HSV infection so as to co-localize with viral proteins in the cell nucleus (66). HSV DNA replication proteins also bind to the nuclear matrix (274), so cellular proteins may be required to anchor DNA replication complexes and thereby promote optimal HSV DNA synthesis. However, HSV blocks cells from progressing into S phase (66), so any cellular proteins required for HSV DNA synthesis may be present in non-S phase cells.

Viruses Can Induce Cellular DNA Synthesis

Some viruses, especially the DNA tumor viruses, rely on the host-cell DNA replication machinery, and to ensure its availability, they induce S phase in their host cells if they are not cycling or are in G0 phase. SV40 and polyoma viruses encode one protein, large T-antigen, which essentially inserts itself into the host-cell replication complex and directs it to replicate viral DNA. The SV40 large T-antigen (a) binds to the SV40 DNA sequences that serve as the origin of DNA replication (344), (b) interacts with the cellular a-DNA polymerase (318), and (c) acts as a helicase (324). Through these and possibly other functions, T antigen promotes replication of the SV40 chromosome. T antigen could be viewed as an origin-binding protein that substitutes for an analogous cellular protein. The specific interaction of T antigen with host proteins is apparent in other ways. SV40 DNA replication can occur in extracts prepared from only certain cell types (196), and the interaction between T antigen and the a polymerase–primase complex seems to define or play a role in defining this specificity (230). Thus, the permissivity of a cell for viral growth may be defined by the ability of a viral DNA replication protein to interact with the cellular DNA replication apparatus.

However, the levels of several critical components of the cellular DNA replication apparatus are limiting, except during S phase. Thus, the host DNA replication machinery would not be available at all stages of the cell cycle. Polyomaviruses have long been known to induce S phase in resting (G0) cells (79), and the mechanisms for this effect are now understood. SV40 T antigen forms complexes with pRb and related proteins (68), releasing transcription factors of the E2F family that are important for expression of cellular DNA replication and cell cycle proteins such as c-fos, c-myc, DNA pol a, dihydrofolate reductase, thymidine kinase, thymidylate synthetase, and cdc-2 (239). Thus, activation of E2F

contributes to the preparation of the host cell for viral DNA replication.

Adenovirus encodes a DNA polymerase, a terminal protein, and an ssDNA-binding protein for viral DNA replication (see Chapter 67), but the remainder of the replication proteins and nucleotide metabolism enzymes are host-cell gene products. Thus, adenovirus also induces its host cell to enter S phase. Like SV40 T-antigen, the E1A proteins bind to pRb (367), releasing E2F and activating transcription of cell cycle genes. It is also becoming clear that adenovirus infection disrupts a number of protein complexes that are involved in regulation of the cell cycle. The adenovirus E1B-55K protein binds to the cellular p53 protein (302), inactivating the G1 cell cycle block imposed by p53. This also contributes to activation of the host-cell S phase and the optimal conditions for viral DNA synthesis.

Maintenance of Viral DNA Within the Host Cell

Viruses whose DNA genomes persist within growing cells have evolved mechanisms for their genomes to be maintained stably in these cells via association with cellular chromosomes. There are two types of mechanisms by which viral DNA is stably maintained within the host cell in association with chromosomes. First, the viral DNA can be integrated into the cellular chromosome and propagated as part of the cellular DNA. For example, retrovirus DNA is integrated into the cellular genome after its synthesis by the reverse transcriptase (see Chapter 58). Integration is promoted by the viral integrase function, but host functions can modulate the process. For example, the mouse Fv-1 gene mediates a postpenetration block to MuLV DNA integration (135,197,330). Thus, this host gene can define the host range of MuLV in mouse cells.

Second, viral DNA can be maintained as an extrachromosomal circular molecule in the infected cell. For example, Epstein-Barr virus (EBV) DNA is maintained in latently infected B lymphocytes as an episomal molecule (1) and requires a specific sequence, oriP, for replication and maintenance in latently infected B cells (377). Epstein-Barr nuclear antigen 1, EBNA-1, is also required for EBV DNA maintenance (377). Although EBNA-1 was thought to serve as an origin-binding protein, recent studies have shown that it plays a role in maintenance of the DNA rather than in its synthesis (3). EBNA-1 binds to specific sequences on viral DNA (277) and also binds to cellular chromosomes (126). Thus, EBNA-1 is thought to maintain EBV DNA in growing B cells by linking the viral DNA to cellular chromosomes. The related gammaherpesvirus, human herpesvirus-8 or Kaposi's sarcoma-associated herpesvirus also encodes a latency-associated nuclear antigen that tethers viral DNA to cellular chromosomes (11,56). Similarly, the papillomavirus genome contains sequences (called plasmid maintenance sequences) needed to maintain and replicate the DNA as an extrachromosomal element (149,203). Long-term maintenance of these plasmid genomes depends on attachment to host chromosomes, which is mediated by the viral E2 protein (151,193,317). In addition, these extrachromosomal elements appear to be subject to the normal copy number control existing in the normal cell because there is a constant number of episomal copies of these viral DNA molecules per cell as the cells divide. In contrast, HSV DNA can apparently persist during latent infection of neurons in a nonreplicating form because the host cell is not dividing.

ASSEMBLY OF FACTORIES FOR NUCLEIC ACID REPLICATION AND VIRION ASSEMBLY

Viral replication complexes, transcriptional complexes, replicative and assembly intermediates, and nucleocapsids and virions often accumulate in specific locations within the host cell and form structures called factories or inclusion bodies. The location of these structures obviously reflects the site of replication of a given virus. They may form in the nucleus, as do the inclusion bodies or factories in cells infected with herpesviruses (Fig. 9) or adenoviruses, or in the cytoplasm, as do the factories in reovirus-infected (Fig. 10) or poxvirus-infected cells or the Negri bodies in rabies virus–infected cells. Inclusion bodies have been useful in diagnostic virology because areas of altered staining can be detected at specific locations in the cell with specific staining properties, either basophilic or acidophilic, characteristic of individual groups of viruses. Crystalline arrays of capsids or nucleocapsids may accumulate in these inclusions (see Fig. 10). The assembly of these new structures in the cell may alter or displace host-cell components and lead to one form of CPE.

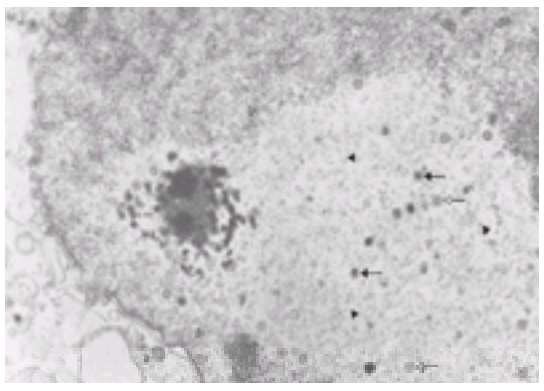

FIG. 9. Electron microscope visualization of nuclear inclusion areas. The *filled triangles* denote the electron-translucent nuclear inclusion area in a human HEp-2 cell infected with HSV-1. The *filled arrows* indicate full capsids, and the *unfilled arrows* indicate empty capsids. The *unfilled triangles* indicate host chromatin compressed to the periphery of the nucleus, apparently by the nuclear inclusion. Micrograph courtesy of D. Furlong and B. Roizman.

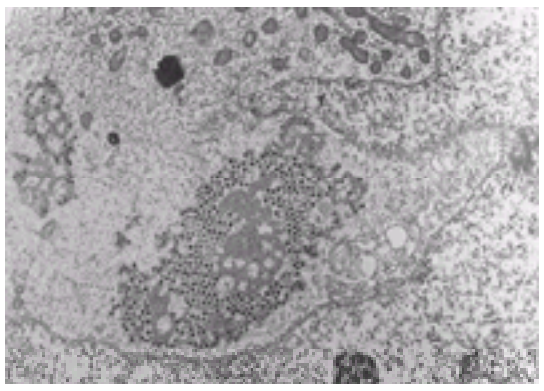

FIG. 10. Electron microscope visualization of cytoplasmic “factories” in a cell infected with reovirus. Micrograph courtesy of B. Fields.

Much as other viral proteins have provided probes for important cell biologic questions, HSV DNA replication proteins and their localization to intranuclear inclusions have provided a situation in which to study intranuclear localization mechanisms. Initial studies characterized the nuclear inclusions of herpesvirus-infected cells and their molecular components. Electron microscopy (EM) of herpesvirus-infected cells showed electron-translucent intranuclear inclusions surrounded by marginated and compacted cell chromatin (63) (see Fig. 9). Light microscopic observation of nuclear inclusions shows an hourglass appearance of the inclusions at early times and an eosinophilic staining at later times (232,321) (see Fig. 3). Immunofluorescence experiments using antibodies specific for HSV DNA replication proteins have shown that viral DNA replication proteins accumulate in intranuclear foci by 3 hours postinfection and that these foci enlarge into globular nuclear structures called replication compartments (Fig. 11) (66,274). The replication compartments are likely to be equivalent to (a) the translucent nuclear inclusions seen by EM (see Fig. 9) and (b) the early nuclear inclusions seen by light microscopy.

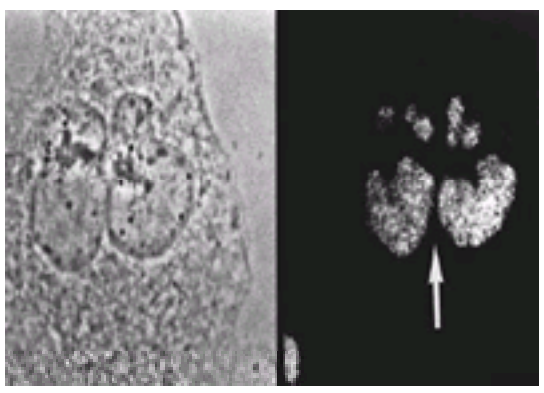

FIG. 11. Immunofluorescence detection of HSV replication compartments in binucleate cells. Micrograph courtesy of A. de Bruyn Kops.

These replication compartments are located in the interior of the nucleus as shown by EM (63,306) (see Fig. 9) and by confocal microscopy (67). Bromodeoxyuridine pulse labeling followed by immunofluorescence detection of bromodeoxyuridine-substituted DNA has shown that viral DNA synthesis occurs in the replication compartments (66). This technique allows the determination of the cellular location of DNA synthesis. Similarly, *in situ* hybridization with a viral DNA probe has shown that progeny HSV DNA accumulates in replication compartments (Fig. 12). The initial sites of formation of these compartments most likely takes place at specific locations in the nucleus defined by the availability of host-cell proteins or structures (67), near ND10 sites in the nucleus (216,352). The accumulation of progeny DNA, the probable template for late gene transcription and the viral transcriptional trans-activator protein ICP4 (177,276), pol II (283), and pulse-labeled viral RNA (260) in replication compartments argue that late gene transcription takes place in the replication compartments. Thus, late gene transcription is likely compartmentalized in infected cell–specific nuclear structures. Empty capsids appear to be assembled around dense bodies or in the inclusions within the infected cell nucleus, whereas encapsidation of viral DNA appears to occur within the inclusion body itself (see Fig. 9). Therefore, these intranuclear compartments in HSV-infected cells are sites of viral DNA replication, late gene transcription, and nucleocapsid assembly.

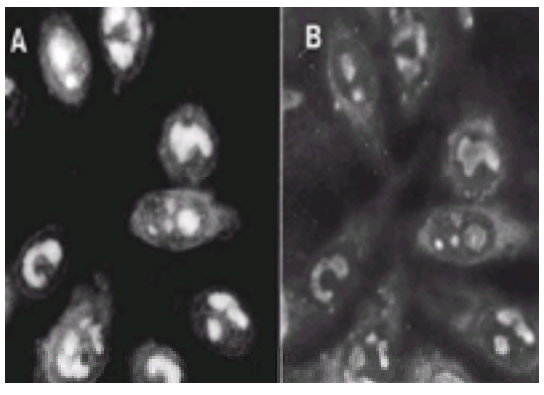

FIG. 12. *In situ* hybridization detection of the location of viral nucleic acids in infected cells. Monkey cells infected with

HSV-1 were fixed in formaldehyde, permeabilized in acetone, and incubated with biotin-labeled HSV DNA. The cultures were heated to denature the cellular DNA and the probe, and the culture and solution were allowed to cool. The cells were then reacted with mouse anti-ICP4 monoclonal antibody followed by rhodamine-conjugated goat antimouse immunoglobulin antibody and fluorescein-conjugated avidin. **A:** Rhodamine fluorescence showing the location of the HSV trans-activator protein ICP4. **B:** Fluorescein fluorescence showing the location of HSV DNA in the infected cells. Micrograph courtesy of S. Rice.

Studies of the nuclear inclusions in cells infected with HSV have raised several important cell biologic questions related to the assembly of nuclear complexes and structures and compartmentalization of nuclear metabolic processes. First, what signals target viral and cellular proteins to these compartments? Intranuclear localization mechanisms have not been studied extensively. Both viral and host proteins localize to these compartments. The HSV replication proteins, including the ICP8 DNA-binding protein, DNA polymerase, polymerase accessory protein, and helicase-primase complex (39,66,116,199,202,274) localize to compartments. These proteins undergo multiple interactions with each other; thus, their targeting could involve binding to other proteins in the replication complex, binding to cellular proteins, or other targeting mechanisms. Cellular proteins, including pRb, p53, and DNA pol a (369) and SV40 large T-antigen (378), also localize to replication compartments in HSV-infected cells.

Second, is there a defined assembly pathway for viral protein complexes in these compartments? Experiments examining protein localization in cells infected with mutants defective for each of the HSV DNA replication proteins have shown that there is a functional order for assembly of HSV DNA replication proteins into nuclear structures (199). The helicase-primase complex of U_L8, U_L42, and U_L52 proteins, the U_L9 origin-binding protein, and the ICP8 ssDNA-binding proteins are the minimal HSV proteins needed to assemble into nuclear structures. The polymerase-U_L42 complex then joins the structure.

Third, is there a receptor on the nuclear framework that anchors viral protein complexes? No cellular molecule has been identified as a receptor for the HSV replication proteins, and nuclear receptors remain an important problem in the targeting of nuclear proteins. One of the few situations where saturable binding of a viral protein to the nuclear matrix has been demonstrated is with the adenovirus preterminal protein (97). The adenoviral preterminal protein interacts with the nuclear matrix, specifically with CAD, a pyrimidine biosynthesis enzyme (5). The identification of a nuclear molecule or receptor that anchors specific proteins in the cell nucleus remains as an important confirmation of the concept of the nuclear matrix, a nuclear structure believed to consist of nuclear lamins under the nuclear envelope and internal fibrous elements.

Fourth, what defines the intranuclear location at which compartments are formed? In binucleate cells infected with HSV, replication compartments often show nearly identical patterns of compartments along a twofold axis of symmetry between many of the sister nuclei (see Fig. 10) (67). Therefore, the location of HSV replication compartments is defined by preexisting nuclear architecture, probably the internal nuclear matrix or receptors thereon. Although the parental HSV genome and DNA replication proteins localize to sites near ND10 sites in the nucleus (216,352), the precise molecular sites of localization remain to be defined.

Nuclear viral inclusions in adenovirus-infected cells (280,331,358) are also sites of viral DNA synthesis and accumulation of progeny DNA (37,212,358) and probably late viral transcription (212,372). Adenoviral inclusions may have an added level of complexity over the HSV nuclear inclusions in that the E1B-55kD/E4-34kD complex of proteins is located in and around the inclusions and is believed to recruit critical components of the host-cell RNA transport process to the sites of late viral RNA synthesis (245).

USE OF THE HOST CELL FOR MATURATION AND BUDDING

As described previously, viruses use the host-cell translational machinery to synthesize the structural proteins for progeny virus production. In addition, viruses may use a cellular polymerase or a virus-encoded polymerase to replicate their genomes. In addition, viruses use cellular proteases, membranes, glycosylation machinery, kinases, and chaperone proteins for their protein maturation (175). Because the sites of viral genome replication—as well as of maturation in general—are different from those where viral protein synthesis takes place, the intracellular trafficking of viral components is crucial for infectious particle formation. Furthermore, it appears that structurally intact cells are essential for efficient virus replication.

The site of assembly and mechanism of progeny virus release from the infected cell depends on the structure of the virus (Fig. 13). Enveloped viruses exit from the infected cell surface either by budding through the plasma membrane (Fig. 14) or by fusion of secretory vesicles containing virus particles with the plasma membrane (326). Thus, nucleocapsids can bud through the plasma membrane (e.g., orthomyxoviruses, paramyxoviruses, rhabdoviruses, and retroviruses), directly producing extracellular virions, or through internal membranes such as the endoplasmic reticulum (rotaviruses) and/or Golgi apparatus (coronaviruses and bunyaviruses) or inner nuclear membrane (herpesviruses).

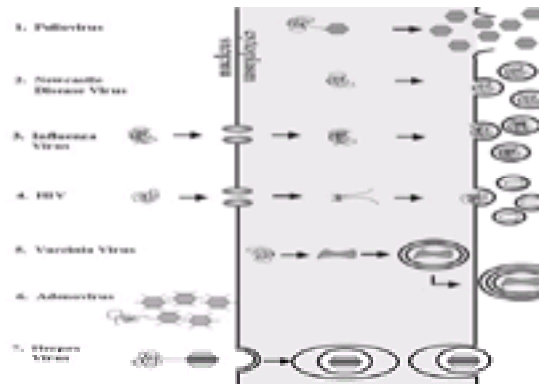

FIG. 13. Pathways of exit from cells for different viruses. Nonenveloped RNA viruses such as poliovirus (*line 1*) and DNA viruses such as adenovirus (*line 6*) leave the cell upon cell lysis. Enveloped viruses that replicate in the cytoplasm such as Newcastle disease virus (*line 2*) exit the cell by budding from the cytoplasmic membrane. Influenza viruses (*line 3*) also leave the cytoplasm in this manner, but the amplified viral ribonucleoprotein (RNP) complexes must first exit the nucleus via the nuclear pore. The amplified genome of HIV (*line 4*) exits the nucleus in a manner similar to influenza virus via the nuclear pore, and the virus buds from the cytoplasmic membrane. Vaccinia virus (*line 5*) replicates in the cytoplasm where it acquires its membrane(s), and in general it remains cell associated. Herpes viruses (*line 7*) acquire envelopes as they bud through the inner membrane of the nuclear envelope. The viral particles are transported within intracellular vesicles to the cytoplasmic membrane, where fusion of the vesicular and cytoplasmic membranes allows release of the virus from the cell. For the sake of clarity, not all viral proteins implicated in exit are shown.

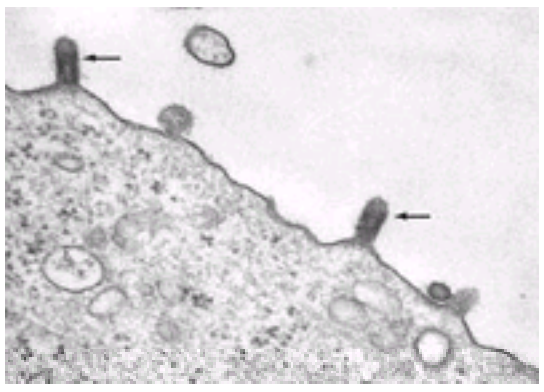

FIG. 14. Electron micrograph of enveloped virus particles budding from the infected cell surface. The *arrows* indicate VSV particles budding from the surface plasma membrane of infected Chinese hamster ovary cells.

Assembly Within the Cytoplasm

Some viruses, including the picornaviruses, replicate exclusively in the cytoplasm, and infectious progeny virus particles can be produced in enucleated cells (85,269). PV, for example, shows a cytoplasmic localization of viral protein synthesis, of viral RNA replication, and of particle assembly. Perhaps this virus is the most “host independent,” because its replication appears to rely the least on trafficking within an intact cell. In a landmark paper (226), Wimmer's group showed that an extract of uninfected HeLa cells permitted cell-free translation of naked PV RNA, synthesis of virion RNA, and assembly of infectious PV particles. However, the successful formation of infectious particles required the presence of membranes in the HeLa cell extract (59) and possibly the presence of chaperones such as heat-shock protein 70 (204). Although the efficiency of the cell-free virus replication was low, this experiment revealed that even such a complex process as viral RNA replication and PV encapsidation may be achieved outside a living cell. It has been generally assumed that unenveloped viruses are released by lysis of the cells. However, PV is released almost exclusively from the apical surface of polarized human intestinal epithelial cells (350). Thus, there may be cellular mechanisms used for viruses for active release from the cytoplasm in a polarized fashion (see Fig. 13, line 1).

Assembly Within the Nucleus

The prototypic viruses restricted to assembly within the nucleus are adenovirus and SV40. For adenovirus, synthesis and subsequent transport of the hexon and penton components into the nucleus are essential for virus formation. The transport from cytoplasm to nucleus involves the presence of NLSs on the adenoviral proteins and is accompanied (or followed) by the assembly of the viral components. Although the presence of a viral nonstructural component (the L1 52/55kD protein) appears to be required for encapsidation (129), little is known about which proteins (structures) are involved in the assembly of adenoviruses. Either an empty protein shell is made first, into which the viral DNA is introduced, or the packaging of DNA occurs along with assembly of the viral proteins. Whatever the precise mechanism turns out to be, it is likely that the formation of infectious adenovirus particles requires an intact nucleus (see Fig. 13, line 6).

Even the assembly of the much simpler SV40 virus is quite complex. Despite numerous efforts, the formation of stable SV40 particles through an *in vitro* assembly system has not yet been achieved (300), and, again, efficient packaging seems to require an intact host nucleus. For both adeno- and SV40 viruses, great quantities of virus particles can accumulate in the nucleus, leading eventually to lysis of the cell and release of virus. Like PV, SV40 may also undergo polarized released from epithelial cells (54).

Assembly of Enveloped RNA-Containing Viruses

Many of the RNA viruses that derive their lipid-containing envelopes from the cell's plasma membrane contain single-stranded RNA as their genome. Newcastle disease, vesicular stomatitis, and influenza viruses are prototype viruses of the negative-strand RNA virus group, the study of which has provided us with much of the information presently known about intracellular trafficking of viral glycoproteins and assembly in the plasma membrane. Viral glycoproteins, especially the influenza HA and VSV glycoprotein (G), have been used extensively as prototypes for the study of biogenesis of plasma membrane proteins. These proteins use the signal receptor particle, endoplasmic reticulum enzymes, Golgi apparatus enzymes, and transport mechanisms to realize their proper structure and cell-surface location.

Part of the evidence for the concept that transmembrane proteins are synthesized on membrane-bound polyribosomes and translocated cotranslationally across the endoplasmic reticulum membrane while peripheral membrane proteins are synthesized on free polyribosomes came from the study of virus membrane proteins (176,229). Detailed studies of *in vitro* insertion of viral membrane proteins into the endoplasmic reticulum membrane came from studies of the VSV G protein (292). Detailed genetic study of the VSV G protein has provided evidence for the loop model for signal sequence insertion into the endoplasmic reticulum (311). Transit along the secretory pathway is well described for the glycoproteins of these three viruses, although the ultimate fate of specific viral proteins may depend on specific signals present in the molecule. For example, epithelial cells have apical and basolateral surfaces that can be targeted by specific viral glycoproteins. Influenza virus buds apically and VSV buds basolaterally. This selective localization may be determined by specific transport vesicles that recognize signals in the viral proteins (184,234).

It should also be noted that the neuraminidase cleaves off sialic acid from the host cell and from budding virus particles, thereby preventing binding of the hemagglutinin to cell surfaces and viral surfaces, respectively. Viruses with a temperature-sensitive neuraminidase aggregate on cell surfaces when grown at the nonpermissive temperature or inhibited by neuraminidase inhibitors (190,247,248 and 249). Inhibiting this interaction of the viral neuraminidase with the host sialic acid receptor is the basis for drugs recently approved to fight influenza virus infection.

Although the role of the glycoproteins in the efficient assembly of enveloped viruses is well established, it is also thought that the M protein of these viruses may be involved in viral assembly and release. For example, when the matrix (M) protein of VSV is expressed in mammalian cells, it is subsequently released from the cells in the form of lipid vesicles that bud through the plasma membrane (161). Recently it was demonstrated that a highly conserved amino acid motif (PPXY, where P is proline, Y is tyrosine) present within the M protein of VSV and other rhabdoviruses, including rabies virus, may play a functional role in budding. It was found that mutating the PPXY motif in the VSV M protein prevented the release of the protein from cells in this functional budding assay. Interestingly, the PPXY motif within rhabdoviral M proteins was shown to be a ligand for proteins that contain a WW (tryptophan–tryptophan) sequence (136). The hypothesis is that cellular WW proteins interact with the viral M proteins and function as “budding” proteins, facilitating the assembly and release of the viral particles. No such hypothetical budding partners have as yet been identified *in vivo.*

The properties of the PPXY motif in the M proteins of rhabdoviruses are similar to those of the late (L) budding domain identified in the gag-specific protein p2b of Rous sarcoma virus, an avian retrovirus (108,370). In a functional budding assay, the region of the Rous sarcoma virus gag protein (57) containing the proline-rich motif can be replaced by the homologous region of the VSV M protein. However, these PPXY-mediated interactions between viral and cellular proteins are not sufficient to allow virus particles to bud from the cytoplasmic surface. The M and gag proteins appear to possess membrane-association domains (different from the PPXY motifs) that are required for the localization to the cytoplasmic membrane (50,375). The M and gag proteins may also interact with the respective viral glycoproteins, which could lead to an enhanced membrane binding of these viral components. Furthermore, the viral RNAs in the form of ribonucleoprotein complexes must bind to these structures in specific ways to prevent packaging and budding of cellular RNAs rather than viral ones. Many questions remain in this area of study because the precise steps leading to the formation and extracellular release of enveloped RNA viruses remain obscure.

The mouse hepatitis virus, a positive-strand RNA virus, follows an unusual pathway toward infectious particle formation. Rather than budding from the plasma membrane, it appears that murine hepatitis virus replication occurs on late endosomal and/or lysosomal membranes (355). We do not know how the mouse hepatitis virus replication components are targeted to the correct membranes or what the advantage to the virus is of localization in these cytoplasmic compartments. It will be interesting to find answers to these questions in the future.

Assembly of Vaccinia Viruses

Vaccinia virus is known to replicate in the cytoplasm, and it does so within specific regions called factories. What is unusual about the use of the host by vaccinia virus is that the infectious intracellular particle derives two membranes from the Golgi network. This “wrapping” mechanism for forming the intracellular mature virions is not well understood, nor are the cellular components involved in this process well characterized. Some of these virus particles become engulfed by another envelope derived from a post-Golgi or endocytic compartment, which allows fusion with the plasma membrane and eventual release. Thus, there are two forms of infectious particles—one inside the cell and one that is released (see Fig. 13, line 5). In another remarkable process, the intracellular enveloped virions can also become associated with actin tails (60,99). It was found that the viral protein A36R in the viral envelope becomes tyrosine-phosphorylated by cellular Src-family kinases. This phosphorylation results in the recruitment of the cellular adaptor protein Nck and of N-WASP next to the vaccinia particle. The latter two proteins are involved in actin polymerization at the plasma membrane. It thus appears that vaccinia virus mimics the receptor tyrosine kinase signalling observed during actin-based motility of (uninfected) cells. Vaccinia virus particles appear to sit on the tips of actin tails and thereby gain mobility that allows the virus to spread from cell to cell. The actin tails decorated by vaccinia virus (or the virulent smallpox virus) push the virus along and may dip into neighboring cells, thus transferring the virus to a new cell.

Assembly of Herpesviruses

Cellular cytoskeletal structures are exploited by yet another DNA virus for trafficking of viral components. Sodeik et al. (322) showed that the incoming herpesvirus capsids are rapidly transported along microtubules with the help of dynein, a microtubule-dependent motor. Transport of the viral capsids proceeds along microtubules from the cell periphery to the nucleus (see Fig. 5, line 7), involving an interaction of capsid proteins with dynein and microtubules. All herpesvirus capsids acquire a membrane from the inner leaflet of the nuclear membrane when they leave the nucleus. In the reenvelopment model of egress, this enveloped particle loses its envelope after transport into the cytoplasm, and naked capsids travel along (reorganized) microtubules (81,84). What determines directionality of this transport remains undefined. Also, this microtubule-mediated transport may be of great importance for the axonal transport in neurons, where large distances have to be overcome by the virus and its components, and it may be less relevant in other herpesvirus-infected cells (see Fig. 13, line 7a).

A second model describing the interactions of herpesvirus and cellular components during egress is the lumenal model. According to this model, viral capsids acquire their envelopes from the inner leaflet of the nuclear membrane and bud from the cell following the host's secretory pathway without leaving the lumenal spaces of the cell (see Fig. 12, line 7b). Thus, the naked capsids observed by EM, for example, would be “dead end” structures (118) and exocytosis would be independent of the organization of microtubules and/or the organization of the Golgi apparatus (6). The relative importance of these two pathways for herpesvirus egress remains to be defined.

Targeting and Release in Polarized Cells

Finally, release of viruses may be asymmetrical in polarized epithelial cells. Polarized epithelial cells have differentiated apical and basal surface plasma membranes. Thus, viruses budding through the plasma membrane or vesicles containing virus particles can traffic specifically through either membrane. For example, orthomyxoviruses and paramyxoviruses bud at the apical surface, whereas VSV and retroviruses bud at the basal surface. Viral glycoproteins have an intrinsic ability to localize to specific surfaces of polarized cells (159,273,290,327), and this is thought to be an important factor in deciding the site of virus budding in polarized epithelial cells. Sorting of proteins destined for the different surfaces appears to occur within the Golgi apparatus (326). Studies of the targeting of chimeric glycoproteins expressed from recombinant clones indicate that these targeting signals are complex (349). Some studies indicated that the ectodomain contains the targeting signal (222,291), whereas other studies found that the ectodomain is not sufficient (10,150,273,326). However, targeting of some viruses is not determined by the surface glycoprotein (205).

Once the progeny viruses have been released, they can initiate infection in new cells, and a whole new round of virus replication and interaction with a host cell can begin.

HOST CELL RESPONSES TO VIRAL INFECTION AND HOW VIRUSES COMBAT THESE RESPONSES

As host organisms for virus infection, we have evolved responses that block the replication and spread of viruses. This is apparent at the system level in the immune responses that are made against viruses and other foreign agents. However, host responses are apparent even at the cellular level, and in fact much of the innate immune response to viruses is initiated by host responses at the cellular level.

Interferon

One of the major host responses to viral infection is the production of interferons, components of the innate immune response. Isaacs and Lindenmann (154), during their seminal studies on virus interference, and Nagono and Kojima (231) observed that virus-infected cells produce a secreted factor which mediates the transfer of a virus-resistant state, and furthermore, that the resistance was displayed against both homologous and heterologous viruses. This secreted factor with antiviral activity was called interferon (IFN). It is now known that IFNs comprise a family of cytokines that play a centrally important role in the host response against viral infection.

The IFNs are grouped into two types: type I IFN (viral IFN, IFN-a/b) that includes the large number of a (leukocyte) IFNs and the single b (fibroblast) IFN, all of which act through the IFN-a/b receptor; and, type II IFN (immune IFN, IFN-g), of which there is a single species that acts through a cognate IFN-g receptor (297). The IFN response represents an early host defense, one that occurs prior to the onset of the immune response.

Pathogenesis studies utilizing knock-out mice in which the type I IFN-a/b receptor function has been eliminated by targeted gene-disruption illustrate the central importance of the interferon response; IFN-a/b receptor-null mice are unable to establish an antiviral state. These mutant animals are highly susceptible to infection by certain viruses despite the presence of an otherwise intact immune system (106,122,354). IFN-g possesses unique immunoregulatory activities. Like IFN-a/b, IFN-g plays an important role in mediating protection against viral infection, especially long-term control of viral infections, as revealed from studies of knock-out mice lacking the type II IFN-g receptor (42,201). Mice lacking both the type II IFN-g receptor and the type I IFN-a/b receptor are especially sensitive to viral infection (354).

The discovery that a number of viruses encode gene products that antagonize the antiviral actions of IFNs further illustrates the fundamental importance of the interferon system as a host defense against viral infection. Numerous mechanisms are utilized by viruses to impair the IFN response (Fig. 15). In most cases, the virus-encoded products antagonize one of two stages of IFN action: (a) the IFN signal transduction pathway that leads to transcriptional activation of the 30 or so cellular genes whose products are responsible for the biologic activities of the IFNs, or (b) the biochemical activity of one or a few specific IFN-induced cellular proteins responsible for inhibition of virus replication. A third possible stage of antagonism of the interferon response by viruses is the inhibition of IFN production. However, the viral gene products and biochemical mechanisms responsible for this level of inhibition are generally less well

characterized than those responsible for the antagonism of either the signal transduction pathway or the action of IFN-induced proteins.

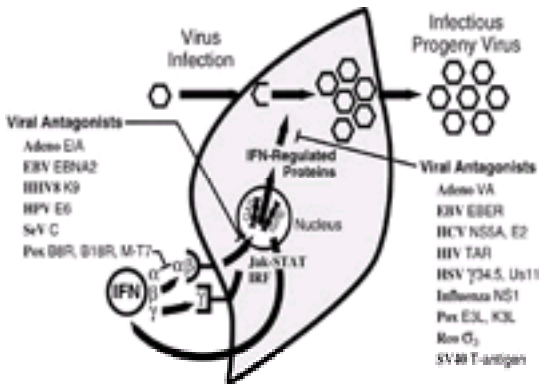

FIG. 15. Antagonism of interferon action by viruses. Virus-coded products that antagonize the IFN signal transduction pathway leading to transcriptional activation of IFN-regulated genes include adenovirus E1A; EBV EBNA2; HHV8 K9; HPV E6; poxvirus B8R, B18R, and M-T7; and Sendai virus C proteins. Virus-coded RNA and protein products that antagonize the biochemical activity of IFN-induced cellular proteins include adenovirus VA, EBV EBER, HCV NS5A and E2, HSV g34.5 and U_S11, influenza virus NS1, and SV40 T-antigen.

Several human viruses, including adenovirus, EBV, Sendai virus, and papillomavirus, encode viral proteins that inhibit the IFN-mediated transcriptional activation of cellular genes. The Jak-STAT signaling pathway utilized by IFN is blocked by the adenovirus E1A oncoprotein. The step affected by E1A appears to reside upstream of the activation of ISGF3, the major transcription factor complex formed of Stat1, Stat2, and IRF-9 (formerly known as p48) in response to IFN-a/b treatment (325), as the DNA-binding ability of ISGF3 is inhibited by the E1A protein (194). Overexpression of the IRF-9 component of ISGF3 restores IFN responses and the transcription of interferon-stimulated response element (ISRE)–driven genes in adenovirus infected cells (194). The Epstein-Barr virus EBNA2 protein also impairs the induction of genes by IFN-a/b but apparently by a mechanism different from that of the adenovirus E1A protein, as formation of the ISGF3 transcriptional activator complex is not significantly affected by EBNA2 (163). Sendai virus, a paramyxovirus that replicates in the cytoplasm of the host, circumvents the IFN-induced antiviral response by interfering with the transcriptional activation of IFN-inducible cellular genes. The C proteins of Sendai virus play a role, because infections with two different C gene mutants eliminate the ability to prevent establishment of an antiviral state against VSV (107). Impairment of the IFN-induced antiviral response appears to be a key determinant of Sendai virus pathogenicity (74,107).

Insight into the biochemical basis of the antagonism of the IFN signal transduction process by impairment of the function of signaling factors other than ISGF3 has been gained from studies of human papillomavirus (HPV) and also adenovirus. IRF-3, a key transcriptional activator affected by viral infection, is constitutively expressed in many cells and tissues. IRF-3 is directly activated by dsRNA or by virus infection, and subsequently plays a role in the activation of the IFN-a and IFN-b promoters and IFN-a/b responsive genes (143). The HPV E6 oncoprotein binds selectively to IRF-3 but only very poorly to other cellular IRFs including IRF-2 and IRF-9. The association of E6 with IRF-3 inhibits the trans-activation function of IRF-3, thereby providing HPV with a mechanism to circumvent the antiviral response (288). Adenovirus E1A protein also inhibits IRF-3–mediated transcriptional activation by a mechanism that depends on the ability of E1A to bind p300. Overexpression of CBP/p300 partially reverses the E1A-mediated inhibition, which is not observed with mutant E1A protein that does not bind p300. CBP/p300 and PCAF histone acetyltransferase (HAT) enzymes are coactivators for several transcription factors including Stat1a, p53, and nuclear hormone receptors; the viral E1A protein represses HAT activity and inhibits p300-dependent transcription and nucleosomal histone modifications by PCAF (45).

There are several known examples in which viruses mimic one or more of the cellular components of the IFN signal transduction pathway. In some instances, this molecular mimicry leads to an antagonism of the IFN signaling process and subsequent impairment of the development of an antiviral state. Virus-coded homologs of IFN signal transduction pathway components include homologs of type I and type II IFN receptors, a viral ISRE-like promoter element that functions as a target of cellular IRF transcription factors, and a viral homolog of the interferon regulatory factor (IRF) family of transcription factors that represses the ISRE element function of IFN-inducible promoters. Soluble viral IFN receptor homologs (vIFN-gRc) encoded by poxviruses are secreted from virus-infected cells and bind IFNs, thereby preventing them from acting through their natural receptors to elicit an antiviral response (320). The first poxvirus receptor homolog identified, the M-T7 protein, was found in myxoma virus–infected cells and acts as a decoy to inhibit the biologic activity of rabbit IFN-g. The vIFN-gRc gene product is a critical virulence factor for poxvirus pathogenesis. Myxoma virus lacking the M-T7 gene is highly attenuated; infected rabbits survive and do not develop myxomatosis. Other poxviruses also encode soluble IFN-g receptor homologs, including vaccinia virus in which the B8R gene encodes the IFN-gRc homolog. Vaccinia virus and several other orthopoxviruses also express a soluble vIFN-a/bRc protein that, in the WR strain of vaccinia, is encoded by the B18R gene. The viral type I IFN receptor homolog of vaccinia virus binds several different IFN-a subspecies as well as IFN-b and blocks IFN-a/b signaling activity.

A viral ISRE-like element (vISRE) has been identified in the Q promoter (Qp) of Epstein-Barr virus (384). Qp is used for the transcription of EBV nuclear antigen 1 (EBNA1) during the highly restricted type I latent infection, but it is inactive in type III latency. Constitutive activation of EBV EBNA1 gene transcription is mediated in part by IRF-1 activation of the Qp promoter. Another IRF factor, IRF-7, binds to the vISRE-like sequence in Qp and represses transcriptional activation by both IFN and IRF-1. Expression of IRF-7 is high in type III latency cells but almost undetectable in type I latency, corresponding to the activity of the Qp of EBV in these latency states (384). The Jak-STAT signaling pathway positively regulates Qp activity, and the Zta up-regulation of p53 leads to p53-mediated interference with Jak-STAT activation of Qp (48). Conceivably, the binding of IRFs and Stats at Qp may be mutually exclusive. Interestingly, EBNA2, which is

expressed in type III but not type I latency, is reported to have an anti-IFN effect, greatly impairing the induction of IFN-inducible genes (163).

Human herpesvirus 8 (HHV8), a gammaherpesvirus associated with Kaposi's sarcoma, encodes an IFN regulatory factor homolog (vIRF) that functions as a repressor of transcriptional activation induced by a, b, and g IFNs (105,143). The vIRF product of the K9 ORF of HHV8 forms heterodimers with cellular IRF-1 and competes with binding of IRF-1 to the coactivator p300, thereby down-regulating transcriptional activation by the cellular IRFs. Thus, the HHV8 vIRF protein potentially plays an important role in HHV8 pathogenesis and neoplastic transformation by antagonizing IFN and IRF-mediated transcriptional control. Expression of vIRF antisense RNA in HHV8-infected cells increases IFN-mediated transcriptional activation and down-regulates expression of HHV8 genes. Overexpression of the viral vIRF in NIH3T3 cells induces transformation resulting in morphologic changes, focus formation, and growth in low serum concentrations (105), characteristics similar to the cellular IRF-2 repressor, which likewise mediates transformation of NIH3T3 cells and displays oncogenic potential in the nude mouse model (143).

Several viruses have evolved strategies to block the function of the IFN-inducible, RNA-dependent protein kinase PKR. Antagonism of PKR and the subsequent phosphorylation of eIF-2a have been directly linked to inhibition of the IFN-induced antiviral response of the host (55,102,215,298). Vaccinia virus, for example, can rescue IFN-sensitive viruses such as VSV and encephalomyocarditis virus from the antiviral effects of IFN by antagonizing the biochemical activity of PKR. The vaccinia E3L protein is a potent inhibitor of the PKR kinase and also the 2',5'-oligoadenylate synthetase (OAS), two IFN-inducible RNA binding proteins (284,297,314). E3L acts in part by sequestering activator RNA of PKR and 2'5'OAS. Deletion mutants of vaccinia virus lacking the E3L gene are sensitive to the antiviral effects of IFN, but RNA-binding proteins (including the reovirus s3 protein, RNaseIII, TRBP, rotavirus NSP3, and E3L mutants that retain RNA binding activity) complement the E3L gene deletion and reverse the IFN-sensitive phenotype. Vaccinia mutants that express E3L proteins unable to bind dsRNA are IFN sensitive. Deletion mutants of vaccinia virus lacking the K3L gene, the eIF-2a homolog, are more sensitive to the antiviral effects of IFN than wild-type virus. Complementation studies suggest that the E3L gene product is most likely responsible for the vaccinia virus–mediated rescue of VSV from the antiviral effects of IFN, and that the K3L gene product is at least partially responsible for the rescue of EMC virus (313).

Adenovirus, influenza virus, PV, and SV40 provide four examples of viruses that antagonize the IFN-induced PKR kinase by different strategies. Adenovirus VAI RNA antagonizes the antiviral state of IFN by preventing activation of PKR; deletion mutants that do not express VAI RNA display IFN sensitivity, whereas wild-type virus that produces large amounts of VAI RNA is relatively resistant to type I IFN (214). The influenza virus NS1 protein, which binds RNA and prevents activation of PKR, plays a crucial role in inhibiting IFN-mediated antiviral responses of the host against influenza A virus (102,106,137). PV infection leads to a degradation of PKR (27), although the protease responsible for the down-regulation has not yet been identified. Translation of SV40 early RNA is relatively resistant to the antiviral effects of IFN (297). SV40 large T-antigen antagonizes PKR function but downstream of the kinase activation step (275). The mechanism is not resolved, but one possibility is a T-antigen–mediated enhancement of the phosphatase activity responsible for the dephosphorylation of eIF-2a similar to that observed in HSV-infected cells. In HSV infection, eIF-2a phosphorylation is reduced even though PKR is activated, because of the interaction of the HSV g34.5 protein with phosphatase 1a (138).

Studies of the genetic evolution of HCV suggest that IFN-a therapy alters virus–host interactions as a result of changes in the nature of circulating HCV quasispecies (253). HCV genotype 1b resistance to IFN-a therapy is associated with changes in the HCV NS5A gene central region quasispecies (254). The HCV second envelope hypervariable region (HVR1), an 81-nucleotide sequence located at the 5' end of the E2 gene, shows changes in HVR1 quasispecies major variants during and after IFN therapy in patients who failed to clear HCV RNA. Although the underlying mechanisms are unknown, one intriguing possibility is an IFN-mediated selection for resistant viruses mediated by editing of HCV viral RNA catalyzed by the IFN-inducible RNA-editing enzyme ADAR1 (252).

Apoptosis

Apoptosis, or controlled cell death, can serve as a defense mechanism for the host cell to combat viral infection. The apoptotic response involves a cascade of intracellular signals initiated in response to a wide variety of stimuli, including viral infection. Morphologic changes associated with apoptosis of virus-infected cells include condensation of chromatin and vacuolization of the infected cell's cytoplasm, and biochemical changes including activation of cellular proteases and nucleases and degradation of cell DNA to nucleosome-sized fragments. The fundamental importance of apoptosis as a component of the host response to viral infection is illustrated by the fact that a number of viruses encode gene products that either induce or inhibit apoptosis (86,132,312,339). Untimely early destruction of infected host cells may greatly reduce virus yields. Hence, viruses have evolved strategies to antagonize the apoptotic response by encoding viral gene products that target effector components in the apoptotic cascade. Suppression or delay of apoptosis can extend the period of time available following infection to produce new virions prior to destruction of the host biosynthetic pathways utilized by the virus. The opposite also occurs. Viral gene products have been identified that function as inducers of apoptosis, possibly to facilitate release and spread of progeny virions from the infected host (86,132,312,339).

A wide variety of strategies is used by viruses to affect the balance between growth and death of the infected host cell. The adenovirus E1A gene product stabilizes p53 and induces p53-dependent apoptosis (312,339). This effect of E1A is countered by the adenovirus E1B-19kD, E1B-55kD, and E3 proteins, each of which can antagonize the apoptotic process. The adenovirus E3 gene product promotes the degradation of Fas which prevents apoptosis (345). The E1B-55kD–mediated block of apoptosis involves antagonism of p53 function (340), whereas the E1A-19kD protein is a Bcl-2 homolog that forms heterodimers with proteins such as Bax (365). Bcl-2 is an apoptosis suppressor that prolongs cell survival (25). Among the viral Bcl-2 homologs identified are the LMW5-HL protein of African swine fever virus that functions to antagonize apoptotic cell death, and the BHRF1 protein of EBV that protects human B cells from programmed death (132). The E6 protein of human papilloma virus and SV40 large T-antigen also impair p53-mediated apoptosis (132,312,339).

Cowpox virus blocks apoptosis by encoding CrmA, a serpin family protease inhibitor that blocks the interleukin-1b-converting enzyme (ICE) protease (100). ICE, a cysteine protease, is a key component of the apoptotic response in mammalian cells. The vaccinia virus B13R gene product is homologous to CrmA and inhibits apoptosis induced by Fas or TNFa (75). The baculovirus p35 protein, which prevents apoptosis during infection of insect cells, likewise inhibits the ICE family of proteases (225). Apoptosis via the Fas and TNF death receptors involving death domain (FADD) signaling cascade involves recruitment of several proteins including the procaspase 8 protease FLICE. Lymphotropic g-herpesviruses (including HHV8, herpesvirus saimiri, equine herpesvirus-2, and bovine herpesvirus-4) encode FLICE-inhibitory proteins known as vFLIPS that are recruited to the activated receptor, but vFLIPS lack proteolytic activity and thus do not activate death signals (348).

Type I IFNs are essential mediators of apoptosis. Primary mouse embryonic fibroblasts undergo apoptosis when infected with EMC virus, VSV, and HSV, but apoptosis induced by these viruses is inhibited by anti-IFN-a/b antibodies and in homozygous null cells lacking either the IFN receptor or the Stat1 signaling factor (335). IFN alone does not induce apoptosis unless the treatment is combined with double-stranded RNA. Two important mediators of the IFN-induced antiviral response, the PKR kinase (334) and the 2'-5'A-dependent RNase L (73,385), play key roles as effectors of apoptosis. Overexpression of wild-type PKR but not catalytically inactive PKR causes apoptosis in the presence of dsRNA (9). Induction of apoptosis by PKR involves eIF-2a and NF-kB, because overexpression of the S51A mutant of eIF-2a or the S32,36A mutant of IkBa led to an inhibition of apoptosis (114). Interestingly, an up-regulation of Fas receptor mRNA accumulation correlates with PKR activation and subsequent apoptosis (77,114). Apoptosis is substantially suppressed following treatment with dsRNA, TNF-a, or lipopolysaccharide of cells from mice with a targeted disruption of either the PKR gene (70) or the RNase L gene (385). Suppression of apoptosis in the PKR null cells was associated with defects in activation of IRF-1 and in Fas mRNA induction (70). Several viral antagonists of PKR function have been described (102,298); presumably, repression of PKR by these viral products would impair the apoptotic response. For example, the antiapoptotic and oncogenic potentials of HCV virus are linked to IFN resistance by viral repression of the PKR protein kinase (103). Resistance to apoptosis is attributed to an HCV NS5A-mediated block in eIF-2a phosphorylation; furthermore, cells expressing NS5A exhibit a transformed phenotype.

SUMMARY

The major points of this chapter can be summarized as follows:

1. The ability of a virus to replicate in a host cell can be determined by the availability of specific macromolecules in that type of cell. These molecules may be external, such as a receptor, or internal, such as a transcription or replication factor.

2. Some of the cytopathic effects of virus infection on a host cell are caused by specific alterations in host-cell metabolism or structure that allow viral replication events. These cytopathic effects are usually not simply toxic effects of virus infection. Instead, viruses have evolved to manipulate the environment of the host cell for their own optimal replication.

3. Interactions of viruses with host cells may involve subtle changes in the host cell, and an understanding of the nature of the interactions between viral gene products and the host-cell molecules often provides insight into the metabolic processes and critical regulatory events of the host cell.

4. The host cell often responds to viral infection, such as by synthesis of IFN and induction of apoptosis. Viruses have evolved to counter these defenses, and this evolutionary chess game continues.

Thus, our challenge continues to be to attempt to relate this information about the interactions of viruses with their host cells to the biology of viruses in their host organisms, and to apply this knowledge to the design of effective antiviral strategies.

CHAPTER 8 Virus Assembly

Eric Hunter

Virus assembly, a key step in the replication cycle of any virus, involves a process in which large numbers of chemically distinct macromolecules are transported, often through different transport pathways, to a point within the cell where they are assembled into a nascent viral particle. A diversity of strategies and intracellular assembly sites are employed by members of the various virus families to ensure the efficient production of fully infectious virions. Nevertheless, a virus, irrespective of its molecular structure (membrane enveloped or nonenveloped) or the symmetry with which it assembles (icosahedral, spherical, or helical), must be able to take advantage of the intracellular transport pathways that exist within the cell if it is to achieve this goal. The end product of this selection process is assembly of each virus at a defined point within the cell. This chapter focuses on the cell biology of these intracellular targeting events, the intermolecular interactions that mediate targeting, and the assembly steps themselves.

Most viruses encode a limited number of gene products. They are, therefore, dependent on the cell not only for biosynthesis of the macromolecules that constitute the virus particle but also for the preexisting intracellular sorting mechanisms that the virus uses to achieve delivery of those macromolecules to the sites of virion assembly. Because these are the same sorting mechanisms that the cell uses to delineate its subcellular organelles, the viral macromolecules must possess targeting signals similar to those of the components of those organelles. For a virus such as adenovirus, which assembles its nonenveloped capsids in the nucleus, this means that, after translation in the cytoplasm, each of the structural proteins of the mature virus must have the necessary protein-targeting information to be efficiently routed through the nuclear membrane to the assembly site. The situation is more complicated for a membrane-enveloped virus, such as influenza virus. For this virus, which assembles and releases virions from the apical surface of the epithelial cells that it infects, there is a necessity to ensure that the surface glycoproteins of the virus are correctly sorted by the secretory pathway of the cell to the apical surface. In addition, nucleocapsids, assembled in the nucleus, must be transported into and through the cytoplasm to the same intracellular location. As will be discussed below, the intracellular site at which the final phase of assembly and budding of an enveloped virus takes place is most often defined by the accumulation of the viral glycoproteins at a specific point in the secretory pathway of the cell. This also implies that there is specific molecular recognition of the virally encoded, membrane-spanning envelope components by the cytoplasmic nucleocapsids in order for a productive budding process to occur. Thus, interactions between proteins of viral and cellular origin, between viral proteins and nucleic acids and lipids, as well as between the viral proteins themselves are at the heart of the assembly process.

PARTITIONING OF PROTEINS WITHIN THE CELL

For an actively growing eukaryotic cell, there is a constant need to transport proteins and nucleic acids from their site of synthesis to the specific intracellular domains where they must function (Fig. 1). Proteins synthesized on cytosolic ribosomes, for example, must be transported to specific regions of the cytoplasm, to mitochondria, and into the nucleus, whereas those synthesized on membrane-bound ribosomes enter the secretory pathway and are targeted to specific organelles along the way. At the same time, messenger RNAs (mRNAs) and integral RNA components of the ribosome, ribosomal RNAs (rRNAs), must be transported out of the nucleus. Proteins that participate in these intracellular trafficking processes have evolved to contain specific motifs that ensure the correct localization of the protein within the cell. Viruses have similarly evolved to take advantage of these preexisting pathways to accumulate the necessary components for assembly of a nascent virus in specific locations.

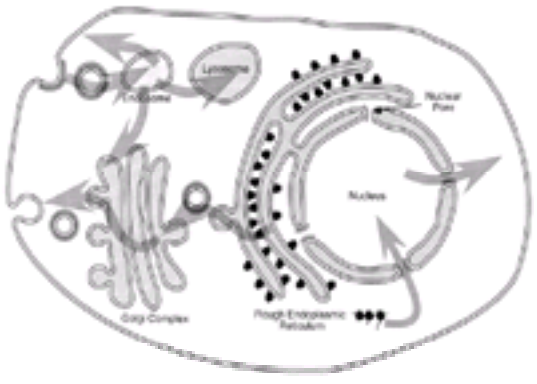

FIG. 1. Protein localization in a mammalian cell. Proteins destined for the plasma membrane traverse the secretory pathway of the cell. They associate with the endoplasmic reticulum (ER) cotranslationally and are translocated across the ER membrane through a proteinaceous pore: the translocon. Proteins are transported from the ER to the Golgi complex and on to the plasma membrane unless they contain specific amino acid motifs that localize or retain them at an intermediate location. Transport from one compartment to the next is by coated vesicles. Some membrane-spanning (integral membrane) proteins contain endocytosis motifs in their cytoplasmic domain that facilitate incorporation into clathrin-coated endocytic vesicles. Such proteins can be sorted back to the plasma membrane, to the *trans*-Golgi compartment of the secretory pathway, or to a lysosome for degradation. Proteins destined for the nucleus contain nuclear localization signals. These are short amino acid sequences that allow interaction with the nuclear pore machinery for transport across the nuclear membrane. Some proteins shuttle between the nucleus and cytoplasm and contain, in addition, a nuclear export signal.

Nuclear Import and Export of Proteins and Nucleic Acids

The Nuclear Pore Complex

Because the nucleus is segregated from the cytoplasm by an inner and outer membrane, access to and egress from this subcellular domain is mediated by specialized structures termed *nuclear pore complexes* (NPCs) (reviewed in 23). There are about 3,000 NPCs on the nuclear envelope of an animal cell, and each provides a proteinaceous channel between the nucleus and cytosol. The NPC itself is a large octagonal structure with a molecular mass exceeding 120 × 10^6 daltons—about 30 times larger than an 80S ribosome. NPCs can be released from nuclear membranes by detergents and show eightfold symmetry. Negative stain and cryoelectron microscopy reconstructions of these complexes reveal a cagelike structure with upper and lower rings (corresponding to the inner and outer faces of the nuclear membrane) linked by radial spokes that form an inner ring with a diameter of about 48 nm (1,49) (Fig. 2). Inside this is located the transporter, which forms a cylindrical pore of about 10 nm. Attached to both faces of the central framework are peripheral structures, cytoplasmic filaments, and a nuclear basket assembly, which interact with molecules that transit the NPC (54). Small molecules and proteins less than 60 kd in mass may be able to diffuse passively through the eight outer channels formed by the spokes and rings of the NPC (see Fig. 2). Larger proteins and macromolecular assemblages must be actively moved through what is presumably a dynamic, malleable transporter structure that has the capacity to accommodate macromolecular complexes up to about 20 nm in diameter.

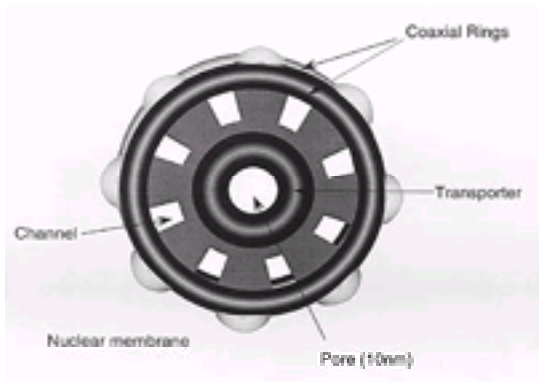

FIG. 2. Schematic representation of a nuclear pore complex. The nuclear pore complex is composed of two ringlike structures that are linked through eight spokes to a central transporter structure. The coaxial rings appear to interact with the outer and inner nuclear membranes. In negative-stain electron microscopy, the pores have a distinct eightfold symmetry. On the cytoplasmic side of the structure, filaments extend outward into the cytoplasm; whereas on the nuclear side, a basket-like structure is formed from the eight filaments that extend from the coaxial ring. Small proteins (5–50 kd) can diffuse into the nucleus, perhaps through the small channels formed by the spokes, whereas larger proteins must be actively transported through the pore.

Nuclear Localization Signals

Proteins that are actively transported into or out of the nucleus are characterized by the presence of amino acid motifs that allow them to interact with the nuclear transport machinery. For import into the nucleus, these motifs are termed *nuclear localization signals* (NLS), and for export, *nuclear export signals* (NES). NLS motifs, such as that first identified in the SV40 T antigen (57), are not only necessary for nuclear localization of the proteins in which they are present but are also sufficient to actively direct large foreign proteins, such as b-galactosidase, into the nucleus. Although there is no

conservation of sequence in different NLS motifs, they are generally short (less than 20 amino acids), rich in basic amino acids, and frequently preceded by proline residues (Fig. 3). Some NLS motifs, such as that in the adenovirus DNA-binding protein, are bipartite and require two separate short clusters of basic residues to be functional (137).

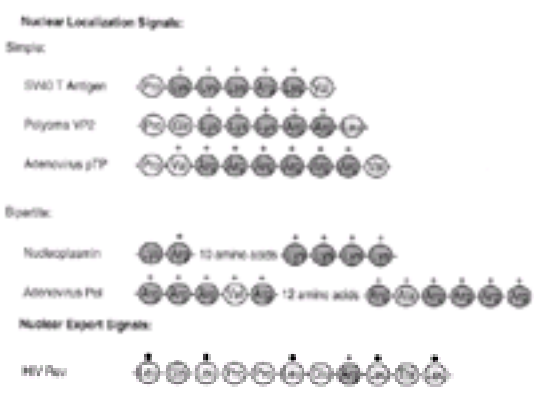

FIG. 3. Nuclear localization and export signals. The amino acid motifs that direct proteins into the nucleus are termed *nuclear localization signals* (NLS). Simple NLS sequences, such as those present in the SV40 virus T antigen or polyomavirus VP2, often contain a proline residue followed by a stretch of basic residues. This short sequence can relocate large proteins, such as b-galactosidase, into the nucleus. Bipartite NLS sequences, such as those present in nucleoplasmin or the adenovirus polymerase, are characterized by two stretches of basic amino acids separated by a variable spacer sequence. These NLS sequences are recognized by import receptor molecules such as importin-a. Proteins that shuttle into and out of the nucleus, such as Rev, possess a second motif, the nuclear export signal (NES). These motifs are characterized by a pattern of conserved leucine residues.

To be exported from the nucleus, proteins contain an NES. This nuclear transport signal is also short (about 10 amino acids) and contains a pattern of conserved leucines (83) (see Fig. 3). Some proteins, such as Rev of human immunodeficiency virus type 1 (HIV-1), possess both an NLS and an NES and appear to shuttle back and forth between the cytoplasm and the nucleus (75).

Nuclear Transport Pathways—In and Out

Nuclear import is a two-stage process. In the first stage, the newly synthesized, NLS-containing, protein interacts with cytosolic carrier proteins that then bind to the cytoplasmic side of the NPC; a process referred to as *docking.* This complex is then translocated, in an energy-dependent process, through the nuclear pore into the nucleus, where the complex is disassembled, allowing the transported protein to become functional (39).

The best characterized carrier protein is importin-a or karyopherin-a. After binding its NLS-containing cargo, importin-a interacts with importin-b, which then mediates docking with the NPC through interactions with members of the nucleoporin family of proteins (79). Other import systems use a single molecule, such as transportin or importin-b3, that mediates both binding of the cargo molecule and the docking process (84). Active transport of large molecules in either direction across the nuclear pore involves a family of proteins, known as *nucleoporins,* as well as a small guanosine triphosphate (GTP)-binding protein termed Ran (78) (Fig. 4). The directionality of transport is regulated by whether Ran is complexed with guanosine diphosphate (GDP) or GTP. In the cytosol, Ran-GDP, together with importin-ab and the cargo, forms a stable transport complex that is subsequently disassembled in the nucleus where GTP replaces GDP. Similarly, stable export complexes that form in the nucleus with Ran-GTP disassociate in the cytosol where a GTPase activity is active. The exact mechanism by which the Ran-GDP and importin–cargo complex is carried through the nuclear pore is not known. It is possible, however, that the process involves a series of docking and release cycles with nucleoporin proteins that make up the transporter machinery.

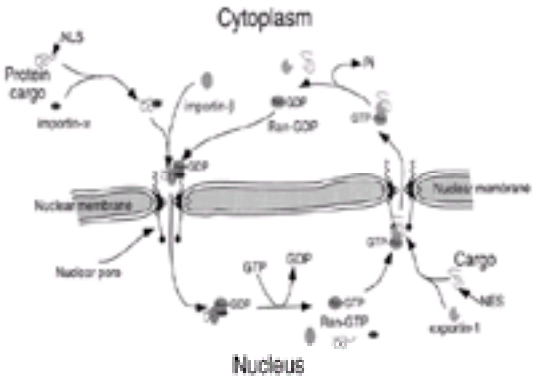

FIG. 4. Nuclear import and export pathways. A protein bearing an NLS is recognized and bound by importin-a. Importin-b binds to this complex and carries it to the cytoplasmic side of the nuclear pore where it binds initially to nucleoporins in the cytoplasmic filaments. Translocation of the protein complex into the nucleus requires the involvement of the guanine nucleoside–binding protein Ran in the form of Ran–guanosine diphosphate (GDP). Ran binds specifically to certain nucleoporins and is thought to mediate the transfer of the complex from the cytoplasmic face of the nuclear pore to the nuclear face. In the nucleus, a Ran-specific guanine nucleotide exchange protein (Rcc) converts Ran-GDP to Ran–guanosine triphosphate (GTP) and the complex dissociates delivering the protein cargo into the nucleus. Proteins destined for export out of the nucleus bind to exportin-1 through their NES. This complex, together with Ran-GTP, binds to nucleoporins localized to the nuclear basket of the pore complex and initiates translocation into the cytoplasm. Once there, Ran-GTP is converted to Ran-GDP by a Ran-GTPase–activating protein (RanGAP-1), causing the

cargo-exportin-1-Ran complex to dissociate, thereby delivering the cargo to the cytoplasm.

Export from the nucleus of large proteins and ribonucleoprotein (RNP) complexes involves interactions with an export carrier protein such as exportin-1 (32,118). This molecule binds to the NES sequence of the cargo protein and to Ran-GTP, which in turn mediates interactions with the nucleoporins of the NPC (see Fig. 4).

The Secretory Pathway of the Cell

Proteins of both viral and cellular origin that are destined for the outer membrane of the cell travel along a highly conserved route known as the *secretory pathway.* This complex series of membrane-bound subcellular compartments, through which proteins pass sequentially, includes the endoplasmic reticulum (ER), an intermediate membrane compartment, and the *cis*-, medial-, and *trans*-compartments of the Golgi apparatus (see Fig. 1). Proteins that traverse this pathway, such as the envelope glycoproteins of viruses, enter through the ER. Insertion of proteins into the ER occurs during translation, through a process termed *translocation.* The ER network of tubules and sacs defines a unique environment in which protein modification and folding can occur isolated from the cytoplasm. Regions of the ER membrane where polybosomes are bound tightly and in the process of translating proteins that are translocating into the secretory pathway are known as *rough ER*.

Translocation

Translating ribosomes are directed to the ER membrane by a short sequence in the nascent polypeptide known as the *signal sequence.* In most proteins, this 15– to 30–amino acid sequence, which contains a core of hydrophobic amino acids, is located at the N-terminus of the protein. Shortly after the signal peptide emerges from the ribosome, it is bound by an RNP complex known as the *signal recognition particle* (SRP) (131). Binding of the SRP transiently arrests further translation and directs the ribosome to an SRP receptor on the ER (Fig. 5). Both the SRP and its receptor have GTP-binding components, and the presence of this nucleotide is essential for efficient targeting.

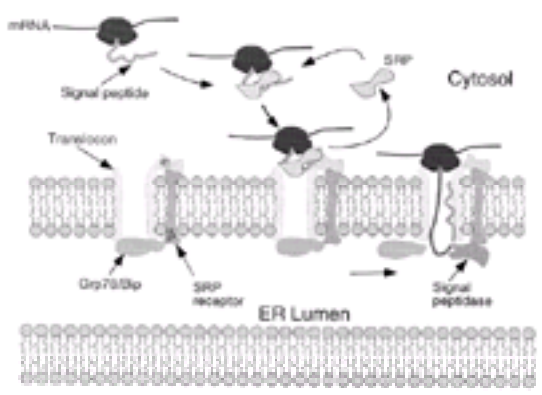

FIG. 5. Protein translocation into the secretory pathway. Translation of a protein destined for the secretory pathway proceeds until the signal peptide exits the ribosome. The signal recognition particle (SRP) binds to the signal peptide and the ribosome and arrests translation. The ribosome–SRP complex moves to the endoplasmic reticulum (ER) membrane where SRP binds to its receptor (*SRP receptor*). This interaction, with concomitant hydrolysis of bound GTP, releases SRP and mediates a tight interaction between the ribosome and a proteinaceous channel, the translocon. The release of SRP and binding of the signal peptide to components of the translocon allows resumption of translation to occur. Grp78/Bip, which appears to block the lumenal side of the translocon before and early in translocation, now allows the extrusion of the nascent polypeptide into the ER as translation continues. The signal peptidase complex removes the signal peptide cotranslationally from those proteins that have a cleavable signal peptide. Secreted proteins continue to traverse the translocon until they are completely located in the lumen of the ER. In contrast, for integral membrane proteins, translocation stops after introduction of the hydrophobic anchor domain into the translocon.

After the initial docking of the translationally arrested complex, the ribosome becomes tightly associated with the ER membrane through the translocon, a gated, aqueous, protein channel that spans the ER membrane (115). Concomitant with this process, the SRP and its receptor are released, the signal peptide is introduced into the channel, and translation resumes. The components of the translocon have been identified through biochemical approaches in mammalian cells and genetic approaches in yeast and are composed of a heterotrimeric complex known as the Sec61p (composed of Sec61 a-, b-, and g-chains). The complex forms a cylindrical structure, with a diameter of 85 Å and a central pore of 20 Å, which spans the ER membrane and is made up of three or four heterotrimers (44). Additional proteins (e.g., the translocating chain-association membrane [TRAM] protein) are necessary for optimal translocation. It is unlikely that the central pore of the translocon ever allows free diffusion between the cytosol and the lumen of the ER because these compartments are chemically distinct (18). More likely, GRP78/Bip, a member of the Hsp70 family of chaperone proteins, seals the luminal face of the translocon pore until the ribosome forms a tight seal on the cytosolic side. The chaperone is then poised to facilitate the folding of the nascent polypeptide chain as it emerges from the pore, although this binding is not essential for translocation to proceed. The signal peptide, in those proteins with a transient N-terminal sequence, is cleaved from the rest of the polypeptide by a complex of five proteins called the *signal peptidase* shortly after it enters the lumen of the ER (see Fig. 5).

For secreted proteins, translocation of the polypeptide through the translocon continues until the entire protein is present in the lumen of the ER. In contrast, integral membrane proteins, such as the envelope glycoproteins of viruses, contain a

stop-transfer, membrane-anchor sequence that is generally located toward the C-terminus of the protein. After the translation of this short (25 amino acids), mostly hydrophobic sequence, the translocon undergoes a conformational change that allows the membrane-spanning domain to be associated directly with the lipid bilayer. The product of this process is a type-I integral membrane protein (Fig. 6), such as the influenza virus hemagglutinin (HA), in which the N-terminal ectodomain is in the lumen of the ER and the C-terminus is in the cytoplasm. In some proteins, such as the influenza virus neuraminidase, a longer N-terminal signal peptide also functions as the membrane anchor. In this case, the signal peptide is not cleaved from the polypeptide chain and the sequences C-terminal to it are translocated into the ER lumen, resulting in a type-II orientation. Multiple membrane-spanning proteins, such as the M protein of the coronaviruses, appear to possess hydrophobic sequences that are alternatively recognized as signal and stop-transfer sequences.

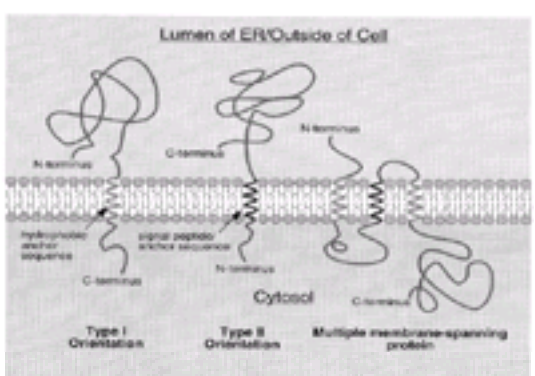

FIG. 6. Protein topology. Proteins with type-I orientation generally have a cleavable N-terminal signal peptide that is removed cotranslationally from the nascent protein. The protein continues to be transferred into the lumen of the endoplasmic reticulum (ER) until a hydrophobic anchor sequence is translated and enters the translocon. Translocation then stops, and the protein transitions from the protein pore into the lipid bilayer. Thus, type-I integral membrane proteins, such as the hemagglutinin of influenza virus, have their C-terminus in the cytoplasm and their N-terminus in the lumen of the ER (topologically equivalent to outside the cell). In type-II proteins, such as the influenza virus neuraminidase, the signal peptide forms the membrane anchor domain, so that at the end of translation, the C-terminal sequences are translocated into the lumen of the ER, leaving the N-terminus in the cytoplasm. For multiple membrane-spanning proteins, such as the M protein of the coronaviruses, translocation is initiated at the first signal peptide sequence and continues until the first anchor domain. It is reinitiated after translation of a subsequent signal sequence and stopped again after translation of a second anchor. The exact mechanism by which this is accomplished without dismantling the translocon at intermediate steps in the process is not understood.

Posttranslational Modifications

Protein Folding and Quality Control

Proteins enter the lumen of the ER in an unfolded state and the process of folding into a transport-competent conformation is facilitated by interactions with molecular chaperones and folding enzymes located there. This collection of proteins includes BiP, calnexin (Cnx), calreticulin (Crt), GRP94, and protein disulfide isomerase (PDI). In addition to assisting in folding the nascent molecules, these proteins retain incompletely folded molecules in the lumen and act as a quality control system for the secretory pathway (27). Oligomeric proteins, such as the receptor and fusion proteins of enveloped viruses, also assemble into their quaternary conformation in this compartment. For many of these molecules, oligomerization appears to be a prerequisite for transport out of the ER.

Glycosylation

Most proteins that traverse the secretory pathway are modified by the addition of oligosaccharide side chains either to the amino group of asparagines (*N*-linked glycosylation) or through the hydroxyl group of serines or threonines (*O*-linked glycosylation). *N*-linked moieties are added cotranslationally in the lumen of the ER, where mannose-rich oligosaccharides are transferred from a lipid (dolichol) carrier to asparagine residues present in NXS/T motifs (where X is any amino acid but proline) within the protein. Trimming of terminal glucose and mannose residues from the branched oligosaccharide occurs in the ER and is closely linked with the Cnx- and Crt-mediated quality control process (reviewed in 27). Further trimming of mannose residues followed by addition of other sugars (*N*-acetylglucosamine, galactose, fucose, and sialic acid), to yield complex oligosaccharide structures, occurs in the Golgi complex. *O*-linked oligosaccharides are also added in this organelle.

Transport Through the Secretory Pathway

Transport of soluble and membrane-spanning proteins from one compartment of the secretory pathway to the next is mediated by the formation of coated membrane vesicles that travel to and fuse with the target organelle. Thus, once the process of protein folding and quality control has been completed in the ER, proteins are sequestered into these transport vesicles before transit to the Golgi complex. The processes of cargo protein selection, budding, targeting, and fusion are probably all mediated by the specific protein coats that define the different transport vesicles involved in shuttling proteins between components of the secretory pathway (107). In the case of ER to Golgi transport, the vesicles have COPII coats (3), whereas retrograde transport of vesicles from the Golgi to the ER, as well as anterograde transport through the Golgi, is mediated by COPI coats (69,93). COP is an acronym for coat protein. Budding is initiated when a small myristylated protein (SAR/ARF) is converted to the GTP-bound form, allowing it to bind to the membrane and recruit coat proteins (coatomers) in a stoichiometric manner (3). Formation of the coat itself induces membrane curvature

and vesicle budding. The N-ethylmaleimide-sensitive factor (Nsf) and the soluble NSF attachment proteins (SNAPs) appear to play a crucial role in subsequent vesicle fusion events. Membrane receptors that mediate docking of the transport vesicle with the target organelle are also incorporated into the coat and appear to define the specificity with which the cargo protein is delivered. These molecules are termed SNAP receptors or *SNAREs* (117). A target-specific SNARE (t-SNARE) that interacts only with a vesicle specific SNARE (v-SNARE) identifies the target membrane. After docking, Nsf and soluble Nsf attachment proteins SNAPs bind to the SNARE complex. Vesicle membrane fusion is initiated when Nsf hydrolyzes adenosine triphosphate (ATP) and induces a conformational change in the complex (reviewed in 107).

Protein Localization

Subcellular localization of proteins within the secretory pathway appears to be determined by a combination of sorting and targeting signals that mediate interactions with the coat complex for inclusion in a transport vesicle and of retention signals that localize the protein to a specific compartment within the secretory pathway. Localization is enhanced by the interplay of anterograde and retrograde transport that allows retrieval of proteins inadvertently transported beyond their target location. The classic example of this is the KDEL peptide sequence found on soluble proteins that are localized to the lumen of the ER (81). Proteins containing this sequence are efficiently retrieved from the *cis*-Golgi by the KDEL receptor, which is incorporated into COPI vesicles for trafficking back to the ER. Similarly, membrane-spanning proteins localized to the ER have at the C-terminus of the cytoplasmic domain a KKXX amino acid motif that ensures their efficient retrieval from the Golgi complex (53). This type of motif is used by the primate foamy viruses to concentrate the envelope glycoprotein complex (gp80 and gp48) in the ER intermediate compartment, where virus budding occurs (37). For integral membrane proteins, retention signals often appear to be associated with the membrane-spanning domains of the protein, as is the case for the coronavirus M protein, and may reflect preferred association with specific lipid compositions of the membrane within a particular component of the secretory pathway (see later).

The Golgi Complex

The Golgi complex represents a unique organelle within the secretory pathway in that it is composed of a series of membrane-bound compartments that are the sites for specific biochemical modifications to proteins and oligosaccharides, as well as locations where specific protein sorting decisions are made. Proteins transported from the ER enter the Golgi complex through the *cis*-Golgi network, and after traversing the *cis*-, medial-, and *trans*-cisternae, exit through the *trans*-Golgi network (107). Each of the compartments provides a spatially distinct site for maintaining an ordered set of enzymes involved in the process of oligosaccharide maturation. They are also the sites at which proteins undergo *O*-linked glycosylation, through the addition, at certain serines and threonines, of monomeric sugar residues. It is in the *trans*-Golgi and *trans*-Golgi network where viral glycoprotein precursors, such as the Env polyprotein of the retroviruses, are cleaved to their mature forms through the action of members of the furin family of proteinases—enzymes that normally function to process cellular substrates, such as polypeptide hormone precursors. This cleavage event is crucial to the generation of a biologically functional glycoprotein and thus to virus infectivity (60).

INTRACELLULAR TARGETING AND ASSEMBLY OF VIRION COMPONENTS

Viruses can be nominally divided into two groups based on the presence or absence of a lipid bilayer envelope. The nonenveloped viruses can assemble in the cytoplasm or nucleus and generally, for those that propagate in animal cells, exhibit icosahedral symmetry (see Chapter 3). For these viruses, the viral structural proteins and genomic nucleic acid must be targeted to or retained at the subcellular domain at which assembly occurs. Enveloped viruses, by their nature, must acquire a lipid bilayer from one of the cell's membranes during the process of assembly. In a few viruses, such as the herpesviruses and some retroviruses, this envelopment step takes place after the assembly of an intact capsid shell, whereas for others, the processes of envelopment and capsid assembly occur concomitantly. Some viruses undergo transient envelopment and, in certain cases, reenvelopment during the process of assembly.

For nonenveloped viruses, the tightly assembled structure of the icosahedral shell forms a protective coat that prevents degradation of the genome by environmental factors. For enveloped viruses, the integrity of the nucleocapsid structure is less crucial because the membrane provides a barrier to external degradative enzymes.

Assembly of Nonenveloped Viruses in the Nucleus

Adenoviruses are nonenveloped icosahedral viruses, 70 to 100 nm in diameter that have a protein shell surrounding a DNA core. The protein shell (capsid) is composed of 252 capsomeres, of which 240 are hexons and 12 are pentons. Each penton consists of a five-subunit base (polypeptide III) and a trimeric fiber (polypeptide IV) that extends out away from the shell. The hexon capsomeres are composed of trimers of three tightly associated molecules of polypeptide II (Fig. 7).

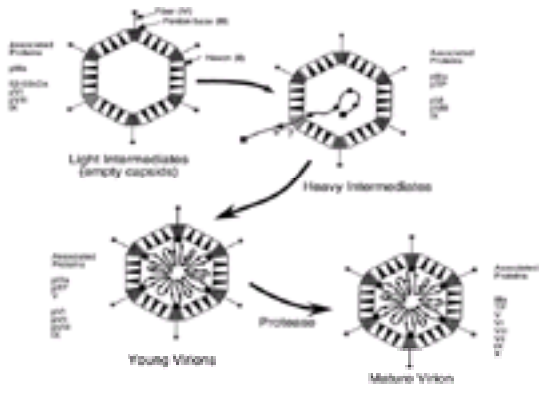

FIG. 7. Assembly pathway for adenoviruses. After transport into the nucleus, the hexons and pentons are proposed to

assemble into *empty capsids* (previously known as *light intermediates of assembly*). This stage of assembly appears to require the L1 region 52- to 55-kd scaffolding proteins. These proteins are lost on association with viral DNA, which is inserted into this structure through a packaging sequence at the left end of the genome. The mechanism of insertion is not known. *Heavy intermediate* forms of the capsid probably represent those in which DNA packaging is incomplete and the DNA is fragmented. Precursor core proteins are packaged into the empty capsid along with the genome to form *young virions.* Proteolytic cleavage of the precursor proteins by the viral proteinase yields the mature virion.

For a nonenveloped virus such as adenovirus, which replicates exclusively in the nucleus, there is a strong dependence on nuclear targeting and transport pathways to export newly synthesized mRNAs out of the nucleus and to import structural proteins back into the nucleus. Nuclear import of the major capsid protein, polypeptide II, depends on the involvement of a second adenovirus protein, the pVI (precursor) polypeptide (59), which provides the necessary NLS for transporting the trimer into the nucleus. Trimer formation is in turn dependent on yet another virus-encoded, chaperone-like protein, L4 100K, which transiently binds to the newly synthesized hexon monomer and mediates its association with two additional monomers (9,10). Thus, the most abundant structural protein of the adenovirus capsid needs to interact with two additional virus-encoded factors to attain the correct tertiary structure and subcellular location for assembly.

The two other proteins that form the 12 vertices of the capsid, penton, and fiber appear to assemble independently in the cytoplasm. Mutations in the C-terminus of the penton that block assembly into pentamers do not prevent transport into the nucleus (58), indicating that each monomer has an active NLS. In contrast, the fiber must form trimers to be efficiently transported to the nucleus (91), even though this protein has an active NLS located at its N-terminus (50). It seems likely that the oligomerized penton base and fibers are transported independently into the nucleus and assemble into the intact penton at the site of assembly.

Two distinct pathways for adenovirus capsid assembly have been postulated from a large body of work in this area. Results from experiments that combined kinetic labeling with temperature-sensitive replication mutants yielded an assembly scheme shown in Figure 7, where, in a manner similar to that observed with DNA phages, an empty capsid is first formed. DNA and associated core proteins are then subsequently packaged into these empty shells to yield “young virions” that then undergo proteolytic maturation. Additional viral products appear to act as scaffolding proteins around which shells are assembled and which facilitate the encapsidation process. These proteins are present in the intermediate capsid-like particles but are absent once DNA has been encapsidated (reviewed in 20). Disruption of adenovirus capsids with denaturants results in the release of groups of nine hexons that are associated with the faces of the icosahedron and that lack the peripentonal hexons. Under acid conditions, these nanomers can reassemble to form icosahedral shells that lack the 12 vertices, which would normally be composed of the penton and the five peripentonal hexons, raising the possibility that hexon nanomers are intermediates of adenovirus capsid assembly.

The empty-capsid intermediate assembly pathway has, however, been brought into question by the observation that DNA packaging appears to be intimately linked with capsid assembly. A mutation in the DNA sequence necessary for genomic packaging, which results in inefficient DNA–capsid interactions, blocks assembly of empty capsids and results in the accumulation of nonassembled capsid precursors in the nucleus (45,46). This would argue that capsid assembly does not occur spontaneously in the absence of an interacting DNA, that DNA–protein interactions play a crucial role in initiating the assembly process, and that assembly might proceed around the DNA-containing core.

Assembly of Enveloped Viruses in the Nucleus

Two enveloped animal virus families, both of which use cell components that are located within the nucleus in their replication, initiate their assembly within that compartment. These are the herpesviruses and the orthomyxoviruses. In addition to importing into the nucleus the necessary components for assembly, these viruses must also export large nucleoprotein complexes back out into the cytoplasm.

In some respects, the herpesviruses represent a hybrid between a nonenveloped virus, such as adenovirus, and a more conventional enveloped virus, such as a retrovirus, in that they use the secretory pathway to transport large capsid structures from the nucleus to the outside of the cell. This group of large viruses assemble, within the nucleus, an icosahedral capsid shell that is 160 Å thick and 1,250 Å in diameter. The major component of this protein shell is VP5, which forms both the pentameric and hexameric capsomeres necessary to assemble the icosahedral structure. Associated with the outer surface of the hexamers is the abundant small protein VP26. Two additional proteins, VP19C and VP23, in a 1:2 ratio, form heterotrimeric triplexes, which fit between and link together adjacent capsomeres (87). Scaffolding proteins are essential for herpes simplex virus type 1 (HSV-1) capsid assembly and maturation, and in their absence, incomplete and aberrantly shaped capsids are assembled. As with adenovirus, the major capsid protein lacks a nuclear targeting signal, and its transport into the nucleus requires an interaction with either the scaffolding protein (VP22a) or the triplex protein VP19C, either of which can presumably provide the necessary NLS. VP23 similarly requires VP19C for nuclear localization, whereas VP26 appears to be directed there by its interaction with VP5 (100).

Studies of virus-infected cells, together with *in vitro* assembly studies, have provided valuable insights into the assembly process (88). These studies point to a pathway in which VP5, VP19C, and VP23 assemble around a scaffold to form an icosahedral, but predominantly spherical “procapsid”—the “B-capsids” identified by electron microscopy. The size and integrity of this structure is defined by the triplex proteins, which mediate the interactions between capsomeres (108,127). Cleavage of the scaffolding protein at a site near its C-terminus removes a 25–amino acid sequence that is necessary for binding to the major capsid protein, VP5. The resulting disassociation and release of scaffold allows for packaging of the viral DNA genome and induction of maturation of the capsid into a more angular icosahedral structure, the previously identified “C-capsids.” In the absence of an active proteinase, the scaffolding proteins remain associated with the protein shell preventing packaging of the viral DNA, and the procapsid is unable to mature (89,101). Several aspects of this

morphogenic pathway parallel the assembly and maturation of the bacteriophage P22 (61).

Unlike adenoviruses, which accumulate in the nucleus and are released on lysis of the cell, herpesviruses exit the nucleus by budding through into the lumen of the nuclear membrane. It is in this way that a herpesvirus initially enters the secretory pathway of the cell; the complexities of this interaction are discussed later in this chapter.

For influenza virus to take advantage of its unusual capacity to “steal” the capped 5' ends of host cell mRNAs to initiate its own mRNA synthesis, transcription and viral RNA replication must occur in the nucleus (see Chapter 7 and Chapter 46). Genomic (minus sense) RNAs are replicated by a different mechanism to yield templates for mRNA synthesis as well as progeny viral genomes. The eight viral RNA segments of this virus are packaged into individual RNPs containing the four proteins of the transcriptase complex (PB1, PB2, PA, and NP, each containing a functional NLS sequence) but are not exported into the cytosol until late in infection when the viral matrix (M1) protein begins to be synthesized (71). Under conditions in which matrix synthesis is inhibited, the viral RNPs (vRNPs) accumulate in the nucleus, tightly associated with the nuclear matrix. The block to export can be relieved by expression of matrix from an independent vector (8). Matrix association with the vRNPs also appears to be important for preventing their reentry into the nucleus because conditions such as acidification or mutations that promote dissociation of M1 allow the RNPs to be reimported (reviewed in 133). Thus, the matrix protein of influenza virus is a key modulator of vRNP transport into and out of the nucleus.

Assembly of Viruses in the Cytoplasm

Although targeting and import of proteins into the nucleus or secretory pathway involves well-characterized motifs on the proteins involved, the processes by which proteins are targeted to destinations within the cytoplasm remains, for the most part, obscure. Most viruses, even those that are nonenveloped, initiate or complete their assembly in association with membranes of the secretory pathway. Nevertheless, the intracellular pathways that function to transport their capsid components and genomes to these sites have not been defined. Reoviruses are the only animal viruses that appear to complete their assembly entirely in the cytoplasm without the involvement of membranes. Both genome replication and virus assembly occur in specialized areas of the cytoplasm known as *virus factories.* Little is known about the establishment and retention of proteins in these sites, but this specialized structure may be a mechanism to avoid the complexities of transporting virion components to a separate cytoplasmic assembly site after translation.

Intracytoplasmic Transport and Assembly of Retroviral Capsids

Retroviruses are enveloped viruses that, for the most part, complete their assembly by budding through the plasma membrane of the infected cell. The immature capsid of the virus is assembled from polyprotein precursors that must be transported through the cytoplasm to the underside of the plasma membrane. The membrane-spanning viral glycoproteins, on the other hand, must be transported through the secretory pathway of the cell to the cell surface, where they co-localize with the nascent, membrane-extruding capsid. All replication competent retroviruses contain four genes that encode the structural and enzymatic components of the virion. These are *gag* (capsid protein), *pro* (aspartyl proteinase), *pol* (reverse transcriptase and integrase enzymes), and *env* (envelope glycoprotein) (see Chapter 57). However, the product of the *gag* gene has been shown to possess all the necessary structural information to mediate intracellular transport, to direct self-assembly into the capsid shell, and to catalyze the process of membrane extrusion known as *budding* (109). In most retroviruses, the nascent Gag polyproteins are transported directly to the plasma membrane, where assembly of the capsid shell and membrane extrusion occur simultaneously (Fig. 8). Viruses that undergo this type C form of morphogenesis include members of the *Alpharetroviruses* and *Gammaretroviruses*. Lentiviruses and *Deltaretroviruses* assemble their capsids in a similar fashion. In the second morphogenic class of viruses, the type B/D class, the Gag precursors appear to be targeted first to an intracytoplasmic site, where capsid assembly occurs. These preassembled immature capsids are then transported to the plasma membrane where they undergo budding and envelopment (see Fig. 8). Viruses that undergo this process of assembly and release include members of the *Betaretroviruse*s. Members of the *spumavirus* genus also assemble immature capsids in the cytoplasm, but they are targeted to the ER for envelopment.

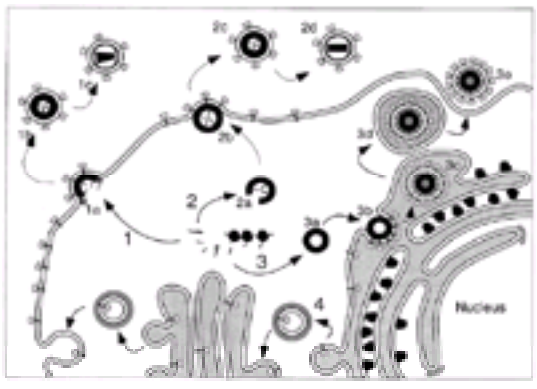

FIG. 8. Assembly of retroviruses. The assembly pathways of retroviruses that exhibit C-type morphogenesis (*Pathway 1*) , B- and D-type morphogenesis (*Pathway 2*) and that of the foamy viruses (*Pathway 3*) are shown. The envelope glycoproteins are translated on membrane-bound polysomes and, for most retroviruses, are transported to the cell surface through the cell's secretory pathway (*Pathway 4*). For all morphogenic classes, the Gag proteins are synthesized on free polysomes. In the case of the C-type morphogenic viruses (i.e., Rous sarcoma virus and human immunodeficiency virus), the Gag and Gag-Pol proteins migrate either individually or in small multimers to the plasma membrane, where immature capsid assembly and envelopment occurs concurrently (*1a*). At some ill-defined point in this pathway, the viral genomic RNAs associate with the Gag and Gag-Pol precursors and are incorporated into the developing capsid. In the case of the B- and D-type viruses, the Gag and Gag-Pol precursors are first transported to an intracytoplasmic assembly site (*2a*), where they assemble into immature capsids. The immature structures are then transported (*2b*) to the plasma membrane, where they associate with the envelope glycoproteins and induce viral budding. For both classes of retroviruses, the capsids of the nascent immature particles appear as doughnut-shaped

structures in thin-section electron microscopy and contain unprocessed Gag and Gag-Pol precursors (*1b* and *2c*). The mature virus particles contain electron-dense cores with morphologies characteristic of the virus (*1c* and *2d*). The maturation step is required for infectivity and is the result of the activation of the viral protease, which cleaves the Gag and Gag-Pol precursors into the internal structural and enzymatic proteins of the virus. For the foamy viruses, Gag and Pro-Pol precursors assemble into immature capsids in the cytoplasm (*3a*). Budding primarily occurs at the endoplasmic reticulum membrane where the viral glycoproteins are retained (*3b*). The enveloped virion is presumably transported to the plasma membrane by transport vesicles (*3d*). Maturational cleavage of the immature core is limited to removal of 4 kd from the C-terminus of the precursor; the mature infectious virion maintains an immature morphology (*3e*).

Although the size and protein content of the precursor varies between different retroviral families, at least three *gag*-encoded proteins are found in all retroviruses; these are the matrix protein (MA), the capsid protein (CA), and the nucleocapsid protein (NC). In addition to these functionally conserved domains, the Gag precursor can, depending on the virus encoding it, contain additional peptide sequences (Fig. 9), whose function in virus assembly and future cycles of infection is only now being resolved. Some of these additional domains appear to allow the correct folding of the precursor protein for assembly and subsequent processing into the mature virion proteins.

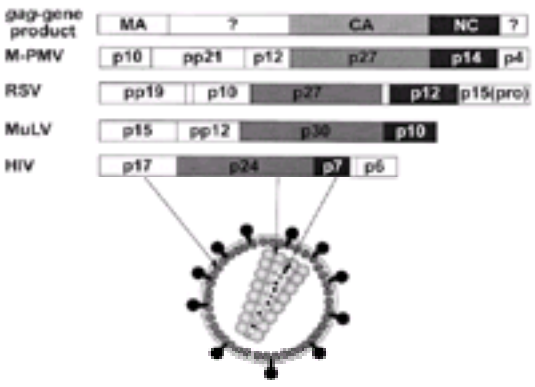

FIG. 9. Organization of the retroviral Gag precursor. The Gag precursor polyproteins of all retroviruses contain, beginning at the N-terminus, matrix (MA), capsid (CA), and nucleocapsid (NC) domains, linked in this order. The *gag* gene products of Mason-Pfizer monkey virus (M-PMV), Rous sarcoma virus (RSV), murine leukemia virus (MuLV), and human immunodeficiency virus (HIV) are shown. The *unshaded boxes* represent regions of the Gag precursor for which no common functions or locations in the mature virion have been established. However, for these three representatives of the alpha-, beta-, and gamma-retroviruses, a “late domain” function required for pinching off of the virus particle from the cell is located between the MA and CA domains. The specific name associated with the Gag cleavage products is derived from their respective apparent molecular weights ($\times 10^{-3}$).

The detailed mechanisms by which the capsid precursor proteins are directed to the site of assembly remains for the most part unknown, but the process is mediated primarily by the MA domain of the Gag precursor. In most retroviruses, the matrix protein contains two elements involved in plasma membrane targeting. The first of these is an N-terminal myristic acid, which is thought to insert into the hydrophobic lipid bilayer. The second is a surface patch of basic amino acids that are hypothesized to mediate the initial interaction of Gag with the negatively charged, phospholipid head groups of the membrane. The bipartite signal created by these two elements appears to be important for intracellular targeting to the plasma membrane because mutations that interfere with either myristylation or the charged residues can abrogate plasma membrane targeting. In some instances, Gag precursors mutated in these sequences are targeted to internal membranes (reviewed in 33).

In the *Betaretroviruses*, where capsid assembly and virus budding are discrete events, a recent genetic dissection of this process suggests that Gag-containing precursors of these viruses express a dominant sorting signal, identified as a surface loop of the MA domain, that targets the proteins to the initial assembly site. A point mutation within this region of the Mason-Pfizer monkey virus (M-PMV) MA domain abrogates intracytoplasmic targeting and results in the type C–like transport of precursors to the plasma membrane, where efficient capsid assembly occurs. In addition, transfer of the protein motif to the Gag of the C-type virus murine leukemia virus (MuLV) results in its retention and assembly in the cytoplasm (11). These results suggest that the *Betaretroviruses* have evolved to use a transport pathway of the cell to target precursors for intracytoplasmic assembly.

By what pathways might preassembled immature capsids of the *Betaretroviruses* or the Gag-containing precursors of the C-type viruses be transported to the plasma membrane? Several studies have suggested that cytoskeletal elements might be involved in this process, but direct evidence for this has not been obtained (reviewed in 62). Recent experiments indicate that the transport process is an active rather than a passive one since it appears to require energy. In cells treated with agents that block ATP synthesis, M-PMV immature capsids are unable to migrate to the plasma membrane from sites deep within the cytoplasm (132).

Irrespective of the assembly site, Gag precursor proteins must associate in a reproducible fashion to assemble into the nascent capsid. Mutational analyses of *gag* genes, as well as *in vitro* assembly studies, have shown that the CA and NC domains of Gag play a crucial role in assembly; MA is dispensable for this process (reviewed in 17 and 33). NC binding to RNA may act to nucleate the capsid assembly process, whereas CA forms a symmetric network of proteins. *In vitro,* the CA protein alone can assemble into tubes that exhibit local sixfold symmetry (hexamers), but cryoelectron microscopy studies of immature capsids has revealed a large heterogeneity in particle size and no evidence of icosahedral

symmetry. It is possible, therefore, that the immature capsid has a fullerene-like structure similar to that proposed for the mature core (34,86).

For most retroviruses, capsid assembly drives the process of membrane extrusion known as budding. As discussed later, in order for an infectious virus to be formed, the Gag precursors (or for other viruses, NPs) and surface glycoproteins of the virus must be targeted to the same region of the same membrane. In this way, during virus budding, a proper complement of glycoproteins can be incorporated into the nascent virion.

Assembly of Enveloped Viruses at Cellular Membranes

For most enveloped viruses, the location within the cell at which envelopment takes place is determined by the targeting to or retention of the viral glycoproteins at that site. Indeed, with the exception of the retroviruses, the efficiency of virus budding and particle release is highly dependent on the presence of the envelope glycoprotein, and in its absence, few particles are produced. Because the glycoproteins define the site of virus budding, specific interactions between the viral NP and the glycoproteins, sometimes mediated by a matrix protein, must take place to ensure that the genome of the virus is incorporated. For each of the viruses that assemble at intermediate points within the secretory pathway, fully assembled viruses must traverse the remainder of the pathway to be released from the cell (Fig. 10). Glycoproteins on these released viruses have complex oligosaccharides and are most likely modified by the Golgi-localized enzymes on the way to the cell surface.

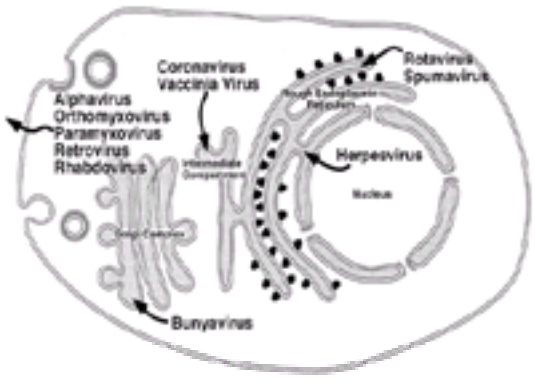

FIG. 10. Viral assembly at cellular membranes. Schematic representation showing the intracellular locations at which enveloped virus assembly takes place. For each virus that is enveloped at organelles within the secretory pathway, the virions must traverse the remainder of the pathway to be released from the cell. For the herpesviruses, two morphogenic pathways have been proposed (see also Fig. 12). In the first, the virus buds into the lumen of the nuclear membrane and is then transported to the cell surface through the secretory pathway. In the second, the virus also buds into the lumen of the nuclear membrane, but then the nascent virus fuses with the outer nuclear membrane to release the capsid, which is then enveloped by membranes derived from the Golgi complex. Rotaviruses appear to use the endoplasmic reticulum (ER) membrane as a scaffold for assembly of virion proteins—the capsids that form during the assembly process are only transiently enveloped, and nonenveloped particles accumulate in the lumen of the ER. Coronaviruses localize the three membrane proteins (E, M, and S) in the ER intermediate compartment, in which virus budding occurs. In contrast, the vaccinia virus nucleocapsid appears to be wrapped by a double membrane derived from this compartment but remains free in the cytoplasm so that it can then be further enveloped by Golgi-derived membranes. The G1 and G2 glycoproteins of bunyaviruses co-localize in the *trans*-Golgi compartment to direct budding of nucleocapsids at this location. For the several families of viruses that assemble at the plasma membrane, the final location of the viral glycoproteins also appears to be important in defining where assembly occurs. Even for the retroviruses, which can assemble and release virus particles in the absence of envelope glycoproteins, these proteins direct virus budding to the basolateral plasma membrane of polarized epithelial cells.

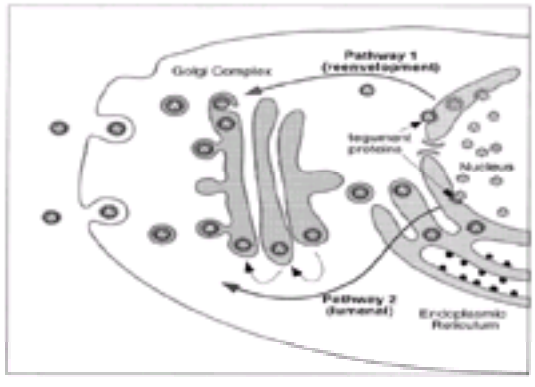

FIG. 12. Herpesvirus assembly. Two pathways are proposed for herpesvirus assembly and release from the cell. In the reenvelopment pathway (*Pathway 1*), nascent assembled capsids bud into the lumen of the nuclear membrane using a subset of virally encoded glycoproteins. These enveloped particles then fuse with and are released from the outer nuclear membrane into the cytoplasm. There, they associate with the tegument proteins and are transported through the cytoplasm to be enveloped by Golgi-derived membranes that contain the full complement of virion glycoproteins. In the lumenal pathway (*Pathway 2*), the nascent capsids associate with tegument proteins in the nucleus before budding through the inner nuclear membrane, which must contain a full complement of virion glycoproteins. The enveloped virus particle now traverses the secretory pathway, and the glycoproteins are modified to their mature form during transit through the Golgi complex.

Assembly at the Endoplasmic Reticulum Intermediate Compartment

The coronaviruses are positive-stranded RNA viruses with large (30 kb) genomes packaged in a helical nucleocapsid. The nucleocapsid acquires its envelope by budding into the lumen of a pre-Golgi compartment of the secretory pathway termed the *endoplasmic reticulum–Golgi intermediate compartment*. Coronaviruses invariably encode three envelope proteins. The spike protein (S), which determines the host range of the virus, is a type I glycoprotein that forms the distinct bulbous peplomers of the virus. Expressed independently of the other glycoproteins, S is transported to the plasma membrane and so is unlikely to determine the site of virus assembly. The most abundant virion protein is the membrane (M) glycoprotein. M spans the lipid bilayer three times, exposing a short N-terminal domain outside the virus and a long C-terminus inside the virion. Because of its abundance and because M is transported to the Golgi complex but not to the surface, it was initially thought to define the site at which this family of viruses were enveloped. Recent studies, however, have shown that the small envelope protein (E), which is only a minor component of virions, is the key to defining the site and nature of coronavirus envelopment. E is a hydrophobic type-I membrane protein that localizes to the intermediate compartment of the ER and induces the formation of tubular, convoluted membrane structures characteristic of virus infection (15,98). How E is retained in the intermediate compartment is not known. Coexpression of E, M, and S results in the assembly and release from cells of virus-like particles containing these three viral membrane proteins. The enveloped particles produced by this system form a homogeneous population of spherical particles indistinguishable from authentic virions in size and shape (129). Only M and E are required for efficient particle formation, and expression of E alone can mediate particle release (68). The E protein plays a key role in morphogenesis because mutations in this protein can result in morphologically aberrant viruses (30). The S glycoprotein is thus dispensable for virus particle assembly but is retained in the Golgi by the M protein, which appears to direct its assembly into virions. M protein also directs the incorporation of nucleocapsids containing the genome length RNA into virions, and nucleocapsids associated with newly synthesized M protein have been localized to the budding site in the intermediate compartment (85).

Although most of the retroviruses are enveloped at the plasma membrane of the cell, members of the spumavirus genus bud into the ER intermediate compartment region of the secretory pathway. Expression of the primate foamy virus Env complex, gp80-gp48, in the absence of other structural proteins, results in its localization to the ER. A dilysine ER retrieval motif at the C-terminus of gp48 is responsible for this location, and mutation of either lysine results in efficient transport of the protein to the plasma membrane. Although a greater fraction of capsids bud from the plasma membrane in mutant virus–infected cells, envelopment of capsids at the ER is still observed (37). A second distinguishing feature of foamy viruses is the dependence of capsid envelopment on Env expression. As with the *Betaretroviruses*, immature foamy virus capsids assemble in the cytoplasm. They are then transported to the ER (or plasma membrane) for envelopment. In the absence of foamy virus Env, these preassembled capsids do not associate with membranes or initiate budding (31). Recent experiments have shown that it is the posttranslationally cleaved (148 amino acids long), membrane-spanning, signal peptide domain of the foamy virus Env that mediates capsid membrane association and envelopment and that this protein is incorporated into the virus in the process.

Assembly in the Golgi Complex

Bunyaviruses are negative-stranded, enveloped viruses with a segmented genome that bud into the Golgi complex (see Fig. 10). The glycoprotein spikes of the best-characterized member of this family, Uukuniemi virus, are composed of two type I glycoproteins, G1 and G2, that determine the site of virus budding. G1 and G2 are cotranslationally cleaved from a single precursor protein by signal peptidase, which cleaves after the internal signal sequence that mediates translocation of G2. The two proteins have been shown to fold with distinctly different kinetics, but once properly folded, they form a G1-G2 heterodimer that is transported to the Golgi complex. G2 expressed in the absence of G1 is retained in the ER, whereas G1 expressed alone is targeted to the Golgi (reviewed in 42). The Golgi localization signal of G1 has been mapped, through analysis of mutations and glycoprotein chimeras, to the membrane proximal half of the 98–amino acid long cytoplasmic tail of the protein. Surprisingly, a region of 81 amino acids, between the putative transmembrane domain and the G2 signal peptide at the C-terminus of the G1 cytoplasmic tail, expressed as a soluble protein or as a green fluorescent protein (GFP) fusion, could localize to the cytoplasmic face of the Golgi complex (2). Glycoprotein retention in this case, therefore, appears to depend on interactions between the cytoplasmic tail of G1 in the G1-G2 heterodimer, with components residing on the cytoplasmic side of the Golgi membrane.

During infection by bunyaviruses, the helical nucleoproteins, consisting of the three single-stranded genomic RNA segments and the associated nucleocapsid (N) protein, accumulate in the region of the Golgi and presumably interact with the G1 cytoplasmic domain to initiate the budding of virus particles into the Golgi lumen. The region of the secretory pathway at which G1-G2 heterodimers accumulate clearly defines the budding site because, in the presence of brefeldin, a drug that redistributes Golgi components to the ER, virus budding occurs into the ER (42).

Assembly at the Plasma Membrane

Members of several virus families undergo their envelopment at the plasma membrane. These families include the togaviruses, rhabdoviruses, paramyxoviruses, orthomyxoviruses, and retroviruses. In each of these cases, the viral glycoproteins, either as hetero-oligomeric complexes or homo-oligomers, have traversed the entire secretory pathway to be delivered to the plasma membrane of the cell. Assembly at the plasma membrane obviates the need for the assembled virus to navigate additional compartments of the secretory pathway because virions are released directly into the external milieu of the cell. Alphaviruses are perhaps the best characterized of these different viral systems because a combination of biochemical, genetic, and structural information has been amassed to shed light on the complexity of this assembly process. The major glycoproteins E1 and E2 of the alphaviruses are translated from a subgenomic 26S RNA as a p62, 6K, E1 precursor complex that is transported to the Golgi, where p62 is processed to E2. Stable trimers of E1-E2 heterodimers are then transported to the plasma membrane, where they associate with assembled core structures composed of the capsid (C) protein and genome-length RNA (reviewed in 35). Recent cryoelectron microscopy analyses of mature alphavirus particles have revealed for the first time a detailed structure of this enveloped virion (see Chapter 3 and Chapter 29). These studies have shown that both the envelope and the core display icosahedral symmetry.

Surprisingly, however, the trimers of E1 and E2 are located at the threefold and quasi-threefold symmetry axes of the pentameric and hexameric order of the nucleocapsid (Fig. 11). Moreover, the heterodimers of each spike splay out above the membrane in a skirtlike fashion, traverse the lipid bilayer individually, and interact with three underlying capsid (C) proteins that belong to three separate capsomeres. This creates a complex network of molecular interactions, where the glycoprotein–capsid protein interactions not only mediate the binding of the nucleocapsid to the spikes but also stabilize the connections between the capsomeres. Above the membrane, the skirts formed by the E1-E2 heterodimers form lateral connections that mimic the pentameric and hexameric arrangement of the capsid. These interactions may facilitate the process of budding by providing a multivalent binding site for the capsid as well as by providing a force for membrane bending (35). Budding, however, requires a cooperative interaction between the glycoproteins and the capsid protein because, in the absence of either, budding does not occur. Moreover, mutations in the cytoplasmic tail of the E2 protein alone can abrogate budding. It has been proposed that alphavirus budding is initiated by NC binding through hydrophobic interactions between the cytoplasmic domain of E2 and the capsid protein to a cluster of E1-E2 trimers at the plasma membrane. The recruitment of additional clusters of glycoprotein heterodimers into the complex by cooperative trimer–trimer and heterodimer–capsid protein interactions would continue until envelopment is completed (35). This model does not, however, take into account a role for the 6K protein, which can clearly influence the budding process and may be present at the cell surface as part of the glycoprotein complex.

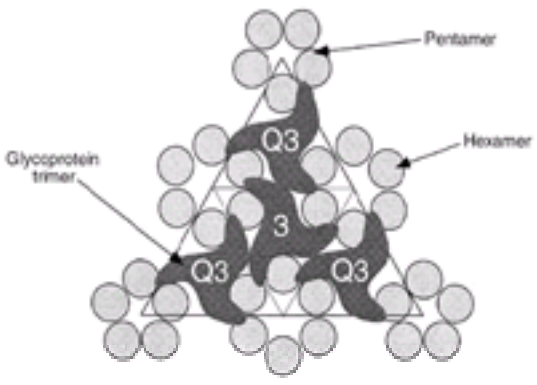

FIG. 11. Alphavirus glycoprotein–capsid interactions. Schematic representation of the interactions between the glycoprotein spikes at the threefold (*3*) and quasi-threefold (*Q3*) axes of the nucleocapsid structure and the capsid proteins of the hexameric and pentameric capsomeres of that structure. The spikes are involved in extensive lateral interactions near the lipid bilayer through their skirts, and through interactions with the capsid protein, they stabilize interactions between capsomeres. (Modified from ref. 35, with permission.)

For the negative-stranded RNA viruses, orthomyxoviruses, paramyxoviruses, and rhabdoviruses, an additional protein, the matrix protein, mediates the interactions between the viral glycoproteins and the RNP and appears to play a key role in envelopment. These proteins are able to bind to membranes through hydrophobic domains or, as with the retroviruses, through a cluster of positively charged residues that initiates electrostatic interactions with the plasma membrane. Cross-linking studies have demonstrated that these M proteins form homo-oligomers in the virus and can self-associate *in vitro* or when expressed at high levels in cells. As discussed earlier, the M1 protein of influenza virus acts to mediate the transport of RNPs from the nucleus to the site of virus assembly on the plasma membrane. Little is known about the intracytoplasmic transport pathways involved in targeting this complex; nevertheless, the RNPs appear to accumulate at regions of the plasma membrane enriched for M1. The importance of the M protein in the paramyxovirus budding process was inferred from the defective measles viruses found in subacute sclerosing panencephalitis (SSPE) that are unable to assemble virus particles and that have mutations in the M protein–coding region (6). However, the recent development of reverse genetics systems for the negative-stranded viruses, in which mutations can be reintroduced into the viral genome, has allowed a more rational approach to examining these questions. Construction of rhabdovirus genomes that lack the M coding region resulted in a dramatic (more than 105-fold) decrease in the release of virus particles, and those that were released lacked the characteristic bullet-shape morphology. The defect could be complemented by expression of M in *trans* (74). Thus, in the rhabdoviruses, the M protein condenses the helical RNP into its characteristic shape and mediates the envelopment process.

Similar approaches have begun to shed light on the role of the G glycoprotein in rhabdovirus assembly. Viruses that lack the G protein–coding domain do assemble and release bullet-shaped particles but at only 3% the efficiency of wild-type viruses (73). Initial studies with G proteins lacking a cytoplasmic tail suggested that this domain might be important in the budding process; however, recent studies have shown that although there is a general requirement for at least a short cytoplasmic tail, it is amino acid sequence independent. Thus, the basis for M protein interactions with G is unresolved. Furthermore, foreign glycoproteins can be efficiently incorporated into rhabdovirus particles, but they do not stimulate budding (102). This is consistent with recent experiments that have identified a domain within the extracellular membrane proximal stem (GS) of vesicular stomatitis virus (VSV) G that is required for efficient VSV budding. Recombinant viruses encoding glycoprotein chimeras with 12 or more membrane proximal residues of the GS, as well as the G protein transmembrane and cytoplasmic tail domains, produced near wild-type levels of particles. In contrast, those with shorter regions produced 10- to 20-fold fewer particles. It is possible, therefore, that this region of the G protein membrane proximal domain modifies the membrane to facilitate the budding process (103).

In influenza virus, the fact that the cytoplasmic domains of both the HA and the neuraminidase (NA) are highly conserved in all subtypes of the virus pointed to a role for this domain in assembly of enveloped virus. Early studies indicated that HA proteins with foreign cytoplasmic tails are not incorporated into virions, although HAs lacking this domain can be incorporated at levels 50% that of wild-type viruses (82). Recent studies using reverse genetics have confirmed these findings and have shown that the short (6 amino acid) cytoplasmic domain of NA also plays an important role in morphogenesis. Viruses encoding the truncated NA protein were released less efficiently and were larger and more filamentous. However, in viruses encoding tail-less versions of both HA and NA, a 10-fold reduction in virus release was

observed, and morphogenesis was drastically altered. Virus particles released from these cells were greatly elongated, with an extended irregular shape and a reduced level of viral RNA. Thus, it appears that for influenza virus, the interactions between M1 and the viral glycoproteins are so important for envelopment and morphogenesis that the virus has developed redundant interaction domains in both HA and NA (55,136).

As described earlier, with the exception of the spumaviruses, glycoprotein–capsid interactions are not required for the assembly and release of enveloped retrovirus particles; the Gag precursor alone contains the information necessary to be specifically targeted to the plasma membrane and to drive budding. Moreover, there is contradictory evidence regarding the role of the cytoplasmic domain in directing the envelope glycoprotein into budding virions because Env proteins lacking a cytoplasmic domain can be efficiently incorporated into retrovirus particles and can effectively mediate virus entry into target cells (reviewed in 51). Nevertheless, for members of the lentivirus family, such as HIV and simian immunodeficiency virus (SIV), that encode envelope glycoproteins with a long (150 amino acids or more) cytoplasmic domain, a specific interaction between the tail of TM and the MA domain of the Gag precursor appears to be necessary for Env incorporation. For these viruses, mutations in MA or in the cytoplasmic tail can abrogate Env incorporation (reviewed in 33). Further evidence for this interaction is derived from polarized epithelial cells, in which retroviral glycoproteins define the plasma membrane domain at which virus budding and release occur (see later).

Targeting of Viral Glycoproteins in Polarized Epithelial Cells Defines the Site of Budding

Many viruses initiate their infection of a host by interacting with cells of an epithelial surface. Individual cells within an epithelial layer are tightly connected by junctional complexes that form a barrier to diffusion of molecules throughout the cell membrane and divide the cell surface into two distinct plasma membrane domains: the apical domain, which faces the exterior; and the basolateral domain, which faces the interior. As a result of differential targeting of lipids and protein components to apical and basolateral membranes, epithelial cells in tight monolayers are highly polarized, with each plasma membrane domain having a distinct lipid and protein composition (105). The assembly and release of many viruses from epithelial cells is also highly polarized, occurring selectively at either the apical or basolateral surface. Influenza virus releases newly assembled virions from the apical surface of polarized epithelial cells, whereas VSV and many retroviruses are released from the basolateral membrane. In the absence of other viral proteins, VSV G protein and retroviral Env proteins are transported to the basolateral surface, whereas HA and NA are targeted to the apical membrane. This delivery to specific membranes is consistent with viral glycoproteins directing the site of virus assembly and envelopment (reviewed in 14). Sorting of proteins to one or the other domain occurs in the *trans*-Golgi network, and recent evidence suggests that proteins destined for the basolateral surface contain within their cytoplasmic domain motifs that direct the protein to that membrane. In the VSV G protein, a tyrosine-based motif within the cytoplasmic tail appears to be crucial to basolateral targeting (124). Similarly, tyrosine-based endocytosis motifs in the cytoplasmic domain of both the MuLV and HIV Env proteins are important for their polarized expression and for basolateral budding of their cognate viruses. In the absence of this signal, Env proteins are delivered to and virus buds from both membranes with equal efficiency (65).

Apical transmembrane proteins appear to contain two signals that probably act cooperatively in targeting to the apical surface. Thus, glycosylation in the ectodomain and a signal in the membrane-spanning domain (MSD) function together to ensure association with sphingolipid-cholesterol–enriched membrane domains or rafts. Rafts have been proposed to mediate apical transport in polarized epithelial cells, and the influenza virus HA partitions into these detergent-insoluble glycolipid-rich membrane fractions through sequences in its MSD (111,112). Polarized virus assembly and release may be important in determining the pathogenesis of viral infections because it can influence in a major fashion the pattern of virus spread in the infected host (14).

Complex Interactions with the Secretory Pathway

Although most enveloped viruses undergo assembly and envelopment at a single site within the secretory pathway, some viruses have a more complex interaction that can involve deenvelopment or reenvelopment as part of their assembly pathway.

Rotavirus Assembly Within the Endoplasmic Reticulum

Rotaviruses are nonenveloped viruses that undergo transient envelopment at the ER as an essential step in the formation of the mature double-shelled (triple-layered) virus that is retained within the lumen of the ER until cell lysis. As with the reoviruses, the nucleocapsid, in this case containing 11 double-stranded RNA segments, is assembled in electron-dense areas of the cytoplasm, located close to the ER membrane, known as *viroplasm* (29,90). These double-layered nucleocapsids have an outer icosahedral shell assembled from VP6, the most abundant protein of the virus, surrounding an inner core (see Chapter 54). They appear to bud directly into regions of the ER that contain the two outershell proteins VP7 and VP4. A nonstructural protein NSP4, which forms hetero-oligomers with the two outershell proteins, mediates the interaction of the immature particle with the ER membrane (77). A hydrophobic N-terminus anchors this integral membrane protein in the ER, whereas the C-terminal 20 amino acids acts as a receptor for the VP6-containing protein shell. A region of NSP4 near the C-terminus, distinct from the receptor domain, adopts an a-helical coiled-coil structure and mediates the oligomerization of the virus-binding domains into a homotetramer. In this way, presumably, a multivalent receptor for the rotavirus single-shelled particle is connected to an a-helical coiled-coil stalk, which projects from the ER membrane, such that membranes containing NSP4 can bind double-layered particles *in vitro* (92,123).

The exact topology of VP7 in the ER is not known. The mature protein has a cleaved signal peptide but is retained in the ER as if it were an integral membrane protein (56,119). Sequences at the N-terminus of the mature protein, which include the highly conserved LPITGS sequence, are important for its retention (67). VP4 is thought to associate with VP7 and NSP4 just before budding of the nucleocapsid into the ER. Enveloped particles can be observed in the lumen of the ER, which then undergo a process of calcium-dependent deenvelopment, forming in the process an outer icosahedral shell of VP7 and VP4 (97). Thus, this nonenveloped icosahedral virus appears to use the ER membrane transiently as a scaffold

on which to assemble an icosahedral shell.

Herpesvirus Transport from the Nucleus

As described earlier, the end product of herpesvirus capsid assembly is a large icosahedral structure that is too large to transit the nuclear pore. To release virus to the exterior of the cell, herpesviruses have evolved to use portions of the secretory pathway. This presumably provides the virus with the ability to propagate progeny virions, whereas the cell and its nucleus remain intact. The precise pathway taken by herpes capsids to the exterior of the cell remains controversial mainly because the bulk of the evidence has come from electron microscopic observations of infected cells (42,99). Nevertheless, there is consensus that the first stage involves budding of the capsid through the inner nuclear membrane into the luminal space. Morphologically, the sites of budding show thickening of the membrane at sites to which viral glycoproteins appear to be targeted (38). Some of these glycoproteins, such as the gB protein of human cytomegalovirus (HCMV), appear to have a novel amino acid motif in their cytoplasmic domain responsible for this intranuclear targeting (76). Little is known, however, about the cellular factors or viral components involved in this envelopment step.

It is equally unclear which of two proposed routes the initially enveloped capsid takes to the exterior (Fig. 12). In the first (Pathway 1: reenvelopment), the membrane of the newly enveloped virus fuses with the outer nuclear membrane to release the capsid into the cytoplasm. It is here that *tegument proteins,* a collection of proteins including transcription factors located between the viral capsid and its lipid bilayer in the mature particle, are proposed to associate with the capsid before its reenvelopment by Golgi-derived membrane vesicles. In the second proposed route (Pathway 2: lumenal transport), the virion retains the membrane derived from budding into the lumen of the nuclear membrane and is released into the cytoplasm within a vesicle formed from the outer nuclear membrane or contiguous ER. In this latter pathway, a full complement of viral glycoprotein and tegument proteins must be incorporated into the virus during the nuclear budding step. Maturation of the viral glycoproteins might then be expected to occur after vesicular transport of virions through the Golgi complex.

Although differentiating between the two pathways might seem straightforward, this has not been the case. However, a recent reanalysis of the evidence for each pathway concludes that the balance favors the reenvelopment pathway (28). Some of the clearest evidence comes from the beta-herpesviruses, HCMV, and human herpesvirus type 6 (HHV-6). In these viruses, the tegument is a dense structure that can be observed in electron micrographs. Enveloped virions in the lumen of the nuclear membrane display no evidence of tegument but acquire this layer after loss of the nuclear-derived envelope and release into the cytoplasm (106,125). Studies of the glycoproteins of the gamma-herpesvirus, Epstein-Barr virus, also support this model. Distribution of the viral glycoproteins gp110 and gp350/220 is consistent with the former being incorporated in virions at the nuclear membrane then lost on budding into the cytoplasm, whereas the latter is acquired only during reenvelopment in the Golgi (38). Similarly, studies of the lipid composition of extracellular HSV-1 virions indicate that it is similar to that of the Golgi complex and distinct from that of the nucleus (128). Thus, it appears likely that herpesviruses have evolved to make use of a two-step pathway of release from the cell. It remains to be seen whether different sets of glycoproteins are used to mediate the envelopment of capsid at each of these steps and what the molecular interactions are that drive each event.

Poxvirus Acquisition of Multiple Membranes

Poxviruses, exemplified by vaccinia virus, exhibit an equally complex interaction with the secretory pathway. These large DNA viruses, which encode all of the machinery necessary for genomic replication and transcription, propagate entirely in the cytoplasm in specialized areas designated virus factories (see Chapter 84). The assembly and envelopment of these viruses is particularly complex because they apparently can be enclosed by as many as four lipid bilayers. Initial electron microscopy studies suggested that the crescent membranes that wrap the immature virions are formed *de novo* within the virus factories (21). Subsequently, it was shown that these envelopes, composed of two closely apposed membranes, are derived from the intermediate compartment of the secretory pathway (116). Co-localization of intermediate compartment resident cellular proteins with several vaccinia virus membrane proteins (A17L, A14L, and A13L) known to be crucial to the formation of immature virion membranes supported this model (63,110). The process by which the nucleoprotein and transcription machinery is targeted into these immature envelopes is unclear. Maturation of the immature virion to the infectious intracellular mature virus (IMV) involves a series of proteolytic cleavages of vaccinia structural proteins (80). The mature virus particles are transported out of the assembly areas toward the periphery of the cell, where they become wrapped by additional membranes that are derived from the *trans*-Golgi or early endosomal compartments to form the intracellular enveloped virus (IEV). The membranes of these compartments contain vaccinia proteins that are present in the external enveloped virus (EEV). Wrapping requires the participation of at least one protein present on the IMV and two EEV membrane proteins and thus appears to be driven by interactions between vaccinia-encoded membrane proteins (7,104). The IEV thus contains four concentric membranes, two derived from the intermediate compartment and two from the Golgi and endosome. These particles are then transported through a reorganized actin cytoskeleton (so called actin tails) to the plasma membrane (19), where membrane fusion releases the infectious three-membrane EEV form of the virus.

Modification of the Secretory Pathway

Transcription and Assembly of Poliovirus on a Disassembled Secretory Pathway

Poliovirus is a nonenveloped positive-sense RNA virus that modifies the host cell extensively during its replication. Once introduced into a target cell, the genomic RNA is translated into a long polyprotein precursor that contains both structural and replicative proteins of the virus (Fig. 13; see Chapter 23). Early in the replication of the virus, membranous vesicles appear in the cytoplasm that are found first near the nucleus and then throughout the entire cytoplasm. Viral RNA transcription occurs in close association with these vesicles, and both viral RNA and viral proteins known to be required for RNA replication have been shown by electron microscopy to be associated with their cytoplasmic surface (5,126). Similarly, priming of RNA synthesis by the protein primer, VPg, appears to require membranes (122). Electron microscopy and inhibitor studies initially suggested that the induced vesicles are derived from the host cell secretory

pathway because they appear to be connected to ER membranes and both their formation and poliovirus replication are blocked by brefeldin A (5,52). More recent studies have shown that a single poliovirus protein, 3A, which also appears to be responsible for attaching VPg to membranes as a 3AB precursor, induces the formation of these ER-derived vesicles and disassembly of the Golgi complex (26). It is hypothesized that 3A interferes with the assembly of COPII vesicles so that newly synthesized membranes, and those recycled from the Golgi, accumulate in the ER (26).

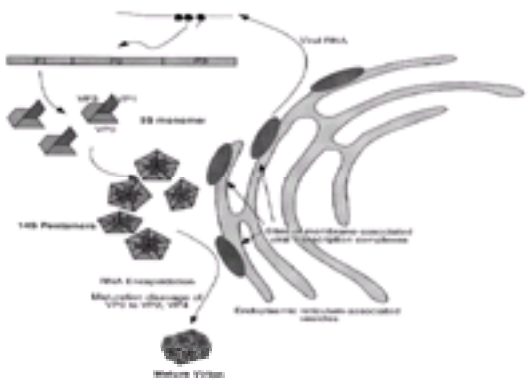

FIG. 13. Poliovirus assembly. The P1 precursor protein is cleaved through an autocatalytic event from the nascent polyprotein and is then cleaved twice by the 3CD-protease to yield VP1, VP3, and VP0. This cleavage is essential for assembly of the 5S monomers into 14S pentamers. It is likely that 12 of these pentamers associate directly with nascent genomic RNA that is being transcribed from membrane-bound transcriptional complexes to assemble an immature 150S provirion. Maturation cleavage of VP0 to yield VP2 and VP4 results in conversion of these immature provirions into the 160S mature virion.

The formation of vesicular platforms for transcription may also be necessary for efficient capsid assembly. The poliovirus capsid appears to be assembled in a sequential process in which the 5S protomers containing VP1, VP3, and VP0 assemble to form 14S pentamers, which in turn are assembled into virus capsids (see Fig. 13). Pentamers may associate with newly synthesized genomic RNA on intracytoplasmic vesicles, then assemble to form RNA-containing capsids upon completion of the RNA. This assembly pathway is supported by immunoelectron microscopy studies showing that pentamers associated with the replication complex can, if released by detergent, rapidly assemble into empty capsids—arguing that the vesicle prevents assembly of the capsid and keeps the pentamer in an appropriate configuration for association with the RNA (95). In this instance, then, poliovirus appears to have circumvented the problems of intracytoplasmic localization of replicative and structural components by using a membranous organizing center.

Modification of Post-Golgi Vesicle pH by the Influenza Virus M2 Protein

The influenza HA is synthesized as a precursor protein (HA_0) that, in the case of the avian influenza viruses, is cleaved in the *trans*-Golgi by furin-like proteinases to the biologically functional HA_1-HA_2 heterodimer, three of which in turn form the trimeric HA complex (see Chapter 3 and Chapter 46). The influenza virus HA present on an infecting virion is activated to its fusogenic state by the low pH of the endosome. Thus, the similarly low pH of the *trans*-Golgi network and post-Golgi vesicles poses a problem for the virus during the assembly phase of its life cycle, if it is to maintain HA in a functional prefusogenic form. This is apparently solved by the action of the M2 protein, a small tetrameric protein that forms cation-selective ion channels that can increase the pH of the *trans*-Golgi network by pumping out hydrogen ions (96,120).

INCORPORATION OF THE NUCLEIC ACID GENOME DURING THE ASSEMBLY PROCESS

Although the processes involved in the assembly of structural components of a virus are complex and interplay intimately with those of the host cell, they merely provide a mechanism by which the genomic information of the virus can be packaged into a protective environment for transfer to additional host cells. As such, the assembling virus must have evolved to select its genomic nucleic acid efficiently out of the pools of RNA or DNA that are present at the assembly site. Packaging of viral genomes generally involves a cis-acting sequence in the nucleic acid (the so-called packaging sequence) and a structural components of the virus that can recognize and bind this element.

DNA Viruses

As we described earlier, questions remain about the linkage of adenovirus DNA packaging to the process of capsid assembly. Nevertheless, early studies indicated that incomplete virus particles contain subgenomic-length viral DNA that have a large overrepresentation of left-end sequences. Subsequent studies showed that a cis-acting packaging sequence is located within the left 390 base pairs. This region is highly conserved between different adenovirus subtypes and, in Ad 5, overlaps with two distinct enhancer elements for E1A transcription. Deletion of the packaging domain abrogates viability, but infectivity can be restored by substitution of the left-end sequences at the right end of the genome (47). The packaging sequence only functions if it is within 600 base pairs of the inverted terminal repeat (ITS). Mutational analyses showed that this region contains at least seven functional adenosine-thymine (AT)-rich units called *A repeats.* Of the seven, elements I, II, V, and VII have been found to be dominant, and associated 11 base pairs downstream from each of these is a CG motif that also appears crucial to function. Overexpression of an A-repeat multimer results in a dramatic decrease in viral yield without affecting DNA replication or late-transcription (41,114), suggesting the involvement of a limiting viral protein component in packaging. Although this protein has yet to be identified, more recent studies have shown that encapsidation of DNA requires the presence of the nonstructural L1 52/55K protein: empty capsids form in its absence (43). How it might mediate packaging is unclear.

Packaging of the herpesvirus genome is equally complex. As with the large DNA phages, herpesvirus DNA replicates to yield concatamers of genomes in a head-to-tail arrangement, and so packaging must be linked to the generation of genomic length units of DNA. In this virus, two packaging sequences, *pac1* and *pac2,* located within the terminal A repeats, appear to be important for both recognition and cleavage of the DNA (see Chapter 72 and ref. 25). As with the DNA phages, a combination of cleavage recognition sequences and “head-full” packaging appears to ensure the incorporation of unit-length genomes into the procapsid. Studies using a temperature-sensitive protease mutant of HSV-1, which accumulates procapsids (containing an uncleaved scaffolding protein) at the nonpermissive temperature, but which can remove the scaffold and package DNA upon temperature shift to the permissive temperature, have shown that ATP is necessary for DNA packaging to occur but that DNA synthesis is not (12,22). At least seven viral proteins are required for cleavage and packaging of HSV-1 DNA. Sequence analysis reveals that one of these, encoded by the *UL15* gene, shares homology with gp17, the large catalytic subunit of the bacteriophage T4 terminase (134). Thus, the product of this gene may play a direct role in the cleavage of viral DNA replication intermediates into monomers. Moreover, it raises the possibility that herpesviruses assemble a portal and terminase structure, similar to phages such as P22 or l, for DNA packaging.

RNA Viruses

For retroviruses, genomic packaging represents a particularly difficult problem because the assembling capsid must select genomic RNAs from a large pool of viral and cellular mRNAs that are also present in the cytoplasm. Viral RNAs to be specifically packaged are identified by the presence of an RNA sequence named the packaging signal or y (psi) and are selected from the cytoplasmic pool by a specific interaction with the NC domain of the Gag precursor (reviewed in 4). The cis-acting RNA element is located at the 5' end of the viral genome and appears to be composed of a series of stem-loop structures that each contribute to the strength and specificity of the signal. The best characterized, although perhaps most complex, y sequence is that of HIV-1, which is now known to span the first 360 nucleotides of the genome. This region, which can confer packaging specificity on foreign RNAs, includes the TAR sequence that is important in Tat-mediated transcriptional control, the adjacent poly(A) loop, and four stem-loops designated SL1 to SL4. Gag has been shown to bind specifically to the latter region, with SL1, SL3, and SL4 each providing independent high-affinity binding sites. It is likely, although less well documented, that Gag can bind to the 5' stem-loops also. Disruptive and compensatory mutations within the TAR, poly(A), SL1, and SL3 elements indicate that it is the structure rather than the sequence of the stem-loops that is important for packaging (13,72). Recent nuclear magnetic resonance analyses of SL3 in the presence and absence of the NC protein have begun to provide insights into how Gag might bind this region (24,135).

Given its role in specifying genomic RNA packaging, one might expect the y sequence to be located downstream of the splice donor site for subgenomic mRNAs. This is the case for the MuLV and reticuloendotheliosis y sequences but is not the case for HIV-1, as shown previously, or for Rous sarcoma virus (RSV). In the case of HIV, the SL3 stem-loop is located in this downstream domain and deletions in this region alone do decrease packaging 5- to 10-fold. In the case of the avian leukosis viruses, however, the entire 5' y sequence is present in both genomic and subgenomic mRNAs; thus, the basis for packaging specificity in this case is unknown (113).

Genomic RNA packaging signals in other RNA viruses are less well defined. In the alphaviruses, this appears to involve direct binding of genomic RNA by the capsid protein. A short (132-nucleotide) segment of RNA in the region of the genome encoding the nonstructural protein NS1 is crucial to this interaction and for packaging of genomic RNA. Like the retroviral y sequence, it has also been predicted to form a series of stem-loop structures. The N-terminal third of the capsid protein is basic and is unstructured in the current crystal structure. Nevertheless, a 32–amino acid region (residues 76 to 107) has been shown to be essential for RNA binding in a gel shift assay (113).

For segmented viruses such as the orthomyxoviruses or the reoviruses, genomic packaging requires that a complete set of segments be packaged together in a single virus particle. For influenza virus, reverse genetic approaches have shown that the signals for transcription, replication, and packaging of an RNA segment are located in the 22 5'-terminal and the 26 3'-terminal nucleotides of the RNA (66). These studies do not, however, address how a full complement of RNAs is selected during assembly. Selective packaging of the eight genomic RNAs would presumably require complex recognition systems and molecular interactions. Although there is some evidence to support such a mechanism, the bulk of the evidence appears to be most compatible with a model in which infectious influenza virus particles are formed from random packaging of RNA segments (reviewed in 113).

POSTASSEMBLY MODIFICATIONS AND VIRUS RELEASE

Proteolytic Cleavage and Virus Maturation

Virus-encoded proteolytic enzymes play important roles in the process of assembly for many viruses and in a postassembly maturation steps that are required for the development of an infectious particle for others. These cleavage events can act as molecular switches that introduce flexibility as well as irreversibility into the assembly process.

Proteolytic cleavage in the case of the alphaviruses, for example, is used to allow protein domains, translated from a single mRNA, to enter different transport pathways in the cell. The C protein, which is encoded at the 5' end of the subgenomic 26S mRNA, folds cotranslationally into an active serine proteinase that cleaves itself from the growing polypeptide chain. This releases the C protein into the cytoplasm for capsid assembly while freeing up the N-terminus of the signal peptide for the p62 glycoprotein precursor, which can then bind SRP and direct the ribosome to the ER.

In the herpesviruses, proteolytic cleavage of the scaffolding protein occurs after assembly of the procapsid is complete and is a prerequisite for DNA packaging. The scaffolding proteins of HSV-1 are encoded by a pair of overlapping genes, *UL26* and *UL26.5*, in which the open reading frame of *UL26* is an in-frame N-terminal extension of that of *UL26.5*. The product of the smaller gene is the abundant scaffolding protein pre-VP22a, whereas the larger gene encodes a protease

precursor, which cleaves itself internally to give the proteins VP24 (protease) and VP21. Temperature-sensitive mutants in *UL26* that have an inactive proteinase at the nonpermissive temperature are blocked at the procapsid stage of assembly (reviewed in 99).

A somewhat more complex proteolytic pathway is used by the picornaviruses to regulate the release of both structural and replicative protein components from the single polyprotein precursor that is translated from its positive-stranded RNA genome (see Fig. 13). The initial event in this proteolytic cascade is the primary cleavage in which the P1 structural protein precursor is separated from the P2-P3 precursor. This reaction is catalyzed by the 2A proteinase, which hydrolyzes a Tyr-Gly bond at its own amino-terminus. Although cleavage of the P2-P3 region is carried out by the 3C proteinase at Gln-Gly bonds, the efficient cleavage of the structural protein precursor at the VP0-VP3 and VP3-VP1 boundaries is catalyzed specifically by the 3CD precursor that includes the viral polymerase. Cleavage of the P1 precursor appears to be a prerequisite for entry of the capsid proteins into the assembly pathway. The final processing step is cleavage of VP0 to VP4 and VP2. This autocatalytic, maturational cleavage occurs late in the assembly pathway and appears to be linked to encapsidation of the viral RNA genome. It is likely that the structural alterations that accompany the cleavage event both stabilize the capsid and irreversibly commit the virus to the conformational changes induced on receptor binding that are necessary for productive infection of cells (reviewed in 48).

A similar maturational cleavage is required after assembly and envelopment of retroviral capsids. As described earlier, the retroviral capsid is assembled from polyprotein precursors that are encoded by the *gag* gene. The viral aspartyl proteinase is encoded by the *pro* region of the genome and is translated from unspliced, genome length RNA by a ribosomal frame-shift mechanism as a Gag-Pro or Gag-Pro-Pol precursor protein (see Chapter 57). The presence of the Gag sequences ensures that this key enzyme is targeted to and incorporated into the assembling capsid. The mechanism by which the protease is activated late in the assembly process (most probably after envelopment is complete) is not known. Because the active enzyme is a homodimer of two protease subunits, it has been postulated that dimerization of proteinase precursors in the nascent capsid might allow a functional enzyme to form. However, in the *Betaretroviruses*, the immature capsid contains a full complement of proteinase precursors, which are not activated until late in envelopment at the plasma membrane.

Cleavage of the Gag precursors in the immature capsid is accompanied by a major morphologic rearrangement in which the mature NC protein condenses the genomic RNA inside a CA shell (see Fig. 8)—the electron-dense core structure of the virus seen in electron micrographs (36). Recent evidence suggests that cleavage at the N-terminus of CA induces a conformational change in the protein, which allows it to assemble the core shell structure (130). Maturational cleavage, as in the case of poliovirus, results in an irreversible commitment to the entry pathway. It prevents a simple reversal of the assembly process and, presumably through the formation of the core, allows the rearrangement of RNA and the reverse transcriptase into a conformation that is optimal for reverse transcription of the genome. In the absence of cleavage, reverse transcription cannot occur, and the virions are noninfectious (reviewed in 121).

Adenoviruses, like retroviruses, undergo a maturational cleavage after assembly that is essential for infectivity. The young virions formed after DNA packaging contain five precursor proteins that must be processed before the mature infectious virion is produced. These include components of the core and the preterminal protein (pTP) used to initiate DNA synthesis. The 23-kd adenovirus proteinase, which is encoded by the L3 region of the genome, is inactive in its purified form. It requires an 11–amino acid peptide present at the carboxyl-terminus of pVI and viral DNA as cofactors for its activity. This unique use of DNA as a cofactor ensures that proteolytic maturation of the virus cannot take place until packaging of DNA is complete (reviewed in 20).

Budding—Role of Viral and Cellular Proteins in Membrane Extrusion

It is clear from the discussions in previous sections that different strategies are used by different enveloped viruses to mediate the process of membrane extrusion that we have termed budding. Envelopment by a lipid bilayer fulfills two functions for a virus: it provides a protective outer layer into which can be embedded the necessary machinery for target cell attachment and entry; and, in most cases, it releases the virus into an environment that is topologically equivalent to the exterior of the cell. The strategies used to drive the budding process can be classified into three general mechanisms (35). In the first, membrane extrusion is driven by envelope glycoproteins alone. This is exemplified by the E protein of the coronaviruses that is capable of inducing the release of virus-like particles in the absence of an RNP. The second strategy is that used by the retroviruses in which the capsid precursors, in the absence of the viral glycoproteins, are able to induce membrane extrusion and particle release efficiently. In this instance, it is hypothesized that the tight interaction between the MA domain of Gag and the lipid bilayer, coupled with the force of Gag-Gag interactions in assembly, drives the budding process. The third mechanism is that of the alphaviruses, which involves interactions between the viral glycoprotein spikes and the assembled capsid. In this case, neither the glycoproteins nor the capsid alone can mediate budding. It appears that lateral interactions between the glycoproteins, coupled with cytoplasmic domain–capsid connections, progressively bend the membrane to form the spherical particle (35,70).

For all of these mechanisms, the final step of budding, the process of pinching off, requires a membrane fusion event. Although for most enveloped viruses, there is no evidence that a viral component is specifically required for pinching off to occur, in the retroviruses, it is clear that this is a separable event that requires the involvement of both viral and host components. Experiments in HIV showed that deletion of the p6 domain at the C-terminus of Gag results in a block to virus release at the pinching-off stage (40). It was later discovered that species within several retrovirus genera encode a similar Gag “late function” domain that is required for efficient release of virions (94). The mechanism by which these “late” domains mediate the pinching-off step is not known, but recent studies of the Yes protein tyrosine kinase have provided a clue. During signal transduction, a PPPY motif on Yes mediates binding through a second amino acid motif called a WW domain—characterized by two widely spaced tryptophan residues—on its partner protein Yap. In the alpha-, beta-, and gamma-retroviruses, the late function of particle release depends on the presence of a PPPY-containing motif that may mediate interactions with WW-containing cellular proteins. The p6 domain in HIV-1 and the late domain of equine infectious anemia virus each appear to bind different cell proteins but can functionally replace the PPPY motif of the *Alpharetroviruses* (reviewed in 121). Interestingly, a similar functional PPPY motif has been found

in the matrix protein of VSV, pointing to a similar role for host cell proteins in the release of VSV (16).

Mechanisms to Facilitate the Release of Nascent Particles

If they are to travel efficiently to an uninfected target cell, viruses face one last hurdle after envelopment and release. This is the need to avoid rebinding to receptors on the producing cell. For viruses such as the orthomyxoviruses and paramyxoviruses, which use sialic acid as a receptor on the cell surface, this problem is circumvented by the incorporation of a receptor-destroying enzyme, a sialidase, that can remove these residues during transit through the secretory pathway. For influenza virus, the neuraminidase is crucial to virus release because, in its absence, nascent virus binds to both the cell surface and other virions in large aggregates (64).

Retroviruses have similarly evolved mechanisms to facilitate release and thereby reduce superinfection of a cell. Cells infected with one retrovirus are generally resistant to subsequent infection by a second virus of the same receptor class. The presumed mechanism for this viral interference is the synthesis of viral glycoproteins in large excess over the levels that are incorporated into virions with the effect that cellular receptors that are transported to the cell surface are already occupied by their ligand. This results in removal or down-regulation of the receptor from the cell surface. For HIV-1, down-regulation of the primary receptor CD4 seems to be crucial because the virus has evolved two additional mechanisms to ensure this. Two of the accessory proteins encoded by HIV, Vpu and Nef, act by binding CD4 in the ER and at the cell surface, respectively, and targeting the receptor for degradation (see Chapter 59). In the context of infected tissue, this down-regulation of an abundant receptor could be essential to facilitate spread to adjacent target cells.

CHAPTER 9 Pathogenesis of Viral Infections

Kenneth L. Tyler and Neal Nathanson

INTRODUCTION

Viral pathogenesis is the process by which viruses produce disease in the host (350,553). Much of our existing knowledge of viral pathogenesis is based on experimental studies using animal models of natural human infections. These are at best imperfect analogs to human infections, but they allow observations and experiments that are not possible in humans and are invaluable in understanding how viruses produce human diseases.

The production of disease, which is the focus of pathogenesis, is in fact a relatively unusual outcome of viral infection of a host (Fig. 1). The virulence of a virus is its capacity, when compared with other closely related viruses, to produce disease in a host. Virulence depends on a variety of viral and host factors, such as the dose of virus, its route of entry, and the host's age, sex, immune status, and species. With many “virulent” viruses, subclinical or inapparent infections often outnumber cases of symptomatic illness. During epidemics of mosquito-borne encephalitis, for example, the ratio of serologically documented infections may exceed cases of acute encephalitis by several hundred fold. However, for certain classic viral infections such as measles, smallpox, rabies, and influenza, almost all infected individuals develop disease.

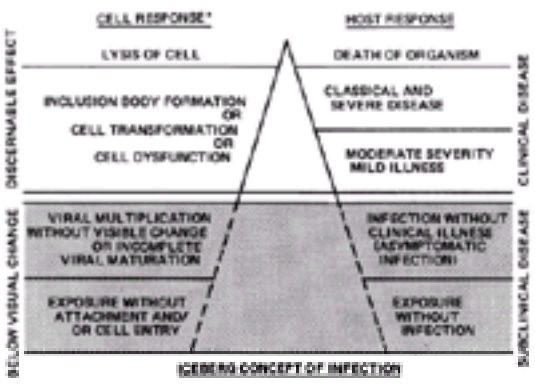

FIG. 1. Varieties of host and cellular responses to virus infection. (From ref. 143, with permission.)

In addition to acute infection, the interaction between a virus and a host may lead to a variety of other outcomes including the development of persistent or latent infection (see later) and cellular transformation (see Chapter 10). As viral infection proceeds, the virus encounters a constant series of obstacles within the host. Among the most important of these are the various components of the host's specific and nonspecific immunity (see Chapter 11 and Chapter 12). Ultimately the interaction between a virus and cell may lead to alterations in host cell function, which are discussed in more detail elsewhere (see Chapter 7).

A virus must survive in the environment until it encounters a susceptible host. It must then enter the host, through one of a number of available portals (e.g., the respiratory or the gastrointestinal tract). Once inside the host, the virus undergoes initial replication, typically at a site near its original portal of entry. Viruses that produce localized infections may be released from surface mucosal epithelium or analogous sites and subsequently shed from the host (e.g., in stool or other bodily fluids or through coughing and sneezing). After entering the environment, these viruses may then reinitiate the cycle of virus–host interaction by transmission to a new host.

Viruses that produce systemic rather than localized infections must cross mucosal barriers and spread to distant sites in the host, using defined pathways of spread such as the bloodstream, lymphatics, or nerves. After spreading, or at the site of local infection, viruses are targeted to specific populations of cells within individual organs or tissues (tropism). Each of these stages in viral pathogenesis is discussed in more detail in the following sections.

Each stage of pathogenesis poses a series of biologic obstacles that the virus must overcome to proceed to the subsequent level. The successful completion of all the stages in pathogenesis results in disease, whereas failure to complete these stages results in either abortive, nonproductive, or failed infection. Viral structure has evolved to enable the virus to overcome obstacles successfully at particular stages in pathogenesis. The structure of the virus must enable it to remain infectious after being exposed to conditions such as temperature and humidity that are present in the ambient environment. For many viruses, environmental stability is determined by the envelope or by outer capsid proteins. Once a virus has entered the host, the parts of the virus that ensure environmental stability or promote transmission become nonessential and are often removed as the virus proceeds through subsequent stages in pathogenesis. For example, the proteolytic removal of capsid proteins may, at this stage, actually enhance infectivity rather than attenuate it (381).

ENTRY

The predominant routes by which viruses enter the host include through the skin, or by way of the respiratory, gastrointestinal, or genitourinary systems (377,378) (Fig. 2).

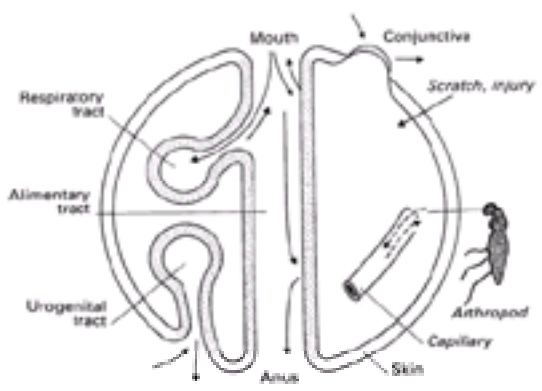

FIG. 2. Portals of entry of viruses into the host, and sites of shedding from the host. (Modified from ref. 350, with permission.)

Skin

Breaks in the integrity of the skin or the mucosa of the respiratory, gastrointestinal, or genitourinary tracts facilitate entry of viruses. The outer layer of the epidermis is composed of the dead keratinized cells of the stratum corneum, which do not support viral replication (553). Underneath the stratum corneum are the living cells of the stratum malpighii. Some viruses, such as papillomaviruses—which produce human warts—enter the skin at sites where scrapes or abrasions have resulted in loss of epithelial integrity. Certain animal papillomaviruses are mechanically transmitted by arthropod vectors, and then replicate in epithelial cells at the site of inoculation (see Chapter 66). Primary infection begins in the basal cells, and virion replication and maturation occur as these cells differentiate. Mature virions are found in the granular layers and are shed with the dead cells of the stratum corneum.

Sheets of keratinocytes, similar to those used for epithelial cell skin grafts, have been used to study the entry and tropism of viruses that can infect the skin. For example, studies of viral infection of epithelial grafts suggest that cell-free inoculums of human immunodeficiency virus (HIV) do not productively infect keratinocytes, which apparently lack HIV receptors, but cell-associated HIV can initiate productive infection of these cells (415).

Because the epidermal layer is devoid of blood vessels, lymphatics, and nerve fibers, viruses that initiate epidermal infection are typically restricted to the site of entry and only rarely disseminate to produce systemic infections. The system of skin-associated lymphoid tissue (SALT), which includes antigen-presenting Langerhans cells, T cells, and cytokine-producing keratinocytes, may provide a pathway for spread of viruses that can initiate systemic infection after inoculation into the skin. T cells and dendritic cells (Langerhans cells) can circulate between the skin and regional lymph nodes. Both HIV and herpes simplex virus (HSV) can infect Langerhans cells, which can emigrate out of the epidermis to

enter regional lymph nodes (342). When macrophage-tropic strains of HIV are inoculated onto abraded epidermis of skin explant grafts, virus can be detected in both epidermal and dermal emigrant cells, which include both T cells and dendritic cells (430). The importance of early dendritic cell infection in the pathogenesis of HIV also can be inferred from the predominance of “macrophage-tropic” viral strains isolated during primary HIV infection (581). Dermal replication in macrophages and fibroblasts also occurs when mouse-, cow-, or rabbit-pox viruses enter the host through traumatic skin lesions in the epidermis (154).

The molecular basis for viral infection of skin remains largely unknown. In the case of varicella-zoster virus (VZV) and HSV, the gC glycoprotein is a critical determinant (354). This suggests that the interaction between viral attachment proteins and specific receptors on skin cells may be critical to initiating epidermal infection.

The bites of arthropod vectors including mosquitoes, mites, ticks, and sand flies allow subcutaneous inoculation of many arthropod-borne viruses (see Chapter 30 and Chapter 33). Transmission of virus may be purely mechanical, as illustrated by transmission of myxomavirus by the mouthparts of biting insects, or may require replication of the virus within the gut or salivary system of the arthropod vector (205,369,376). Most of the arthropod-borne toga- and flaviviruses, which include the agents of epidemic encephalitis and yellow fever, appear to replicate in the gut of the insect vector, with subsequent spread to salivary tissue. Virus is then inoculated into the host during feeding, and part of the inoculum enters the general circulation, while part remains in the local tissue. Once a virus has reached the dermis, it has access to blood vessels, lymphatics, and dendritic cells, including macrophages present in the skin.

Some viruses are inoculated directly through the epidermis and dermis into deeper tissues. Deep inoculation, into the subcutaneous tissue and muscle, can follow hypodermic needle injections, acupuncture, ear piercing, tattooing, or animal bites. Hepatitis B virus (HBV) may gain access to the host through needle inoculation of various types (313). Infection with both rabies and herpesvirus simiae is characteristically initiated by the bites of infected animals (18,557).

Respiratory Tract

Inhibition of viral entry through the skin depends primarily on the mechanical integrity of the epidermal barrier. By contrast, more complex host defense systems are involved in inhibiting viral entry through mucosal surfaces (1,569). In the respiratory tract, goblet cells secrete mucus that is propelled by the action of ciliated epithelial cells and acts to clear foreign material from the respiratory tract. Clara cells, a type of nonciliated secretory cell, produce trypsin-like proteases that may act to cleave viral proteins such as the hemagglutinin (HA) of influenza virus (269).

Both humoral and cellular immune mechanisms also act to protect the host against mucosal infection (1). Bronchial-associated lymphoid tissue (BALT) includes collections of lymphocytes and macrophages in the tonsils and adenoids as well as in the subepithelial tissue of the nasopharynx and trachea. Specialized epithelial cells known as M cells participate in generating mucosal immunity by delivering antigens to underlying lymphoid tissue (470). Viruses and other microbial pathogens can exploit these cells as transport pathways, enabling them to traverse mucosal surfaces. This has been elegantly demonstrated for reoviruses (360) (reviewed later in the discussion of the analogous pathway in the gastrointestinal tract).

Cytokines also appear to play a critical role in preventing systemic dissemination of some viruses that initiate infection through the respiratory tract. For example, knock-out mice with disruptions in the STAT1, interferon (IFN)a-receptor, or IFNg genes all show markedly enhanced severity of influenza A infection and systemic dissemination compared with that in their wild-type counterparts (168). Similarly, mice with targeted mutations inactivating the IFNa/b receptor show enhanced spread of measles virus to the lungs and more prominent inflammation than wild-type mice (366).

An additional factor in host defense is the cool temperature of the upper respiratory tract, which acts to inhibit the replication of many viruses (569), but is optimal for the replication of rhinoviruses, a major cause of upper respiratory infections (see Chapter 25). The temperature differential between the nose and the body has been exploited in viral vaccine development. Temperature-sensitive (ts) mutants of viruses such as influenza, parainfluenza, and respiratory syncytial virus can replicate in the upper respiratory tract and generate host immune responses, but will not survive higher body temperatures and therefore do not disseminate (569). Despite the nature of host barriers to respiratory infection, a number of viruses including herpesviruses, adenoviruses, myxoviruses, paramyxoviruses, and rhinoviruses can initiate either local or systemic infection via this route.

Viruses that enter the respiratory tract do so primarily in the form of either aerosolized droplets, saliva, or through spread from infected nasal secretions to hands and then subsequently back to the nose (nose–hand–nose transmission). Site of penetration is influenced by droplet size, with only the smallest inhaled droplets reaching the alveoli of the lungs. Initial infection occurs predominantly at the epithelial surface with subsequent spread of virus from cell to cell or by inhalation.

Receptors (see later) for viruses that initiate spread via the respiratory route are predominantly ubiquitous cell-surface molecules such as sialic acid (influenza), and cell adhesion molecules (rhinovirus). In some cases these receptors may be distributed preferentially on certain surfaces of polarized respiratory epithelial cells. For example, the CAR receptor for adenoviruses 2 and 5 and coxsackie B is located predominantly on the basolateral surface of epithelial cells (542), whereas the measles virus receptor CD46 is found preferentially at the apical surface (42). The subsequent propensity of some viruses to produce disease predominantly confined to respiratory mucosal surfaces (e.g., influenza, respiratory syncytial virus), whereas others induce systemic infection after primary replication in respiratory mucosa (e.g., measles, varicella), may be determined in part by the pattern of viral release from infected cells (polarized infection, see later) (98,521). For example, viruses such as influenza and respiratory syncytial virus (436), which are released predominantly from apical surfaces, tend to produce infection confined to the respiratory mucosal surface. Conversely, release of viruses, such as certain murine coronaviruses (447), from the basolateral surface of epithelial cells may facilitate systemic spread (see polarized infection later).

A unique situation occurs in the superior portion of the nares, which contains olfactory receptor cells. These cells have

distal rods that extend beyond the outer epithelial surface and proximal axon processes (fila olfactoria), which join to form olfactory nerve fibers. The olfactory nerve fibers penetrate the arachnoid space and form synapses with mitral cell neurons in the olfactory bulb. A variety of experimental studies using polioviruses, herpesviruses, coronaviruses, togaviruses, and rhabdoviruses have shown that these viruses can spread to the central nervous system (CNS) through the olfactory nerve (396,496). This situation, although postulated to explain some cases of human rabies and HSV infection, is probably an extremely unusual route of natural viral infection (251).

Experimental models of natural aerosol infection have been developed, as exemplified by aerosol inoculation of bovine respiratory syncytial virus into calves, and seem to be reasonable facsimilies of natural infection (567). Explant organ cultures, such as those of fetal trachea, and cell cultures of nasal epithelial and adenoidal cells also have been used to study early events in respiratory infection (561,569).

Coughing and sneezing can generate enormous numbers of small aerosolized particles that may travel up to 5 feet at velocities that approach 100 ft/sec. Coughing generates even higher aerosol velocities that can approach 850 ft/sec (569). Particles smaller than 5 µm in diameter can remain airborne for long periods, a property that can be dramatically enhanced by the presence of air currents. The distribution of inhaled aerosol particles within the respiratory tract is largely a function of particle size (277). Large particles rarely escape the filtering action of the nasal turbinates, whereas small particles (<5-µm diameter) are capable of reaching the alveolar spaces.

Environmental factors including air temperature and humidity also influence the stability of aerosolized viral particles (277). The physicochemical properties and structure of virion particles also can influence their stability as aerosols. For example, enveloped viruses are less susceptible to desiccation than are their nonenveloped counterparts. This may provide one explanation for the fact that enveloped viruses (e.g., influenza, parainfluenza, respiratory syncytial virus) are more common causes of lower respiratory tract infections than are their nonenveloped counterparts (e.g., adenovirus, rhinovirus).

The proper functioning of the mucociliary transport system appears to be an important determinant in resistance to viral infection of the respiratory tract. Drugs that inhibit this transport process increase host susceptibility to a number of viral infections (21). Susceptibility to Sendai virus infection in mice has been linked to a genetic polymorphism in mucociliary transport function (58). Patients with HIV infection often have decreased rates of mucociliary clearance, which also facilitates recurrent upper respiratory and sinus infections (347). Acquired ciliary defects, which inhibit host antiviral defense, appear to be a common feature of many other viral upper respiratory infections, even in immunocompetent hosts (75).

Gastrointestinal Tract

Many viruses enter the host via the gastrointestinal (GI) tract, where they may either initiate local infection (e.g., rotaviruses, coronaviruses, adenovirus, and Norwalk agent) or cross the mucosal layer to invade underlying tissues and spread within the host (e.g., enteroviruses, hepatitis A).

The physicochemical environment in the upper GI tract would appear to be extremely inhospitable to invading microorganisms (103). The secretion of acid by gastric parietal cells may reduce the intraluminal pH to 2.0 or lower. In addition, a variety of proteases are secreted by gastric and pancreatic cells, and bile salts enter the duodenum from the biliary tract. Mucus is secreted by both gastric and intestinal cells and may contain both specific [e.g., immunoglobulin A (IgA)] and nonspecific inhibitors of viral infection. To initiate infection via the GI route, a virus would ideally have the properties of acid stability, resistance to loss of infectivity in the presence of bile salts, and resistance to inactivation by proteolytic enzymes. In fact, the majority of viral pathogens that enter via the GI tract generally exhibit all these properties.

Almost all picornaviruses are capable of producing enteric infections in humans. A notable exception to this rule is the rhinoviruses. Unlike other picornaviruses and rotaviruses, rhinoviruses are extremely acid labile and undergo complete inactivation with loss of infectivity at low pH (Chapter 25). The pH-induced inactivation appears to result from the loss of the VP4 surface protein and resulting leakage of the viral RNA, which produces noninfectious “empty capsids.” Interestingly, many of the enteroviruses undergo an analogous type of degradation under alkaline conditions (263). Similar investigations with reoviruses suggest that under certain circumstances, exposure to alkaline pH can result in the loss of the viral cell-attachment protein from the viral outer capsid (129,130). Changes in the outer capsid structure of rotaviruses also have been observed at both extremely acidic or alkaline pH (Chapter 54).

The effect of proteolytic enzymes, such as those present in the GI tract, on the infectivity of enteric viruses also has been investigated. Trypsin, pancreatin, and elastin have all been shown to enhance rotavirus infectivity (92,141) and are routinely incorporated into procedures to isolate and cultivate these viruses. Likewise, inhibition of proteolysis may result in attenuation of rotavirus infection (536), and the importance of proteolytic processing of virions *in vivo* has been demonstrated for reoviruses (24,45). Reovirus particles present in the intestinal lumen are converted into infectious subviral particles (ISVPs) by proteolytic processing of their s3 and µ1C outer capsid proteins. ISVPs appear to be the form of the virion responsible for the subsequent initiation of intestinal infection, and inhibition of intraluminal proteolytic digestion dramatically inhibits intestinal infection by reoviruses (7,24,45).

Studies with a number of viruses indicate that host proteases act primarily to alter the viral outer capsid or envelope proteins. For example, proteolytic digestion of rotaviruses with trypsin, pancreatin, or elastase results in cleavage of the outer capsid protein VP4 and the appearance of two cleavage products, VP8 and VP5 (141). Enhancement of coronavirus infectivity also occurs in the presence of proteolytic enzymes (489) and may be due to the cleavage of the E2 peplomer glycoprotein (the viral cell-attachment protein) from an inactive precursor into its active form. Genetic studies with reovirus reassortants derived from parental viruses that differ in their susceptibility to proteolytic digestion indicate that the reovirus major outer capsid protein µ1c is the major determinant of protease sensitivity (450).

Detailed studies of the mechanism of action at a molecular level of proteolytic digestion of viral proteins have been made with influenza viruses and Sendai virus (169,174,294,460,559). These studies provide insights into how proteolytic processing of viral proteins can influence viral pathogenicity. Cellular exopeptidases cleave the HA of influenza into two disulfide-bonded subunits (HA_1 and HA_2). After virus enters target cells through the process of receptor-mediated endocytosis, the amino terminus of the HA_2 protein undergoes a pH-dependent conformational change that facilitates the subsequent fusion of the influenza virus envelope with the inner membrane of the endocytic vesicle (473). This in turn results in the escape of the viral nucleocapsid into the target cell's cytoplasm, where replication occurs. If cleavage of the HA does not occur, then influenza virus still binds to cell-surface receptors but is unable to initiate a productive infection. Inhibition of HA cleavage by administration of protease inhibitors results in attenuation of influenza virus infection *in vivo* (502,559).

In the case of measles virus, the fusion glycoprotein gene encodes an inactive precursor protein (F_0) that is cleaved within a region containing a stretch of basic amino acids (108,109,110,111 and 112) to generate two disulfide-linked active fusion proteins (F_1 and F_2). Cleavage occurs within the trans-Golgi network (TGN) and involves host-cell enzymes belonging to the family of proprotein convertases. Furin has been identified as the likely candidate (46).

Thus many viruses have evolved so that proteolytic processing actually facilitates rather then inhibits viral infection. The mechanisms by which this facilitation occurs are gradually becoming better understood. As a general principle, proteolytic processing of these viruses usually results in partial cleavage of specific viral surface proteins, which in turn facilitates specific events, such as membrane fusion or transcriptional activation, in the viral replicative cycle. Conversely, viruses that are easily inactivated by proteolytic processing are unlikely to initiate infection via sites such as the GI tract where proteolytic enzymes are a prominent part of the internal milieu.

The presence of bile salts in the intestinal lumen also may play an important role in determining the types of viruses that are capable of initiating GI infection. Viral envelopes are derived from host-cell lipoprotein bilayer membranes and are particularly susceptible to dissociation by bile salts. Conversely, the protein capsids of nonenveloped viruses are quite resistant to the action of bile salts. This may explain why, with the exception of coronaviruses, enveloped viruses do not initiate infection via the upper GI tract. Coronaviruses are susceptible to inactivation by bile salts in vitro, and the factors that enable them to survive inactivation *in vivo* remain unknown.

Viruses associated with gastroenteritis can infect a variety of cell types within the GI tract. Some viruses such as adenoviruses, calciviruses, rotaviruses, and coronaviruses infect predominantly the mature nondividing absorptive enterocytes. Other viruses have a predilection for the dividing cells of the crypts (e.g., animal parvoviruses) or infect specialized epithelial cells such as the M (microfold cells) overlying Peyer's patches (e.g., poliovirus, HIV, and reovirus) (103). Factors that determine the capacity of viruses to infect intestinal cells are becoming better understood. In the case of coronaviruses, a critical determinant is the presence of cell-surface receptors such as members of the carcinoembryonic antigen (CEA) family including human biliary glycoprotein and aminopeptidase N (83,227,512,513). Other enteric viruses use more ubiquitously distributed receptors such as sialic acid residues (rotavirus). Some viruses, such as the rotaviruses, produce enteric infections that are typically limited to the intestinal epithelial cells (Chapter 55). Local involvement of intestinal epithelial cells also occurs during infection with adenovirus, astrovirus, calcivirus, coronavirus, and parvovirus (110,455).

The factors that determine whether viral infection remains limited to the GI tract or spreads to produce systemic illness are largely unknown. Increasing interest has focused on the role of gut-associated lymphoid tissue (GALT) in viral entry. Several enteric viruses, including reoviruses, HIV, and poliovirus, spread from the lumen of the small intestine to collections of submucosal lymphoid tissue known as Peyer's patches (362,470). The early events in the spread of reoviruses after intestinal infection have been investigated extensively using electron microscopy. Virus initially adheres to the surface of specialized intestinal epithelial cells (“M cells”) that overlie the surface of Peyer's patches. Reovirions can be sequentially visualized at the surface of M cells, being transported in vesicles through these cells, and subsequently free in the extracellular space of Peyer's patches (26,564,565) (Fig. 3). The M cell pathway also is used by poliovirus and HIV to penetrate the intestinal epithelial barrier (6,282,469), suggesting that this may be a general pathway for the entry of viruses that spread beyond the mucosal surface. Once cells have traversed the epithelial barrier, the macrophages and lymphocytes, present within GALT, may play a role in further dissemination, as has been suggested for reo- and rotaviruses (362).

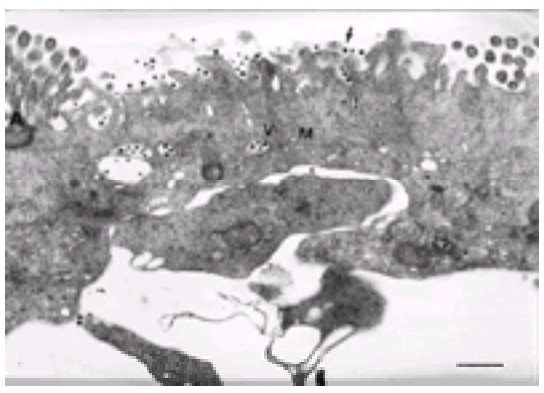

FIG. 3. Reovirus serotype 1 strain Lang virions on the surface (*arrow*) and within vesicles (*V*) of an M cell in the ileal epithelium overlying a Peyer's patch. (From ref. 565, with permission.)

Additional factors favoring localized infection may be the pattern of release of virus from intestinal epithelial cells with

apical release (toward the intestinal lumen) favoring local cell-to-cell spread, as exemplified by rotaviruses (256) and basolateral release facilitating systemic invasion (see later). For example, infection with the porcine coronavirus transmissible gastroenteritis virus (TGEV) occurs at the luminal (apical) surface of epithelial cells, as does release. This facilitates local cell-to-cell spread but reduces the probability of systemic infection. Conversely, the mouse coronavirus mouse hepatitis virus (MHV)-A59 enters cells at the apical surface, but may be preferentially released from the basolateral surface, facilitating systemic spread (447).

The recognition that anal intercourse is a major risk factor for the transmission of HIV infection also has led to the recognition that some viruses that produce systemic disease may gain entry to the host through the lower GI tract. HIV has been detected in bowel epithelium and enterochromaffin cells of patients with HIV, and can infect human colonic cell lines in culture (305,379,397). The mechanisms by which HIV infection is further spread from the lower GI tract remain to be established.

Genitourinary Tract

In addition to the respiratory and GI tracts, other mucosal surfaces may provide sites for viral entry into the host. Sexual activity may produce tears or abrasions in the vaginal epithelium or trauma to the urethra, allowing viral entry via the genitourinary route. Sexually transmitted viruses in humans include HIV, herpes simplex, human papillomaviruses 11, 16, and 18 (the agents responsible for genital warts or condyloma acuminata), and hepatitis B and C (456). In the case of HIV, infection may be facilitated by breaks in the genital epithelial barrier, but the virus also may productively infect cervical epithelial cells and dendritic (Langerhans) cells within the vaginal epithelium (295,296,501). HHV-6 (85) and human papillomavirus (HPV) 16 and 18 also have been shown to infect cervical epithelial cells in culture (566). As might be expected, for sexually transmitted viruses, the degree of sexual promiscuity and the number of sexual partners are risk factors for transmission (456).

The sequence of events that follow vaginally initiated virus infections has not been comprehensively investigated. In a macaque model, after intravaginal inoculation of a simian immunodeficiency virus (SIV)/HIV chimeric virus, virus is first detected in T lymphocytes in the submucosal epithelium, followed by the pelvic and mesenteric lymph nodes within 2 days of inoculation, and virus-infected cells are found in the thymus and spleen within 4 days (248).

Acute hemorrhagic cystitis in young boys has been associated with adenovirus 11 and 21 (Chapter 68); however, it is not known whether these viruses reach the bladder directly through the urethra or indirectly via another site of entry. Other viruses, including polyomaviruses, can produce viruria, but this is generally not associated with symptomatic disease. In some of these cases, virus appears to reach the kidney, presumably through the bloodstream, and then enters the urine (Chapter 64). Little is known about the nature of host factors that influence viral invasion by these routes. The nature of the cervical mucus, the pH of vaginal secretions, and the chemical composition of the urine all may play a role in host defense against infection.

Conjunctiva

The conjunctiva also may provide a route for the entry of viruses that produce either local disease (conjunctivitis) or more rarely disseminate from this site to produce systemic infection (e.g., paralytic illness with enterovirus 70 and experimental Ebola infection). Direct inoculation of virus onto the conjunctiva during ophthalmologic procedures (e.g., foreign-body removal and tonometry) can produce keratoconjunctivitis, and many cases have been attributed to adenoviruses 8, 19, and 37. Similarly, the conjunctivitis that follows swimming in public areas (“swimming pool conjunctivitis”) appears to be frequently due to direct infection most often with adenoviruses (see Chapter 68). Conjunctivitis also can occur in association with enteroviral infections (e.g., echo 7, 11; coxsackie A24, B2) (112). Coxsackie-adenovirus receptor (CAR)-mediated binding of adenoviruses to conjunctival cells via the distal domain of the fiber protein has recently been demonstrated. Mutations at amino acid 240 within the fiber protein can either facilitate or abrogate binding of adenovirus strains to these cells (235).

Systemic spread of virus after conjunctival entry is rare, although as noted, it is an important feature of the acute hemorrhagic conjunctivitis produced by enterovirus 70. This virus can spread from the conjunctiva to the central nervous system, where it can produce poliomyelitis, radiculomyelopathy, or cranial nerve palsies (448). Ebola virus also can be transmitted effectively via the conjunctival route in nonhuman primates, suggesting that this, like the oral route, could be a potential mode of transmission (247).

Conjunctivitis also may occur as part of a systemic viral infection in which virus reaches the conjunctivae after the induction of viremia rather than directly from the external surface. The conjunctivitis associated with acute measles infection is usually considered in this category, but recent experimental studies indicated that systemic measles infection can be produced in rhesus monkeys after conjunctival inoculation with measles, indicating that the conjunctiva also may serve as a portal of entry (335).

SPREAD IN THE HOST

Localized Versus Systemic Infection

Some viruses produce tissue injury predominantly near the site at which they enter the host. This pattern of infection characterizes the upper respiratory infections of influenza, parainfluenza, rhinoviruses, and coronaviruses; the GI infections caused by rotaviruses; and the skin infections of the papillomaviruses. In these cases, spread of virus occurs primarily as a result of contiguous infection of adjacent cells. Virus rarely spreads beyond the epithelial cell layer, although in some cases, involvement of regional lymph nodes and even systemic invasion can occur.

Polarized Infection of Epithelial Cells

Certain viruses preferentially bud from either the apical or basal surfaces of polarized epithelial cells, and this pattern may be an important determinant of whether infection remains localized or becomes systemic (98,99,521) (Fig. 4). Apical release of virus from epithelial cells lining mucosal surfaces favors the development of localized infection and facilitates cell-to-cell spread along the epithelial layer, whereas basolateral release directs virus toward underlying deeper tissues, facilitating mucosal invasion and the development of systemic infection. This pattern may be further reinforced by differences in the susceptibility of polarized epithelial cells to infection at their apical and basolateral surfaces (427). Finally, in some cases, viruses may preferentially enter cells on one surface and be released from another. This is illustrated by the coronavirus MHV-A59, which enters polarized murine kidney epithelial cells through the apical membrane, whereas progeny virions are released preferentially from the basolateral domain (447). Changes in the patterns of polarized release may dramatically alter viral virulence. For example, wild-type Sendai virus buds from the apical surface of polarized bronchial epithelial cells and produces localized bronchial infection, but mutant viruses with the capacity to bud from basolateral as well as apical surfaces have extended tissue tropism and enhanced virulence in vivo (503).

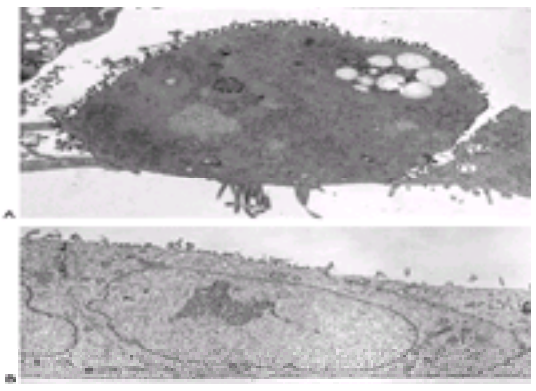

FIG. 4. A: Polarized budding of SV5 and vesicular stomatitis virus (VSV) virions from different surfaces of the same Madin–Darby canine kidney (MDCK) cell. Filamentous SV5 buds from the apical surface, while bullet-shaped VSV particles assemble at the basolateral domain of the cell. (From ref. 100, with permission). **B:** Budding of influenza virus from the apical surface of an MDCK cell. (From ref. 442, with permission.)

Examples of viruses with polarized patterns of release from epithelial cells include vaccinia, vesicular stomatitis virus (VSV), and certain retroviruses that are assembled at and bud from the basolateral cell membrane, and influenza, parainfluenza, SV40, poliovirus, rotavirus and Sendai virus which use the apical surface (98). Not all viruses exhibit polarized patterns of infection and release, and some, such as poliovirus, are capable of bidirectional entry into polarized epithelial cells (42,522). Viruses within the same family also may differ in their patterns of release. For example, the Hantavirus Black Creek Canal shows predominantly apical release from polarized epithelial cells, as opposed to the basolateral release characteristic of most other bunyaviruses (427).

In cases of polarized infection by enveloped viruses, envelope glycoproteins are inserted into the appropriate region of the cell membrane before viral budding. This suggests that it is the initial targeting and localization of these proteins to specific regions of the cell membrane that determine the subsequent polarity of viral budding. The information required for appropriate targeting of these proteins to the cell surface is contained in specific regions of the targeted proteins, and even single amino acid substitutions in the appropriate domain can alter polarized delivery (49,236,290,308,506,524).

In the case of retroviruses, including HIV, a tyrosine-based motif located in the intracytoplasmic domain of the envelope glycoprotein is highly conserved and functions as a critical basolateral targeting signal (309). Measles virus may be an exception to the general rule that sorting signals are contained in envelope glycoproteins, as its capacity to bud from apical surfaces of polarized epithelial cells does not appear to depend on prior localization of the H and F surface glycoproteins, which are transported in a nonpolarized fashion (323).

Not all membrane glycoproteins play an equivalent role in determining the site of polarized release. For example, the polarized release of coronaviruses is not determined by the spike (S) glycoprotein, but rather by the membrane (M) and hemagglutinin-esterase (HE) envelope glycoproteins (446).

Patterns of polarized infection not only depend on viral factors, but also are influenced by specific host-cell transport proteins. Transport of proteins to the plasma membrane uses specific signal-mediated constitutive pathways through the trans-Golgi network that involve a variety of “cargo” proteins that form transport vesicles. Distinct cytosolic proteins appear to be involved in the assembly of apical and basolateral transport vesicles. Interruption of these processes or interference with specific plasma membrane proteins may disrupt polarized sorting and release of virions. For example, depletion of MAL/VP17 protein, a nonglycosylated cellular membrane protein, from polarized epithelial cells dramatically reduces transport of influenza HA to the apical surface of infected Madin-Darby canine kidney (MDCK) cells (418).

Hematogenous Spread

Viruses that produce systemic disease typically spread from their initial site of entry to distant target tissues through either the bloodstream or inside nerves. Direct inoculation of virus into the bloodstream can occur with the bite of arthropod vectors, through iatrogenic inoculation with a contaminated needle, or by the transfusion of contaminated blood products (“passive viremia”). If the inoculum size is sufficient, a passive viremia may be adequate to initiate infection in target organs without requiring preceding replication. A more common sequence of events, exemplified by viruses such as flaviviruses, measles, and polio, is for virus to undergo primary replication near the site of entry, followed by spread to

regional lymph nodes. From the regional lymph nodes, virus can gain access to efferent lymphatics, the thoracic duct, and the systemic circulation. Some viruses can even replicate in lymphatic endothelial cells, further facilitating the development of viremia.

In almost all cases, some degree of replication at a primary site near the site of entry in the host appears to precede the onset of viremia. In some cases, primary replication is followed by a transient low-titer viremia (“primary viremia”), which serves to spread virus to sites such as the reticuloendothelial system, where additional replication leads to a more sustained and higher titer (“secondary viremia”; Fig. 5). Fenner (153) elegantly defined these events in a series of classic studies of the pathogenesis of ectromelia (mousepox; Fig. 6). Although viremia occurs in many human infections (*vide infra*), it is often difficult to demonstrate discrete phases of primary and secondary viremia.

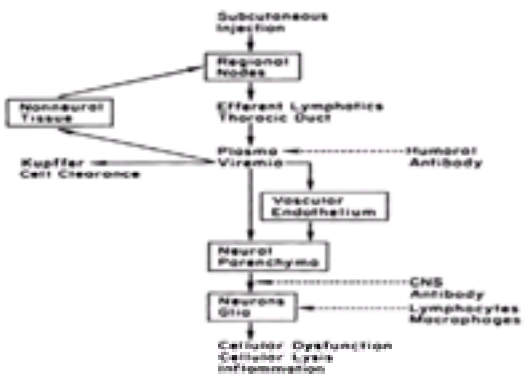

FIG. 5. Stages in the pathogenesis of flavivirus infection. (From ref. 376, with permission.)

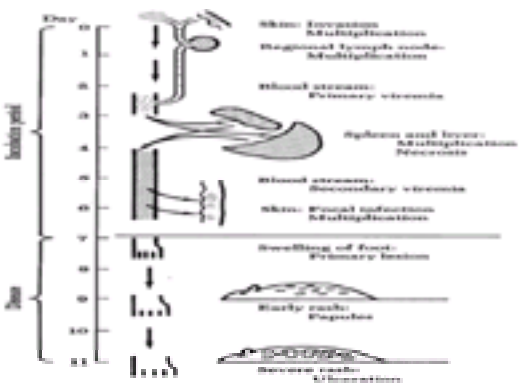

FIG. 6. The pathogenesis of mousepox (ectromelia). (From ref. 153, with permission.)

Once virus has reached the circulation, it can travel either free in the plasma or in association with cellular elements (Table 1). Cell-associated viruses can replicate in monocytes and T or B lymphocytes [see (377) for review and additional references]. Colorado tick fever virus (CTFV) provides an unusual example of a virus that is found in association with circulating erythrocytes (red blood cells). CFTV infects bone marrow erythroblasts, which are subsequently released into the circulation as mature erythrocytes. Platelets, their precursor cells (megakaryocytes), and neutrophils do not typically support virus replication and do not appear to be a significant source of circulating virus *in vivo*. Circulating monocytes can be infected by viruses belonging to a number of viral families (see Table 1) including retroviruses (e.g., HIV), herpesviruses [e.g., cytomegalovirus (CMV)], flaviviruses (e.g., dengue), and togaviruses (e.g., measles). Examples of viruses that replicate in lymphocytes include HIV, human T-cell lymphoma virus type I (HTLV-I), and human herpesviruses 6 and 7 (T lymphocytes) and Epstein-Barr virus (EBV; B lymphocytes). Some of the most comprehensive studies of cell-associated viremia have involved HIV. It has been estimated that the percentage of HIV-infected $CD4^+$ T lymphocytes increases from 0.2% to 10% in asymptomatic individuals to as high as 60% in some patients with acquired immunodeficiency syndrome (AIDS). Based on these figures, the blood of asymptomatic HIV^+ individuals contains 5,000 infected cells per milliliter.

Free in plasma	Togaviruses, picornaviruses
Red cell associated	CTFV
Platelet associated	HSV, LCMV, retroviruses
Lymphocyte associated	CMV, EBV, HBV, HHV 6 & 7, HIV, HTLV-I, JC & BK, LCMV, mumps, measles, rubella
Monocyte/macrophage associated	African swine fever, CMV, dengue, HIV, lentiviruses, LCMV, measles, mousepox (ectromelia), polio, rubella
Neutrophil associated	Influenza

When a virus family is listed, this indicates that one or more members of the family may spread in association with these cellular elements. Association of a virus with a formed element of the blood does not necessarily imply replication or a pathologic effect. See text and ref. 378.

Abbreviations: CMV, cytomegalovirus; CTFV, Colorado tick fever virus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HHV, human herpesvirus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; HTLV, human T-lymphotropic virus; LCMV, lymphocytic choriomeningitis virus.

TABLE 1. *Selected examples of viruses associated with or replicating in circulating blood cells*

The magnitude and duration of viremia reflect the outcome of a series of interactions between the virus and the host. Viral replication at the primary site, and subsequently in a variety of other tissues, provides a continuing source of virus input into the circulation. Important sites of primary replication for viruses that spread through the bloodstream include skeletal muscle for togaviruses, connective tissue, muscle, endothelial cells, and reticuloendothelial organs for flaviviruses, and brown fat for enteroviruses (193,368,376).

At the same time that virus is entering the blood compartment from these sites, a variety of clearance mechanisms are actively removing virus from the circulation. The magnitude of viremia varies as a result of the dynamic interrelationship between the amount of virus entering the blood compartment and the efficiency with which it is removed. The extent to which virus input into the bloodstream exceeds the rate of host clearance determines the magnitude of viremia. Viremia persists for as long as virus input into the bloodstream equals the host's capacity to clear virus from the circulation. The turnover rate for infectious virus in the bloodstream (as opposed to the duration of viremia) varies for different viruses. For example, exogenously infused SIV and HIV particles have been reported to have a plasma half-life that may be as low as 3 (580) to 26 (242) minutes.

Phagocytic cells in the reticuloendothelial system (RES) and serum factors including complement and antibody act in concert to facilitate clearance of virus from the bloodstream. One of the most important determinants of clearance is particle size (351). Rapid clearance (>99.99% of an intravenous inoculum cleared within an hour) is seen after inoculation of a large virus such as vaccinia into the bloodstream of a mouse. A similar pattern of clearance is seen with small viruses opsonized by antibody or complement. The coating of virus with antibody or complement may facilitate clearance by phagocytic cells such as macrophages because of the presence of receptors on these cells for the Fc portion of antibody molecules and for complement (C3 receptor). For example, the plasma half-life of infused cell-free HIV particles is reduced from a range of 13 to 26 minutes in HIV nonimmune macaques to 3.9 to 7.2 minutes in animals with high-titer HIV-specific neutralizing antibodies (242).

The nature of the protein(s) on the outer surface of the virus also may be an important determinant of the pattern of clearance. For example, the sialic acid content of the envelope of Sindbis virus appears to influence the degree of viral clearance (217). The net charge on a viral particle also may influence its clearance.

The nature of the interaction between virus and the macrophages of the RES seems to be an important determinant of the development of viremia (351). The capacity of a virus to avoid phagocytosis by macrophages facilitates the maintenance of viremia. Inhibition of the phagocytic capacity of macrophages can serve to amplify viremia and potentiates the severity of experimental viral infections caused by viruses as diverse as yellow fever virus, Semliki Forest virus, and HSV (244). Infection of macrophages with one pathogen may facilitate their infection with another. For example, infection of macrophages with opportunistic pathogens such as *Mycobacterium avium* and *Pneumocystis carinii,* or their exposure to bacterial products such as lipopolysaccharide (LPS), may promote HIV-1 replication through modulation of macrophage cytokine expression and alteration in cell-surface distribution of HIV chemokine coreceptors (361).

Certain viruses may replicate in macrophages, which serves to amplify viremia further rather than terminating it. Viruses known to replicate in macrophages include herpesviruses (e.g., HSV, CMV) (471), togaviruses (e.g., lactate dehydrogenase–elevating virus, Sendai), flaviviruses (e.g., dengue) (87), poxviruses (e.g., ectromelia), lentiviruses (e.g., HIV, visna, equine infectious anemia virus, Aleutian disease virus) (387,398), coronaviruses (e.g., mouse hepatitis virus, human coronavirus OC43) (97), arenaviruses (e.g., lymphocytic choriomeningitis virus [LCM]), reoviruses, picornaviruses (500), rhabdoviruses (428), and myxo- and paramyxoviruses (e.g., influenza, measles) (299). Because macrophages have receptors for the Fc portion of antibody, these cells may more readily take up viruses coated with antibody. In some cases this facilitated uptake actually leads to an enhanced replication of these viruses in macrophages ("antibody-mediated enhancement"). Antibody-mediated enhancement may play an important role in the pathogenesis of viral infections such as dengue fever and foot-and-mouth disease (27).

Differences in the susceptibility of macrophages to viral infection may account for variation in the age-related susceptibility of animals to certain types of viral infection (216) (see section on host factors). For example, alveolar macrophages derived from young mice will support the replication of HSV. Transfer of adult macrophages to young mice increases their resistance to HSV infection (216,359). More recently it has been suggested that certain HIV strains may differ in their capacity to infect neonatal monocytes as compared with placental macrophages and adult adherent macrophages. This difference may result from maturity-related changes in the levels of HIV coreceptor CCR-5 on macrophages, in combination with differences in HIV gp120 V3 loop sequences (151). Differences in the capacity of Theiler's virus and CMV to infect macrophages after infection also have been correlated with the state of macrophage differentiation (477).

As noted earlier, specific viral proteins may influence the capacity of viral strains to infect macrophages, and this may in turn influence viral pathogenicity and disease expression. Determinants of macrophage infection have been found on envelope proteins, such as the V3 loop of HIV gp120 (151), and on nonenvelope proteins such as the L* protein of Theiler's virus (500) and HIV accessory protein Vpx (218). Examples of macrophage tropism correlating with patterns of pathogenesis have been extensively investigated for HIV (Chapter 59 and Chapter 60) and lentiviruses such as visna (510) as well as for the Theiler's virus (500).

The interaction between viruses and macrophages also is influenced by both cytokines and chemokines (see Chapter 12 for review and references). Some cytokines, such as g-IFN, tumor necrosis factor (TNFa), interleukin 2 (IL-2), and IL-16 inhibit replication of viruses such as HIV in macrophages. These cytokines may be secreted by infected macrophages and act via autocrine pathways or be produced by other activated leukocytes including neutrophils, natural killer (NK) cells, or T and B cells. Paradoxically, cytokines also may facilitate the capacity of some viruses to infect macrophages productively. For example, certain opportunistic infections may promote macrophage infection by HIV by modulating chemokine receptor expression. Not surprisingly, viruses have adopted a wide variety of strategies (reviewed in Chapter

11) to circumvent the antiviral defenses of macrophages, including down-regulation of HLA antigens and inhibition of the production of antiviral molecules such as nitric oxide (NO).

Vascular endothelial cells also appear to play an important role in the maintenance of viremia for certain viruses. The capacity of viruses to infect endothelial cells has been studied both *in vitro* and *in vivo* for a large number of viruses (107,157,161,297,334,405,532,541,582). Viruses may differ in their capacity to infect endothelial cells derived from vascular beds in different organs, which may be a factor in their organ-specific tropism and invasion (156). This may be of particular importance in influencing viral invasion of the CNS. For example, mouse hepatitis virus A59 binds to receptors expressed on the endoluminal surface of liver-derived endothelial cells, but fails to bind to endothelial cells derived from brain, which in turn prevents entry of virus into the CNS after intraperitoneal (but not intracerebral) inoculation (179). Conversely, the capacity to infect the CNS and the pattern of disease induced by some strains of adenovirus correlate with their ability to infect cerebral vascular endothelium (81). Viruses that infect circulating cells may enhance their capacity to spread subsequently to endothelial cells by up-regulating integrins such as LFA-1, which facilitate binding of circulating cells to vascular endothelium. This suggests that, in some circumstances, cell-to-cell spread may be an important mechanism of initiating endothelial infection (238).

There is a general correlation between the capacity of blood-borne neurotropic viruses to generate a high-titer viremia and their neuroinvasiveness 376). Similarly, attenuated virulence may reflect incapacity to generate sufficient viremia, even for viruses that are fully virulent after direct CNS inoculation (181). For example, mutants of Semliki Forest virus (SFV) generate high-titer viremia but, unlike their wild-type counterparts, are unable to invade the CNS (13). Thus the capacity to generate a viremia of adequate magnitude and duration may be necessary for neuroinvasiveness, but is not always sufficient. A similar relationship between the degree of virus present in the plasma and clinical outcome has been repeatedly noted in HIV infection, in which plasma viral load at diagnosis correlates with subsequent risk of progression to AIDS and death (341).

Tissue Invasion

The factors that determine the capacity of blood-borne virus to escape the vascular compartment and invade specific organs are poorly understood. The problem has probably been most extensively investigated as it applies to invasion of the CNS by blood-borne viruses (Fig. 7) (251). In most regions of the CNS, tight junctions (zona occludens) join capillary cells of the cerebral microvasculature, and there is an underlying dense basement membrane. A notable exception to this pattern occurs in the choroid plexus, where the capillary endothelium is fenestrated and the basement membrane is generally sparse. This was originally postulated as a potential site of invasion for polioviruses, and subsequently established as an important site of infection for lentiviruses such as visna (307). Recent studies suggest that HIV also may infect the choroid plexus (147), and that choroid plexus dendritic cells, which are similar to antigen-presenting dendritic cells elsewhere in the body, may serve as a reservoir and source for CNS disease (203).

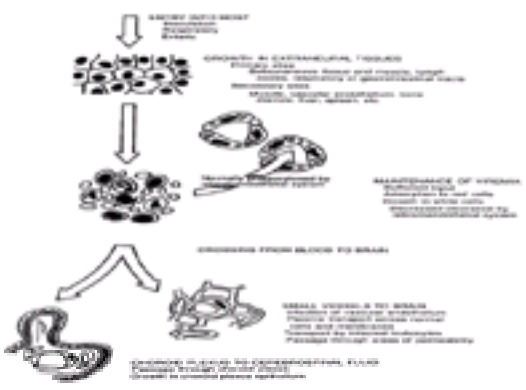

FIG. 7. Pathways of entry of blood-borne viruses into the central nervous system. (From ref. 251, with permission.)

Some viruses invade the CNS from the bloodstream by entering the stroma of the choroid plexus through the fenestrated capillary endothelium and then either infecting or being passively transported across the choroid plexus epithelial cells into the cerebrospinal fluid (CSF). Once in the CSF, virus can infect the ependymal cells lining the walls of the ventricles and can then invade the underlying brain tissue. This pattern of infection has been shown for a number of viruses including mumps, arboviruses, and rat virus (251). Visna, a lentivirus, can be shown to infect cultured choroid plexus epithelial cells *in vitro* (372), suggesting that this pathway may be used by this virus *in vivo* as well. In some cases, direct infection of choroid plexus may not be demonstrable, although the sequential appearance of virus in CSF and ependymal cells suggests the possibility that virus has used this route initially to reach the CSF.

A number of viruses that invade the CNS do so by either directly infecting or being passively transported across capillary endothelial cells. Ability to infect endothelial cells has been demonstrated *in vitro* for many viruses (107,161,297,532,541). Infection of endothelial cells has been proposed as a mechanism for CNS invasion of such disparate groups of viruses as picornaviruses (107,582), togaviruses (376), bunyaviruses (252), parvoviruses, and murine retroviruses (336,411). In the case of some murine retroviruses, there is a close association between neuropathogenicity and capacity to bind to brain endothelial capillary cells *in vitro* (334).

Transendothelial transport of viruses including measles, mumps, canine distemper virus, togaviruses, and lentiviruses may provide another route of penetration of the endothelium and may occur via the diapedesis of infected monocytes, leukocytes, and lymphocytes (159,199). This process may be facilitated by viral modulation of the activity of LFA-1 and other cell-surface adhesion molecules (14,211). Finally, factors that increase vascular permeability, such as vasogenic

amines, also may facilitate viral invasion of sites such as the CNS (465).

Neural Spread

Another important route for viral spread is through nerves (251,285) (Fig. 8). Although this was first postulated as a mechanism for the spread of rabies as early as the 18th century (251), it was not clearly demonstrated until the elegant work by Pasteur and his contemporaries (382). During the first half of the 20th century, experiments by Goodpasture, Hurst, Sabin, Bodian, and others established that herpesviruses, polioviruses, and certain arboviruses also were capable of neural spread (183,234,453). These early observations have been repeatedly confirmed in more modern studies (108,177,291,293,389,432,495,517,527). The group of neurally spreading viruses has now expanded to include reoviruses (157,363,525), pseudorabies virus (71,74,573), coronaviruses (23,407,408), and Borna disease virus (68,358).

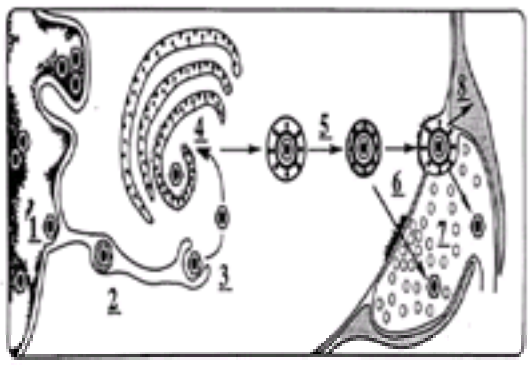

FIG. 8. Significant events that lead to replication and transneuronal passage of pseudorabies virus. Virions replicate in the cell nucleus and acquire a membrane envelope as they bud from the nuclear membrane (*1*), traverse the endoplasmic reticulum (ER) (*2*), and are subsequently released into the cytoplasm after a fusion event between the virion membrane and ER (*3*). Virions acquire an envelope at the Golgi apparatus (*4*), which consolidates and becomes denser (*5*). Transneuronal passage of virus occurs after fusion of the virion envelope with the postsynaptic membrane (*6*); the nucleocapsid can subsequently undergo retrograde axonal transport toward the neuronal cell body (*7*). Alternatively, the virus particle can be released into the extracellular space to infect other cells in the neural parenchyma (*8*). (From ref. 71, with permission.)

Classic experiments on the spread of poliovirus through the sciatic nerve of the monkey by Bodian and Howe (234) established several important principles of neural spread, which have been repeatedly confirmed in other systems (17). They demonstrated that primary replication of virus in extraneural tissues was not an absolute prerequisite for neural spread by showing that poliomyelitis could develop in monkeys after immersion of the cut distal end of the sciatic nerve into a solution containing virus. They also established that the incidence of subsequent neurologic disease, which reflected the efficiency of neural spread, depended on a variety of factors including the amount of nerve exposed to virus, the duration of this exposure, and the concentration of virus present. Under circumstances of natural infection, direct exposure of a nerve to virus is presumably unusual, and primary replication of virus at peripheral sites, although not essential for subsequent neural spread (108,467), may facilitate this process by amplifying the size of the initial inoculum.

Techniques for localizing viral antigens have been used to document the sequential progression of viral infection along neural pathways (251,291). The direct visualization of herpesvirus and rabies virus particles within axons provided further evidence for intra-axonal transport (214,245,285,367,420). A natural corollary of these observations was the finding that axonal transport could also be demonstrated in cultured neurons *in vitro* (318,319,518,519), as well as in isolated nerve preparations (327), and that inhibitors of axonal transport also inhibited the spread of neurally spreading viruses *in vivo* and *in vitro* (39,76,77,283,285,319,516,525).

Both kinetic studies and experiments using pharmacologic inhibitors indicated that most viruses that spread neurally do so via fast axonal transport (285,327,389,525). *In vivo* studies, in which the rate of viral transport is generally measured by dividing the distance traveled by the elapsed time between inoculation and detection at a distant site, have resulted in calculated transport values of 2 to 16 mm/day for viruses as diverse as polio, rabies, herpes simplex, and reovirus T3 Dearing (234,245,285,525). These rates are faster than those associated with slow axonal transport, but far slower than the rate of fast axonal transport (>100 mm/day). The discrepancy may be due to the fact that viral transit times also reflect the time required for a variety of events in addition to transport (e.g., adsorption, penetration and uncoating, and in some cases, replication). The rate of viral transport in *in vitro* systems is often (318,518,519) but not invariably (319) considerably faster than that calculated from *in vivo* experiments.

Further confirmation of the use of fast axonal transport by viruses comes from pharmacologic studies. For example, selective inhibition of fast axonal transport with colchicine, but not the inhibition of slow axonal transport with imidodiproprionitrile (IDPN), inhibits the neural spread of reovirus T3 (525). Colchicine also has been repeatedly shown to inhibit the neural spread of both rabies virus and HSV both to the CNS (39,77) and within the CNS (76). Similarly, taxol, nocodazole, and vinblastine, agents that disrupt the microtubules that serve as the structural guides for fast axonal transport, can inhibit neural spread of viruses *in vivo* and *in vitro* (90,285,319). These results are all consistent with morphologic studies showing a close association between neurally transported viruses and microtubules (258). A selective inhibitor of retrograde axonal transport, erythro-9-3-(2-hydroxynonyl)adenine, also has been shown to inhibit transport of HSV (283), as has an inhibitor of axonal transport in sensory neurons (capsaicin) (482).

The exact mechanism(s) by which axonal transport of viruses occurs has not been established. As described earlier, in the case of several enveloped viruses, such as rabies and herpes simplex, both mature virions and naked nucleocapsids

have been visualized within axons. Fast axonal transport typically involves the movement of material contained in vesicles along microtubules. It is easy to see how viruses that initially enter nerve cells via receptor-mediated endocytosis, and thus appear in vesicles, could be transported to the perikaryon in a vesicle-associated fashion. In some cases, virus might be inserted into vesicles via the Golgi apparatus, in a fashion akin to the sorting of certain cellular macromolecules. However, it remains unclear whether virus is transported in this fashion. Some viruses, including reoviruses and adenoviruses, are capable of binding to isolated purified microtubules (16), suggesting that movement of extravesicular virus also could occur.

In vivo studies clearly indicated that viruses can cross the neuromuscular junction and travel transneuronally at both synaptic and nonsynaptic sites (72,284,285,483,490,527), with the predominant route depending on the virus. In some cases, transneuronal spread may be facilitated by the pattern of viral release from the nerve cell or myocytes. Polarized sorting of viral glycoproteins to the axon and dendrites of cultured neurons, a process analogous to that seen in epithelial cells (*vide supra*), has been described (127), and undoubtedly plays a role in the patterns of viral release and transport in neurons. Rabies virus accumulates in myocytes at the neuromuscular junction (367) and may bind to the nicotinic acetylcholine receptor at the neuromuscular junction (see receptors) (62,202). The synaptic terminals of nerve cells may contain increased numbers of receptors for certain viruses including herpes simplex and rabies (318,319), perhaps explaining how entry at the distal axon terminal is facilitated. Rabies virions also bud from peripheral nerve cells along their axons at the nodes of Ranvier, at the boundary between opposing myelin-producing Schwann cells (367). A related virus, vesicular stomatitis virus (VSV), will preferentially bud from synaptic sites in the presence of antiviral antibody, suggesting that the synaptic region of the axon terminal may have unique structural features that facilitate the exocytosis of some viruses (134).

Viral factors that influence neuron-to-neuron spread are still poorly understood. In the case of herpes simplex virus, it has been suggested that a heterodimer of the envelope glycoproteins gE and gI may be required to facilitate efficient neuron-to-neuron transmission through synaptically linked neural pathways (125).

Different strains of the same virus may show a predilection for retrograde, anterograde, or bidirectional systems of fast axonal transport. This direction-specific predilection has been seen with certain strains of herpes simplex virus and pseudorabies virus (70). The capacity of viruses to spread along discrete neuronal pathways and transneuronally across synapses has made them valuable tools for defining neuroanatomic pathways. Viruses have been used to map synaptically linked interneuronal circuits both within the CNS and between the peripheral and central nervous systems. Injection of virus into a particular target tissue, and sequential study of its central transit, may allow the peripheral and central innervation of these structures to be mapped with exquisite fidelity. HSV and pseudorabies virus have both been used extensively for this purpose (69,71,72,229,230,291,311,384,483,490).

It is important to recognize that viremia and neural spread are not mutually exclusive processes. Some viruses may use different pathways to reach different organs or different pathways at different stages in pathogenesis. For example, it has been suggested that certain flaviviruses may spread via the bloodstream to reach the neurons of the olfactory bulb and then travel retrogradely via neural spread within these specialized neurons to reach the CNS (355). VZV disseminates to the skin via the bloodstream to produce the classic exanthemal rash of chickenpox but then travels up the axons of sensory neurons to reach sensory ganglia where the virus remains latent. Reactivation of VZV is associated with spread of virus via nerves to reach the skin and the appearance of the dermatomal lesions of shingles (Chapter 79).

As discussed earlier, different strains of the same neurotropic virus may differ in their capacity to spread at synaptic versus nonsynaptic sites and to use anterograde or retrograde systems of fast axonal transport. Different strains of the same virus also may differ in the predominant pathway (neural or hematogenous) they use to spread in the host. For example, under experimental conditions, some strains of poliovirus spread to the CNS via nerves (389,432), whereas others do so via the bloodstream (145,234,374,454). Similar differences have been noted for reoviruses, with reovirus serotype 1 strain Lang spreading to the CNS predominantly through the bloodstream, whereas reovirus serotype 3 strain Dearing uses predominantly neural spread (525).

Molecular and Genetic Determinants of Viral Spread

Although the capacity of viruses to spread via different routes in the infected host has been recognized for some time, only recently have the specific viral genes involved in determining this process been identified. Thus several studies with reoviruses indicated that their pattern of spread in the infected host is determined by the nature of the viral S1 gene and the outer capsid protein (s1) that it encodes. After intramuscular inoculation, reovirus T1 Lang (T1L) spreads to the CNS via the bloodstream, whereas T3 Dearing (T3D) spreads via nerves. The viral S1 gene, which encodes the outer capsid protein s1, determines the capacity of T1L × T3D reassortants to spread via either the bloodstream or the nerves to reach the CNS (525). T1 and T3 also show different patterns of spread after oral inoculation into mice. T3 does not disseminate to extraintestinal organs, but T1 does. The pattern of spread of T1 suggests that virus initially spreads via local lymphatics and then via the bloodstream. Studies with T1L × T3D reassortants indicate that the capacity of T1 to spread extraintestinally also is determined by the S1 gene (Chapter 53).

Genetic factors that influence the capacity of HSV to spread to and invade the CNS also have been investigated. There appear to be numerous factors that influence HSV neuroinvasiveness, neurovirulence, and latency (486). The region of the HSV genome between 0.25 and 0.53 map units (m.u.) appears to contain genes that are critical in allowing HSV-1 to spread to the CNS after footpad inoculation in mice (“neuroinvasiveness”) (507). An area contained within this region (0.31–0.44 m.u.) also has been shown to influence the capacity of intertypic HSV-1 × HSV-2 recombinants to spread to the CNS via nerves after corneal inoculation in mice (116). A number of viral proteins including the DNA polymerase, thymidine kinase, the nucleoprotein p40, and the gB envelope glycoprotein are encoded by genes contained in these regions. Mutations in gB may be particularly important in influencing the neuroinvasive capacity of certain HSV strains including KOS and ANG (578). Another genetic mapping study has implicated the DNA polymerase (0.413–0.426 m.u.) (116). The mechanisms by which alterations in the polymerase gene enhance or attenuate neural spread remain speculative. It would appear likely that the effect is an indirect one having to do with replication competence rather than a direct effect on axon transport of virus, because it can be shown that recombinants with differences in this region of the

genome vary dramatically in their capacity to replicate in peripheral nervous system tissue.

Mutations within the gD envelope glycoprotein can also influence HSV neuroinvasiveness. For example, the neuroinvasive HSV 1 ANG-path strain differs from its nonneuroinvasive parent by only a single amino acid substitution within gD (246). Finally, as noted earlier, the glycoproteins gE and gI play an important role in determining the capacity of HSV to spread transsynaptically between neurons (125).

These studies suggested that, in the case of HSV, neuroinvasiveness may be affected by mutations involving a number of steps in pathogenesis. Mutations in envelope glycoproteins such as gB and gD may affect viral attachment or penetration. Polymerase mutations and mutations in viral immediate early proteins may hamper viral replication.

Strain-specific patterns in the transport of herpesviruses have been investigated for both HSV and pseudorabies virus (PRV). For example, the PRV-Becker, PRV-Bartha, and PRV-91 strains all differ in their pattern of neuronal uptake and subsequent neural spread (70,74). The PRV-Becker and PRV-91 strains differ only in the deletion of the gene encoding the PRV gI and gp63 glycoproteins, suggesting that the complex formed by these proteins may be critical in determining differences in neuronal uptake and spread (73,272,551).

A number of studies in the bunyavirus system have identified viral genes that are important in the capacity of these viruses to spread from the periphery to the CNS (“neuroinvasiveness”). Comparisons between nonneuroinvasive and neuroinvasive strains indicate that the viral M genome segment, which encodes the two envelope glycoproteins (G1, G2), is the major determinant of the neuroinvasive phenotype (Chapter 9). Subsequent studies with monoclonal antibody–resistant bunyavirus variants suggested that the viral G1 glycoprotein may be the important determinant.

Studies with monoclonal antibody–resistant mutants of the flavivirus, Japanese encephalitis virus (JEV) indicated that mutations in the E envelope glycoprotein can reduce the neuroinvasiveness of these variants without altering their virulence after intracranial inoculation (78). Thus studies in a number of viral systems including reoviruses, togaviruses, herpesviruses, and bunyaviruses indicated that viral surface glycoproteins may be critical determinants of the capacity of these viruses to reach the CNS from peripheral sites.

TROPISM

The pattern of systemic illness produced during an acute viral infection depends in large part on the specific host organs infected and in many cases on the capacity of viruses to infect discrete populations of cells within these organs (tropism). The tissue tropism of a virus is influenced by the interaction between a variety of host and viral factors. Although a great deal of attention has focused on the importance of viral cell attachment proteins and specific viral receptors on target cells, it also has become clear that a variety of other virus–host interactions can play an important role in determining the ultimate tropism of a virus (207,385). This fact is clearly indicated by experiments that demonstrate that the mere presence of a functional viral receptor may be insufficient to allow viral infection of target cells, as has been shown with HIV, polio, rotaviruses, measles, and MHV (88,91,206,383). For example, intracellular factors and the route of viral entry may be important determinants of tropism (see later). Increasing attention also has focused on the importance of “coreceptors” in mediating viral binding and entry. For example, entry of HIV-1 into target cells requires the presence of both CD4 and a second coreceptor protein that belongs to the G-protein–coupled seven-transmembrane receptor family and includes the chemokine receptor proteins CCR5 and CXCR4 (123). As a result, cells expressing CD4 but not the coreceptor are resistant to HIV infection (see earlier).

Binding to Target Cells and Penetration of Cell Membranes

The importance of viral receptors in determining tissue tropism was initially emphasized for polioviruses (224). Since that time, there has been an explosion of knowledge concerning the nature of viral cell-recognition proteins and their target cell receptors. A full discussion of each viral system and its target cell receptor is beyond the scope of this chapter, and readers are directed to the chapters dealing with individual viral families for more detailed information and more complete references. A partial list of virus families and examples of possible associated host cell receptor(s) can be found in Table 2.

TABLE 2. *Cell-surface molecules proposed to play a role in virus binding and entry*

As the list of potential receptors for specific viruses becomes more and more complete, it is possible to identify certain common themes. Different viruses may use the same cellular structures as receptors. For example, sialic acid residues have been reported to be components of the receptor for certain coronaviruses (human coronavirus OC43, bovine coronavirus) (533), orthomyxoviruses (influenza A and B) (546), Sendai virus (571), and reoviruses (certain serotype 3

strains and rotaviruses) (172,406). Similarly gangliosides have been implicated as potential receptors for rotaviruses (SA11, OSU) (497), paramyxoviruses (Sendai) (329), and rhabdoviruses (rabies) (498). Sometimes several different viruses belonging to the same family use the same receptor, as appears to be the case with heparan sulfate proteoglycan molecules that are used by HSV-1, human cytomegalovirus, pseudorabies, and bovine herpesvirus-1 for initial attachment. Interestingly, heparan sulfate proteoglycans may also serve as receptors for nonherpesviruses including Sindbis (64) and adeno-associated virus type 2 (AAV-2) (494), demonstrating that the same surface molecule can potentially serve as a receptor for distinct families of viruses. Another example of this shared receptor use is represented by the CAR, which, as its name suggests, serves as a receptor for adenoviruses 2 and 5 as well as Coxsackie B viruses (33). In some cases, even though the receptor molecules are not identical, they may share enough structural similarity to merit inclusion together as part of superfamily. For example, many rhinoviruses, poliovirus, and HIV-1 bind to molecules that are members of the immunoglobulin superfamily (190,343,484,509,556).

Certain types of cell-surface molecules appear to be used as viral receptors far more frequently than would be expected by chance. Among this group are the human membrane cofactor proteins, which include regulators of complement activation such as the measles receptor, CD46 (371), which binds C3b and C4b, the EBV receptor, CD21 (155), which serves as a C3d receptor, the coxsackievirus and enterovirus 70 receptor CD55, another complement regulatory protein also known as decay-accelerating factor (DAF) (261), and the canine distemper virus receptor CD9 (312). HIV-1 and certain other retroviruses bind to CD4 (113).

Major histocompatibility complex (MHC) antigens have been implicated as putative receptors for CMV (196), SFV (208), and lactate dehydrogenase elevating virus (LDEV) (243), although in some cases, the assignment remains controversial (395).

Other cell-surface antigens, including the members of the CEA family (coronaviruses) (138) and the erythrocyte P antigen (parvovirus B19) (57), also serve as viral receptors. Integrins also have been identified as receptors or coreceptors for a large and diverse group of viruses including adenovirus type 2 (558), AAV-2 (493), hantaviruses (171), and papillomaviruses (142).

Receptors for neurotransmitters, growth factors, and extracellular matrix molecules including the acetylcholine receptor (rabies) (197), the epidermal growth factor (EGF) receptor (vaccinia, reovirus T3D) (492), and the laminin receptor (Sindbis) (544) may be involved in virus–cell recognition, although controversy again exists about the validity of certain of these assignments.

Among the new categories of proteins that have been implicated as potential receptors are permeases (Gibbon leukemia virus) (249), aminopeptidases (coronaviruses) (513), amino acid–transporter proteins (Mahoney leukemia virus) (270), a-dystroglycans (66), and lipoprotein receptors (356).

A number of general principles have emerged from studies of virus–receptor interactions (207). Many viruses appear capable of interacting with more than one receptor molecule (see Table 2). HIV-1 binding to different receptors by a single virus may be mediated by either a single cell-attachment protein, or by different proteins. For example, HIV-1 uses the gp120 envelope glycoprotein to bind to both CD4 and to galactosylceramide (see Chapter 59), although different domains of the protein appear to be involved. Adenovirus 2 binds to certain integrin molecules through the penton base, which contains an Arg-Gly-Asp (RGD) sequence of the type recognized by cell-adhesion receptors of the integrin family (19,558). For initial entry into target cells, adenovirus also attaches with high affinity to cell-surface receptors via the fiber protein (186). Similarly, Sindbis virus binds to the high-affinity laminin receptor on many mammalian cells (544), but appears to use a distinct receptor for binding to mouse neuronal cells (526). Single amino acid substitutions in the Sindbis E2 protein can alter binding to neuroblastoma cells but not to BHK cells, suggesting that distinct receptor-binding domains may exist on the E2 spike.

It appears that attachment is often a multiphasic interaction between viral attachment protein(s) and several host-cell receptors. In the case of the alphaherpesviruses, it appears that internalization is better understood in terms of a cascade of events that involve different glycoproteins and different cell-surface molecules at different stages (166,207,385,479). Different cell-surface proteins may be used for initial attachment and entry into target cells and for cell-to-cell spread across closely apposed populations of cells (124). An initial HSV attachment step appears to involve the interaction between gC, and possibly gB, with heparan sulfate molecules (210,287). This is followed by a stable attachment phase that involves gD, and possibly gH, and occurs independent of heparan sulfate binding (166). Other glycoproteins including gE and gI may facilitate cell-to-cell spread across contiguous cell layers (124). An analogous series of events has been postulated to occur with other alphaherpesviruses including pseudorabies (259), human CMV (101), and bovine herpesvirus (BHV-1) (391).

Even for viruses that may use only a single receptor, a progression from weak initial binding to secondary stable attachment (“adhesion strengthening”) may occur, as a result of factors such as temperature shifts, or recruitment of receptors to allow multivalent binding (207,385).

For all viruses, initial attachment serves as the first in a series of steps that ultimately delivers the genome to a site in the cell where it can begin replication. For enveloped viruses, penetration of the cytoplasmic membrane takes place after fusion between the viral envelope and the cell membrane. For nonenveloped viruses, penetration of the cytoplasmic membrane is still not completely understood, but involves different strategies (220,331,555). In some cases, as discussed earlier for alphaherpesviruses, initial attachment and subsequent fusion may be mediated, entirely or in part, by different viral proteins. In other cases, the interaction of a virion cell-attachment protein (VAP) with its target cell receptor may initiate conformational changes in other virion proteins that may in turn be essential for subsequent steps in virus–cell interaction including fusion. In some cases, an envelope glycoprotein, such as the vaccinia HA, may have fusion-inhibitory activity, with removal of the protein activating the fusion protein(s) (390). As another example, binding of the alphaviruses Sindbis and SFV to host cells results in structural reorganization of the envelope glycoproteins on the virion surface, which expose previously hidden hydrophobic fusogenic domains (56,158,538). In the case of SFV,

dissociation of the E1/E2 heteromer is followed by the appearance of E1 homotrimers that initiate subsequent fusion events (538). In the case of HIV, a conformational change in the gp120 envelope glycoprotein, which serves as the cell-recognition protein, may increase exposure of the N-terminus of the transmembrane (TM) protein, which contains a stretch of nonpolar amino acids that are essential for fusion activity (339). Conformational changes in the envelope glycoproteins required for fusion also may occur after initial receptor binding has resulted in internalization of the virion into acidified vesicles, as occurs with influenza (419,555) and lymphocytic choriomeningitis virus (LCMV) (122). Given these results, it is not surprising that alterations in fusion proteins can dramatically alter viral host range and cell tropism, independent of changes in viral cell-recognition proteins (165,253).

Fusion events may occur under pH-independent or pH-dependent conditions (294,555). The fusions of the envelopes of herpesviruses, coronaviruses, paramyxoviruses, and certain retroviruses with the plasma membrane of target cells are all examples of pH-independent fusion. Conversely, fusion activity may occur only after endocytosis has delivered virions into the acidic environment of endosomal vesicles. This type of pH-dependent fusion is characteristic of orthomyxoviruses, togaviruses, rhabdoviruses, bunyaviruses, and arenaviruses (47,555). It is important to recognize that the type of entry pathway used by a virus may depend on the cell type. For example, EBV entry into lymphoblastoid and epithelial cells seems to occur by direct fusion of the viral envelope with the target cell plasma membrane, whereas entry into normal B cells involves initial internalization into intracellular vesicles (349). In some cases, a single protein serves both as the viral cell-recognition and fusion protein (e.g., the HA of influenza A), whereas in other viruses, these activities are separated (e.g., paramyxoviruses, HIV).

A number of general features of virion fusion proteins have been identified (554,555). For enveloped viruses, typical fusion proteins have external N-termini and internal C-termini, with most of their mass lying outside the viral envelope. Many of these proteins exist as oligomers, typically trimers or less frequently tetramers. This is perhaps best exemplified by the influenza HA, which is a trimer composed of three identical disulfide-linked subunits, each of which is involved in fusion. Many fusion proteins contain a distinctive stretch of apolar amino acids referred to as a fusion sequence, although in some cases, proteins capable of fusion do not have obvious “fusion sequences.” Fusion sequences vary from short stretches of three to six amino acids to longer sequences 24 to 36 amino acids in length, and often appear to have a predicted secondary structure either of amphipathic helices with hydrophobic amino acids on one helical face and nonpolar residues on the other, or of stretches of nonpolar amino acids. Because fusion proteins are typically inserted into viral envelopes via apolar transmembrane anchoring segments, the presence of a second apolar region (the fusion peptide sequence) presumably facilitates their simultaneous interaction with the target cell membrane. The fusion sequence may be located at the N-terminal of the fusion protein, as is the case with orthomyxovirus HAs, paramyxovirus F proteins, and many retroviral envelope fusion proteins.

Nonenveloped viruses, like their enveloped counterparts, undergo conformational changes consequent to receptor binding. Intracellular delivery of the viral capsid also may be a complex event involving several viral proteins. For example, in the case of reoviruses, the s1 outer capsid protein serves as the viral cell-recognition protein (see Chapter 52). Proteolytic removal of other outer capsid proteins, such as occurs during natural infection in the lumen of the intestine, is associated with a change in the s1 cell-recognition protein from a compact to an extended fibrous form (132). This transition may facilitate subsequent receptor binding. Proteolytic digestion also exposes a fragment on another outer capsid protein, μ1, that is proposed to have a role in membrane penetration (228,511).

During the entry of polioviruses into target cells, conformational transitions also occur that are dependent on binding of the virion to its cell-surface receptor (364). The VP4 capsid protein and the amino terminus of VP1 are extruded from virion interior (160,364). These proteins appear to play a role in membrane-binding interactions that are important postattachment steps in poliovirus entry.

Viral Gene Expression

For some viruses, the interaction between VAP and host-cell receptors is the principal determinant of tropism (see Table 2). However, as more cellular receptors become identified, it has become apparent that the interaction between a virus and its receptor is not the only determinant. Other important factors, especially for retroviruses and papovaviruses, are the elements in the viral genome that regulate the transcription of viral genes in a cell-, tissue-, or disease-specific fashion, including enhancers and transcriptional activators. A full review of the many examples of viral transcriptional regulatory elements is beyond the scope of this chapter, and readers should refer to the individual chapters dealing with specific viruses for more complete discussion and references.

Both SV40 and polyoma have enhancer elements that show some degree of cell-type specificity (see Chapter 63 for review and references), although they also behave in a “promiscuous” fashion and stimulate viral gene expression to some degree in many varieties of differentiated cells. When the SV40 enhancer and early promoter are linked to a marker gene (CAT, chloramphenicol acetyltransferase), gene expression is about fivefold greater in monkey kidney cells as compared with murine cells. The SV40 enhancer consists of tandemly repeated sequences that contain a number of functionally independent elements, that have distinct patterns of cell-type specificity, which can be mimicked by synthetic oligonucleotides corresponding to the nucleotide sequences of the individual elements.

Wild-type polyomavirus does not replicate in undifferentiated mouse embryonal carcinoma cells (ECs), and there is no early gene expression. Polyoma virus mutants that can infect EC cells have point mutations and duplications within the polyoma enhancer. Polyoma enhancer sequence alterations can alter enhancer-specific viral DNA replication in an organ-specific way and affect acute and persistent infections differently (438). It appears that certain types of EC cells make a negative regulatory factor that represses activity of the wild-type polyomavirus enhancer, but not that of the mutant enhancer. Aging and age-specific transcription factors also affect organ-specific transcription in polyoma virus–infected mice (562).

Another striking example of enhancer-related cell specificity occurs with JC papovavirus, the agent responsible for the neurologic illness progressive multifocal leukoencephalopathy (PML). When the JCV enhancer is coupled to the gene for

CAT and this construct is tested for activity in human fetal glial cells and HeLa cells, the enhancer is active only in the glial cells (267). This corresponds well with the fact that, within the CNS, JCV productively infects only oligodendroglia.

Further information on the tissue specificity of papovavirus enhancers has come from studies using transgenic mice (50,474). The offspring of transgenic mice made with early region genes (promoter, enhancer, and T-antigen genes) from JCV develop a neurologic disorder characterized by tremor and seizures. Pathologically, they have abnormalities in CNS myelin due to dysfunction of the myelin-producing oligodendrocytes. Oligodendrocyte dysfunction correlates with the expression of JCV DNA and the presence of high levels of JCV-specified messenger RNA (mRNA) in these cells. It has been suggested that the cell specificity of JCV gene expression is due to the viral enhancer and that cell dysfunction itself is due to expression of virally encoded T antigen.

Transgenic mice made by using the early control region and early genes of SV40 virus often develop choroid plexus epithelial cell tumors. Deletion of the SV40 enhancer region from the microinjected DNA results in a dramatic decrease in the incidence of these tumors, suggesting that the enhancer region may play an important role in the choroid plexus specificity of tumor development, with large-T antigen expression accounting for tumor development (50,399,530). Further studies with polyoma virus indicated that enhancer requirements determine differences in cell-specific control of DNA replication in normal versus transformed pancreas cells (439).

Papillomaviruses also contain enhancers with both inducible and constitutive elements (178). In the case of human papillomavirus 11, the enhancer may play an important role in tissue tropism, as it can be shown that the enhancer is specifically active in keratinocytes (485). Replication and gene expression of papillomaviruses increase as skin cells differentiate from basal cells to mature keratinocytes (29).

The role of enhancer elements in tissue and disease specificity also has been investigated extensively with avian and murine retroviruses and HIV (see Chapter 57 and Chapter 59 for review and references). Enhancer elements within the long terminal repeats (LTRs) play a key role in the capacity of avian and murine retroviruses to produce both neoplastic and nonneoplastic diseases. For example, certain strains of avian leukosis virus induce lymphomas, whereas other strains produce osteopetrosis in avian hosts. The capacity of these viruses to produce these different disease patterns is determined by enhancer regions with the LTR region of the viral genome, although non-LTR gene sequences also may play a role. Enhancer regions also determine the disease specificity of murine leukemia viruses. After inoculation into mice, Friend murine leukemia virus (F-MuLV) produces erythroleukemia, and Moloney murine leukemia virus (M-MuLV) produces T-lineage lymphoid cell neoplasms (Chapter 57). When recombinant viruses are made containing the enhancer regions of either F-MuLV or M-MuLV, the pattern of disease production correlates with the enhancer type. Similarly, replacement of the M-MuLV enhancer sequences in the LTR with the enhancer sequences from SV40 results in loss of the capacity of recombinant viruses to produce T-cell lymphomas and the appearance instead of B-lineage lymphomas and acute myeloid leukemia in infected mice. Recombinant polyoma virus that has its B enhancer element replaced with the 72–base pair repeat enhancer from Moloney leukemia virus genome has strong specificity for the pancreas. The LTRs also appear to play a role in the induction of neurodegenerative disease by certain murine retroviruses (404). A variety of cellular factors regulate HIV gene expression and may influence viral load and disease progression (402). These findings indicate that tissue specificity can be achieved by elements within many viral genes.

Enhancer regions also are present in the genomes of herpesviruses (see Chapter 72 for references). EBV virus contains at least two relevant enhancer domains. The A domain is constitutively active in fibroblasts, epithelial cells, and certain myeloid lineage cells but not in B lymphocytes. The B domain is active in B lymphocytes but requires the presence of a viral transactivating factor for activity (Chapter 74).

Viral enhancers also have been found within the hepatitis B virus (HBV) genome (Chapter 86). Some HBV enhancer elements are more active in liver-derived cells (575) compared with nonhepatic cell lines. Transgenic mice injected with the entire HBV genome (15,61) also show a tissue-specific pattern of HBsAg expression, although antigen expression is not exclusively confined to liver tissue.

Site of Entry and Pathway of Spread

The tropism of a virus may depend on both its site of entry and pathway of spread in the infected host. This principle has clearly been illustrated for a number of neurotropic viruses. For example, in a series of classic studies, Howe and Bodian (234) inoculated the Rockefeller MV strain of type 2 poliovirus into rhesus monkeys via various routes and then studied the distribution of lesions within the CNS. Some areas of the brain, including the sensorimotor cortex and certain thalamic nuclei, were always infected regardless of the route of viral inoculation. Other areas, such as the hippocampus and striate cortex, were never involved. Finally, a number of areas were selectively involved only after viral inoculation via specific routes (e.g., the septal nuclei and olfactory bulbs after intranasal inoculation). Similar results have been obtained with a variety of viruses that depend exclusively on neural spread to travel from the site of inoculation to distant target tissues including VSV (453), HSV (8), herpes suis (332), and rabies (18) viruses (see section on neural spread).

The dependence of neural localization on the site of viral inoculation also is illustrated by the appearance of neurally spreading viruses such as herpes simplex, rabies, and reovirus T3D in the region of the spinal cord innervating the skin and muscles at the site of inoculation. The ultimate lesions depend on the neural pathways innervating the site of inoculation.

The effect of portal of entry on the ultimate tropism of viruses has not been extensively investigated for hematogenously spreading viruses. For polyomaviruses, the route of inoculation appears to determine the site of primary replication and the eventual site of persistent replication. The mechanism for this effect has not been clearly established, although the viral VP1 protein type appears to be involved in this effect (133).

For viruses whose ultimate tissue tropism depends on the generation of viremia, it is difficult to understand how route of entry should alter tropism unless inoculation at different sites results in differences in the magnitude or duration of

viremia. An interesting and unexplained exception to this rule may be the “provoking effect” described in studies with poliomyelitis. It was shown that if intracardiac injection of poliovirus serotype 1 into a monkey was preceded by an intramuscular injection, paralysis tended to occur more frequently in the injected limb (hence the so-called provoking effect of trauma or intramuscular injection on the subsequent development of paralysis) (234). It was suggested that local trauma could selectively increase the permeability of blood vessels in the region of the spinal cord innervating the traumatized site. This in turn would allow blood-borne virus to localize specifically in that region of the spinal cord and produce preferential paralysis of the traumatized limb. Direct evidence for this sequence of events is lacking, and the mechanism of the provoking effect is still under study (194).

The provoking effect has been suggested as a possible mechanism to explain the high incidence of paralysis in the inoculated limb of individuals injected with incompletely inactivated lots of poliovirus vaccine (375). The provoking effect also has been suggested as a possible mechanism to explain reports of a higher than expected incidence of paralytic poliomyelitis associated with the oral polio vaccine when it was administered within 30 days of intramuscular inoculations (491). The provoking effect may represent an example of the dependence of the tropism of a hematogenously spreading virus on the site of viral inoculation. However, it remains unclear how intramuscularly inoculated poliovirus in humans reaches the CNS. If virus spreads from the site of inoculation to the CNS via nerves, a similar preferential distribution of paralysis also might be expected.

For some viruses, the pathway of spread may vary depending on the site of inoculation, and this difference may in turn influence tropism. This possibility is illustrated by studies in mice with the neurotropic NWS strain of influenza (431). After intraperitoneal inoculation, virus spreads through the bloodstream, and viral antigen is found in the meninges, choroid plexus, ependymal cells, and in perivascular locations in the brain parenchyma. After intranasal inoculation, virus spreads through nerves, and antigen is noted primarily in the olfactory bulbs, trigeminal ganglia, and brainstem. In this instance, the site of inoculation influences the mechanism of viral dissemination, which then determines the ultimate tissue tropism.

PATTERNS OF VIRAL INFECTION

As noted earlier, viral infection of a susceptible host can result in the production of acute infection that may be clinically symptomatic or asymptomatic. Clearance of initial acute infection may be permanent, or conversely, the host may develop periodic reactivations of infection with intervening disease- and symptom-free intervals. Viruses that produce recurrent infection, exemplified by the herpesviridae, have developed strategies for establishing, maintaining, and reactivating from the latent state (117). If the host fails to clear the initial acute infection, it may become chronic or persistent. In persistent active infections, virus is continuously present in infected tissues and may be continuously shed from the infected host. Selected examples of viruses known to cause persistent infections of humans and animals and their major sites of persistence within the host are shown in Table 3, Table 4 and Table 5. Viruses capable of producing persistent infections include both enveloped and nonenveloped viruses, viruses with DNA and RNA genomes, and members of many viral families.

TABLE 3. *Viral strategies for evading the immune system*

Category	Status of Viral Genome	Virus–Cell Interaction	Antiviral Immune Response	Example
Latent	Latent, recurrent activation	Lytic, latent	Present, normal	HSV, VZV
“Overshoot”	Active replication (continuous high level)	Noninfectious	Impaired or absent to some viral Ags)	HBV
“Breakthrough”	Active replication (continuous but low level)	Lytic, latent	Present (may be reduced or elevated)	SSPE, HIV

Abbreviations: Ags, antigens; HBV, hepatitis B virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; SSPE, subacute sclerosing panencephalitis; VZV, varicella-zoster virus.

TABLE 4. *Selected examples representing major categories of persistent viral infections in humans*

Recognition System	Target Molecule	Mechanism of Viral Control
Antibody (B-cell product)	Surface glycoproteins Outer capsid proteins Viral glycoproteins expressed on infected cell membranes	Neutralization Opsonization of virus particles ADCC, ADMC Down-regulation of intracellular viral gene expression
CD4+ T cells	Viral peptides presented by MHC class II (10–20 mer peptides derived from exogenous proteins)	Release of antiviral cytokines Activation/recruitment of Mϕ Help for Ab production Help for CD8+ CTL responses Killing of virus-infected cells
CD8+ T cells	Viral peptides presented by MHC class I (8–10 mer proteins derived from endogenous proteins)	Killing of virus-infected cells Release of antiviral cytokines Activation/recruitment of Mϕ

Abbreviations: Ab, antibody; ADMC, antibody-dependent complement-mediated cytotoxicity; ADCC, antibody-dependent cell-mediated cytotoxicity; CTL, cytotoxic T cell; Mϕ, macrophage; MHC, major histocompatibility complex.

Persistent Infections

Reduced CPE

For a virus to establish persistent infection [see (84) for review], it must be able to limit its cytolytic effects, maintain its genome within host cells over time, and avoid elimination by the host's immune system (3). It has recently been recognized that numerous viruses are able to induce apoptotic cell death in target cells (429). Conversely, many viruses have developed an extensive variety of strategies to limit or restrict apoptosis in target cells (176) (see also previous references). It has been suggested that inhibition of apoptosis may favor the development of persistent rather than lytic infection (302). Additional factors that may influence the balance between lytic and nonlytic infections include the state of cellular differentiation (301), or the specific type of cell involved. In the case of Sindbis virus, lytic infection occurs in neuroblastoma cells, but differentiation of these cells into mature neurons in the presence of nerve growth factor favors persistent infection. Conversely, CMV causes productive infection in differentiated teratocarcinoma cells, but restricted gene expression in their undifferentiated counterparts. Retinoic acid–induced differentiation of the undifferentiated cells results in a conversion from nonlytic to lytic CMV infection. In a more biologically relevant system, CMV tends to produce nonproductive infection with restricted gene expression in monocytes, but productive infection results when these cells are induced to differentiate into macrophages (504). Like CMV, LDEV also fails to induce permission infection in macrophage precursors, but does so in differentiated cells.

Some viruses, for example, arenaviruses, have evolved to induce predominantly nonlytic infections in their natural hosts (117). For viruses that are normally lytic, persistent infection generally requires restriction of viral gene expression or the generation of attenuated viral variants. For many viruses, the appearance of persistent infection is associated with the generation of defective interfering (DI) particles that are subgenomic deletion mutants lacking one or more components of the wild-type viral genome. These mutant viruses may be unable to generate productive infection, or may act by modulating infection of associated wild-type virus. Viral gene mutations involved in the establishment and maintenance of persistent infection have been studied in reoviruses. Mutations in the S1 and S4 genes, which encode the virus-attachment protein and a major surface protein, result in alterations in early stages of viral replication and in viral effects on host cell macromolecular synthesis that favor the establishment and maintenance of persistent infection (550). Similarly, coronaviruses, which produce persistent infections in cell culture, frequently contain mutations within the S glycoprotein and show delayed cell penetration (180), and mutations in the Sindbis virus envelope glycoproteins reduce the virus' capacity to induce lytic neuronal infection (301).

In cell culture, persistent infections result from a dynamic interplay between mutations in the infecting virus and alterations in the target cell, as has been reported for reoviruses, coronaviruses, and picornaviruses and parvoviruses (120). This coevolution of cells persistently infected with viruses has been associated with alterations in the expression of cell-surface receptors, or changes in intracellular vesicles.

It has been suggested that a critical factor in the restriction of viral cytolytic effects may be infection of target cells that are only semipermissive. This type of restricted gene expression is characteristic of latent HSV infection of sensory neurons, EBV infection of B cells, and papillomavirus infection of basal skin cells (3). It is important to recognize that noncytolytic persistent infections may be associated with loss of a variety of physiologic cell functions including hormone, cytokine, or neurotransmitter synthesis that may have deleterious effects on the host, even though the infected cells appear anatomically normal (117).

Obviously persistence requires that the viral genome be maintained in infected cells. This is not an issue in nondividing cells, such as mature neurons. Persistent infection of dividing cells requires replication of the viral genome during cell division. Retroviruses, such as HIV (see later), and dependoviruses like AAV (106) integrate their genome directly into the host chromosome, so that each cycle of cell replication also replicates the viral genome. Some viruses, including the herpesviruses HSV and EBV and some papovaviruses, maintain their genome as a circular extrachromosomal “episome” that is readily maintained during latent infection (4).

Evasion of the Immune Response

In addition to developing strategies for avoiding induction of cytolysis, and maintaining their genomes, viruses that persist must also evade host immune responses. The interaction between viruses and the immune system is discussed in detail in Chapter 11, and has been comprehensively reviewed elsewhere (84), but some of the basic strategies used by viruses to avoid host immunity are described later (see Table 4).

Obviously one of the most effective strategies to avoid host immunity is to induce a state of virus-specific immune

suppression within the host, by infecting T or B cells and inhibiting their function, by inducing tolerance by deleting virus-specific T cells within the thymus or peripheral lymphoid organs, or by destroying antigen-presenting cells. These mechanisms are discussed in detail in Chapter 11 [see also (84)] and are not considered further. Viruses also have developed specific strategies to evade host cell immunity. Among the more important of these are restricted expression of viral genes and proteins in infected cells, infection of immunoprivileged sites in the host, interference with the effector arm of cellular immunity through down-regulation of MHC molecules or cell-adhesion molecules, interference with antigen processing and presentation, inhibition of cytokine activity, antigenic variation and the development of escape mutants, and spread through syncytial fusion (3).

Latency

Perhaps the best-studied example of limited gene and protein expression is that of HSV (see later). During latent infection, the only viral transcripts that are detected are the latency-associated transcripts (LATs), and no proteins are expressed. Similarly, latent EBV infection is associated only with expression of the EBNA-1 protein. In less dramatic fashion, many viruses appear to show decreased expression of their glycoproteins in persistently infected cells (394).

Privileged Sites

Persistent infection of immunologically privileged sites is perhaps best exemplified by viral infections of the brain, testes, and parts of the eye (488). In the case of the CNS, this may have to do with the specialized nature of the lymphocyte surveillance and trafficking system within the CNS (549). In addition, the absence or markedly reduced expression and induction of MHC molecules on neurons hampers their capacity to serve as effective targets in cytotoxic T lymphocyte (CTL) responses (232,423). In other tissues, including the eye, testes, and possibly CNS, immune privilege also may be maintained in part by the apoptosis of infiltrating activated lymphocytes bearing Fas (CD95) receptor that interact with resident cells bearing Fas ligand on their surface (365,437). In experimental HSV infection, Fas-triggered apoptosis of antiviral lymphocytes may contribute to immune evasion and persistence of HSV (422). The kidney, although not classically considered an immunologically privileged site, is frequently involved in persistent infections (3). This may reflect the fact that although lymphocytes traffic through the kidney, they may have only limited access to epithelial cells because of the presence of a dense basement membrane (9). In some immunologically privileged sites, MHC class I expression may be low or absent, and low levels of transporter proteins may be necessary for antigen processing (see later) (254).

Escape Mutants

Viruses, especially those with RNA genomes, generate mutations resulting in the creation of viral variants with high frequency (225); the potential biologic significance of these viral “quasispecies” is unclear (see 126). Certain quasispecies may replicate better in specific types of cells, as has been shown for LCMV quasispecies in neurons (126). These variants might also facilitate development of persistent infection by avoiding either antibody neutralization (antibody-resistant variants) or by escaping from T-cell recognition (reviewed in 392). The appearance of antibody-resistant variants also is a characteristic of many lentivirus infections including those caused by equine infectious anemia virus, visna virus, caprine arthritis encephalitis virus, and both SIV and HIV. Although the appearance of these variants was once considered a key feature in the pathogenesis of persistent infections, more recent studies suggest they are not in fact essential to the generation of disease (84,317) (see Chapter 61).

Just as viruses can escape recognition by the humoral immune system, they can also escape T-cell recognition (392). CTL escape mutants have now been identified in a wide variety of viral systems including arenaviruses (LCMV), herpesviruses (EBV), retroviruses (HIV and SIV), and reoviruses (281). The significance of these viruses in the generation of persistent infections, like that of antibody-escape variants, is difficult to establish. At least in the case of SIV and HIV, these mutants do not appear essential for viral persistence, nor do they typically become the predominant viral species in infected hosts (82).

As noted, one strategy for viruses to evade host antiviral CTLs is to develop mutations within regions of their proteins (epitopes) recognized by virus-specific CTLs (CTL escape mutants) in the context of MHC and the T-cell receptor (TCR). In some cases, viral mutants are still recognized by the TCR, but fail to induce a stimulatory signal, and instead inhibit T-cell responses and induce T-cell anergy (TCR antagonism) (36). HIV variants of this type have been identified with mutations within the gag protein (275).

Decrease in Expression of MHC Molecules

In addition to anergy induced by TCR antagonism, suppression of virus-specific host T-cell responses can result from down-regulation of cell-surface MHC class I (for $CD8^+$ cells) or class II (for $CD4^+$ cells) molecules or other cell-surface molecules essential for efficient induction of T-cell responses including integrins and adhesion molecules (434).

In the MHC class I pathway, viral proteins synthesized within infected target cells are ubiquitinated and then processed within 26S proteosomes into peptide fragments, which are transported to the endoplasmic reticulum (ER) in association with transporter associated with antigen processing (TAP) proteins. These transporter proteins are encoded by two genes (TAP1, TAP2) within the MHC, and have homologies to the adenosine triphosphate (ATP)-binding family of transmembrane transporter proteins. Deficiency of TAP proteins results in a failure to load peptides onto class I MHC molecules and a resultant defect in MHC class I restricted antigen presentation. Once inside the ER, peptide antigens bind to the MHC molecules and the antigen/MHC I complex is then exported through the Golgi and trans-Golgi apparatus to reach the cell surface (162).

In the MHC class II pathway, extracellular soluble viral proteins are taken up by endocytosis and processed within endosomes into peptide fragments. Endosomes containing these peptide antigen fragments fuse with vacuoles containing newly synthesized MHC class II molecules derived via the Golgi and trans-Golgi apparatus from the ER.

These antigen/class II complexes are then transported to the cell surface.

Viruses known to down-regulate MHC class I include HSV, CMV (murine and human), EBV, measles, retroviruses including HIV, and adenoviruses (434). A variety of mechanisms, affecting virtually all steps in the MHC class I processing pathway, have been implicated.

Viral proteins, exemplified by EBV EBNA-1, can inhibit ubiquitin-proteosomal protein processing of antigens (303). Similarly, a CMV matrix protein with kinase activity appears to modify other viral proteins in a way that limits their proteolytic processing (175). Viruses also can interfere with the processing and export of the MHC class I molecules. In the case of adenoviruses, the adenovirus E3/19K protein localizes to the ER, where it binds directly with MHC class I molecules and inhibits their terminal glycosylation and processing and blocks their transport out of the ER, so that class I/peptide complexes never reach the surface of infected cells.

Cells infected with human CMV show rapid degradation of the MHC class I molecular complex. Deletion of a viral fragment that encompasses eight genes in the unique short region of the CMV genome abrogates the effects of CMV on MHC expression. These genes appear to encode proteins that act to inhibit the intracellular transport of MHC complex molecules, promoting their retention in the ER and Golgi apparatus and subsequent degradation (162). CMV also encodes a homolog (UL18) of the MHC class I heavy (H) chain protein (146). This protein associates directly with b_2-microglobulin, and was originally postulated to decrease MHC class I expression in CMV-infected cells. More recent studies suggested that this protein may actually result in the appearance of a “decoy” MHC molecule on the cell surface that does not activate CTLs, but does decrease the likelihood that NK cells will recognize the infected cell (119,146,149,162,286,413).

The HSV protein ICP47 binds directly to the TAP molecule within infected cells and prevents the translocation of processed antigen peptides to the ER (213). Down-regulation of TAP also has been seen in cells infected with adenovirus 12 (449). Another strategy is exemplified by HIV, in which the viral tat protein has been shown to decrease MHC class I mRNA transcription. Another HIV protein, Nef, causes down-regulation of MHC class I expression in infected cells by causing the accumulation MHC class I molecules in the Golgi apparatus and then subsequently in clathrin-coated vesicles, where they undergo degradation (298).

Down-regulation of MHC class II has been described after infection with CMV, coronaviruses (JHM), measles, and retroviruses including HIV (434). Down-regulation of MHC class II molecules may involve either the reduction of MHC class II expression or interference with the induction of increased cell-surface expression of class II that usually accompanies virus-induced production of g-IFN and other cytokines (40). Some viruses encode soluble homologs of cytokine receptors including TNF-R (e.g., poxviruses), or encode cytokine homologs such as IL-10. In both instances, the action of antiviral cytokines such as IL-2 and g-IFN is inhibited (e.g., EBV) (475). Myxomaviruses encode a secretory protein that binds to g-IFN and prevents its interaction with its cell-surface receptor. Vaccinia, reovirus, adenovirus, and HIV all encode proteins with double-stranded (ds)-RNA binding activity. These proteins effectively “trap” dsRNA molecules and prevent them from acting to stimulate g-IFN induction in infected cells (182).

Latency: The HSV Example

An exhaustive discussion of the mechanisms by which viruses establish, maintain, and reactivate from latency is beyond the scope of this chapter. However, the basic principles are well illustrated by HSV latency (537) and HIV latency and persistence (see later).

Primary infection with HSV-1 typically involves epithelial cells of the oropharyngeal mucosa producing gingivostomatitis. Productive infection of epithelial cells at the primary site involves the orderly transcription of a (immediate early), b (early), and g (late) genes and their cognate proteins. Replication of the viral DNA and structural proteins is then followed by assembly of progeny virions. Progeny virions and/or their nucleocapsids bind to and enter the distal terminals of sensory neurons innervating the oropharynx, and spread through retrograde axonal transport to reach the perikarya of these neurons within the trigeminal ganglion. A similar sequence of events occurs after primary HSV-2 infection of the epithelial cells of the mucosa of the genital tract, with virus spreading to reach sacral dorsal root ganglia.

Once virus reaches the sensory ganglia, it may either produce acute infection with subsequent neuronal cell death or become latent. Acute infection is associated with virus that is easily detectable on direct culture of infected tissue. By contrast, during latent infection, no infectious virus is detectable on direct tissue culture, but virus can be detected when tissues are cocultivated with permissive cells. During the latent state, there is restricted gene expression limited essentially to the production of what are referred to as LATs (43), and minimal or absent expression of any viral proteins. Viral DNA is maintained as a nonreplicating circular episome (340), and probably occurs as between 10 and 1,000 viral genomes per latently infected neuron (212). It has been calculated that 10% or fewer neurons are latently infected (189), although some estimates are substantially higher (424).

The mechanism of reactivation of latent HSV is poorly understood. Reactivation is associated with neuronal injury, stress, fatigue, hormonal changes such as those occurring during menses or lactation, immunosuppression, malnutrition, and exposure to ultraviolet light. Recurrences may be clinical or subclinical, and can occur as frequently as monthly (31). It is presumed that these events trigger the activation of as yet unidentified signal-transduction transcription and kinase pathways within neurons. Reactivation results in initiation of gene transcription and translation, assembly of progeny virions, and their transport through anterograde axonal transport back to mucosal surfaces where active infection results in herpes labialis (cold sores, fever blisters) or herpes genitalis (genital herpes). Under unusual circumstances, reactivated virus may spread to nonmucosal sites including the meninges (herpes meningitis), CNS (herpes encephalitis, myelitis), or eye (herpes keratitis).

The mechanisms responsible for establishment of HSV latency are not yet completely understood. It is possible that special characteristics of neuronal cells, as compared with their epithelial counterparts, may be necessary for HSV to

establish latency (280). The key determinant may be the quantity of immediate early and early proteins present within particular neurons. If sufficient quantities of viral a gene products are present, then neurons undergo lytic infection, whereas if only low levels are present, virus becomes latent. This suggests that restriction of HSV a gene transcription within sensory neurons may be a critical determinant in initiating latency (487). This restriction in turn may result from the presence of cellular inhibitors of HSV gene transcription such as the octamer binding proteins Oct-1 and Oct-2 (266), or the absence of cellular transcription factors required for HSV gene transcription (233). In an alternative model, HSV-encoded proteins such as ICP4, 8, or 27 have been suggested to serve as negative regulators of HSV a gene expression in infected neurons (see Chapter 72 for review of HSV replication).

The commitment by virus to latent neuronal infection, as opposed to productive infection (328), appears to occur at an early stage in the virus replication cycle, and does not require an initial cycle of completed viral replication (464). No specific viral product absolutely required for HSV to establish latency has been identified. Viruses lacking functional thymidine kinase, immediate early regulatory genes, and even LATs can all establish latent infection (see Chapter 72), although LAT mutants may be less efficient at establishing latency than are their wild-type counterparts (458).

During latency, no infectious virus can be detected in sensory ganglia by direct culture. Viral DNA is present in a nucleosome-associated circular episomal state (440), and can be detected in infected cells by *in situ* hybridization and polymerase chain reaction (PCR) (264). Neurons are postmitotic cells, and therefore maintenance of latent episomal HSV DNA does not require ongoing DNA replication. Maintenance of the latent state is associated with gene expression limited to the LAT transcripts (43). No protein products of LATs or other HSV genes are detectable in latently infected neurons.

Stimuli that induce reactivation of HSV from latency are well documented, but the mechanism has defied analysis (537). It has been suggested that an early event may be stimulus-induced expression of ICP0, which in turn may lead to a cascade of events starting with the expression of other a gene products including ICP4 and ICP27 (300). ICP0-minus HSV mutants can still reactivate from the latent state, but appear to do so with markedly reduced efficiency compared with their wild-type counterparts (300). LAT-minus mutants also show a similar reduction in efficiency and frequency of reactivation, suggesting a possible role for LATs in this process (515). It appears that frequent reactivation from latency in sensory ganglia can occur without inducing significant neuronal cell loss (105), suggesting that HSV must also have a mechanism for limiting neuronal cell death during reactivation. It is possible that the ICP34.5 protein, which has antiapoptotic activity (89), plays a role in this process.

Persistence: The HIV Example

Another example of persistent infection is provided by HIV (337). In HIV infection, unlike latent HSV infection, high levels of virus are continuously being produced in the infected host. Estimates suggest that patients with advanced AIDS may produce more than 10^7 virions/day (219). The major source of new virus appears to be recently infected cells, rather than chronically infected cells or latently infected cells undergoing reactivation (93). Initial exposure to HIV frequently causes an acute viral syndrome with high levels of HIV cell-free and cell-associated viremia. These levels subsequently decline by 100- to 1,000-fold, but the virus does not disappear, and patients enter a clinically asymptomatic stage of infection (410). During this phase, high levels of virus are detectable in lymphoid organs and extralymphatic follicular dendritic cells, even when plasma viremia is of only modest proportions (139,401).

Although HIV induces a persistent infection associated with continuous production of new virus, latently infected $CD4^+$ lymphocytes also can be detected. After infection of target cells, HIV preintegration complex is transported through nucleopores into the cell nucleus. In nondividing (G_0 phase) T lymphocytes, HIV does not undergo proviral integration, but remains as a nonintegrated extrachromosomal replicative intermediate. In this state of “preintegration” latency, the genome is vulnerable to degradation, and is often rapidly lost from infected cells (337). More commonly, proviral integration occurs, and may then lead to a latent state without production of progeny virions, which has been referred to as “postintegration latency” to distinguish it from preintegration latency (337). After initial inoculation of HIV at skin or mucosal surfaces, the associated local activation of $CD4^+$ T cells, facilitated by their interaction with local skin and mucosal dendritic cells, enhances the likelihood of integration of proviral DNA (416). Stimulation of T cells harboring integrated provirus—by antigen, cytokines, phorbol esters, and other activators of transcription—may then result in active viral production (187). The *nef* gene and its product may play a role in regulating this process, as patients with HIV isolates containing mutations within this gene appear to have markedly reduced levels of productive infection from latently integrated genomes (273).

It has been suggested that there are three distinct broad populations of infected T lymphocytes in lymphoid organs of HIV-infected hosts (337). One population encompasses cells that are actively producing virus, and the other two populations include latently infected cells harboring integrated proviral genomes. Of this latter group, one population includes cells harboring “defective” proviral genomes that appear to be blocked in their capacity to produce virions, and another population carries latent proviral genomes that can produce progeny virions. The body load of HIV presumably reflects a balance between the number of actively infected cells and the rate at which virus spreads to uninfected cells, counterbalanced by the host's ability to destroy productively infected cells. The reservoir of latently infected cells probably plays a minor role except under special circumstances, such as treatment with antiviral drugs. Studies suggested that differences in these various parameters may be one factor accounting for differences in disease progression among infected individuals (67). Based on mRNA expression and RNA-splicing pattern in infected cells, it appears that the proportion of latently infected—as opposed to productively infected—cells declines with advancing disease (346). These shifts from latent to productive infection may reflect factors that trigger proliferation of latently infected cells such as cytokine exposure (414), or may even result from direct transactivation of the latent HIV genome by co-infection of latently infected cells by opportunistic pathogens (262).

TRANSMISSION OF VIRAL INFECTIONS

After infecting a susceptible host, the virus is shed into the environment, where it encounters a new susceptible host and

the infectious cycle begins anew. Many of the basic issues and concepts in the transmission of viral infection are reviewed in Chapter 14 and are only briefly covered here. Virus transmission typically begins with dissemination from the infected host through respiratory, enteric, or genitourinary secretions. However, there are a number of important exceptions to this general pattern. Arbovirus infections typically involve the ingestion by an arthropod vector of a blood meal from a viremic host, and transmission occurs when the vector feeds on another susceptible host. The transmitting fluid, blood, is never really “shed” from the body. A similar pattern of transmission can occur when contaminated tissues or blood products are removed from an infected individual and transplanted, transfused, or inoculated into a susceptible host. This pattern is exemplified in the transmission of HIV and hepatitis B virus infection by blood, blood products, or between drug addicts sharing blood-contaminated needles. It is important to recognize that both patients and physicians are at risk for viral transmission resulting from needle-stick exposure and surgical procedures (314).

A number of factors influence the subsequent likelihood of blood-borne transmission of viral infection. These include the titer of virus in the blood, the duration of the viremic state, the amount of material transmitted, and the route of transmission. Before the advent of adequate tests for screening donated blood, HBV infection was a serious potential complication of transfusion. This reflected the incidence of infection in certain populations (e.g., professional blood donors), the frequency of a chronic carrier state with persisting viremia, and high virus titer (up to 10^{7} infectious doses of virus per milliliter) (22). By contrast, posttransfusion infection with hepatitis A virus is an extremely rare event, due to the short duration of viremia and the low virus titer in the blood (226).

Skin

Viral infection of the skin is a hallmark of many types of viral infection including those produced by measles, rubella, certain enteroviruses, herpes simplex, varicella-zoster, various poxviruses, and the HPVs (350). In many of these cases, even though infectious virus can be demonstrated in skin lesions, this does not appear to be a significant source of viral transmission. Exceptions to this rule include the spread of genital herpes simplex and occasionally herpes labialis from infected skin lesions (114), rare cases of chickenpox contacted after exposure to shingles, and the mechanical transmission of HPVs. In the case of certain poxviruses and papillomaviruses of animals, skin lesions provide a source of virus that can infect biting arthropods, which in turn transmit the virus to new hosts (553). Smallpox virus remained infectious in dried skin crusts for extensive periods, and fomites provided an important route of transmission for this disease before its eradication.

Respiratory Tract

Viral transmission from the upper and lower respiratory tracts depends on aerosols generated during coughing or sneezing, or in infected saliva. Some of the factors that influence the stability of viruses in aerosols are reviewed in the section dealing with viral entry. Transmission via infected secretions, which can contain large amounts of infectious virus (400), is important in the genesis of upper respiratory infections, as well as a number of systemic viral infections (e.g., measles, varicella) that enter the host via the respiratory route.

Viruses isolated from saliva include rabies (18,109,152), EBV (315), CMV (316), HIV, and HTLV (2), human herpesviruses 6, 7, and 8 (316), and hepatitis viruses (86). Rabies is the most widely recognized example of salivary transmission of virus (18). Inoculation of infected saliva through the bite of a rabid animal appears to be the predominant mode of rabies viral entry (109). Infected saliva plays an important role in the transmission of EBV, either through intimate oral contact or possibly by salivary residues left on cups, food, toys, or other objects. Mumps virus is shed in the saliva and can be transmitted after nasal or buccal mucosal inoculation of virus.

Salivary excretion of CMV can frequently be demonstrated, but the importance of oral secretions in disease transmission remains unknown. Hepatitis B, C, and G have all been isolated from saliva, but experimental transmission studies with HBV-infected saliva have demonstrated transmission of hepatitis only after saliva is parenterally inoculated, suggesting that transmission via this route is unusual (321). Saliva has also been shown to contain HIV and HTLV, but salivary secretions have never been shown to play a significant role in viral transmission. Certain murine retroviruses can be isolated from saliva, which may play a role in male-to-male viral transmission when infected saliva is parenterally inoculated during fighting (417).

Enteric Tract

Many viruses are shed in feces. This route of transmission is central to the pathogenesis of enterovirus infection (e.g., polio) (234) and also occurs with rotavirus (433) and hepatitis A virus (577). Enteroviral excretion in feces is prolonged, magnifying the opportunity for person-to-person spread. Transmission to susceptible hosts typically occurs by way of fecal–oral transmission, which is particularly common among young children or institutionalized patients. Colonoscopy also has been implicated as a unusual potential source for transmitting hepatitis C virus between patients (55). Infected stool also can contaminate water supplies when sewage and waste-disposal conditions are substandard. Some viruses, such as HIV (528), that can be detected in feces are not readily transmitted by the enteric route.

Urine

A number of viruses including CMV, hepatitis A, HBV, mumps, polyomaviruses, and HIV have been isolated from urine (11), but are not thought to be transmitted by this fomite. However, urinary excretion is central to zoonotic transmission of many arenaviruses and hantaviruses via human exposure to aerosolized urine-contaminated material.

Sexual Transmission

Sexual transmission plays a critical role in the spread of HIV, HSV, papillomaviruses, and hepatitis B and C viruses (239). Viral infection of semen occurs with HIV (63), herpesviruses including HSV (540), CMV (326), and HHV 8 (44), HPVs (292), and HBV (463). In the case of CMV, virus can be detected in about 5% of cryopreserved semen samples collected

for donor insemination (326), although this may not be representative of the prevalence of this virus in the population at large. HSV has been detected in about 3% of semen samples from men with a history of genital herpes, and probably occurs in even higher frequency at the time of clinical reactivation (539).

HIV-infected semen appears to be important in disease transmission. HIV has been found both in cell-free seminal fluid and as cell-associated virus (63) in 85% of HIV^+ men (135). In up to 35% of HIV infections, viral titers in semen are equal to or exceed those found in blood plasma (135). The genotype of HIV found in semen may be genetically distinct from that HIV strains found in blood, suggesting that in some instances, semen and blood compartments are distinct (63,104). HIV-1 can be detected in semen of HIV^+ men who received highly active antiretroviral therapy (HAART), even at times when plasma HIV is undetectable (579), showing that the genital compartment may harbor residual virus. Male-to-female heterosexual transmission of HIV-1 is facilitated by breaks in the cervical, vaginal, or urethral epithelium often associated with sexually transmitted disease, although infection of intact epithelial cells also may occur. Cases of HIV infection related to insemination of women with HIV^+ donor sperm also have been reported (568). Many aspects of HIV transmission parallel events described for the horizontal transmission of murine retroviruses (304).

Several viruses, including HIV and HSV, also have been isolated from the genital secretions and cervix of infected women (415,535,539,563). Infected secretions play a role in female-to-male heterosexual transmission of HIV infection as well as in perinatal vertical transmission from pregnant infected mothers to their neonates (10). Virus shed in vaginal secretions also may play a role in the perinatal transmission of papillomaviruses (505).

Milk

Several viruses, including CMV (201), mumps, rubella, HIV and other retroviruses (478), human herpesviruses (164), hepatitis C (289), certain flaviviruses, and minute virus of mice (MVM), have been isolated from human or animal milk or colostrum. Infected breast milk provides a source of transmission of CMV from mother to child during the perinatal period. In one study (534), it was estimated that up to 85% of CMV-seropositive mothers excrete CMV in breast milk. Nearly 60% of preterm infants born to these mothers will develop CMV infection. Infection of preterm infants born to CMV-seropositive mothers was significantly lower if these infants were not breast fed, indicating that this is an important mode for viral transmission. Hepatitis B and C viruses also can be transmitted from mother to child during the perinatal period. Although this type of transmission is well documented, and virus can be found in the milk of infected mothers, it is unclear what role infected milk plays in disease transmission. In the case of hepatitis C, it appears that the risk of maternal–infant transmission occurs predominantly with symptomatic HCV-infected mothers who breast feed their infants as compared with breast-feeding mothers who were asymptomatic carriers (289). This may reflect the fact that symptomatic mothers had dramatically higher viral loads than did their symptomatic counterparts (289). Maternal milk also has been implicated in the vertical transmission of visna maedi and may play a role in human transmission of HTLV-I.

HIV RNA is detectable by quantitative competitive reverse transcription–PCR (RT-PCR) in the milk of 40% of HIV-1–seropositive women (306). Virus may be either cell-free (306) or present in the T cells and macrophages found in colostrum and milk (478). Recent data showed that 5% to 20% of infants born to HIV-infected mothers may be infected by breast feeding, with transmission occurring up to age 18 months (478). Although mumps virus can be found in human milk, and rare cases of perinatal mumps infection occur (255), infected milk is not important in viral transmission.

Maternal–Child Transmission

Maternal–child transmission can result from intrauterine infection, infection during delivery from virus present in the maternal birth canal, of from neonatal exposure to infected breast milk. Maternal–child transmission of infection has been documented for a number of viral infections (324) as exemplified by HIV, hepatitis B and C, CMV, HSV, human herpesviruses (472), HPVs (505), varicella, measles, mumps, rubella, and human parvoviruses (B19) (279). In the case of HPV, the vertical transmission rate from infected mothers to their infants born vaginally may be as high as 30% (505). Premature rupture of membranes appears to be an important risk factor, with increasing rates of maternal–child transmission being directly correlated with the time elapsing between rupture of membranes and delivery (505). The risk of transmission of parvovirus B19 infection has been estimated to be as high as 50%, but is fortunately only rarely associated with symptomatic disease (279). The risk of transmission for hepatitis C appears significantly lower (2–11%), but may be increased in mothers with associated HIV infection, HCV viremia, and elevated liver-function tests (185).

Perhaps the most extensively studied example of maternal–child viral transmission is that of HIV infection. The risk of transmission of HIV infection from an infected mother to her child appears to be directly proportional to maternal HIV-1 viral load (102,167,353). The risk may be as small as 5% or less in mothers with fewer than 1,000 copies/mL and can reach 40% or higher in those with more than 100,000 copies/mL (102). In another study, the HIV viral load was found to be more than 65,000 copies/mL in mothers who transmitted infection to their children, as compared with 5,139 copies/mL in nontransmitters (412), again indicating a general correlation between the degree of maternal viremia and the risk of transmission. It has been suggested that for each 10-fold increase in maternal HIV RNA level, there is an approximately twofold increased risk of maternal–child transmission (265). Premature delivery, prolonged duration between premature rupture of membranes and delivery, and the presence of genital warts have all been reported to increase the risk of intrapartum transmission of HIV infection (288).

The mechanism by which HIV infection is transmitted transplacentally may involve the presence of maternal chorioamnionitis (529). Infection of placental chorionic villi has been documented in HIV infection (344), although only a subset of the HIV quasispecies found in maternal blood are detectable in chorionic villi (344). This suggests that the capacity of certain HIV strains to infect the placenta may be an important factor in maternal–child transmission. Interestingly, certain HIV-1 p17 matrix protein amino acid sequence motifs appear to be found in nontransmitting HIV isolates as compared with those associated with maternal–child transmission. For example, the p17 matrix protein amino acid sequence K_{103} IEEQN$_{109}$ was found in all HIV B subtype isolates from mothers who had transmitted infection to children, whereas nine of 17 nontransmitting mothers had a valine $_{104}$ in place of the isoleucine $_{104}$ (373).

Organ Transplantation

Organ transplantation has provided an entirely novel method for iatrogenic transmission of viral infections. A full discussion of this subject is beyond the scope of this chapter (192). Transplanted bone marrow, kidneys, livers, and hearts have provided the source for infection with CMV (215), EBV and other herpesviruses (192), and retroviruses including HIV and HTLV-I (409). In one case, HTLV-I–associated myelopathy was attributed to acquisition of infection during cardiac transplantation (184). There also are reports of rabies and hepatitis B transmission resulting from corneal transplantation (222). Increasing use of animal-derived tissues for transplantation (xenotransplantation) has raised fears that these tissues may be the source for transmission of infectious agents (80), although no viral infections have yet been reported.

Little is known about the role played by specific viral genes and the proteins they encode in determining the transmissibility of viral infections (268) (see earlier discussion of maternal–child transmission of HIV). In the case of reoviruses, the capacity of certain strains of virus to spread from an infected mouse to its uninfected littermates is related to both the magnitude of viral growth in intestinal tissues and the amount of virus shed in the stool (268). Studies with reassortant viruses derived from low- and high-transmission reovirus strains indicated that the viral L2 gene, which encodes the core spike protein l2, is the major determinant of transmission (268). Because this gene also is a major determinant of the capacity of reoviruses to grow in intestinal tissue after peroral inoculation (Chapter 53), it may facilitate transmission by increasing viral growth and shedding.

Studies also have been made of the aerosol transmission of influenza virus between mice (462). Although a highly transmissible influenza strain (Jap/305) and a poorly transmissible one (Ao/NWS) grow to equivalent titer in the lungs, the amount of Jap/305 is considerably higher in bronchial secretions and in exhaled air. It was suggested that the neuraminidase protein might account for differences in the amount of virus released from respiratory epithelial cells into bronchial secretions and expelled air, although direct evidence is lacking.

HOST FACTORS

The outcome of viral infection of a particular host depends not only on viral factors but also on a variety of host factors. The role played by host factors in infection has been comprehensively reviewed (553), and interested readers are referred to these sources for more detailed information. The impact of host variation on the epidemiology of viral infection also is discussed in Chapter 14.

Experience with human infections has repeatedly shown that when a large population is exposed to the same viral pathogen, such as occurs, for example, during epidemics of encephalitis, the result is a range of outcomes varying from asymptomatic infection to significant and even fatal disease. The same pattern has been reproduced in inadvertent natural experiments such as the inoculation of HBV-contaminated lots of yellow fever virus vaccine into 45,000 military personnel (459). Clinical hepatitis occurred in only 2% of those vaccinated (914 cases), and of this group, only a small minority (4%) developed severe disease. The variation in outcomes appears to have been due to differences in host susceptibility, because the amount of HBV inoculated can be presumed to have been fairly uniform among those vaccinated.

In 1955 nearly 120,000 grade-school children were vaccinated with improperly inactivated lots of poliovirus type 1 prepared by Cutter Laboratories (375) (“Cutter incident”). It was subsequently estimated that about 50% of those vaccinated were susceptible to infection (the remainder had preexisting antibody), and of this group, at least 10% to 25% became infected (as estimated by the presence of minor illness or fecal excretion of virus). However, only 60 cases of paralytic poliomyelitis were ultimately documented among those vaccinated. Thus the Cutter incident again emphasizes the fact that when a large population of individuals is inoculated with approximately similar doses of virus, there is a wide range of possible outcomes that presumably depend on a variety of factors specific to the host.

The importance of host factors in determining the outcome of viral infection has been repeatedly demonstrated in animal models (51). Classic studies with VSV infection of mice clearly illustrated the importance of host factors including immune status, genetic background, age, and nutrition in determining the outcome of infection (453). The role of the host immune response and mediators such as cytokines in influencing viral infection are discussed separately (see Chapter 11 and Chapter 12).

Genetic Determinants

The genetic constitution of the host is undoubtedly one of the most important factors influencing the outcome of viral infection, and has been extensively investigated using inbred strains of mice (20). It was recognized as early as 1937, by Webster (545), that it was possible to breed selectively strains of mice that differed in their resistance to flaviviruses, including St. Louis encephalitis virus and louping ill. This observation was later extended to a number of other flaviviruses (115) including yellow fever virus and West Nile virus (195). In general, susceptibility correlated with increased levels of viral replication in tissues. In some cases resistant mice appeared to be more susceptible to the antiviral action of IFN (204), although at least one resistance gene (Flv^r) confers flavivirus-specific resistance by an IFN-independent mechanism (52).

Since the early studies with flaviviruses, genetic factors influencing susceptibility to infection have been found for herpesviruses (5), poxviruses (386), papovaviruses (53), rhabdoviruses (310), coronaviruses (48,278), retroviruses (53), myxoviruses (200), arenaviruses (393), and Borna disease virus (451). In almost all cases, the genes determining resistance to different types of virus appear to segregate independently, suggesting that a variety of mechanisms are involved rather than a single universal type of resistance or susceptibility.

Although it would seem logical that genetic resistance to infection would be linked to host genes controlling the immune

response (e.g., H-2 in the mouse), this is surprisingly infrequent. An exception to this rule may be human infection with HTLV type I in which HLA class II alleles are associated with different patterns of disease expression and may influence whether infected individuals develop adult T-cell leukemia (ATL) or HTLV-associated myelopathy (HAM) (325). Transmission of HIV-1 from infected mothers to their offspring also has been linked to the infant's MHC class II allelle (560). Recently it was observed that certain MHC class II haplotypes appear to influence the outcome of SIV infections in rhesus macaques, and that HLA alleles may influence viral load and rate of progression to AIDS after HIV infection in humans (209,452).

Susceptibility to virus infection may be associated with the presence or absence of the appropriate host-cell receptors on target cells. This mechanism may explain the susceptibility of some strains of mice to intestinal infection with MHV (48). However, some strains of mice remain resistant to MHV infection despite the presence of functional virus receptors (576), indicating that other factors also are involved. The recognition of chemokine coreceptors in HIV infection has documented one determinant of susceptibility to HIV infection. Individuals homozygous for a deletion (D32) within the chemokine receptor 5 (CCR5) gene have a markedly decreased incidence of HIV infection compared with those with a functional CCR5 gene (209) [see (94) for review]. Polymorphisms within the CCR2 allele also may influence the rate of HIV progression in infected individuals (476). However, factors other than CCR genotype are clearly involved in susceptibility to HIV (370).

Another example of a host gene influencing susceptibility to human viral infection occurs with the TNFa gene encoded within the MHC locus. Polymorphisms within the promoter for this gene have been linked to susceptibility to the development of chronic active hepatitis C infection (223).

The genetic basis for resistance of certain strains of mice to infection with influenza viruses has been extensively investigated. A2G mice are resistant to infection with influenza A. Resistance is inherited as an autosomal dominant trait that is associated with the Mx allele on mouse chromosome 16 (481). Resistance is mediated by the actions of IFN-g and IFN-b that induce a 72-kd protein (Mx protein) in cells derived from resistant mice. The Mx protein accumulates in the nucleus of cells and inhibits viral replication by inhibiting viral mRNA synthesis (131). Treatment of A2G mice with antibody to interferon renders them susceptible to infection (200). Transfection of cells derived from susceptible mice with cDNA encoding the Mx protein confers protection against influenza A infection *in vitro* (481). Mice that are susceptible to infection appear to have either deletions or nonsense mutations in the Mx gene (480).

Other Physiologic Determinants

Human viral infections provide numerous examples of the correlation between the age of the host and the severity of viral infection. Some viruses tend to produce less severe infection in infants (e.g., varicella, mumps, polio, EBV, hepatitis A), whereas others are more severe (e.g., rotaviruses, RSV, WEE, and measles). Age-related susceptibility to virus infection also occurs in a variety of experimental viral infections in mice (30,188,191,257,320,562). Conversely, the case/infection ratio is higher in older persons for a few infections such as St. Louis encephalitis (see Chapter 14).

The basis for the age dependence of viral infection is poorly understood. Some types of enhanced resistance to viral infection with increasing age may reflect the maturation of both specific and nonspecific components of the host's immune system including phagocytosis, NK activity, cell-mediated cytotoxicity, and antibody production. Organ-specific differences in the immune response may explain why some tissues in adult animals become resistant to viral infection, whereas others do not (562). Finally, age-specific restrictions may reflect changes in the maturity and state of differentiation of target cells, as has been suggested for SFV infection of neurons (396).

For Sindbis (alpha) virus encephalitis, the state of neuronal maturity appears to be an important factor in determining age-related susceptibility (388), whereas immunologic factors play little or no role in this process (191,520). It has recently been shown that changes in the Sindbis E2 glycoprotein can compensate for age-dependent neuronal restriction of replication (520). Dependence of viral infection on the state of cellular differentiation also has been described with coronaviruses (37), herpesviruses (137), polyomaviruses (29,163,322), parvoviruses (198), retroviruses (111), and arenaviruses (118).

Some viruses preferentially infect dividing cells, and differences in the organ distribution of these cells during development and maturation may influence the pattern of disease. For example, prenatal infection of cats with feline parvovirus results in destruction of the germinal cells of the cerebellum and subsequent cerebellar aplasia. Conversely, infection of adult cats involves primarily dividing bone marrow and intestinal epithelial cells and does not result in neurologic illness (250). Induction of cellular damage or injury also may trigger responses that make previously nonpermissive cells able to support viral replication (12).

Hormones also can influence the outcome of viral infection. This may provide one explanation for the frequent observation that male mice are more susceptible to a variety of viral infectious than are their female counterparts (310). A number of infections, including those with polio, hepatitis A and B, and smallpox virus are commonly more severe during pregnancy, although it is not known whether this reflects hormonal alterations or other factors. Reactivation of polyoma virus infection also occurs more commonly during pregnancy, although this typically occurs without associated clinical disease (96). Pregnant mice are more susceptible to intravaginal infection with HSV but not to intraperitoneal or intranasal infection. It has been suggested that this may be due to local hormonal effects. In experimental studies, the administration of both steroid and thyroid hormones can be shown to affect adversely the outcome of certain types of viral infection (reviewed in 350).

The nutritional state of the host also can exert a marked influence on the outcome of viral infection (79). For example, protein malnutrition dramatically exacerbates the severity of measles infection, perhaps by depressing host cellular immunity (79). A similar increase in susceptibility to coxsackievirus and flavivirus infection occurs in experimental infection of malnourished mice. It has been suggested that dietary-induced oxidative stress resulting from deficiency of vitamin E and selenium can increase the severity of certain viral infections, as exemplified by the potentiation of

coxsackievirus B3 myocarditis in selenium– and vitamin E–deprived mice (28). Deficiency of vitamin A may result in enhanced severity of respiratory syncytial virus infection in children (380). As a result of these studies, it has been suggested that supplementation with vitamins A, B, C, D, and E may provide an inexpensive form of supplemental therapy for HIV infection, although data directly supporting this approach are still lacking (150). Vitamin A also has been shown to reduce the rate and severity of complications and the duration of hospitalization in children with measles infection (241), and may facilitate healing in HSV keratitis. At the opposite extreme, hyperalimentation and the induction of hypercholesterolemia also may be associated with increased severity of viral infection (65).

Other physiologic factors also may play a role in the severity of viral infection. For example, the severity of influenza is increased in chronic smokers (260), related to the deterioration in mucociliary clearance. Preceding vigorous exercise may worsen the severity of a subsequent bout of poliomyelitis (234), although the mechanism for this has never been clearly established. Experimentally, exercise also can be shown to increase the severity of coxsackievirus infection in mice (170).

The role of host responses such as fever and inflammation in combating viral infection has been examined (435). Classic studies of myxoma infection in rabbits clearly demonstrated that increasing body temperature increased protection against infection and that decreasing temperature increased severity of infection. Similar results have been found with ectromelia and coxsackievirus infections in mice. Blocking the development of fever with drugs (e.g., salicylates) increases the mortality of vaccinia infection in rabbits and increases the shedding of influenza by ferrets (240), providing additional evidence for an antiviral effect of fever. Virus infection exacerbates host stress responses, which in turn may contribute to the pathogenesis of disease. For example, mice infected with Sindbis virus have dramatically increased levels of IFNa/b, TNFa, adrenocorticotropic hormone (ACTH), and corticosteroids. Stress also is associated with high levels of circulating catecholamines including norepinephrine (514). In one recent study, norepinephrine was shown to accelerate HIV replication through its action on protein kinase A–dependent pathways and the subsequent reduction in host levels of several antiviral cytokines including IL-10, IFN-g, TNFa, IL-1b, and IL-2, -4, and -6 (95).

The importance of host-cell enzymes in influencing the outcome of viral infection was discussed earlier in this chapter. It is well exemplified in the role played by host-cell enzymes in the pathogenesis of myxovirus infection (Chapter 46 and Chapter 47). Influenza requires cleavage of the viral hemagglutinin from an inactive precursor (HA_0) form into two disulfide-bonded subunits (HA_1 and HA_2) to become infectious. This cleavage is mediated by host-cell trypsin-like proteases, and without this cleavage, virus is avirulent. The HA proteins of mammalian influenza viruses and nonpathogenic avian viruses are susceptible to proteolytic cleavage in a limited number of cell types, whereas the HAs of many pathogenic avian influenza viruses are cleaved by proteases present in many types of host cells (276). Differences in the susceptibilities of these HAs to cleavage is due to the presence of only a single arginine residue at the cleavage site in the mammalian and nonpathogenic avian viruses, whereas the pathogenic avian viruses typically have several basic amino acids present at the cleavage site (276). Mutations in the influenza HA near the cleavage site can dramatically alter both the host range and pathogenicity of influenza viruses (121).

A host-cell protease-mediated cleavage similar to that required for influenza virus is required for activation of the fusion activity of paramyxoviruses such as Sendai virus. Virus containing an uncleaved fusion (F_0) protein does not replicate after inoculation into mice. However, virus will replicate if the F protein has previously been cleaved *in vitro* into the disulfide-bonded F_1 and F_2 subunits by trypsin. Mutant viruses whose F protein can be cleaved by chymotrypsin but not by trypsin also do not produce disease unless the protein is cleaved *in vitro* (352).

Host-cell enzymes also may play an indirect role in susceptibility to Sindbis virus infection. The envelope of the virus contains sialic acid residues derived as the virus buds from host-cell plasma membranes. If the membranes are rich in sialic acid, virus is a more potent activator of complement. Complement activation and subsequent opsonization of virus facilitate viral clearance and thus decreases viral virulence (217). In this example, the biochemical composition of host-cell membranes alters the subsequent virulence of virus.

CHAPTER 10 Cell Transformation by Viruses

Joseph R. Nevins

GENERAL FEATURES OF VIRUS-INDUCED CELL TRANSFORMATION AND ONCOGENESIS

The science of virology includes studies directed at understanding the mechanisms by which pathogenic viruses cause disease. In addition, viruses serve as simple model systems to explore complex cellular events. Also, the ability of the oncogenic viruses to deregulate or disrupt cellular biochemical pathways has led to a better understanding of the role of these pathways in cell growth and differentiation.

Viruses that induce cell transformation and tumor formation can be found in several taxonomic groups. All RNA tumor viruses belong to the retrovirus family and in general represent the generation of viruses that have developed an oncogenic capacity by acquiring and modifying cellular genetic material. There are exceptions, such as the viruses that induce tumors by inserting next to key cellular genes and human T lymphotropic virus-I (HTLV-I), in which the oncogenic activity is due to the action of an essential viral gene. But in the majority of cases, the RNA tumor viruses can be seen as cloning events that select for cellular genes with the capacity to transform when deregulated. The replication of oncogenic retroviruses is not cytocidal, and therefore oncogenic transformation is compatible at the cellular level with the production of infectious progeny virus. However, virus production is not a prerequisite of oncogenesis (115,241).

The DNA tumor viruses come from seven different groups encompassing both nonenveloped and enveloped viruses (Table 1). Regardless of taxonomic provenance, the oncogenic potential of the DNA tumor virus is tightly linked to the genetic strategy of virus replication. In general, the synthesis of infectious progeny is linked to cell death; hence oncogenic transformation can occur only if the viral life cycle is aborted (354).

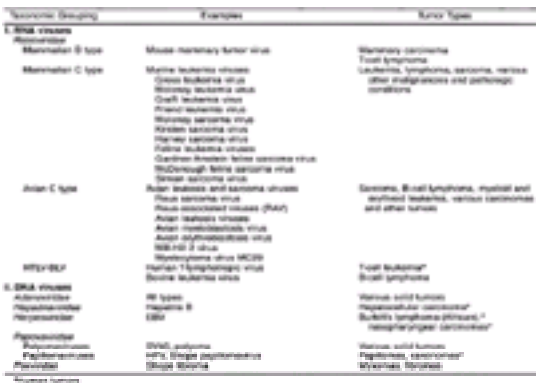

TABLE 1. *Oncogenic viruses*

Some viruses can act as carcinogens in the natural setting, whereas others reveal their oncogenic potential only in experimental systems. The potency of viruses as inducers of tumors varies widely. The most effective retroviruses can initiate tumorous growth in virtually all infected animals within a matter of days. Most other viruses, however, require a much longer latent period, and only a small fraction of the infected hosts eventually develop the virus-induced malignancy. All human tumors associated with virus infections belong in this category. The fact that tumor formation is not an inevitable consequence of virus infection reflects the multistep nature of oncogenesis, in which each step constitutes an independent and irreversible genetic change that incrementally contributes to the deregulation of cell growth. Viral infection represents one of these steps; only if the others occur in the same cell does a cancer develop. In cell culture, viruses can transform cells to a fully oncogenic phenotype. Such cells display all the altered properties of the tumor cell and are capable of initiating a cancer in a susceptible host animal. In some instances, however, the

transformation is only partial, discernible in culture by changes in morphology and growth properties but not capable of inducing a tumor *in vivo.*

Virus-induced transformation in cell culture has played a major role in the conversion of modern cancer research into a genetic science. Much of what we know today about molecular mechanisms of oncogenesis has its origin in the study of tumor viruses. These studies have led to an almost universal consensus among cancer researchers that the oncogenic phenotype results from discrete changes in key cellular control genes. Detailed mechanisms of virus-induced oncogenic transformation diverge widely, but all have important characteristics in common. These include a single infectious virus particle is sufficient for transformation: virus-induced transformation is a “single hit” process; all or part of the viral genome persists in the transformed cell, although there is often no production of infectious progeny virus; in virtually all cases of virus-induced transformation, at least part of the viral genome is expressed in the transformed cell; transformation results from corruption of normal cellular growth signals; and reversion of the transformed cellular phenotype can be achieved by specific interference with the function of viral effector molecules (e.g., by transdominant negative mutants of oncogenes).

Viral mutants that are temperature sensitive in their transforming potential can be used to compare cellular properties at the permissive temperature, when the cell is transformed, with the nonpermissive temperature, when the cell is not transformed, but all viral functions not required for the maintenance of transformation are still active. Expression vectors carrying single viral oncogenes have likewise been instrumental in determining the effects of these genes on cellular properties. The alteration of cellular parameters accompanying transformation can be divided into changes in cell growth and changes in cell morphology; the latter affect the cytoskeleton, the cell surface, and extracellular matrix (Table 2). Both kinds of change are interrelated, but not all of the changes are seen in every type of transformed cell.

Cellular Property	Oncogenic Change or Component
Growth	Increase in saturation density
	Reduced growth factor requirement
	Increased nutrient transport
	Anchorage independence of growth
Cytoskeleton	Loss of “stress fibers”
	Redistribution of microfilaments
Cell surface	Increased agglutinability by lectins
	Increased lateral mobility of transmembrane protein
	Increased production of surface proteases
	Decreased adhesion to solid substrates
Extracellular matrix	Decreased levels of fibronectins

TABLE 2. *The transformed cellular phenotype*

Alterations in cell growth affect three parameters: saturation density, growth-factor requirements, and anchorage dependence. When normal cells replicate to form a confluent layer, covering the available solid substrate surface, they stop dividing, even if ample nutrients are supplied. This saturation density of a culture is significantly higher when the same cells are transformed, reflecting an enhanced ability of the transformed cells to pile up and to grow in multiple layers (20). If a monolayer of normal cells is infected and transformed by a few individual virus particles, these changes in cellular growth behavior lead to the outgrowth of microtumors, referred to as transformed cell foci (349). Normal cells also are highly dependent for their growth on the presence of growth factors in the culture medium. Viral transformation often abrogates or reduces these growth-factor requirements.

Normal fibroblasts and epithelial cells must have a solid glass or plastic surface on which to spread before they can grow and divide. Transformation leads to a loss of this anchorage dependence. Transformed cells are able to form colonies if suspended in a semisolid gel nutrient medium. This anchorage independence allows the selection of a few transformed cells occurring within a population of mostly normal cells (219). The latter will survive in the nutrient gel for a few days, but will not grow and form colonies. In contrast to fibroblasts and epithelial cells, normal hematopoietic cells can often form colonies in semisolid medium, provided the appropriate growth factors are supplied.

As the name implies, transformation also leads to changes in cell morphology. These changes affect the cytoskeleton, the cell surface, and the extracellular matrix (354,374). Cytoskeletal changes are detectable by light-microscopic inspection and show up as a loss of “stress fibers.” At the electron-microscopic level, they are seen as a rearrangement and redistribution of microfilaments. Several proteins are involved in this reorganization. The major structural components are actin, myosin, and tropomyosin, and near the plasma membranes, a-actinin, vinculin, and talin (50,341). For instance, actin cables prominent in normal fibroblasts disappear on transformation; the actin becomes diffusely distributed in the cytoplasm. Particularly important in the process of maintenance of cell morphology through the interaction with the extracellular matrix is the action of the focal adhesion kinase, a nonreceptor tyrosine kinase that is intimately involved in the processing of signals from the cell–matrix interaction involving recruitment of the Src kinase (66,153).

Changes in cell-surface glycoproteins make transformed cells agglutinable by lectins such as wheat germ agglutinin or concanavalin A (276). Viral transformation also stimulates the production of surface bound and secreted proteases (59,62,251). These have a mitogenic effect on the cell and facilitate tumor invasion and metastasis in the animal. Finally, cells synthesize macromolecules that form an extracellular matrix important in the attachment, spreading, and movement of the cell. Major components of this matrix are fibronectin, laminin, and collagen. Matrix molecules bind to specific cell-surface receptors called integrins, heterodimeric transmembrane proteins that form a connection between the extracellular matrix and the cytoskeleton (162). Transformed cells show decreased levels of fibronectin because of the action of extracellular proteases, reduced fibronectin synthesis, and reduced expression of fibronectin receptors

(61,161,162,249).

VIRUS-INDUCED TRANSFORMATION: MODELS FOR CELL-CYCLE CONTROL AND SIGNAL-TRANSDUCTION PATHWAYS

Much of our present understanding of the cell cycle and cell growth control events derives from an elegant combination of genetics and biochemistry that the budding and fission yeast have provided (143). The ability to identify critical regulatory activities through mutation, to identify the genes that specify these activities, and then to understand the biochemical mechanisms of action of these gene products has been enormously productive. Although the study of the cell cycle in mammalian cells clearly suffers from the limited genetic analysis possible in mammalian systems, studies of the oncogenic action of the proteins encoded by the tumor viruses, particularly the DNA tumor viruses, have provided important insights into the mechanisms controlling mammalian cell growth. Such studies have helped to elucidate roles for the retinoblastoma and p53 tumor-suppressor proteins as regulators of mammalian cell growth (Fig. 1). Each of these proteins controls the progression of cells through the G_1 phase of the cell cycle. The p53 gene plays an additional role in triggering programmed cell death (apoptosis) in response to various signals. In each case, DNA tumor virus oncoproteins act to inhibit the action of these two key tumor-suppressor proteins, thereby driving an otherwise quiescent cell to enter S phase. Indeed, this is the key to understanding the link between the replication strategy of the DNA tumor viruses and their oncogenic potential. The natural host cell for the viruses is a quiescent, differentiated cell that presents an environment that is not conducive to viral DNA replication. Thus the strategy of these viruses is to alter this environment, by deregulating the normal cell-cycle control of entry to S phase to induce the genes encoding activities necessary for DNA replication. In the normal replicative infection by these viruses, this cell-cycle deregulation is of no consequence because the infected cell eventually dies. However, when the infection is in some way impaired, then the events causing deregulation of the cell cycle contribute to oncogenic transformation.

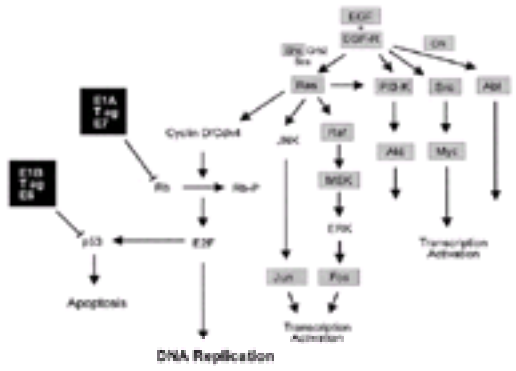

FIG. 1. Cell growth-regulatory pathways, activated by growth factor–receptor activation, which are targets of viral oncoproteins. The DNA tumor virus oncoproteins (*black boxes*) target the Rb and p53 tumor suppressors, leading to an inactivation of their function and deregulation of the G_1 cell-cycle pathway and the apoptotic response pathway. In contrast, the transforming genes found in the RNA tumor viruses (*gray boxes*) represent activated oncogenes, encoding various proteins that function in growth factor–signaling pathways.

In many respects, the virus-mediated disruption of a cell growth control pathway is analogous to the genetic analysis afforded by yeast. For instance, the inactivation of p53 function through the action of the adenovirus E1B protein is, in principle, equivalent to the isolation of a p53 mutant cell; in essence, the viral protein is a mutagen. Moreover, the ability to understand this “mutation” in the context of a viral infectious cycle provides an additional physiologic context, the evolution of a viral replication strategy, in which to view the mutation.

Likewise, the analysis of the oncogenes recovered in the RNA tumor viruses has been particularly important for the elucidation of signal-transduction pathways linking the cell surface with the regulation of the genetic apparatus in the nucleus. Unlike the DNA tumor viruses that have adopted a strategy of inactivation of key tumor-suppressor proteins, the RNA tumor viruses have identified oncogenes, the products of which function to drive cell proliferation when deregulated. Perhaps most striking is the fact that the oncogenes recovered in the RNA tumor viruses encode proteins involved in virtually every step in the pathway of signal transduction (see Fig. 1). Indeed, the study of these viral oncogenes has identified many of the participants in these complex pathways. Unlike the oncogenes of the DNA tumor viruses, the RNA tumor virus oncogenes are not essential viral genes but rather, in most cases, are cellular genes that have been acquired during viral replication and selected based on transforming function. As such, the study of these genes cannot be placed in the context of a strategy of viral replication. The presence of these genes usually renders the virus defective for replication. Nevertheless, the real utility of the RNA tumor viruses is the facility with which cellular genes encoding proteins that participate in cell growth control are trapped within the viral genome, altered in the process, and converted to a form that can radically change cell growth properties. The power of this approach is enormous, as evidenced by the sheer number of cellular genes so identified.

Without question, the study of these tumor viruses has been of immense value in elucidating events of cell growth control, providing reagents for further dissection of pathways, and in providing a perspective in which to view the action of various regulatory events. The contributions of the DNA tumor viruses and the RNA tumor viruses are distinct, each group providing unique advantages and approaches to the elucidation of mechanisms of oncogenesis. Indeed, the nature of the oncogenic activities of the two groups of viruses defines the two distinct events of oncogenesis seen in cancer cells: the RNA tumor viruses create oncogenes, whereas the DNA tumor viruses encode proteins that inactivate tumor suppressors. Like the combination of yeast genetics and biochemical analysis that has propelled the analysis of the cell cycle, the combination of these two viral oncogenic systems has provided a wealth of information and afforded an enormously valuable approach to the study of cell growth control and differentiation and the disruption of this control that

is evident during oncogenic transformation.

MECHANISMS OF CELL TRANSFORMATION BY THE RNA TUMOR VIRUSES

Since early in the 20th century, retroviruses have been known to cause cancer in animals. Lymphoid tumors in chickens were among the first diseases to be recognized as having a viral etiology; shortly thereafter, virus-induced sarcoma in fowl was discovered (106,295). But these tumors were regarded as somewhat of an oddity, having uncertain relevance for our understanding of cancer in higher animals, let alone cancer in humans. Only when mammary tumors, leukemias, and sarcomas in mice were traced to virus infections did the idea of virus-induced tumors gain some measure of acceptance and respectability as a worthwhile and relevant subject matter for cancer research (34,118,134,137,142,183,233).

The single most important development to open the field of tumor virology as a quantitative science was the advent of cell culture, making it possible to induce oncogenic transformation of individual cells inoculated with cell-free virus. These *in vitro* transformation assays, first established for Rous sarcoma virus (220,349), provided the basis for cellular and molecular studies that distinguished RNA from DNA tumor viruses and set RNA tumor viruses apart as a unique group of microbes (206,357,375). The salient features of the RNA tumor virus life cycle include reverse transcription of the single-strand RNA viral genome into double-strand DNA; integration of this DNA into the host chromosome; and expression of the integrated provirus under the control of viral transcriptional regulatory sequences. It is the process of reverse transcription that has given this viral group the name retroviruses. Integration into the host genome, together with an absence of cytocidal action, is the basis for the genetic permanence of retroviral infection. Retroviral genomes that become established in the germline are then transmitted as a set of mendelian genetic elements. Of particular importance for oncogenesis are two additional features of the retroviral growth cycle that are direct consequences of integration into the host genome: the ability to acquire and transduce cellular genetic material and the insertional activation (and occasional inactivation) of cellular genes by the integrated provirus. The analysis of retrovirus-induced transformation in cell culture and in animals led to the discovery of a set of cellular genes, called oncogenes, that function as effectors of viral carcinogenesis and play key roles in the control of cell growth and differentiation (for reviews, see refs. 31,46,282,358,370,371). Retroviruses, through their interaction with oncogenes, have provided independent and often exclusive access to these important regulatory elements of the cell. Today, retroviruses are recognized as significant natural carcinogens in several animal species: fowl, mice, cats, cattle, and monkeys. A rare but aggressive form of human leukemia has been linked to infection with a retrovirus, HTLV-I (122,232,263).

Retroviruses transform cells and induce tumors by three distinct mechanisms (Table 3). Most retroviruses effect oncogenesis through the action of cellular oncogenes. This majority comprises two well-defined groups: retroviruses that carry a cellular oncogene within their genomes, called *transducing retroviruses,* and retroviruses that lack cellular information but transform by integrating in the vicinity of a cellular oncogene, the *cis-activating retroviruses.* Almost all of the transducing retroviruses have lost some viral coding information in exchange for cellular sequences. Consequently they are defective with respect to the production of progeny virus and depend on the co-infection by a closely related helper virus for reproduction. They also are highly efficient carcinogens that transform cells in culture and cause tumors with short latent periods, often within days after infection. All of the cis-activating retroviruses retain the full complement of viral genes and multiply efficiently in solitary infection. Characteristically, they induce tumors more slowly, within weeks or months. In cell culture, these cis-activating retroviruses fail to cause oncogenic transformation. Although the establishment of infection by transducing and by cis-activating retroviruses is dependent on viral coding sequences, such viral coding information does not play an essential and direct role in the processes of oncogenesis induced by these viruses. Transducing retroviruses often have none of their basic coding domains intact, and in cis-activating retroviruses, these also become expendable once the provirus integrates near a cellular oncogene.

Virus Category	Tumor Latency Period	Efficiency of Tumor Formation	Oncogenic Effector	State of Viral Genome	Ability to Transform Cultured Cells
Transducing retroviruses	Short (days)	High (per weight of animal)	Cell-derived oncogene carried in viral genome	Viral-cellular chimera, replication defective	Yes
Cis-activating	Intermediate (wk, mo)	High to intermediate	Cellular oncogene activated in situ by provirus insertion	Intact, replication competent	No
Trans-activating	Long (mo, yr)	Very low (<5%)	Virus-coded transcriptional regulatory protein	Intact, replication competent	No

TABLE 3. *Retroviruses: Mechanisms of Oncogenicity*

Although only poorly understood, a third mechanism of retroviral oncogenesis involves the action of nonstructural viral regulatory proteins that function primarily to enhance transcription from the viral long terminal repeat (LTR). An example is seen in the HTLV-I virus, associated with the development of adult T-cell leukemia, where the viral *Tax* gene, responsible for activation of viral LTR-dependent transcription, has been implicated in oncogenesis. Such a mechanism, involving the action of a viral protein that is essential for viral replicative growth, is analogous to transformation by the DNA tumor viruses. However, in contrast to the DNA viruses in which expression of the viral gene can be observed in the tumor, HTLV-I *Tax* expression is not found in tumors. Moreover, the precise mechanism of action of *Tax,* particularly with respect to how it might contribute to cell transformation, is not understood.

Retrovirus-Mediated Oncogenesis Defines Components of Cellular Regulatory Systems That Control Growth and

Differentiation

The vast majority of the oncogenes found in the genomes of retroviruses are derived from the cell. Most cellular proto-oncogenes or c-oncogenes are conserved over long evolutionary distances. For instance, the *ras* oncogene and parts of the *jun* oncogene are found in eukaryotes ranging from yeast to humans. This evolutionary conservation of proto-oncogene sequences suggests that they are indispensable for a broad spectrum of life forms, fulfilling some fundamental function that permits little change. All known oncogenes encode protein products, referred to as *oncoproteins.* There are no cell-derived oncogenes that consist only of noncoding, regulatory sequences. Oncoproteins must, by definition, harbor the potential for inducing oncogenic cellular transformation.

The carcinogenic action of oncogenes is usually a corruption, or deregulation, of their normal physiologic function. To understand oncogene-mediated viral carcinogenesis, it is therefore important to uncover the normal functions of cellular oncogenes. In many instances, the function of the normal cellular gene counterpart has been determined, whereas for a significant fraction of oncogenes, information on physiologic roles remains general and tentative. In general, these genes are involved in the regulation of cell growth, representing components of signaling networks that receive input from outside the cell and propagate the signal to the nucleus, where the information is converted into patterns of gene activity.

A typical growth signal may arrive at the cell surface in the form of a polypeptide growth factor and bind to its specific receptor (see Fig. 1). The receptor, often an integral membrane protein with tyrosine-specific kinase activity, becomes activated by binding to the ligand. It may dimerize, leading to activation of kinase activity and autophosphorylation of specific cytoplasmic residues of the receptor molecule. The signal is further propagated by sequential and specific protein–protein interactions involving numerous participants and ending in the nucleus. The ultimate recipients of incoming signals are transcription factors that control the expression of specific sets of genes.

Of special importance in the transduction of cellular signals are two protein domains that were first recognized in the Src oncoprotein: SH2 (Src homology region 2) and SH3 (Src homology region 3). These domains occur on several protein components of signal-transduction chains; they mediate specific binding of interacting proteins. The SH2 domains bind to phosphotyrosine-containing sequences. The binding specificity is determined by the SH2 sequences in one molecule and the amino acid context of the phosphotyrosine in the other. SH3 domains have an affinity for proline-rich sequences. Proteins carrying SH2 or SH3 domains often also have an enzymatic activity, such as the Src protein tyrosine kinase, but some of these proteins are devoid of any catalytic activity; they function as linker–adaptor molecules and as regulators in binding to and controlling the activity of key enzymes (37,229,236,307).

Table 4 lists the principal retroviral oncogenes, arranged according to function. The *sis* oncogene is derived from the gene encoding the platelet-derived growth factor (PDGF) (95,369). The *int-2* oncogene, which has not been found in a retrovirus genome but which can be cis-activated by mouse mammary tumor virus (MMTV), codes for a protein related to fibroblast growth factor (FGF) (91). *ErbB, fms, kit,* and *mpl* code for altered growth-factor receptors with known ligands (97,124,245,328,337); several other oncogenes produce proteins that have the general structure of a polypeptide growth-factor receptor, but specific ligands remain to be identified. The products of the *ras* genes belong to a family of small guanosine triphosphatases (GTPases) that occupy central positions in signal transduction (38,42,128,228,330). The precise functions of *src, abl,* and other genes coding for nonreceptor tyrosine kinases are not clear; they may be active in the amplification stage of growth signals (49,70,72,262,316).

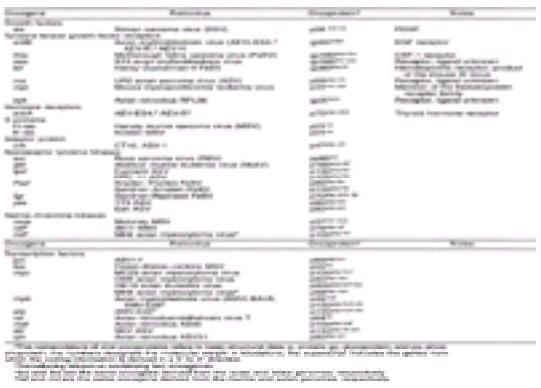

TABLE 4. *Oncogenes recovered in transducing retroviral genomes*

Another class of signaling molecules are those involved in phosphoinositol signaling, initiated by the activation of phosphatidylinositol 3-kinase (PI-3K) after growth factor–receptor activation. PI-3K activity is stimulated in many cell types in response to extracellular signals, generating a variety of phosphoinositides. One downstream target for PI-3K signaling is the Akt protein kinase, a serine/threonine kinase that is activated by phosphoinositides. A number of lines of study have implicated Akt in signaling pathways that control cell fate, in part through control of GSK-3 activity, but likely other targets as well. Although not initially identified by retroviral transduction, both PI-3K and Akt have been recovered in transforming retroviruses (7,55).

A number of oncogenes code for cytoplasmic kinases that are either tyrosine (*fps*) or serine/threonine specific (*raf, mos*). The oncogene, *crk,* is of interest because it lacks enzymatic activity but contains both SH2 and SH3 domains. Similar to the Grb-2 protein, it belongs to a class of linker–adaptor molecules that connect various catalytic steps of signal transduction (227). Finally, a large number of oncogenes encode proteins that control transcription. Notable are the Jun and Fos proteins that make up the AP-1 transcription factor, Rel, a member of the NF-kB family, and Myc, of interest because of its frequent involvement in human tumors (5,29,39,75,125,319). Other oncogenes are related to the control of development, such as *wnt*-1 and *qin. Wnt*-1 is frequently activated in MMTV-induced tumors. It shows a striking

tissue-specific distribution during mammalian embryogenesis and is homologous to the *Drosophila* gene *wingless,* which participates in the control of segmentation polarity in *Drosophila* embryos (286). Qin is a transcription factor with homology to the *Drosophila* forkhead gene product, which controls fore- and hindgut development in the early embryo (208). It is self-evident that qualitative or quantitative alterations of these growth regulatory genes carry the risk of uncontrolled growth.

Cellular Transformation by Retroviral Transduction of an Oncogene

With a combination of genetic and biochemical studies, mutants of Rous sarcoma virus (RSV) were isolated that are temperature sensitive for transformation; additional mutants were isolated that nonconditionally lost transforming capacity (222,224,355,363). The temperature-sensitive transformation mutants fail to induce or maintain oncogenic transformation at the nonpermissive temperature, while remaining fully oncogenic at the permissive temperature. Their replication is not temperature sensitive. These temperature-sensitive mutants provide unequivocal evidence for the dependence of oncogenesis on viral genetic information. The properties of these mutants also show that viral information must be expressed continuously to maintain the transformed phenotype. The nonconditionally transformation-defective RSV represents a deletion mutant that has lost about 20% of the genome. This loss does not affect the replicative properties of the virus; the deleted sequences, although essential for transformation, are therefore dispensable for virus production. This nonessential characteristic of transforming information for the viral growth cycle presaged the cellular origin of retroviral oncogenes. In temperature-sensitive and transformation-defective mutants, the same gene is affected: the two types of mutants cannot complement each other or form wild-type virus by recombination (25). The gene of RSV initially defined by these mutants is now known as the *src* gene. The deletion of *src* sequences in transformation-defective RSV also allowed the production of the first nucleic acid probe specific for *src.* A cDNA transcript of wild-type virus was generated and then was hybridized to the genome of the transformation-defective deletion mutant lacking the *src* gene. The nonhybridizing single-strand cDNA sequences of this reaction were separated from the double-strand hybrids. These single-strand sequences represented the viral oncogenic information. The cDNA *src* probe was found to hybridize to cellular DNA, providing conclusive evidence that *src* is not a viral but a cellular gene (340).

The basic characteristics discovered with the *src* gene apply to transduced retroviral oncogenes in general (32,282,358,370). All are derived from the cellular genome, and all are nonessential for virus replication. The virus serves as a vehicle of transduction, but it also exercises transcriptional control over the transduced oncogene. The cellular origin of retroviral oncogenes is of far-reaching significance because the transforming potential of a cellular oncogene can become activated independent of any viral intervention. Point mutations, gene amplification, and chromosomal rearrangements that can affect transcriptional regulation, as well as altering protein structure and function, can uncover the oncogenic potential of an otherwise normal gene. Activated oncogenes play important roles in nonviral, as well as viral, carcinogenesis; they may be the common denominator of all kinds of cancer.

In several cases, isolated temperature-sensitive as well as nonconditional mutants convincingly show that the gene is required for the initiation and maintenance of the transformed cellular phenotype (27,28,180,222,258,331,355,388). Transduced oncogenes also can be excised from their native viral genomes and inserted into an expression vector (156,157). They then confer oncogenicity on this new vector. In the transducing retrovirus, the cell-derived oncogene is the only coding information that is needed for oncogenicity. Most or all retroviral coding information may be either nonfunctional or deleted without affecting the oncogenicity.

Transduced retroviral oncogenes cause transformation within a very short time; moreover, in appropriate target cells, transformation is an inevitable consequence of infection and of expression of the oncogene. With some retroviruses (e.g., RSV), it is possible to transform all cells of a culture synchronously with one inoculum in the first round of infection. Because transformation occurs with high frequency, tumors induced by transducing retroviruses are usually polyclonal in origin. Unlike most cancers that result from a multistep transformation process, the tumors caused by transducing retroviruses probably result from single-step carcinogenesis. Some retroviruses are vectors for two oncogenes; for instance, avian erythroblastosis virus strain R carries the *erbA* and *erbB* genes, and MH2 avian carcinoma virus transduces *raf* and *myc* (33). In these cases, one of the two oncogenes is sufficient to induce transformation (*erbB* or *myc* in the earlier examples). The second enhances oncogenicity of the virus and conveys greater nutritional and growth-factor independence on the tumor cells. This is interesting in the case of MH2, which carries the *mil* gene together with *myc,* in that biochemical experiments have shown that the stability of the Myc protein is significantly extended by the action of Raf (the murine equivalent of avian Mil), leading to an enhanced accumulation of active Myc (314).

Mechanism of Acquisition of Cellular Sequences by Retroviruses

Because incorporation of an oncogene into a retroviral genome is a rare event, it can be studied only after the fact. A plausible model involves the integration of a retrovirus upstream of a potential cellular oncogene. The provirus has a deletion that includes its 3' LTR and is integrated in the same transcriptional orientation as the adjacent oncogene (67,131,343). Transcription from the 5' LTR will extend through the oncogene, creating a chimeric RNA that contains the packaging signal located near the 5' terminus of the viral genome. Complete introns are removed from this transcript, and the processed RNA can be exported in virus particles. The model also envisages infection of the same cell by a second virus that has not had a deletion and replicates complete progeny RNA as well as all structural proteins. Because retroviruses are diploid, such a cell will produce heterozygous progeny virus containing a complete viral genome and the defective chimeric RNA. In the next round of infection during reverse transcription of such a heterozygous particle, nonhomologous recombination between the two virion RNAs may take place, possibly as a result of template switching by the polymerase.

This model proposes two formal steps of recombination. The first step involves the integration of the defective provirus near the cellular oncogene, the formation of the 5' junction of cellular with viral sequences, and the generation of the packageable chimeric RNA. This recombination event occurs at the DNA level. The second recombination event takes place during reverse transcription and involves the formation of the 3' junction of cellular sequence with viral information. The resulting recombinant is a provirus with two LTRs and 5' coding information derived from the chimeric RNA; 3' sequences come from the nondefective retrovirus. Recent evidence supports this model (109,110). If chicken neuroretina

cells are infected with the avian leukemia virus RAV-1, their growth is stimulated, and the culture releases a virus that transduces the *raf* oncogene. The identifiable steps in this acquisition of a cellular gene are in accord with this model. However, other possible models, suggested by exceptional provirus structures, have not been ruled out. RNA splicing of viral and cellular sequences would be an alternative mechanism for recombination (164,225). A third possibility is that viral–cellular recombinants derive from packaged read-through transcripts of a nondefective retroviral genome and an oncogene located downstream (150). It also is possible that transducing retroviruses can be generated by more than one mechanism.

The defectiveness of transducing retroviruses is caused by the replacement of viral coding sequences with cellular oncogene sequences. There are only rare exceptions including some strains of RSV, in which the *src* oncogene is added to a complete viral genome (Fig. 2). In contrast, the MC29 virus has acquired the *c-myc* gene at the expense of viral *pol* and part of *gag.* The defective viruses go through a partial life cycle that includes reverse transcription, integration, RNA synthesis, and translation. The expression of the defective provirus leads to oncogenic transformation; however, because one or several of the essential virion proteins cannot be synthesized, no infectious progeny are made. Only if the same cell is infected by a replication-competent retrovirus that supplies the missing protein(s) in *trans* is infectious transforming virus released. This transforming progeny virus remains, however, genetically defective and helper dependent.

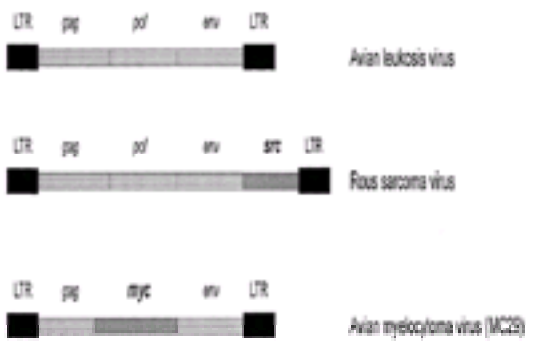

FIG. 2. Genomic structure of avian leukosis virus (ALV) and two transducing retroviruses. In addition to the long terminal repeat (LTR) sequences that provide transcriptional regulatory elements, the normal genome of ALV contains three major coding regions including *gag, pol,* and *env. Gag* encodes structural proteins of the virus, *pol* encodes enzymes involved in reverse transcription and integration, and *env* encodes the virion surface glycoproteins. In Rous sarcoma virus, the cellular *src* sequences are added to an otherwise intact retroviral genome. In contrast, in the MC29 virus, the addition of *myc* sequence is at the expense of the entire *pol* gene and parts of both *gag* and *env*.

It is interesting that cellular oncogenes have been found only in one subfamily of retroviruses, appropriately called the oncornaviruses. They have not been seen in the genomes of the lenti- and spumaviruses, although the steps of replication that are thought to favor acquisition of cellular sequences are the same for all retroviruses. A possible explanation is the greater complexity of the lenti- and spumaviral genomes. Oncoviruses efficiently replicate without virus-coded regulatory proteins, whereas lenti- and spumavirus replication depends on nonvirion proteins that are generated from the provirus by way of multiply spliced messages. Generation of these messages and their cis-acting targets would be destroyed by a cellular genetic insert, essentially inactivating the virus. Oncornavirus genomes, conversely, can accept cellular inserts without such debilitating effects (31,33,40,282,361,370).

Activation of the Transforming Potential of Oncogenes by Retroviral Transduction

Part of the process of turning an otherwise normal cellular gene into an oncogene is simply the process of viral transduction, resulting in misexpression of the gene due to control by the viral LTR in a cell when it would normally not be expressed. There are proto-oncogenes that, if sufficiently overexpressed, can transform cells. The *mos* gene is an example of this category (385). For such oncogenes, structural changes of the transduced or insertionally activated oncogene are not essential to bring forth the oncogenic potential, although they may contribute to it. Increased dosage is then the main factor in oncogenesis.

In many cases, the mere insertion of a proto-oncogene into a retroviral vector, resulting in expression at levels comparable to the viral gene, is not, in and of itself, sufficient to transform cells. Thus specific structural changes in the viral version must be responsible for eliciting the transforming potential. For example, the cellular *src* gene, overexpressed in a retrovirus vector, does not induce oncogenic transformation (163,255,320). As outlined later, specific changes in *c-src* are necessary to reveal its oncogenic trait. Another example is the ErbB oncoprotein, derived from the avian erythroblastosis virus, in which the ligand-binding domain of the EGF receptor has been deleted and replaced with a fused viral *gag* sequence (Fig. 3).

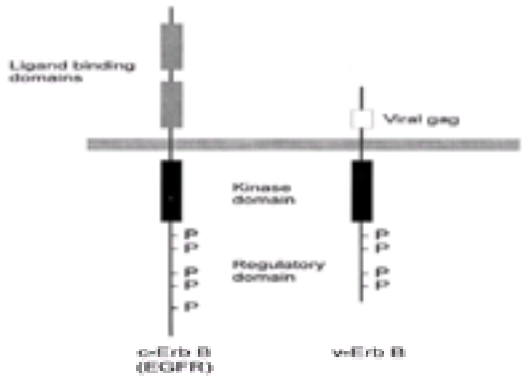

FIG. 3. Structural comparison of the cellular Erb B protein (the epidermal growth factor receptor, EGFR) with the transduced retroviral version, the v-Erb B protein of avian erythroblastosis virus H (AEV-H). The oncogenic v-Erb B lacks a regulatory phosphorylation site in the carboxyl terminal of the protein and has lost the extracellular ligand-binding domain. It functions as a constitutively activated EGFR.

Various approaches have defined oncogenically relevant structural changes for a number of oncogenes (e.g., *src, ras,* and *fms*) (282,370). These changes are always found in the oncogene proper; the viral sequences that are sometimes fused to it may facilitate oncogenicity by increasing the stability of the oncoprotein, determining the cellular localization, or enhancing efficiency of translation, but they do not participate directly in the transformation process.

It also is true that a comparison of activated oncogenes and their cellular counterparts often reveals structural and functional changes. Transduced oncogenes are usually truncated at one or both ends (for reviews, see refs. 282,370). The remaining coding sequences carry point mutations and sometimes deletions. They are often fused with viral sequences that are themselves truncated. Commonly, the viral sequences constitute the 5' end of the chimeric transcription unit, providing splice acceptor site and initiation codon. Occasionally, the oncogene sequences also may be fused to other, unrelated cellular sequences as, for instance, in viral *src* (345).

Examples of Oncogenes Identified by Retrovirus-Mediated Transduction

It is now clear that deregulation of virtually any step in the process of growth factor–mediated signal transduction can represent an oncogenic event. This can be seen from the identification of mutations in tumors but also from the recovery of oncogenic retroviruses. The isolation and analysis of transforming retroviruses has illuminated many of the details of signaling pathways critical for cell growth. Starting from the extracellular environment and working through the cell to the nucleus, examples will illustrate the process.

Sis: *Growth Factor and Autocrine-Mediated Transformation*

Sis is the oncogene of simian sarcoma virus (SSV) (for reviews, see refs. 289,377,383); it is an insert that was acquired from the genome of the woolly monkey, a New World monkey. A homologous oncogenic determinant derived from the genome of a cat was discovered in the Parodi Irgens feline sarcoma virus (FeSV). The amino acid sequence of the SSV Sis protein shows about 88% identity with the sequence of the B-chain of the human PDGF. The discovery of this homology provided the first direct and exciting link between oncogenes and cellular growth signals. The immediate cellular precursor of the *sis* gene is most likely the PDGF-B gene of the woolly monkey genome, with the deviation from the human sequence being a species difference.

Sequence analysis of the SSV genome shows that *v-sis* is expressed as a fusion product containing, at its N-terminus, sequences derived from the retroviral envelope (Env) protein, including the Env signal sequence that effects the translocation of the Env-Sis protein into the vesicles of the endoplasmic reticulum. The initial *v-sis* product is a 28-kd glycoprotein that is rapidly dimerized to a gp56 dimer and then proteolytically processed to become a p24 homodimer, similar in structure to the homodimer of the PDGF-B chain. This Sis protein is firmly associated with cellular membrane fractions, but only about 1% is secreted by the SSV-transformed cell. Primary and processed *v-sis* products show PDGF-like activity: they react with anti-PDGF antibodies, bind to PDGF receptors, induce internalization of the receptor–ligand complex, induce phosphorylation of the receptor on a tyrosine residue, and stimulate the mitogenic response of the cell. This biologic activity of the *v-sis* product suggests an autocrine transforming mechanism for SSV-infected cells. Additional support for this suggestion comes from the following observations: SSV transforms only those cells that express a PDGF receptor. Transformation appears to be dependent on the interaction of the *v-sis* product with the PDGF receptor. In addition, the nascent *v-sis* product must be translocated into the endoplasmic reticulum to be transforming. Deletion of the Env signal sequence from the Env-Sis fusion protein abolishes transforming activity. Because the v-Sis protein is functionally equivalent to PDGF, the cellular PDGF gene also can function as an oncogene by autocrine mechanisms similar to those of v-Sis: The PDGF B-chain expressed under the control of a strong retroviral promoter induces oncogenic transformation in cells expressing the PDGF receptor.

The transforming signal of Sis could be generated by binding to receptors at the cell surface, but intracytoplasmic receptor binding also may play a role in transformation. The PDGF receptor is processed along the same cellular compartments as is the v-Sis protein, and it is conceivable that the two interact before reaching the cell surface. SSV-transformed cells, exposed to antibody against Sis, sometimes assume a near-normal phenotype. This observation was interpreted to suggest that the relevant interaction between growth factor and receptor, leading to transformation, is a cell-surface event. However, if a signal sequence (KDEL) that effects retention in the endoplasmic reticulum is added to the PDGF-B chain, the transforming potential for PDGF receptor–expressing cells is not abolished. Therefore PDGF may interact with the receptor intracellularly and then become translocated to the cell surface as a complex.

ErbB *and* Fms: *Growth Factor Receptors and Constitutive Mitotic Signals*

The oncogene *erbB* has been studied in two avian retroviruses that cause erythroblastosis and fibrosarcoma in chickens: avian erythroblastosis virus strain H (AEV-H) and strain ES4 (for reviews, see refs. 146,223,359). AEV-H contains *erbB* as its only oncogene. AEV strain ES4 carries, in addition to *erbB,* the *erbA* oncogene derived from a thyroid hormone–receptor gene (373). However, *erbB* alone is both necessary and sufficient to induce the pathogenic effects associated with AEV infections, erythroblastosis, and fibrosarcoma.

The nucleotide sequence of *erbB* shows close homology to that of the epidermal growth-factor receptor (EGFR) gene (95). The *erbB* of AEV strains H and ES4 is derived from the chicken *EGFR* gene. The EGFR contains four major structural and functional domains: an amino-terminal extracellular ligand-binding domain, a transmembrane segment, a kinase domain, and a carboxyl-terminal regulatory segment with at least five tyrosine phosphorylation sites: P1 through P5 (see Fig. 3). In *erbB,* most of the growth-factor–binding domain is deleted. Furthermore, carboxyl-terminal deletions have removed P1 from the *erbB* of AEV-H and have removed P1 as well as P2 from *erbB* of AEV ES4.

The mechanism of *erbB*-induced oncogenesis probably includes elements of the same mitotic signal that is initiated by the binding of epidermal growth factor (EGF) to its receptor (see Fig. 1). Ligand binding appears to induce an allosteric change and oligomerization of the receptor (305,306 and 307). The kinase activity of EGFR is elevated, and the protein becomes autophosphorylated on tyrosine residues at its carboxyl-terminal regulatory sites. EGFR substrates of potential importance in mitotic signaling include the SHC proteins (containing an SH2 domain but no recognizable catalytic domain), GAP (GTPase activating protein), PI-3K, and phospholipase C. At least one of the phosphotyrosines in the cytoplasmic tail of EGFR is recognized and bound by the SH2 domain of a small adaptor protein called Grb2 that also binds with its SH3 domains to the nucleotide releasing factor Sos. Sos, in turn, interacts with the product of the proto-oncogene *ras,* leading to an exchange of the Ras-bound guanosine diphosphate (GDP) for GTP, thereby activating the Ras protein. From Ras the signal is propagated through a kinase cascade involving the product of the proto-oncogene *raf* and the MAP kinase (mitogen-activated protein kinase) among other kinases. Translocation of the signal into the nucleus and activation of the ultimate recipient of the signal pathway, presumably a transcription factor, are still poorly understood. The tyrosine-specific kinase activity of EGFR is essential for the mitogenic effect of EGF. Binding of EGF to the receptor is followed by internalization of the receptor–ligand complex. This process removes available EGFR from the cell surface and results in a down-regulation of EGF responsiveness. Reduced EGF responsiveness also can be caused by an activated protein kinase C, probably through phosphorylation of a threonine residue near the EGFR kinase domain.

The transforming activity of *erbB* has been analyzed with the help of several conditional and nonconditional mutants of AEV (133,244). Transforming activity of ErbB requires localization of the protein at the plasma membrane as well as truncation of the carboxyl-terminal regulatory domain. The ErbB protein is glycosylated. Intracellular forms are gp65 and gp68 proteins; the mature cell-surface molecule is a gp74. The *erbB* coding information lacks a conventional signal sequence, so targeting to the plasma membrane appears to be a function of the transmembrane domain. Temperature-sensitive mutants of AEV ES4 that prevent membrane localization at the nonpermissive temperature also are temperature sensitive for the transformed cellular phenotype. Deletions from the carboxyl-terminal end of the c-ErbB protein have shown that loss of the P1 phosphorylation site is important for both erythroblast and fibroblast transformation. As the size of the carboxyl-terminal deletion increases, there is a loss of erythroblast transformation, while still retaining fibroblast transformation.

A somewhat different picture emerges from the study of AEVs that have recently acquired *erbB* (230,273,274) (see section entitled cis-activation of oncogenes). These newer *erbB*-transducing agents carry a version of c-*erbB* that lacks the ligand-binding domain of EGFR, but some have an intact carboxyl terminus and yet can induce erythroblastosis in a highly susceptible chicken line. They do, however, fail to transform fibroblasts. A separate analysis of fibroblast transformation using mutants of AEV ES4 has shown that an intact kinase domain is essential for this biologic effect. These observations are compatible with the proposal that ErbB transforms cells as a constitutively activated EGFR. Membrane localization and kinase activity are essential.

Ligand-independent activation of receptor tyrosine kinase also plays an important role in the oncogenicity of v-*fms* (for reviews, see refs. 283,292,293,326,327). *Fms* is the oncogene of the McDonough strain of feline sarcoma virus (SM FeSV). It also has been found as the oncogenic insert in the Hardy Zuckerman 5 (HZ5) FeSV. *Fms* is derived from the gene of the receptor for the macrophage colony-stimulating factor CSF-1 (328). In SM FeSV, it replaces most of the viral *gag* and practically all of the *pol* gene, whereas the *env* gene of the virus has remained intact. *Fms* is fused in frame to the partial *gag* sequences. The crossover point in the *fms* gene is located in the 5' untranslated region of c-*fms* messenger RNA and preserves the signal sequence of c-*fms*. The 3' recombination point in *fms* is located 120 nucleotides upstream of the c-*fms* termination codon. SM-FeSV and HZ5-FeSV induce fibrosarcomas in cats but no hematopoietic malignancies, notwithstanding the normal function of CSF-1 as a hematopoietic growth factor.

The CFS-1 receptor has a structure similar to that of growth-factor receptors such as the PDGF receptor, the Kit protein and Flt (26,151,329,390). The extracellular domain consists of five immunoglobulin-like repeats; the three amino-terminally located of these repeats form the ligand-binding region. The fourth immunoglobulin-like domain functions in receptor dimerization; the point mutations contributing to the oncogenicity of v-*fms* are in or near this domain. Important cytoplasmic regions of Fms are the tyrosine kinase domain and the C-terminal tail, which contains targets for negative regulation. Activation of Fms by ligand or by mutation results in autophosphorylation of several tyrosines in the cytoplasmic domain of the receptor. These phosphotyrosines are then bound by the SH2 regions of effector molecules including PI-3 kinase, members of the Src family of proteins, and Grb2. From Grb2, propagation of the signal continues via SOS-1, Ras and Raf, and the MAPK cascade. An alternative pathway to the nucleus may involve the interferon-stimulated gene factor 3, but molecular details of this signal chain are still sketchy.

The v-*fms* genes of SM-FeSV and of HZ5-FeSV differ from c-*fms* by several point mutations leading to amino acid

substitutions and by a deletion that removes the 50 carboxyl-terminal amino acids from the protein. The deleted residues are replaced in SM- and HZ5-FeSV by 14 and 11 unrelated amino acids, respectively. The oncogenicity of the v- *fms* genes can be attributed to two point mutations in the extracellular domain and to the carboxyl-terminal deletion. The deletion removes phosphorylation sites that negatively regulate the kinase activity of the receptor, and the point mutations in the extracellular domain lead to a ligand-independent activation of the receptor.

Src *and* Abl: *Membrane-Bound Nonreceptor Tyrosine Kinases*

Src was the first retroviral oncogene discovered and defined (for reviews, see refs. 130,316). It was also the first whose origin from the cellular genome was recognized and the first for which a protein product was identified (49,340). The discovery of the *src* gene product was soon followed by observations that showed that this protein is a tyrosine-specific protein kinase, providing suggestive evidence for a regulatory function of Src and raising hopes for an immediate understanding of its oncogenic action (68,160,205). Throughout this period of rapidly expanding work on oncogenes, *src* has served as an important and pace-setting model. Yet despite this paradigmatic role and despite much additional data on structural and functional properties of cellular and viral *src,* the mechanism by which Src transforms cells is only now emerging. *Src* codes for a 60-kd phosphoprotein that is bound to cytoplasmic membranes. (This protein has been termed $pp60^{src}$; we will refer to it as Src protein, to remain consistent with the terminology applied to other oncoproteins.) The cellular Src protein contains several well-defined functional domains: an amino-terminal myristilation domain, followed by a region that diverges among related nonreceptor tyrosine kinases, an SH3 and an SH2 domain, a catalytic domain, and a C-terminal regulatory region. The viral Src protein shows the same general structure but has had a deletion in the carboxyl-terminal regulatory domain. Because c-Src expressed at levels comparable to transduced v-Src does not transform cells (163,255,320), structural differences between the cellular and viral version of the Src protein must activate oncogenic potential. The oncogenicity of Src requires binding to the plasma membrane and is correlated with increased kinase activity. The kinase activity of Src is controlled positively by phosphorylation of tyrosine 416 in the catalytic region and negatively by phosphorylation of tyrosine 527 in the C-terminal regulatory region. Tyrosine 527 is the target of Csk (C-terminal Src kinase), which appears to be a specific regulator of Src family kinases. The phosphotyrosine 527 is most likely bound intramolecularly by the SH2 domain of the Src protein. This folding of the Src protein is believed to affect the catalytic domain and to turn off kinase activity. Significantly, the viral Src lacks tyrosine 527 and is constitutively active as a kinase. Activation of Src in the presence of tyrosine 527 may involve dephosphorylation of this residue by a specific phosphatase. However, access to tyrosine 527 may depend on an allosteric change of the molecule that includes dissociation of phosphotyrosine 527 from the SH2 domain. Consequently, such allosteric interactions could target the SH2 and SH3 domains of Src that connect to other members of the signal transmission chains. Accordingly, oncogenic activation of Src can result from mutations in SH3, SH2, the kinase domain, and the C-terminal tail (69,256,348), suggesting that all of these may be important in the allosteric transitions that affect Src kinase activity.

Over the years, numerous proteins have been identified that can serve as downstream targets and substrates of Src. Most of these are probably not relevant in oncogenic transformation. Exceptions appear to be an SH2-containing protein (SHC) and focal adhesion kinase (FAK) (66,154,229,278,294). SHC is an adaptor protein that is phosphorylated by Src and related kinases and then binds to Grb-2; the SHC–Grb-2 complex then interacts with the SOS, making a nucleotide exchange factor that activates Ras. FAK is bound by the SH2 domain of Src, and this interaction appears to keep FAK in the activated state. The resulting overphosphorylation of cytoskeletal proteins may be responsible for the poor adhesion and altered shape of Src-transformed cells.

Src is highly expressed in some cell types such as blood platelets, neurons, and osteoclasts. Src-deficient mice develop osteopetrosis, the result of dysfunctional osteoclasts, but show no other major abnormalities in development and growth, possibly because the Src defect can be compensated by related kinases (336).

The product of the oncogene *abl* shares with the Src protein two important properties: attachment to the cytoplasmic face of the plasma membrane by a myristic acid residue and tyrosine-specific protein kinase activity (for reviews, see refs. 281,287,384). *Abl* was first identified as the oncogene of the Abelson murine leukemia virus (A-MuLV). More recently, it also has been found as a cell-derived oncogenic insert in the Hardy–Zuckerman HZ2 FeSV. In A-MuLV (with which most of the work on *abl* has been carried out), the *abl* gene is merged to partial *gag* sequences and is expressed as a Gag–Abl fusion protein. The *abl* insert in A-MuLV is truncated at its 5' terminus as compared with the cellular gene, but the *abl* coding sequences in p160v-abl begin downstream of the SH3 domain. Point mutations also are found in the *abl* sequences in v-abl. The v-Abl protein contains three domains: the amino-terminal Gag domain, an SH2 and SH3 domain mediating interactions with other signal-transduction proteins, and a catalytic domain that is homologous to the corresponding domain of other tyrosine kinases. Mutational analysis of the *abl* gene shows that for oncogenic transformation to occur, two properties are essential: membrane association through myristilation and elevated tyrosine kinase activity. In the v-Abl protein, the Gag domain provides the myristilation signal and therefore becomes indispensable for transformation—in contrast to the Gag domain of most other oncoproteins, which can be deleted without affecting oncogenicity. The Gag sequences of v-Abl also increase the half-life of the protein in hematopoietic cells. The c-Abl protein localizes to both the cytosol and the nucleus, and it is phosphorylated in a cell cycle–dependent manner (181,182). In some cell types (for example, primary neuronal and epithelial cells), c-Abl is primarily cytoplasmic, whereas in other cell types (for example, hematopoietic cells), the protein is largely nuclear. Recent observations suggest that it may function as a negative regulator of cell growth; transdominant negative mutants of c- *abl* disrupt the control of the cell cycle and enhance cellular susceptibility to oncogenic transformation (302). The SH2 and SH3 domains of Abl have complex regulatory functions. The SH3 domain appears to be the target of a negative control mechanism; deletion of this domain activates the oncogenic potential of Abl. The SH2 domain of Abl may have multiple functions—controlling the kinase activity of Abl by intramolecular binding to phosphotyrosine residues and interacting with signal-transduction proteins apparently in a phosphotyrosine-independent manner. Replacement of the Abl SH2 domain with a heterologous SH2 domain also may activate the oncogenic potential of this nonreceptor kinase (65,236,237). A-MuLV is an effective transforming agent for early B cells. Other hematopoietic cells can be transformed, but special conditions and additional selective pressure are required to reveal these less frequent transforming events. A-MuLV also can transform fibroblasts. The HZ2 FeSV induces only sarcomas and does not transform hematopoietic cells either *in vitro* or *in vivo.* An activated *abl* oncogene also is found in human chronic myelogenous leukemia. The leukemic cells carry a chromosomal translocation that gives rise to the marker Philadelphia chromosome and joins *abl* sequences of chromosome 9 to *bcr*

(breakpoint cluster region) sequences of chromosome 22 (149,333). *Bcr* and *abl* sequences are found in a single, fused transcript in leukemic cells. Although the junction point between *bcr* and *abl* varies in different patients, the regularity with which this translocation occurs in chronic myelogenous leukemia strongly suggests that the Bcr-Abl protein conveys a growth advantage to the leukemic cells.

Ras: *Growth-Regulatory GTPase*

Mammalian cells contain three *ras* genes: H-*ras*, K-*ras*, and N-*ras* (for reviews, see refs. 38,44,45,204). All three are composed of four coding exons that contain information for a protein of about 190 amino acids, or 21 kd, plus an upstream noncoding exon. The amino-terminal halves of these cellular p21 proteins are virtually identical. About two thirds of the carboxyl-terminal halves are also closely related, and only the most 25-carboxyl-terminal amino acids show divergence. Two of the mammalian *ras* genes—H-*ras* and K-*ras*—have been found transduced by retroviruses; N-*ras* has not been detected in a naturally occurring virus. More than half a dozen independently isolated retroviruses that transduce a *ras* gene; the best studied are Harvey and Kirsten murine sarcoma viruses (H-MuSV and K-MuSV). Their *ras* inserts are derived from the rat genome and carry sequences of an endogenous rat retrovirus VL30.

Ras proteins are GTPases that act as nodal points in cellular growth control, receiving inputs from several signal-transmission chains and propagating the signal through kinase cascades toward the nucleus. Ras proteins belong to a superfamily of low-molecular-weight GTPases that also encompasses the Rho proteins, important in the control of the cytoskeleton, and the Rab proteins, which function in membrane protein trafficking. Other related proteins with GTPase activity and homology to Ras are the heterotrimeric G proteins involved in signal transduction and the elongation and initiation factors of the protein-synthesizing machinery.

Ras proteins must be anchored in cellular membranes for proper functioning. They are posttranslationally modified by covalent attachment of prenyl groups to cysteines near their C-terminus, providing a lipophilic tail. Ras proteins can be considered as binary switches that are either on (bound to GTP) or off (bound to GDP). They are regulated by at least three types of proteins; the guanine nucleotide exchange factors (GEFs), the GTPase-activating proteins (GAPs), and guanine nucleotide dissociation inhibitors (GDIs) (38). GEF proteins activate Ras through exchange of Ras-bound GDP for GTP. An example of a GEF is the SOS protein, which is instrumental in transmitting growth signals from tyrosine kinases to Ras. Gap proteins have an attenuating effect on Ras. They stimulate the conversion of active GTP Ras to the inactive GDP Ras. They are represented by p120 GAP and by NF1 (neurofibromin). The GDI proteins are the least understood regulators of Ras. They bind to GDP Ras, thereby interfering with the action of GEF activators and possibly also with GAP-like attenuators.

Oncogenicity of Ras is greatly elevated by specific point mutations, notably in codons 12, 13, and 61. These mutations inhibit the binding of GAP proteins to activated Ras and thus prevent the stimulation of Ras GTPase activity. The mutant Ras proteins remain bound to GTP and are constitutively active, contributing to oncogenic transformation. Retroviral Ras proteins carry these activating mutations. Additionally, the transforming potential of Ras can be elicited by changes in upstream nontranslated regions; the endogenous VL30 sequences also can have an enhancing effect on transformation.

Activated Ras with a mutation in one of the critical codons also is found in human cancers, notably in carcinomas of the bladder, colon, and lung. A significant minority of the primary tumors in these sites contain the mutated oncogene. Normal tissue surrounding the tumor is free of the mutation. The possibility that activated Ras plays an important role in human tumor development also is supported by animal studies. Virtually all tumors induced by certain chemical carcinogens contain an activated *ras* gene (19,342). Examples are mammary carcinomas in the rat induced by nitrosomethylurea and skin carcinomas in the mouse caused by dimethylbenzanthrazene.

Mos *and* Raf: *Cytoplasmic Serine/Threonine Kinases*

The *mos* oncogene was originally found in Moloney sarcoma virus as a cell-derived insert into the retroviral *env* gene (for reviews, see refs. 40,318,394). Moloney sarcoma virus induces rhabdomyosarcomas in mice and transforms cultured murine fibroblasts. The viral Mos protein is an Env–Mos fusion product; it has a molecular mass of 37 kd, and its first five codons are derived from the 5' end of the retroviral *env* gene. The v-Mos protein is localized in the soluble portion of the cytoplasm. Several strains of the Moloney murine sarcoma virus differ by point mutations and deletions. The HT1 strain, which is probably closest to the original isolate, carries a *mos* insert that is identical to c-*mos* if amino acid sequences are compared. Another *mos*-containing retrovirus, myeloproliferative sarcoma virus, has a frameshift mutation and appears to initiate *mos* translation from an internal site downstream of this mutation.

The cellular *mos* gene can transform cells in culture with virtually the same efficiency as the viral gene, suggesting that the transforming potential of this gene can be activated by deregulated expression of the cellular product (385). *Mos* shows homology to cyclic adenosine monophosphate (AMP)-dependent protein kinase and to the Src family of tyrosine kinases. The Mos protein is a serine–threonine kinase; the cellular *mos* is an intronless gene that is expressed at very low levels (less than one copy of *mos* RNA per cell) in most tissues. Notable exceptions are germ cells, where *mos* is highly expressed (132,269,299). Recent investigations show that the cellular Mos protein is a regulator of meiotic maturation. It is required for meiosis, and as a component of the cytostatic factor (CSF), it is essential for the normal arrest of meiosis at metaphase II. Mos also stabilizes maturation-promoting factor (MPF p34 ^{cdc2}) in meiosis. It further associates with and phosphorylates tubulin and can activate MAP kinase. One hypothesis of *mos*-induced oncogenic transformation suggests that Mos imposes a mitotic program onto the interphase cell and thus contributes to reduced adhesiveness, cell rounding, and cytoskeletal reorganization, all part of the transformed phenotype (394).

The *raf* oncogene has been found to be the sole oncogenic determinant in murine sarcoma virus 3611 but has also been isolated as a second oncogene, together with *myc,* from the genome of the MH2 avian carcinoma virus (for reviews, see refs. 147,277). This avian homolog is still sometimes referred to as *mil.* In the mammalian genome, other *raf*-related genes have been identified, among them A-*raf* and B-*raf*. Cellular *raf* sequences inserted into a retroviral vector induce oncogenic transformation. These sequences are truncated at the 5' end, a modification that is probably instrumental in

activating the oncogenic potential. In cells infected with the 3611 murine sarcoma virus, Raf is expressed as a 79-kd Gag–Raf fusion protein. This protein is myristilated in its Gag domain and is phosphorylated on serines and threonines. Because the murine Gag protein also occurs in a glycosylated form, there is a corresponding Gag–Raf glycoprotein in cells transformed by virus 3611. In contrast to the mammalian *raf* genes, the avian homolog *mil* does not induce transformation on its own. The *mil* insert of the MH2 avian carcinoma virus also is expressed as a fusion product with Gag. The 100-kd Gag–Mil and the 70-kd Gag–Raf proteins are both cytoplasmic serine–threonine kinases, and they show some homology to the Src family of tyrosine kinases. Raf is emerging as a second important nodal point besides Ras for the propagation of growth signals. Raf is distal to Ras but upstream of the MAP kinase cascade. Activated Ras binds to the amino terminal regulatory domain of Raf, and there is a suggested association of Raf with MAP kinase kinase.

Fos, Jun, *and* Myc: *Transcriptional Regulatory Proteins*

Finally, a large number of oncogenic retroviruses have been recovered that encode nuclear proteins that act as transcription factors. In this category belong *myc, myb, fos, rel, ski, jun, erbA, maf,* and *qin* (6,76,77,80,102,108,152,253,267,280,339,359,365).

Myc is the oncogenic determinant in avian retroviruses MC29, CMII, MH2, and OK10 (108). Besides c-*myc*, the human genome contains several other *myc*-related genes including N-*myc* and L-*myc*: the latter two have not been found as oncogenes in retroviruses. *Myc* plays an important role in a number of human cancers. In all Burkitt lymphomas, *myc* is translocated into the vicinity of an immunoglobulin gene and, unlike the nontranslocated allele, is actively expressed in B cells (139). An understanding of the Myc protein has been advanced with the discovery of a small Myc dimerization partner, the Max protein (36,216,266) and a variety of other interacting proteins that determine the function of Myc and related complexes (Fig. 4). Max associates with Myc by a helix–loop–helix and a leucine zipper motif. Genetic experiments show that dimerization with Max is required, not only for Myc DNA binding (consensus sequence CACGTG) but also for oncogenic transformation and for Myc-induced apoptosis (3,4). Through the use of protein-interaction assays, an additional Max-interacting partner was termed the Mad protein (11). Further studies have shown that, depending on the growth and differentiation state of a cell, there exists an equilibrium between homodimers of Max and heterodimers of Myc–Max or Mad–Max (10). Whereas the Myc–Max heterodimer is associated with transcription activation, no unique activity has been attributed to the Max–Max homodimer. In contrast, various experiments have now shown that the Mad–Max heterodimer functions as a transcription repressor through the recruitment of the Sin 3 protein and a histone deacetylase (12,195).

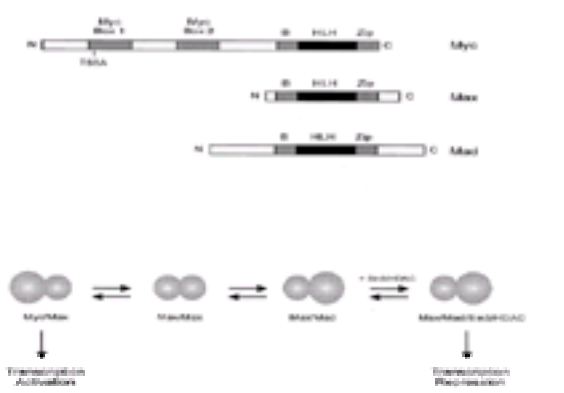

FIG. 4. Comparison of the Myc protein, the dimerization partner Max, and the alternate Max partner Mad. Myc and Max, as well as Max and Mad, associate through the leucine zipper helix–loop–helix domains. The heterodimers bind to the sequence CACGTG. Association with Max is necessary for transcriptional regulation and for transformation by Myc. Myc box-1 and -2, and the acidic region represent sequences conserved in various *myc* genes. The threonine 58 residue (corresponding to threonine 61 in avian Myc), which is a site for phosphorylation, is the most frequent site of mutation in oncogenic forms of *myc* recovered in viruses and is often found in Burkitt's lymphomas (1). Shown is a schematic depiction of the relationship between the various interacting proteins, changing the function from one of transcription activation (Myc–Max) to one of transcription repression (Mad–Max).

Myb is the oncogene of avian myeloblastosis virus AMV BAI-1 and of the avian leukemia virus E26; it binds to a specific DNA sequence, and the viral oncogenic version of the gene may transform by interference with normal transcriptional control (29,93,217,324). The cellular *myb* gene is preferentially expressed in hematopoietic tissues, controls the expression of myeloid-specific genes, and is required for normal fetal hematopoiesis (235,272,280,312).

The *rel* oncogene of avian reticular endotheliosis virus belongs to the NF-kB transcription factor family. The viral version of this gene corrupts normal transcriptional regulation by NF-kB (210,285). The *ets* oncogene is the second oncogene of E26 AMV. It is a member of an important transcription factor family (167,253,368) and can be activated by insertional mutagenesis as well as by transduction (21). *Fos* is the oncogene of the FBJ and FBR murine osteosarcoma viruses. It is a component of the cellular AP-1 transcription factor complex, and like other transcription factor oncoproteins, it transforms by altering normal transcriptional controls (77,113). The product of the *maf* oncogene is structurally and functionally related to the AP-1 family of transcription factors. *Maf* was originally found in avian retrovirus AS42; it can interact with AP-1 proteins (178). *Qin,* the oncogene of avian sarcoma virus 31, codes for a transcription factor of the fork head/HNF-3 family. Fork-head proteins are important regulators of embryonal development (208).

Jun is the cell-derived insert in the genome of avian sarcoma virus 17 (6,77,365). In cells transformed by this virus, *jun* is expressed as a 65-kd Gag–Jun fusion protein concentrated in the nucleus. Together with Fos, the cellular Jun protein is a component of the AP-1 transcription factor complex (5,39). It belongs to a multigene family together with the related

genes *junB* and *junD* (154,296). Areas of homology among these genes roughly correspond to functional domains: a carboxyl-terminal leucine zipper dimerization domain, an adjacent basic region that makes contact with DNA, and an amino-terminal domain required for transcriptional activation (77,196,248). Jun proteins can form homodimers, but under physiologic conditions are usually found in heterodimers with Fos family proteins, with proteins of the ATF transcription factor family, and with other leucine zipper proteins. In the heterodimers, the leucine zipper of Jun joins with that of the partner protein in a coiled structure (64,126,138,187,310,356). The DNA contact domain extends from the leucine zipper, forming a fork that interacts with the major groove for the DNA double helix. The principal functions of Jun show a hierarchic dependence: dimerization is a prerequisite for DNA binding and transactivation, and DNA binding is required for transactivation. All three domains, for dimerization, DNA binding, and transactivation, are needed in oncogenic transformation.

Transformation by Jun reflects a disturbance of normal transcriptional controls (364), but the molecular details of this process are still unknown. Viral Jun differs from cellular Jun by a 27-amino-acid deletion in the transactivation domain, by two amino acid substitutions affecting important regulatory sites of the molecule, and by the loss of the 3' untranslated region, which appears to be responsible for the short half-life of *jun* messenger RNA (Fig. 5). All these mutations contribute to the oncogenic potential of *jun. Jun* acts as a single oncogene in transforming avian cells, and there appears to be no requirement for auxiliary genetic changes. In mammalian cells, *jun* transforms only in cooperation with a second oncogene such as activated *ras* or another growth-stimulatory gene. Transactivation by the Jun protein is regulated through phosphorylation. Phosphorylation of amino-terminal serines and threonines increases transactivation potential, and phosphorylation of a serine and a DNA-binding domain inhibits transactivation. Transformation depends on the presence of the transactivation domain, but it is not correlated with a general increase in AP-1–dependent transcription that is controlled by AP-1 consensus sequences. The transforming potential of Jun reflects more subtle changes that may involve altered preference for heterodimer partners, for DNA consensus sequences, and hence for target genes. Although numerous target genes responsive to AP-1 are known, the target genes important in the oncogenic action of Jun have not been identified. The possibility that the oncogenic change in Jun reflects a loss of function rather than a gain of function also has not been ruled out.

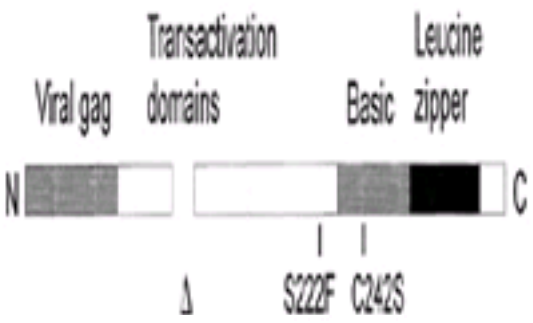

FIG. 5. Alterations in the *jun* sequences recovered in avian sarcoma virus 17. The viral *jun* differs from the cellular progenitor found in chicken cells in the following ways: v- *jun* has fused at its amino terminal partial Gag sequences derived from an avian retrovirus. It has a 27-amino-acid deletion affecting the transactivation domains. Two amino acid substitutions interfere with normal posttranslational regulation, and an absence of 3' untranslated sequences in the message contributes to the greater stability of the v-Jun mRNA. With the exception of the Gag sequences, all changes seen in viral Jun contribute to its enhanced transforming activity as compared with cellular Jun.

An entirely different regulator of transcription is the product of the oncogene *erbA* (for reviews, see refs. 80,133). *ErbA* occurs as the second oncogene in AEV strains ES4 and R, which also carry the *erbB* oncogene. *ErbB* alone is sufficient for the induction of erythroblastosis and sarcoma. In cultured erythroblasts, expression of the v- *erbB* oncogene induces a high rate of self-renewal without completely blocking a low incidence of spontaneous differentiation to erythrocytes. V-*erbA* does not induce proliferation in erythroblasts, but it blocks spontaneous differentiation and allows cell growth in a wide range of Na^+ concentrations and pH. Erythroblasts transformed by *erbB* and *erbA* together are nutritionally less fastidious than are erythroblasts transformed by *erbB* alone. Through its inhibitory effect on differentiation and by inducing nutritional vigor, *erbA* augments the oncogenicity of *erbB. ErbA* is the homolog of the thyroid hormone receptor (300,372,373,397). It belongs to a protein family that also includes receptors for glucocorticoid hormones, retinoic acid, and estrogen. These receptor proteins are related in structure and mechanism of action. They contain a ligand-binding domain, a transactivation domain, and a DNA-binding domain with two zinc fingers. They bind to similar, but not identical palindromic DNA consensus sequences. Initially the homology of v- *erbA* to the gene encoding thyroid hormone receptor led to the suggestion that the oncogenic effect of the *erbA* is due to its interference with the thyroid receptor function. Indeed, the v-ErbA protein can act as a repressor of thyroid hormone–dependent transcription, functioning as a transdominant negative mutant. However, recent investigations have shown that the oncogenic potential of v- *erbA* is primarily due to its inhibitory effect of the retinoic acid receptor rather than the thyroid hormone receptor (309,322). The transformation-related target genes that are retinoic acid (and possibly thyroid hormone) dependent and affected by the v-*erbA* still remains to be determined.

Oncogene Activation by Retrovirus Insertion

Many retroviruses that do not carry an oncogene are nevertheless capable of inducing tumors in animals (for reviews, see refs. 192,193,247). The kinds of tumor seen with these viruses are similar to the ones caused by transducing retroviruses. They include sarcomas, various forms of leukemia, and carcinomas. However, a uniform difference with respect to the tumors induced by transduction is the latent period of tumor formation. Nondefective retroviruses lacking a transduced oncogene induce tumors only after a long latent period of several weeks to several months. None of these viruses induces oncogenic transformation in cell culture. These differences largely reflect the mechanism by which

viruses induce transformation. As discussed in detail later, transformation results from the cis-activation of a proto-oncogene by the insertion of the retrovirus. Thus the long latency *in vivo,* as well as the absence of transformation *in vitro,* is due to the infrequency with which an insertion occurs adjacent to a potential oncogene.

The tumors caused by these nontransducing retroviruses have several common properties that are important in understanding their origin. They all contain an integrated provirus. The proviral sequences are found in the same chromosomal site in all cells of a given tumor; hence each tumor is monoclonal, having originated from a single transformed cell. Although infection is initiated with a nondefective virus that undergoes multiple rounds of replication, the proviruses seen in tumors are usually defective, containing only part of the viral genome. The part that is always present and conserved is at least one LTR, whereas a portion or all of the viral coding sequences may be missing. This observation suggests that viral coding sequences are not required for the maintenance of the transformed state. Most important in the genesis of these tumors is the fact that viral sequences are integrated at preferred sites of the cellular genomes. In several tumor systems, these sites are located in the immediate vicinity of a cellular oncogene that has also been found in transducing retroviruses. As a result of retroviral integration nearby, the transcription of the cellular oncogene is elevated in the tumor cells. This is referred to as insertional activation, or cis-activation, of an oncogene.

The active replication of a nontransducing competent retrovirus in a susceptible host and the presumably accidental insertional mutation or cis-activation of a cellular oncogene are not the only factors important in tumorigenesis by nontransducing retroviruses.

A systematic genetic analysis of the nontransducing retrovirus genomes for oncogenic potential has revealed a surprising multiplicity of important sequences and has demonstrated the complexity of their interactions. Among both avian and murine retroviruses, there are strains of high and low leukemogenicity. Recombinants between these strains, as well as mutants of these strains, show that the LTR is a major determinant (but not the sole one) of oncogenicity (48,89,290,291). The coding information for *gag, pol,* and *env* can be involved to varying degrees as well. In some murine leukemia viruses (e.g., Moloney leukemia virus), viral replication during the latent period of the disease gives rise to recombinants with endogenous retroviral information in the *env* gene (67,142). These recombinant “MCF” viruses multiply more actively in hematopoietic target tissue than does parental virus, and this increased replication is an important factor in leukemogenicity. The multiplicity of contributing factors suggests that every step of virus replication—from efficient entry into specific target cells to active transcription of the provirus and maturation of highly infectious progeny—is important in increasing the probability of cis-activation.

A number of questions on the mechanism of cis-activation remain to be answered. For instance, although the insertional activation of the cellular oncogene is a rare event, it does not account for the fixed minimal duration of the latent period, suggesting that some sort of threshold condition has to be met. The monoclonality of the tumors indicates that the transformation to the oncogenic phenotype is rare. It is compatible with the idea that two or more independent events are necessary to convey tumorigenicity to the infected cell. The possibility of more than one necessary event also is suggested by the fact that retroviruses that cause cancer through cis-activation of a cellular oncogene have not been found to induce transformation in cell culture. If a single cis-activating event were sufficient, it should be detectable *in vitro.* Another puzzling aspect in cis-activation is the tissue tropism of oncogenesis. It is not clear why RAV activates the *myc* gene in some chicken lines and the *erbB* gene in others or why some mouse strains develop B-cell and others T-cell or myeloid lymphomas in response to infection with the same murine leukemia virus.

Two principal mechanisms of cis-activation have been identified: promoter insertion and enhancer insertion. In promoter insertion, a chimeric mRNA is generated that combines R and U5 sequences of the viral LTR with sequences of the cellular oncogene. If the transcripts originate in the 5' LTR of the provirus, they also may contain partial viral coding sequences. However, transcription starts in the 3' LTR are more common; in these cases, the provirus has usually had extensive deletions that extend into, and may include, the 5' LTR. In fact, the activation of the 3' LTR promoter may depend on the inactivation of the 5' promoter. The preferred integration sites of promoter insertions may lie within the cellular oncogene and either truncate the coding sequences or effectively remove noncoding domains that contain negative regulatory elements. For enhancer insertion, the provirus need not be integrated in the transcriptional orientation of the cellular oncogene, and its position may also be downstream of the cellular gene. In enhancer insertion, the oncogene transcripts do not contain viral sequences. To illustrate the essential aspects of insertional oncogenesis, selected representative examples will be discussed.

Myc *and* ErbB *Are Activated by Insertion of Avian Leukosis Virus*

The Rous-associated viruses types 1 and 2 (RAV-1 and RAV-2) are replication-competent avian retroviruses that do not carry a cell-derived oncogene. In young chickens, these avian leukosis viruses induce B-cell tumors originating in the bursa of Fabricius. The tumors arise after a prolonged latent period, they are monoclonal with respect to proviral integration site, and they overexpress c-*myc*. Most contain a defective provirus that has suffered a 5' deletion. The provirus is integrated in the vicinity of the cellular *myc* gene (147,258). The exact integration site varies from tumor to tumor. Most commonly, the integrations are located between exon 1 (which is noncoding) and exon 2 of c-*myc* or within exon 1 (Fig. 6). The cis-activation of c-*myc* then occurs by promoter insertion, generating a chimeric viral–cellular fusion transcript that starts in the 3' viral LTR. In some tumors, the provirus is found downstream of *myc,* and it may also be integrated in the opposite transcriptional orientation. These situations suggest that viral enhancer activity elevates *myc* transcription; the *myc* transcripts do not contain viral sequences. Although provirus insertion often leads to a truncation of the *myc* gene, the deleted sequences are noncoding. Their removal or inactivation seems to contribute to the elevated expression of c-*myc*. The Myc protein in avian B-cell lymphomas has been found to contain point mutations, but there is no evidence that these are necessary for transforming activity. The part played by *myc* in avian lymphomagenesis requires only overexpression of the normal cellular gene. Insertional activation of c-*myc* also is seen in murine and in feline leukemias induced by nontransducing, replication-competent retroviruses.

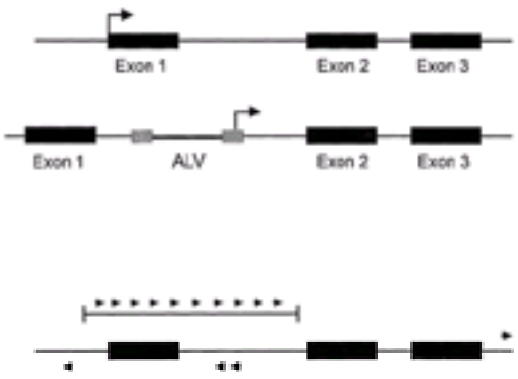

FIG. 6. Integration sites (*black triangles*) in avian B-cell lymphoma. The majority of integrations (*bracketed region*) are clustered in the noncoding exon 1 of the cellular *myc* gene and in intron 1. Most of the proviruses are integrated in the orientation of myc transcription (*triangles pointing to the right*), but some are found in opposite orientation.

In certain lines of chicken, notably those with the B5 MHC haplotype, RAV-1 induces erythroblastosis instead of lymphoma (119,230,273). These tumors also appear after a long latent period of almost 3 months, and they are monoclonal. Unlike the lymphomas, however, they contain an intact, nondefective provirus, integrated near the cellular *erbB* gene, and *erbB* expression is elevated in the tumor cells. The provirus integration sites in *erbB* are tightly clustered in a region that corresponds to the carboxyl terminus of the ligand-binding domain of the EGF receptor. Primary read-through transcripts are synthesized containing the entire proviral sequences and the truncated c-*erbB* sequences. RNA processing then creates an mRNA of uniform size with R, U5, partial *gag, env,* and *erbB* sequences. This overexpressed *erbB* mRNA codes for an EGF receptor that has deleted the ligand-binding domain at the same site as transduced viral *erbB.* The mechanism of transformation is probably similar to that of v-*erbB*: a constitutive mitogenic signal originating from the truncated EGF receptor. However, unlike v-*erbB*, the cis-activated gene contains the complete 3' terminus, and the resulting protein retains the regulatory tyrosine phosphorylation sites of the EGF receptor. The absence of some of these sites in the *erbB* insert of AEV is therefore not the only factor determining increased tyrosine kinase and oncogenic activity. In RAV-1–induced erythroblastosis, the activated *erbB* gene also is incorporated into the viral genome with comparatively high frequency. This results in the generation of new *erbB*-transducing viruses that now induce polyclonal erythroblastosis within a short latent period.

Activation of Wnt-*1 by Mouse Mammary Tumor Virus Integration*

Another retrovirus that does not carry an oncogene in its genome and induces tumors by insertional activation of a cellular oncogene is the MMTV. MMTV has several preferred integration sites in tumor target cells. Those most frequently used are close to three cellular genes *int*-1, *int*-2, and *int*-3 (for reviews, see refs. 193,246,247,259). These genes are located on different chromosomes; furthermore, despite the identical names, there is no sequence relationship between the three. The integrated MMTV provirus enhances transcription of the adjacent cellular *int* locus in the mammary tumors, and this increased expression probably plays a key role in tumor development. Although none of the *int* sequences has been found as transduced oncogenes in naturally occurring retroviruses, there are good reasons to believe that these cellular loci represent oncogenes.

Int-1, now referred to as *wnt*-1 (an abbreviation derived from the name of the homologous *Drosophila* segment polarity gene *wingless* and *int*), belongs to a gene family that fulfills important functions in pattern formation during embryonal development from *Drosophila* to mammals (193,286). *Wnt*-1 codes for a glycoprotein that is secreted but remains closely associated with the cell of origin. It is probably a component of a short-range developmental signal. Ectopic expression of *wnt*-1 in mammary cell lines induces at least partial oncogenic transformation (47).

Int-2 codes for a protein that belongs to the FGF family (91). It also appears to be a secreted protein and may act as a growth factor. Another member of this family, *hst,* is occasionally activated in mammary tumors. *Hst* also has been isolated from human tumors (Kaposi's sarcoma and stomach cancer) as a transforming oncogene (87,344). The *int*-3 oncogene also codes for a protein with presumed developmental function and belongs to the notch family of developmental regulators (288).

Transformation by Molecular Mimicry and Insertional Mutagenesis: Friend Leukemia Virus

The Friend leukemia virus occupies a unique position among retroviruses with respect to mechanism of oncogenic transformation. Key factors in this process are an altered viral envelope protein and preferred sites of provirus integration that lead to cis-activation. However, Friend virus also inactivates the cellular p53 tumor-suppressor gene, and some of this inactivation occurs by insertional mutagenesis. Friend leukemia virus causes erythroid malignancies that result from a two-step transformation (for reviews, see refs. 21,173). Virus stocks contain two agents: a replication-competent retrovirus and a replication-defective virus called spleen focus-forming virus (SFFV), with the former acting as a helper virus for the latter. Infection of mice with SFFV and its helper leads first to a polyclonal proliferation of infected erythroblasts, causing pronounced splenomegaly. The replicating erythroblasts are neither immortal nor transplantable in syngeneic animals. The pool of dividing cells is maintained and increased through recruitment of new target erythroblasts by replicating virus. The second step of transformation in Friend disease occurs in only one or a few cells in an infected animal. It results in immortality and tumorigenicity and is due to a discrete genetic change.

A molecular analysis of this two-step leukemogenesis has revealed complex interactions between SFFV, helper virus, and target cells and tissues. Helper-free stocks of SFFV have been produced in packaging cell lines. These cell lines contain helper virus information necessary to produce infectious SFFV, but cannot synthesize infectious helper virus. Helper-free SFFV infects cells but does not produce infectious progeny. Its pathogenicity appears to be restricted to the

first stage of Friend disease. Mutant analysis of the SFFV genome indicates that this initial, polyclonal proliferation of erythroblasts is caused by the expression of the altered Env protein of SFFV, gp55. Gp55 is the only gene product of SFFV, and it acts as a mitogen for erythroblasts, by binding to and activating the erythropoietin receptor (78,207). As we shall see later in the discussion of the DNA tumor viruses, this is not a unique situation—in many respects, the suspected action of the SFFV gp55 protein is analogous to the action of the E5 product of bovine papillomaviruses (see Fig. 11). The E5 protein, a transmembrane protein that interacts with the PDGF receptor, has been to shown to activate the PDGF receptor–mediated signaling by causing a ligand-independent dimerization of the receptor.

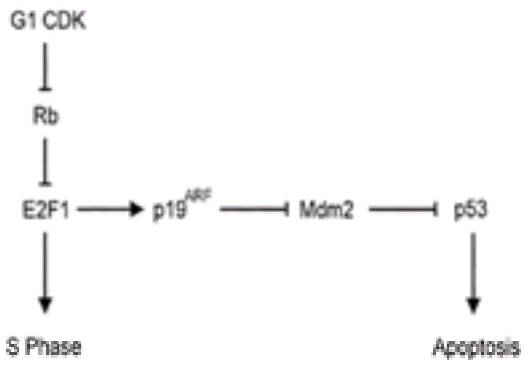

FIG. 11. The E2F1/ARF/Mdm2/p53 pathway. The accumulation of E2F1 protein, after inactivation of Rb by G_1 cyclin–dependent kinase action, leads to the activation of transcription of the $p19^{ARF}$ gene. The ARF protein has been shown to interfere with the ability of Mdm2 to target p53 for ubiquitin-mediated degradation. Thus as a result of activation of the ARF pathway, p53 levels increase due to reduced turnover.

The second step in Friend virus–induced leukemia is due to a rare event that leads to the development of a monoclonal tumor consisting of transplantable, immortal, transformed erythroblasts. Second-stage Friend virus–induced malignancies have two important properties in common: the provirus is integrated in either one of two preferred loci, referred to as *fli*-1 and *spi*-1, and a high percentage of Friend virus–induced leukemias also show inactivation of p53. The cellular *fli*-1 and *spi*-1 genes code for members of the Ets family of transcription factors; the Fli-1 and Spi-1 proteins are functionally distinct; their activation is associated with different variants of Friend virus disease. Some of the p53 inactivation events are the result of proviral integration in one of the p53 alleles with consequent loss of wild-type function and reduction to inactivated homozygous state (21,169). The activation of Ets-related transcription factors and inactivation of p53 represent rare genetic changes probably contingent on continuous helper virus–dependent replication that increases the probability for critical integration events.

Oncogenesis Mediated by Essential Retroviral Proteins

Although the vast majority of oncogenic retroviruses mediate transformation by either transducing an oncogene or activating a gene after insertion, there is at least one example whereby oncogenesis is the consequence of action of an essential viral gene product. Specifically, the *tax* gene product of HTLV-I has been implicated in the development of adult T-cell leukemia (ATL) (for review, see refs. 122,240,311). The fundamental features of HTLV-I in ATL are as follows: all cases of ATL harbor the HTLV-I provirus; the provirus is found in the same chromosomal site in all cells of a given case of ATL, and hence ATL is a monoclonal disease; integration of HTLV-I does not occur in preferred sites of the host genome; HTLV-I does not carry a cell-derived oncogene within its genome; the HTLV-I provirus is not expressed in ATL cells; and if ATL cells are placed in culture, viral gene expression is turned on.

The presence of HTLV-I provirus in all cases of ATL indicates an etiologic association between HTLV-I and ATL. The monoclonality of the tumors indicates that oncogenic transformation is a rare, and by no means inevitable, consequence of infection. It also suggests the necessity for second and possibly third contributing event. Fewer than 0.1% of all individuals infected with HTLV-I later develop ATL; the latent period can be in excess of 20 years. The absence of a preferred integration site for HTLV-I in ATL shows that there is no cis-activation of a cellular oncogene; because there is no transduced oncogene in the HTLV-I genome, ATL must be caused by a unique mechanism of viral transformation. The lack of viral expression distinguishes ATL from most other retroviral tumors and implies that although a viral gene product may be required for the initiation of transformation, it is not required for the maintenance of the transformed phenotype. The absence of viral gene expression in the fully developed leukemia also supports the probable necessity for additional events that make the growth of the leukemic cell independent of continuous viral intervention.

The HTLV-I genome contains coding information for several nonstructural proteins (Fig. 7). The best studied of these is the p40 product of the *tax* gene (58). This protein functions as a transcriptional activator for the HTLV-I genome, probably in conjunction with cellular transcription factors. The target sequences are located in the LTR of the virus. The possibility that Tax could affect the transcription of cellular genes has received support by work with transgenic mice carrying *tax* as a transgene under the control of the HTLV-I LTR. A group of these animals expressed p40 in muscle tissue. These mice developed multiple soft-tissue sarcomas of independent origin (239). The Tax protein also has been shown to transform fibroblasts in culture together with Ras (265). Similar results have also been obtained with transgenic mice that carry the *tat* gene of human immunodeficiency virus (HIV). These animals develop Kaposi's sarcoma (362). Could *tax, tat,* and other regulatory genes of retroviruses function as oncogenes? Because *tax* is a viral gene without a cellular homolog and is required for efficient replication of HTLV, the situation is formally similar to that of DNA-virus–induced transformation, where the oncogenic effectors also are essential viral genes. The data on ATL and on transgenic mice are compatible with the proposal that the Tax protein affects the expression of some key cellular regulatory genes. In the case of ATL, important targets appear to be the transcription factors CREB/ATF and NF-kB, which become stably up-regulated. Inhibition of NF-kB in leukemic cells with antisense constructs leads to tumor regression in the nude mouse model

(184,334).

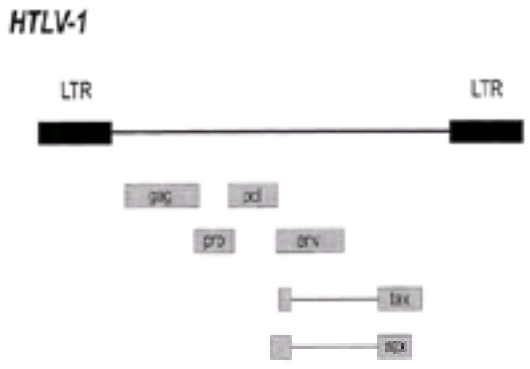

FIG. 7. Coding organization of human T-lymphotrophic virus I (HTLV-I). Gag and Env code for the major structural virion proteins; Pro for a protease, and Pol for the reverse transcriptase. Two nonstructural proteins are Tax and Rex. Tax is suspected of playing a role in HTLV-induced leukemogenesis.

MECHANISMS OF CELL TRANSFORMATION BY DNA TUMOR VIRUSES

Each major DNA virus family, except the parvoviruses, includes viruses that have the capacity to elicit cellular transformation (see Table 1). This represents an extremely diverse group of viruses with very different structures, genome organizations, and strategies of replication. In some cases, the DNA viruses have been shown to be responsible for inducing tumors in their natural hosts, including the induction of human cancers, whereas in other cases, they are known only to induce transformation of cells in culture and form tumors in experimental animal systems. For instance, a variety of data strongly implicate various types of the human papillomaviruses (HPVs) with the development of almost all cervical carcinomas (400). Epstein-Barr virus (EBV) has long been associated with the development of Burkitt's lymphoma as well as nasopharyngeal carcinoma, and epidemiologic data provide compelling evidence for a role of hepatitis B virus in the development of hepatocellular carcinoma (401). In contrast, although adenoviruses can form tumors in rodents and the viral genes E1A and E1B can transform human cells in culture, there is no evidence that adenoviruses are responsible for any human cancers (218). Likewise, SV40 and polyomavirus, which are clearly capable of forming tumors in experimental settings, have not been shown to be oncogenic in a natural setting. Nevertheless, it is these small DNA tumor viruses, which includes the adenoviruses, polyomaviruses, and papillomaviruses, that have been studied in greatest depth and that have provided much of our current understanding of virus-mediated oncogenic transformation. This is principally due to the small genome size and utility of these viruses as model systems for the study of gene expression and DNA replication, to name but two examples. The understanding of the oncogenic process has been aided by the concurrent elucidation of molecular mechanisms of action of the tumor virus oncoproteins. Because of the role these viruses have played in uncovering many of the details of cell-growth control, and the elucidation of the mechanisms that couple cell proliferation with cell-fate determination, the discussion focuses on the properties of cell transformation by the small DNA tumor viruses. For further discussion of the particulars of oncogenesis by either EBV or hepatitis B virus, please refer to Chapter 74, Chapter 75, and Chapter 87.

Transformation by the DNA Tumor Viruses: The Relationship to the Viral Replication Cycle

With the exception of HTLV-I, the oncogenic properties of the retroviruses (RNA tumor viruses) are unrelated to the requirements for productive viral growth. In the vast majority of cases, the oncogenic retroviruses are defective for replication because of the loss of essential viral sequences during the formation of the oncogenic virus. In sharp contrast, the oncogenic properties of the DNA tumor viruses are intimately associated with the ability of these viruses to carry out a productive infection. Whereas the oncogenes of the retroviruses are cellular genes that have been acquired as a consequence of the integration of the viral genome into the host cell chromosome, and then selected by virtue of their oncogenic activity, the DNA tumor virus oncogenes are essential viral genes that bear little or no relationship to cellular counterparts. Thus infection of a cell that is permissive for viral replication will generally result in a productive infection, liberating increased numbers of viral particles, and eventual cell death. A transformation event that may have been initiated would never be scored. It is only when the viral infection takes place under nonpermissive circumstances, in which the viral replication process is aborted, that a transformation event can be observed.

The frequency of cellular transformation after infection of a nonpermissive cell by adenovirus, SV40, or polyomavirus is very low, usually less than 10^{-5}. In large part, this inefficiency reflects the lack of a specific mechanism for integration of the DNA tumor virus genome into the host cell chromosome. Thus the transformation process is extremely inefficient because of the low probability that the viral genes that are essential for transformation will integrate intact and in a state that will allow transcription at appropriate levels. The lack of a system for analyzing a productive papillomavirus infection precludes such determinations for this virus group.

The oncogenic events mediated by the DNA tumor virus oncoproteins reflect the ability of these viruses to stimulate a quiescent, nongrowing cell to enter the cell cycle. For instance, a normal target for infection by adenovirus is a terminally differentiated epithelial cell that lines the upper respiratory tract. Because this cell is not in the cell cycle, the essential substrates for the replication of both viral and cellular DNA are in short supply and thus limiting. In particular, the levels of deoxyribonucleotides are tightly regulated during the cell cycle, and increase to non–rate-limiting levels only during S phase (351). The ability of the virus to stimulate such a cell to enter S phase, creating an environment for DNA replication, is thus critical for the efficient replication of the virus. This virus-mediated S-phase induction is dependent on the viral genes that also elicit transformation in other contexts. Thus if the infection does not proceed to completion, either because of a nonpermissive cell type or as a consequence of a viral mutation that blocks viral growth, the

disruption of cell-growth control that was intended to prepare the cell for viral DNA replication may instead lead to the development of a transformed cell. It is the elucidation of the mechanisms of action of these viral proteins, and in particular the cellular pathways that are targeted by the action of these viral proteins, that has propelled much of the knowledge of mammalian cell-growth control.

The DNA Tumor Virus Oncogenes

A viral infection can be divided into an early and late phase, as defined by the timing of viral gene expression relative to viral DNA replication. In general, the early genes encode proteins that prepare the infected cell to replicate viral DNA, whereas the late gene products include the structural components of the virion. For the DNA tumor viruses, these early gene products, or at least a subset of the early products, are responsible for oncogenic transformation. What follows is a general description of the adenovirus, polyomavirus, and papillomavirus genes that encode the transforming activities. For a more detailed description of these viral genes and gene products, refer to the appropriate sections in the chapters on the specific viruses.

Adenovirus

The identification of the adenovirus genes responsible for oncogenic transformation was accomplished by the mapping of viral sequences that were retained in an integrated state in transformed cells (94,121), as well as by mapping the viral transcripts present in the transformed cell (323). Such analyses indicated that a full range of viral DNA sequences could be recovered from transformed cells but that it was the left end of the viral chromosome that was common in every case. Transfection assays provided a direct demonstration that these viral sequences could indeed mediate transformation (135,136). Subsequent studies identified two distinct transcription units within this region that encode stable mRNAs found in the cytoplasm of transformed cells, as well as during the early phase of a productive infection (24). The two transcription units, termed E1A and E1B, each encode two major messenger RNAs through alternative splicing of the two primary transcripts (Fig. 8).

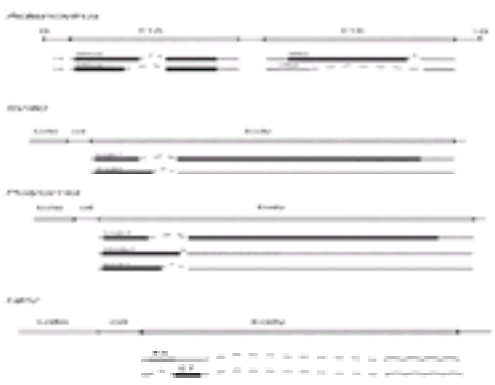

FIG. 8. The DNA tumor virus transforming genes. The left end of the adenovirus chromosome (0 to 10 map units) includes the E1A and E1B transcription units. The major mRNA products of each region are depicted, as well as the coding sequences contained within each (*black boxes*). The E1A mRNAs are commonly referred to by their sedimentation coefficients (13S and 12S), and the protein products by the amino acid residues. The E1B products are generally identified by their molecular weights. The early regions of SV40 and polyomavirus are depicted, together with the major mRNA products. The region between the early and late coding sequences referred to as “ori” contains the origin of DNA replication as well as transcriptional regulatory sequences. Coding sequences for large, middle, and small T antigen are shown by the *boxes*. The splice acceptor for polyoma large T and middle T are distinct, resulting in a change in the reading frame. The early region of the human papillomavirus genome is depicted, together with the structures of the major mRNAs that encode the E6 and E7 products. Both RNAs derive from a common promoter that starts transcription at nucleotide 97. The *wavy lines* representing 3' sequence in the mRNAs reflect the use of splice acceptors found in cellular sequences at the site of integration of the viral DNA.

The major products of the E1A gene include proteins of 289 and 243 amino acids, encoded by the so-called $E1A_{13S}$ and $E1A_{12S}$ mRNAs, respectively, that are identical in sequence except for the additional 43 amino acids found in the middle of the $E1A_{13S}$ product. The $E1A_{13S}$ product is critical for the activation of viral transcription during a lytic infection (23,171), dependent on the CR3 sequences unique to this protein (284). This activity is not important, however, for transformation. Rather, the ability of distinct domains of the protein to interact with a series of cellular proteins, including the retinoblastoma gene product (Rb), does coincide with the transforming activity. The two major E1B gene products, a 55-kd protein of 495 amino acids and a 19-kd protein of 175 amino acids, are encoded by alternatively spliced mRNAs. The two E1B proteins do not share sequence, and they appear to perform distinct although related functions. The 55-kd E1B protein, in concert with a 34-kd product of the early region 4 gene, functions to facilitate transport of viral mRNA from the nucleus to the cytoplasm (13,201,261). In addition, the 55-kd protein interacts with at least one cellular protein, the p53 tumor suppressor (301), and it is this latter activity that correlates with transforming function (395).

Polyomaviruses

Although this group includes a large number of viruses that infect a variety of cell types and host species, the two best studied viruses include the mouse polyomavirus and the monkey SV40 virus. These two viruses are very closely related in genome structure and DNA sequence, but they differ with respect to the organization and function of the early genes that carry the transforming activity of the virus (see Fig. 8). Both viruses encode a multifunctional protein, termed large T antigen, directly involved in the initiation of viral DNA replication through specific binding to the origin of replication (88,170). Although the origin binding capacity, as well as associated ATPase (127,353) and helicase (82,338) activities,

are essential for DNA replication and a productive infection, these activities are not important for transformation (9,129,174,221,268). Rather, the ability of the viral protein to bind to a variety of cellular proteins is critical for transformation. In this regard, the function of large T antigen of SV40 and polyomavirus overlap but also are distinct. Specifically, although both bind to Rb, only SV40 large T antigen binds to p53.

In addition, both viruses encode a low-molecular-weight protein termed small t antigen that contains sequence in common with the amino terminus of large T antigen, in addition to a unique sequence. Two activities have been associated with the small t antigen: the ability to bind to the PP2A cellular protein phosphatase (252,367), inhibiting activity for some substrates (392), and the capacity to activate polymerase II– and polymerase III–dependent transcription (212). At least one target for this transcription activation is the E2F transcription factor (213), which also is a target for activation by adenovirus E1A, SV40 large T antigen, and the HPV E7 protein (242). Although small t antigen does not appear to be essential in a lytic infection of tissue culture cells, it does contribute to transformation efficiency in conjunction with large T antigen (30,43).

Unlike SV40, polyomavirus encodes a distinct third early protein, termed middle T antigen, that is the principal transforming activity of the virus. Middle T antigen also shares sequence with the N terminus of large T antigen and small T antigen, but then as a result of the use of an alternative splice acceptor, the reading frame is changed from that used to encode the large T antigen (see Fig. 8). Unlike the other polyomavirus and adenovirus transforming proteins, which are localized in the nucleus, the polyoma middle T antigen is an integral membrane protein primarily associated with the plasma membrane (166,317). As we shall see later, middle T antigen binds to and activates *src* family tyrosine kinases as well as the phosphatidylinositol-3 kinase, PI-3 kinase (74,185,186,240,347).

Papillomavirus

Although the papillomaviruses are grouped within the general category of the papovaviruses, they are quite distinct from the polyomaviruses with respect to structure, gene organization, and nucleotide sequence. The majority of initial work directed at papillomavirus-mediated transformation focused on the bovine papillomaviruses, particularly BPV-1. Attention has now tended to shift to the study of the HPVs, particularly given their association with human cervical carcinoma, as well as the realization of the mechanistic similarities with the adenovirus and SV40 oncogene products.

The papillomavirus genetic information is read from only one strand, with distinct transcripts being produced by alternative transcription start sites, alternative splicing, and alternative polyadenylation (refer to Chapter 65). The genes responsible for oncogenic transformation have been identified through transfection assays using *in vitro* cell-culture systems (99,215), as well as from the identification of viral sequences that are retained and expressed in tumor cells (16,308,313,335). These studies have shown that the E5 gene of BPV encodes the major transforming activity of this virus. The E6 and the E7 gene products also contribute to transformation, but E5 is clearly the major activity. In contrast, E6 and E7 gene products of the HPVs (see Fig. 8) are primarily responsible for eliciting transformation and are always found to be expressed in tumor cells. In addition, the integrated papillomavirus DNA found in human tumor cells usually is disrupted in the E2 gene, the product of which negatively regulates transcription of the E6,E7 promoter (16).

Common Cellular Targets and Strategies for the DNA Tumor Virus Oncoproteins

Although the adenoviruses, polyomaviruses, and papillomaviruses are quite distinct and do not share a common evolutionary relationship, the actions of the transforming proteins of the three groups of viruses are remarkably similar and have defined a shared strategy that relates to the common need of these viruses to prepare the host cell for efficient viral replication. That is, the host environment in which each of these viruses must replicate is a quiescent, nondividing cell that represents a poor environment for viral DNA replication. It is the common ability of these viruses to alter this environment, through the action of the proteins that are also oncogenic, that relates replicative growth to oncogenicity.

Much of the current understanding of the actions of the DNA tumor virus proteins has derived from the analysis of physical associations of these viral proteins with a variety of cellular polypeptides. Initial studies, directed at the function of SV40 large T antigen, led to the identification of a 53-kd cellular protein that was found in T antigen immunoprecipitates (197,209). Further work demonstrated a specific interaction between T antigen and this cellular protein, which became known as p53, and subsequent studies have shown that most of the small DNA tumor viruses encode a protein that interacts with p53 (Table 5). The one clear exception among the small DNA tumor viruses is polyomavirus, which shows no evidence of encoding a protein that binds to p53. Most important, the ability of the adenovirus 55-kd E1B protein, the HPV E6 product, and SV40 T antigen to associate with p53 coincides with the transforming activity of the viral proteins (197,209,376,395).

Virus	Gene Product	Cellular Target
Adenovirus	E1A	Rb
	E1B	p53
SV40	Large T antigen	Rb, p53
Polyomavirus	Large T antigen	Rb
	Middle T antigen	Src, PI 3-K
Papillomavirus	E7	Rb
	E6	p53
	E5	PDGF receptor

TABLE 5. *Cellular targets of the DNA tumor virus oncoproteins*

Similar studies identified a large number of cellular polypeptides associated with the adenovirus E1A product (140,393). Analysis of E1A sequences essential for binding to these cellular proteins revealed two domains of interaction. One, involving N-terminal sequence and a portion of the CR1 domain, bound to a 300-kd protein, whereas the other, including the CR1 and CR2 domains, bound to a series of proteins ranging in molecular mass from 130 kd to 33 kd. Two subsequent findings with respect to these E1A interactions were of enormous significance, with respect to developing an understanding of the action of both the DNA tumor virus oncoproteins and normal mechanisms of cell-growth control. First, one of the E1A-associated proteins, a polypeptide of 105 kd, was identified as the product of the retinoblastoma susceptibility gene (382). This simple finding had immediate and far-reaching implications, because this was the first suggestion that the action of a DNA tumor virus transforming protein could be viewed as inactivating the function of a cellular growth-suppressing protein.

Second, it soon became evident that the binding of the adenovirus E1A protein to the Rb tumor-suppressor protein was an activity shared with the other DNA tumor viruses (see Table 2). SV40 and polyomavirus large T antigen, as well as the E7 product of the HPVs, were all found to bind to Rb (84,101). Moreover, the ability of each viral protein to bind to Rb was found to be dependent on viral sequences that were also important for oncogenic activity. Comparison of sequences of the viral proteins revealed a short region of homology that included the sequence important for binding to Rb (111) (Fig. 9). Although the homology between the viral proteins is limited to these sequences and is not consistent with an evolutionary relationship among the viruses, it does suggest that the viruses have each acquired a common activity.

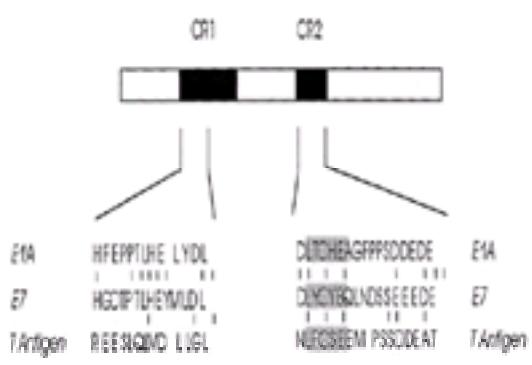

FIG. 9. Homology in the viral sequences involved in binding to the Rb family of proteins. The regions in E1A that exhibit homology with sequences in SV40 T antigen and HPV E7 are depicted (111). The L-X-C-X-E motif found in the CR2 region of E1A, that is also shared with various cellular proteins (85) including the D-type cyclins (227,390), is indicated by the *hatched box*.

Given that the ability of the various DNA tumor virus proteins to interact with Rb and p53 coincides with the transforming activity of the viral proteins, together with the fact that it is the loss of Rb and p53 gene function that is associated with the development of tumors, implies that the viral proteins achieve the same result by binding to the cellular regulatory proteins. This point is further emphasized by the relationship between HPV gene expression and the state of the Rb and p53 genes in cervical carcinoma cell lines. The vast majority of cervical carcinomas are associated with the so-called high-risk types of HPV, primarily HPV 16 and HPV 18 (400). An analysis of cell lines derived from cervical carcinomas revealed the presence of normal, wild-type Rb and p53 genes in those cells that were HPV positive and that expressed the E6 and E7 viral gene products, whereas mutations were found in the Rb and p53 genes in cell lines that were HPV negative (303). It is apparent from these results that loss of Rb and p53 function is a common event in the development of these human tumors, either as a result of mutation or through the action of the viral proteins.

Common Mechanisms of Action of the DNA Tumor Virus Oncoproteins

The physical association of the DNA tumor virus proteins with the same two cellular growth-regulatory proteins implies that these otherwise diverse viruses share a common need. Although the inactivation of Rb and p53 is most often viewed in the context of oncogenesis, the targeting of these proteins by DNA virus regulatory proteins implies a role in facilitating a productive infection. Given the common properties of the DNA tumor virus oncoproteins in the binding to key cellular growth-regulatory proteins, we discuss the common aspects of their function rather than discussing each individual viral protein in isolation.

Inactivation of Retinoblastoma Protein Function

As described earlier, adenovirus E1A, SV40 large T antigen, and HPV E7 physically interact with the retinoblastoma protein. A variety of studies have now shown that these interactions involve viral protein sequences that also are critical for transforming activity, and thus it is clear that this association is part of the transforming function. A very large body of work has now elucidated the role of the Rb protein in normal cell-growth control and provided a rationale for the strategy of the DNA tumor virus oncoproteins in disrupting this function (see Fig. 1).

Studies directed at the action of the E1A proteins in viral transcription activation during a lytic infection led to the identification of a cellular transcription factor, termed E2F, that was important for transcription of the adenovirus E2 gene (188). Subsequent studies revealed that this cellular transcription factor was normally complexed to other cellular proteins in most cell types, that these interactions prevented the activation of E2 transcription, and that the E1A protein possessed the capacity to disrupt these complexes, releasing E2F that could be used for E2 transcription (14). The ability of E1A to carry out this dissociation was found to be dependent on viral sequences that were known to be important for oncogenic activity, including binding to the Rb protein (279). This finding suggested the relationship depicted in Fig. 10A,

in which the interaction of E1A with a cellular protein such as Rb, as previously described by immunoprecipitation assays, results in disruption of the E2F complex. A variety of experiments have now shown that the Rb protein, along with the majority of the other proteins previously identified as E1A-binding proteins, is a component of the E2F complexes (15,17,18,53,57,90,332). Moreover, not only does E1A have the capacity to release E2F from interactions with Rb and Rb-family proteins, but so also do the other DNA tumor virus oncoproteins including T antigen and E7 (56).

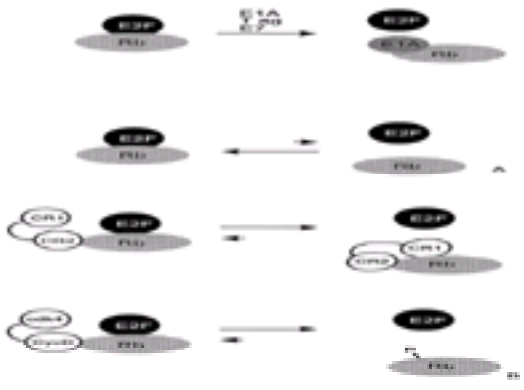

FIG. 10. Inactivation of Rb-mediated control of E2F activity. **A:** Depicted is the process of E1A (and T antigen and E7) mediated release of E2F from the complex with Rb. This action leaves the viral protein firmly associated with Rb, releasing a transcriptionally active E2F. **B:** A mechanism for E1A or D/cdk4-mediated disruption of E2F–Rb interaction.

The realization that E2F was a target for control by Rb, together with the observation that Rb function was controlled by the action of G_1 cyclin-dependent kinases, led to the eventual delineation of a G_1 regulatory pathway that ultimately controls the accumulation of E2F activity. The G_1 cyclin-dependent kinase–mediated phosphorylation abolishes the ability of Rb to interact with E2F proteins; thus the physiologic control of Rb function is mediated by G_1 CDK phosphorylation. The viral oncoproteins E1A, Tag, and E7 effect an inactivation of Rb through a direct physical interaction, independent of phosphorylation. Interestingly, the mechanism for recognition of Rb by either the viral oncoproteins or the G_1 cyclin may be similar. As depicted in Fig. 10B, the E1A-mediated disruption of the E2F–Rb complex would appear to involve first the recognition of Rb by the CR2 domain of E1A, followed by interaction of the CR1 domain with a site on Rb involved in E2F interaction (165). The conserved LXCXE sequence element found in CR2, which is shared in the other DNA tumor virus oncoproteins (see Fig. 8), also is found in the cyclin D1 protein and has been shown to be important for the interaction of cyclin D1 with Rb (96). Thus the LXCXE motif may be responsible for targeting either a viral protein or a kinase to Rb to achieve an inactivation of function.

The consequence of inactivation of Rb, either by phosphorylation or by binding of a viral oncoprotein, is to allow the accumulation of E2F activity. A large body of work has now shown that the genes subject to E2F control include the majority, if not all, of the genes encoding proteins essential for DNA replication (100,243). These include components of the enzymatic machinery such as DNA polymerase a and PCNA as well as the enzymes generating the necessary deoxyribonucleotide substrates such as ribonucleotide reductase, thymidine kinase, and dihydrofolate reductase. Moreover, it also is now clear that the majority of genes encoding proteins that function at the origins of replication, including the proteins of the origin recognition complex (ORC), the Mcm proteins, and Cdc6 are all E2F targets (200). Thus the Rb/E2F pathway, which is normally controlled by the action of G_1 cyclin-dependent kinases in response to a growth stimulus, or deregulated by the action of the DNA tumor virus oncoproteins, is responsible for the synthesis of the apparatus of DNA replication.

Numerous previous experiments have shown that the infection of quiescent cells by adenovirus, SV40, and polyoma results in the activation of S phase in these infected cells and that this coincides with the induction of the activities normally associated with entry into S phase and that are now known to be E2F targets (98,116,177,198,391). Very likely, this activation reflects the need of the virus to create an environment appropriate for viral DNA synthesis. Thus when a DNA tumor virus infects a quiescent, nongrowing cell, which is the normal target for infection by these viruses, the environment for DNA replication, whether it be viral or cellular, is not suitable. For instance, the levels of deoxynucleotides are very low in quiescent cells and they only increase as a consequence of the induction of ribonucleotide reductase activity when such cells are stimulated to grow and enter S phase (35,107). Thus through the ability to activate genes encoding the enzymes that create the appropriate environment, the virus is then able to achieve efficient replication of viral DNA.

Inactivation of p53 Function

After the discovery of p53 as a protein in association with SV40 T antigen (197,209), various analyses suggested that p53 functioned as an oncoprotein (105,168,254). Thus early speculation centered on a role for the association of the viral protein with p53 in stimulating or somehow augmenting the action of this oncoprotein. A radical change in thinking occurred when it was realized that the p53 gene used for the initial studies of transformation was in fact a mutated version and that the transforming activity of the previously assayed p53 gene was dependent on this mutation (104,113). Moreover, assays of the normal wild-type version of p53 revealed that it possessed characteristics of a tumor-suppressor molecule (112). It is now clear that the loss of p53 function, as a result of mutation or deletion of the gene, occurs during the development of a large number of human cancers (202). These studies suggest that loss of p53 function may be an event involved in the majority of human tumors.

Once again, each of the DNA tumor viruses encodes a protein that has the ability to interact with p53 and, as a consequence of this interaction, inactivate p53 function. In contrast to the targeting of Rb, however, the viral protein sequences involved in these interactions, as well as the result of the interaction, appear to be distinct among the different

viruses. That is, an examination of amino acid sequences known to be involved in the targeting of p53 in adenovirus E1B, SV40 T-antigen, and HPV E6 show no evidence for sequence similarity. Moreover, it would appear that distinct domains of the p53 protein are recognized by the viral proteins. Finally, it also is apparent that the targeting of p53 represents a point of divergence in the polyomavirus group, in that the primate polyomavirus SV40 has evolved a protein to target the p53 molecule, whereas the mouse polyomavirus lacks this function and shows no evidence of perturbing the function of p53.

Although the actual mechanism by which E1B, T antigen, and E6 target p53 does not appear to be conserved, the ultimate consequence of the interaction of these viral proteins with p53 is the same: a loss of p53 function. For instance, whereas T-antigen interaction with p53 appears to stabilize the p53 protein, presumably in an inactive state, the interaction of the HPV E6 protein with p53 triggers a ubiquitin-mediated degradation of the p53 protein (304). The process of E6-mediated degradation of p53 has been studied in some detail because these events can be assayed in cell-free extracts. These studies have led to the identification of an additional cellular protein, termed E6-AP (E6-associated protein), that functions in concert with E6 to target p53 for destruction (158,159). E6-AP functions as an E3 ubiquitin protein ligase and may be targeted to p53 through the interaction with E6, because E6-AP does not appear to be involved in p53 degradation in the absence of E6 (346).

What normal function of p53 is disrupted by these viral oncoproteins? Most likely, it is the ability of p53 to function as a transcription factor that is targeted by the viral proteins. The p53 protein has been shown to bind to DNA in a sequence-specific manner (180) and, as a consequence of this binding, activates transcription if the binding site is part of a promoter element (120,396). The *WAF1* gene, which encodes the p21 cyclin kinase inhibitor (141), was originally identified as a target for p53 transcriptional activation (103). Thus the p53-mediated suppression of cell growth may be due in part to the inhibition of G_1 cyclin-dependent kinases, the activity of which is critical for G_1 progression and cell growth.

p53 Has been extensively characterized as a transcription factor that can contribute to the activation of many genes as well as the repression of others. The transcriptional activity of p53 appears to underlie its ability to induce growth arrest, and at least in some contexts, its ability to induce apoptosis. p53 Binds DNA as a tetramer, recognizing a DNA consensus consisting of two inverted repeats of 5'-PuPuPuC(A/T)-3'. p53 Directly regulates, through p53 binding sites in the promoters, the expression of several genes involved in cell-cycle control, apoptosis, and the response to cellular stress, including p21, Bax, GADD45, IGF-BP3, and 14-3-3g (185,203). p53 Also can repress the expression of other genes lacking p53 binding sites in their promoters, including the antiapoptotic *Bcl2* gene, apparently by interacting with the TATA-containing basal promoter (185,203). Transcriptional repression by p53 may be important for its proapoptotic function, as the expression of *Bcl2* or E1B 19K blocks p53-dependent apoptosis and transcriptional repression without affecting transcriptional activation (297,325). As a further indication that p53-dependent growth arrest and apoptosis are genetically separable, p53 that is deleted of its proline-rich domain (amino acids 62–91) retains the ability to induce growth arrest, but is deficient in the induction of apoptosis (360). Interestingly, this p53 mutant can still transactivate some genes such as *mdm2*, *p21*, and *bax*, but fails to activate the PIG3 redox enzyme gene or to repress the transcription of genes normally repressed by p53.

The importance of transcriptional control by p53 is highlighted by the fact that most mutational hotspots found in human cancers map to the DNA-binding domain of p53 (185). Nonetheless, DNA damage-induced p53-dependent apoptosis can occur in the presence of inhibitors of RNA and protein synthesis (51,366), and overexpression of transactivation-defective p53 can induce apoptosis in HeLa cells (145). In other contexts, however, such as apoptosis induced by the adenoviral E1A oncoprotein, apoptosis is abrogated when the expressed p53 possesses mutations that reduce DNA binding or transactivation (8,298). Thus p53 appears to mediate both transcription-dependent and transcription-independent apoptosis.

The Actions of the DNA Tumor Virus Proteins Suggest a Functional Link Between the Rb and p53 Pathways

Although the combined action of adenovirus E1A and E1B leads to the oncogenic transformation of susceptible cells in culture, E1A expression alone most often leads to cell death as a result of apoptosis (275,380). Expression of the adenovirus E1B gene suppresses this E1A-induced apoptosis response, allowing the cells to become stably transformed. This phenomenon was first observed in cells infected by adenovirus E1B mutants, in which the infection led to the degradation of both viral and cellular DNA (260,379), a hallmark of the apoptosis response.

Further studies have shown that the induction of apoptosis in an adenovirus infection not only is dependent on E1A expression but also involves an induction of the p53 tumor-suppressor protein. In particular, there is no such apoptotic response in cells that are lacking a functional p53 gene, but the response can be restored on transfection of the wild-type p53 gene (83). It is now evident that the action of E1A to induce apoptosis is tightly linked to its ability to deregulate the Rb pathway. Direct evidence for this has come from studies of E1A mutants, in which it is clear that the ability of E1A to promote apoptosis and induce p53 accumulation is dependent on the domains involved in Rb binding (214). As discussed previously, the inactivation of Rb leads to deregulation of E2F. Indeed, overexpression of the E2F1 protein, a key target for Rb control, leads not only to an induction of S phase but also to an induction of apoptosis, which is largely p53 dependent (190,270,321,387). Further work has shown that the ability of E2F to induce apoptosis when expressed in quiescent cells is an activity unique to E2F1 (86). Moreover, E2F1, but not E2F2, also induces an accumulation of p53 protein (189). Thus one can now envision the apoptotic response and the induction of p53 accumulation as a response to the deregulation of the Rb pathway, with the E2F1 protein providing a signal to trigger p53 accumulation.

The inactivation of p53 function by the viral oncoproteins may mimic the normal activity of the product of the cellular *mdm2* gene. *Mdm2* was originally identified as a gene amplified in various tumors, primarily sarcomas (52). Subsequent studies revealed that the Mdm2 protein could physically interact with p53 and inhibit the transactivation function of p53 (60,250). In addition, it is now evident that Mdm2 functions to target p53 for ubiquitin-mediated degradation (144,191). Thus like the HPV E6 protein, Mdm2 can control the accumulation of p53 by controlling the stability of the protein.

A variety of studies have now elucidated a pathway that links the deregulation of the Rb pathway with the induction of p53 accumulation. A key component in this pathway is the $p19^{ARF}$ gene product. ARF (alternate reading frame) was identified as an alternate reading frame contained within the locus encoding the p16 cyclin kinase inhibitor (271). ARF has now been shown to interact with and control the activity of Mdm2; specifically, ARF prevents Mdm2 from targeting p53 for degradation (81,175,264,400,401). Moreover, other work has demonstrated that the $p19^{ARF}$ gene is activated by E2F1 (86), thus linking the deregulation of the Rb pathway with the activation of ARF, inactivation of Mdm2, and thus the accumulation of p53 protein (see Fig. 11).

Mdm2 may play a normal role in regulating the action of p53, possibly during normal growth stimulation (386). Although it is straightforward to envision the E2F1–ARF–Mdm2 pathway as a mechanism to monitor the integrity of the Rb pathway, triggering cell death when mutations or viral oncoproteins disrupt the normal control of the pathway, it also is possible that the balance of these two regulatory pathways (Rb and p53) plays an important role in normal cell growth and tissue homeostasis. Perhaps the most striking observation relating Mdm2 to p53 in the context of normal physiology is the analysis of mice bearing deletions of the p53 or Mdm2 locus. Targeted deletion of the Mdm2 gene leads to an early embryonic lethality, with mice not surviving beyond embryonic day 6. Although loss of p53 is without discernible effect during embryonic development, combining the p53 deletion with the Mdm2 null leads to a complete suppression of the Mdm2 lethality (172,234). Thus under circumstances in which there is likely to be no DNA damaged–induced p53 response, or oncogene activation, p53 and Mdm2 are seen to function in relation to one another. Given the fact that normal proliferation leads to the accumulation of E2F1 as a consequence of Rb phosphorylation, it may be necessary to block the ARF–Mdm2–p53 pathway each time cells are stimulated to grow.

The paradigm established by the analysis of the DNA tumor virus oncoproteins, whereby the dual inactivation of Rb and p53 can be seen as a mechanism to deregulate cell proliferation (inactivation of Rb) and block the response to this deregulation (inactivation of p53), may reflect events occurring during the development of human tumors. With the exception of colon cancer, virtually all human cancers exhibit a deregulation of the Rb pathway. This might take the form of amplification of a D-type cyclin gene, amplification of the cyclin-dependent kinase gene, loss of a cyclin kinase inhibitor, or loss of Rb. Even in colon cancer, the pathway may be deregulated, because recent data have shown that loss of the APC tumor suppressor, which controls the b-catenin/TCF transcription factor, leads to an activation of Myc (148) as well as D cyclin transcription (350). Certainly, a role for TCF in the activation of D cyclin transcription provides one direct connection to the Rb/E2F pathway, but, in addition, other experiments provide evidence for a direct role for Myc in the activation of E2F genes (199,315).

In addition to the fact that virtually all tumors exhibit a loss of Rb pathway control, roughly half of all human tumors exhibit an inactivation of p53, resulting from either inactivating mutations or generation of dominant negative mutant forms of p53. Amplification of the Mdm2 gene is seen in a fraction of those tumors that appear to be p53 wild-type, and recent data indicated that loss of ARF is frequently seen in p53 wild-type tumors. Thus as is the case for the Rb pathway, one way or another there is a loss of p53 function. One might speculate that the deregulation of the Rb pathway, leading to loss of proliferative restraint, coupled with loss of the p53 pathway that abolishes the response to loss of Rb, are events that will always be found in the course of tumorigenesis.

Other DNA Tumor Virus–Transforming Activities

Although the inactivation of Rb and p53 function is an activity that is common to the small DNA tumor viruses, at least two other virus-specific activities have evolved that do not appear to be shared in common among the DNA tumor viruses, but that do clearly contribute to the transforming capacity of the viruses. In one instance, the activity may represent an alternate path to p53 inactivation.

Although the bovine papillomaviruses (BPVs) show considerable homology and related function to the human viruses, the major transforming activity of BPV is the product of the E5 gene, a 44-amino-acid transmembrane protein. Studies of the mechanism of action of the E5 protein has revealed a role in activating tyrosine kinase signaling. In particular, the E5 homodimer interacts with, and promotes dimerization of, the PDGF receptor, leading to the activation of kinase activity of the receptor and thus the signaling cascade normally activated by binding of PDGF (see Fig. 12) (for review, see ref. 92). As such, the E5 protein can be seen to act as a molecular mimic of a growth factor, providing a growth stimulus in the absence of the normal proliferative signal. This action of E5 is quite analogous to the action of the SFFV gp55 protein, also a transmembrane protein that leads to a ligand-independent activation of the Epo receptor.

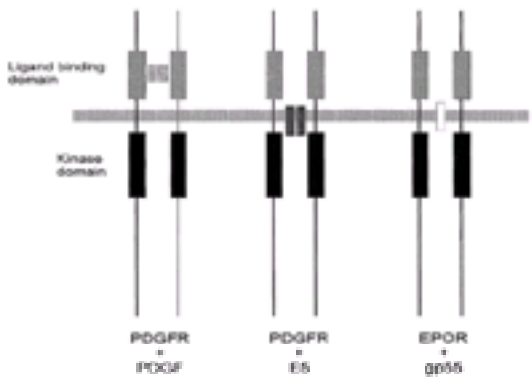

FIG. 12. Oncogenesis by molecular mimicry. The platelet-derived growth factor (PDGF) receptor is normally activated by PDGF-mediated receptor dimerization, which then activates the tyrosine kinase activity of the receptor and initiates a signal-transduction cascade. The E5 transmembrane protein of bovine papillomavirus provides a mimic of the PDGF signal by inducing a ligand-independent dimerization of the receptor through a direct interaction. Although not proven in detail, the gp55 protein of SFFV may act similarly to activate the EPO receptor independent of erythropoietin.

A second example of virus-mediated activation of a kinase signaling pathway, independent of normal proliferative signals, can be seen in the analysis of the polyomavirus transformation. The polyomavirus middle T antigen, a product unique to polyoma, revealed the association of this viral protein with the c- *src* proto-oncogene (73,74). The interaction of middle T with the c-*src* product results in an activation of the tyrosine kinase activity of the Src protein (41,71), as a consequence of the prevention of a phosphorylation-mediated inhibition of the Src kinase (54,71). Subsequent experiments have revealed that middle T can complex with other members of the Src kinase family including the Yes and Fyn kinases (63,155,186,194). In addition, formation of the middle T antigen/Src kinase complex leads to a recruitment of the PI-3 kinase (176,381), resulting in the formation of a ternary complex involving middle T, Src, and the PI-3 kinase. The formation of this complex is dependent on the phosphorylation of middle T at tyrosine 315 by the Src kinase (347). One role for the middle T–mediated activation of Src kinase activity for a lytic viral infection would appear to be the promotion of phosphorylation of the late viral capsid protein VP1, an essential modification for viral morphogenesis (123).

The interaction of middle T with Src family kinases and the PI-3 kinase appears to be a unique feature of polyomavirus, because an equivalent interaction is not found with proteins encoded by SV40, adenovirus, or papillomavirus. Moreover, this association and concomitant activation of Src kinase activity appear to be sufficient for transformation by polyomavirus. Given that this activity does mediate transformation, together with the observations that the common aspect of the other small DNA tumor viruses appears to involve an ability to drive quiescent cells into a cell cycle, one suspects that the action of middle T in activating the Src kinase pathway achieves a similar result: the creation of a proliferating cell environment that is conducive to viral replication. Indeed, analysis of a polyomavirus mutant that is defective in binding and activating PI-3 kinase suggests that this activity of middle T is important for the ability of polyomavirus to prevent apoptosis (79).

A number of previous experiments have identified polyomavirus mutants that exhibit a host range and transformation defective phenotype (hr-t) (22) that have mutations in the small and middle T specific sequences. These mutants are unable to induce a permissive state for virus replication in certain cell types, presumably a reflection of the requirement for middle T function in altering the growth properties of the target cell. Although in most instances there is a tight link between the two phenotypes, isolate middle T mutants continue to grow but fail to transform (123).

The analysis of middle T antigen–mediated transformation and tumor induction *in vivo* has shown that the presence of the src kinase is not essential for this activity because infection of src-negative mice with a middle T–expressing retrovirus led to the formation of tumors with a frequency nearly the same as that for Src-positive mice (352). Nevertheless, although the association of middle T with Src may not be absolutely critical, it is certainly possible that other Src family kinases compensate for the loss of Src because middle T is found in association with *yes* and *fyn.* These results do raise the question, however, of the nature of the underlying specificity in the interaction of middle T with one of the kinases.

Finally, although the action of middle T antigen is clearly sufficient to transform cells, one suspects that the ability of polyoma large T antigen to bind to and inactivate the Rb protein may well contribute in some circumstances. For instance, although polyomavirus mutants that are defective in large T function with respect to Rb binding are still capable of transformation and induction of tumor formation, they are defective in immortalization assays (117). Thus it may well be true that it is the combination of large T function in inactivating Rb together with the action of middle T in activating the Src kinase pathway that is necessary to facilitate fully the creation of a suitable environment for polyomavirus replication.

EVOLUTION OF COMMON STRATEGIES OF THE DNA TUMOR VIRUSES

Given that the small DNA tumor viruses represent a diverse group of viruses with little or no evolutionary relationship, it is striking that they share common targets and strategies for replication and transformation. Although the inactivation of Rb and p53 by the DNA tumor virus oncoproteins is generally considered in the context of oncogenic transformation, these events must be important for the normal process of a productive infection by these viruses, because it is the ability to replicate that provides the driving force for the evolution of these viral genes. Clearly, these evolutionarily distinct viruses share a common need and have developed a common strategy, not to transform cells, but to replicate.

As discussed previously, these otherwise diverse viruses do have a common need to induce a quiescent, nondividing cell to enter S phase so as to create an environment that is favorable for viral DNA replication. The inactivation of Rb function through the action of E1A, T antigen, or E7 would appear to facilitate this process by activating the E2F transcription factor and possibly the D type G_1 cyclins. At least for E2F activation, this would lead to an induction of various genes that create the environment for DNA replication.

The virus-mediated inactivation of p53 function also appears to facilitate entry to S phase, because expression of p53 can result in a G_1 arrest, particularly in response to DNA-damaging events (211), or to initiate a pathway of programmed cell death in response to various proliferative signals (378). As discussed in previous sections, the ability of E1A to stimulate S phase also coincides with the induction of apoptosis. The mechanism for this response remains to be determined, but it does involve the p53 tumor-suppressor protein. Indeed, there is an induction of p53 expression in cells expressing E1A. The E1B 55-kd protein, SV40 T antigen, and HPV E6 all block the action of p53 and thus block the apoptosis pathway. Thus one might view these actions as “allowing” the E1A-mediated process of S-phase induction to continue.

Given the common activities exhibited by adenovirus, SV40, and HPV, it is perhaps equally striking to find a distinct activity that is unique to polyomavirus, the middle T antigen–mediated induction of tyrosine kinase activity. Presumably polyomavirus has evolved a mechanism to accomplish the same result, the creation of a favorable environment for viral replication, without the need of eliminating the Rb and p53 suppression events. Nevertheless, it also is true that polyoma large T antigen does target Rb, and given the pairwise relationship between Rb inactivation and p53 inactivation seen

with the other viral oncoproteins, one wonders if the ultimate action of middle T might lead to the same result.

Finally, if the small DNA tumor viruses have evolved a common mechanism to drive a quiescent cell into S phase to allow efficient viral DNA replication, one might also anticipate that other DNA viruses that must replicate DNA at a high level, such as the herpesviruses or the poxviruses, would also find this to be a beneficial event, yet there is no compelling evidence that any of the herpesviruses or poxviruses encode proteins that inactivate Rb or p53. It is striking, however, that many of the genes whose products create the S-phase environment, and that are suspected to be activated as a consequence of the release of E2F from inhibition by Rb, are also found within the genomes of the large viruses of the herpesvirus and poxvirus family (2). Although it is clear that the entire complement of genes is not found within every virus of these groups, it is nevertheless true that each virus contains a ribonucleotide reductase, the rate-limiting enzyme in deoxynucleotide biosynthesis (351). Thus a common strategy of the DNA viruses, whether oncogenic or not, may be to induce activities that create the appropriate environment for viral DNA replication to take place in an efficient manner. If this involves the disruption of normal cell-growth control events to force a quiescent cell into S phase, then transformation can result if the infection does not go to completion.

CONCLUSIONS

The study of virus-induced oncogenic transformation has defined paradigmatic changes that differentiate cancer cells from their normal progenitors. These changes affect the components of signal-transduction pathways and circuits that control the cell cycle. RNA tumor viruses mutate the sequence information of growth-regulatory genes. These mutations are causative events in oncogenesis. DNA tumor viruses, conversely, disrupt various growth regulatory events as a consequence of the interaction of viral proteins with cellular regulatory proteins, temporarily inactivating the function of the cellular protein. The genes encoding these cellular proteins remain unaltered.

We have seen from the study of the RNA and DNA tumor viruses that the induction of oncogenic transformation results from the targeting of two distinct classes of cellular genes and their products: oncogenes and tumor-suppressor genes. Oncogenes encode components of cellular signal transduction, and their activation leads to a constitutive growth signal. Most often, it is this process that is seen in the retroviruses. By contrast, tumor-suppressor genes encode negative regulators of cell growth, particularly the cell cycle, and their inactivation removes such attenuating controls. The oncogenic activities of the DNA tumor viruses most often target the tumor suppressors.

The activation of cellular oncogenes can occur by all manner of mutagenic events, which include, besides viral intervention, point mutation, and chromosomal translocation and amplification. DNA-transfection techniques have identified numerous genes that can confer oncogenic properties of recipient cells. Some of these genes are closely related to the oncogenes that have also been identified in retroviruses. Many others, however, have no known association with viruses. However, the normal functions of all these genes are related to the control of cell growth, providing strong evidence for their oncogenic potential as altered control elements.

The genetic inactivation of tumor-suppressor genes clearly plays an important role in the heritable forms of human cancer. Although the action of the tumor virus proteins in achieving a phenotypic inactivation of these gene products is clearly not relevant to the understanding of the genetic basis of human cancer, it is true that somatic mutations of tumor-suppressor genes are also increasingly recognized as critical factors in sporadic cancers. Virus-induced and genetic inactivation of tumor suppressors have the same net effect as most dramatically seen in the case of cervical carcinomas: the loss of tumor-suppressor activity and thus the study of the events after inactivation by viral proteins has been and will continue to be an important approach for the study of human cancer.

Finally, despite strong evidence for the genetic etiology of cancer, it is likely that epigenetic factors also play important, but much less well defined and understood roles. In certain circumstances, such factors can exert a dominant effect, thereby converting tumor cells into normal cells. A dramatic demonstration of such epigenetic reversion is seen with murine embryonal carcinoma cells that, when injected into a normal mouse blastocyst, become subject to developmental control and contribute to the development of normal mouse tissues (231). Because molecular biology is biased in favor of genetic analysis and interpretation, it is especially important to keep a watchful eye for such epigenetic phenomena. Although the influence of these events on the development of a tumor is often difficult to measure, it is nevertheless true that these epigenetic factors also will influence the development of virally induced tumors, and thus one might expect that use of tumor viruses will play a role in the understanding of these more subtle events.

CHAPTER 11 The Immune Response to Viruses

J. Lindsay Whitton and Michael B.A. Oldstone

Virus infections have long been a major cause of human morbidity and mortality, at times substantially affecting the course of human history (167). However, due mainly to the astonishing benefits of antiviral vaccination in the past 50 years, smallpox has been eliminated, worldwide polio eradication is on the horizon, and at least in the “developed” countries, many of the childhood illnesses (measles, mumps, rubella, chickenpox, etc.) appear under control. Therefore as we reach the millenium, it is tempting to become sanguine, to conclude that we are close to completing the catalog of viruses and their associated diseases, and perhaps even to suggest that virus infections no longer pose a significant threat to human health. Nothing could be further from the truth. First, viruses still exact a heavy toll in human suffering, increasingly so with the spread of human immunodeficiency virus (HIV), which in 1998 became the fourth leading cause of death worldwide (behind ischemic heart disease, cerebrovascular disease, and acute lower respiratory tract infections). Second, new (or at least newly recognized) diseases continue to appear, most tragically demonstrated by the mushrooming acquired immunodeficiency syndrome (AIDS) epidemic, first recognized 18 years ago, and for which the causative virus was identified in 1983 (11). More recently, an outbreak of a “mysterious virus” occurred in Malaysia, killing more than 100 people (1). This virus is related to, but distinct from, Hendra virus, an equine morbillivirus first isolated in stables in Hendra, Australia, which had high pathogenicity in humans (214). Whereas Hendra virus is associated with horses, and may be spread by cats and bats (276), the Malaysian paramyxovirus is associated with pigs. Third, diseases that in the past have been geographically constrained may plausibly be spread worldwide by rapid intercontinental travel (e.g., Ebola, Lassa). Fourth, we must be continually wary of the reappearance of old foes; there were 90 deaths from measles in the United States in 1990 (200) and over 150,000 cases in 1998, 1999, and 200 in Japan, as a result of reduced vaccine compliance; and the 1997 outbreak (fortunately limited) of influenza in Hong Kong had a 30% fatality rate (219). Fifth, it is becoming increasingly clear that virus infections are associated with various cancers; for example, human papillomavirus with cervical carcinoma; human herpesvirus 8 with Kaposi's sarcoma; and hepatocellular carcinoma may be causally associated with hepatitis B virus (149), which infects hundreds of millions. Finally, there remain many diseases whose causes are undefined, and for which undiscovered viruses remain prime etiologic candidates.

To counter the continuing threat, it is vital that we understand the antiviral immune response. Studies of antiviral immunity can help us evaluate clinical problems (at the most basic level, our knowledge of the kinetics of the antibody response has been the basis of many viral diagnostic procedures, at least until recently). Furthermore, in the last decade we have begun to uncover the mechanisms that underlie the success of antiviral vaccines, and with this knowledge in hand, we may now be able to design better vaccines. In addition, viruses are powerful tools with which to probe the workings of the host immune system, and the knowledge that accrues may yield benefits in diverse fields. For example, the relationship between virus infection and subsequent immunity was noted more than 200 years ago by Jenner (85), whereas virus-induced immunosuppression was first suspected more than 90 years ago by von Pirquet (260). Major histocompatibility complex (MHC) restriction—described later in this chapter—was discovered with a viral model system (286); so pivotal was this finding to almost all aspects of antigen-specific immunity (not only in virology, but also in tumor immunology and autoimmunity) that its discoverers were awarded the 1996 Nobel Prize in Medicine.

OVERVIEW OF THE IMMUNE RESPONSE TO VIRUS INFECTION

Virus infections are countered by host immune responses. Acute virus infections represent a race between viral replication and host immunity; the usual outcome is either death of the host or termination of infection followed by recovery. In chronic virus infections, the time scale is lengthened, and both ongoing virus replication and a continuous host immune response may be present. In both acute and chronic infections, the antiviral immune response can itself be harmful to the host; this is termed immunopathology. For example, host responses may kill virus-infected cells, perhaps eradicating the agent, but at the cost of local tissue destruction. In addition many of the systemic clinical signs and symptoms manifested during viral infection are a consequence not of virus replication *per se,* but rather of the host immune reaction; cytokines released in response to infection may cause systemic symptoms (fever, headache, myalgia, anorexia, weight loss, etc.) (248,255). Furthermore, particularly during chronic infection, viral antigen–antibody complexes may form with subsequent manifestations of immune complex disease. Finally, the immune response triggered by the virus may be aberrant, focusing not on the virus but instead on self proteins, and possibly causing autoimmune disease (166,273).

The immune response can be subdivided in several ways, the two most useful of which are shown in Fig. 1. Immune responses may be categorized either by the *nature of the effector function* or by the *antigen specificity of the response.*

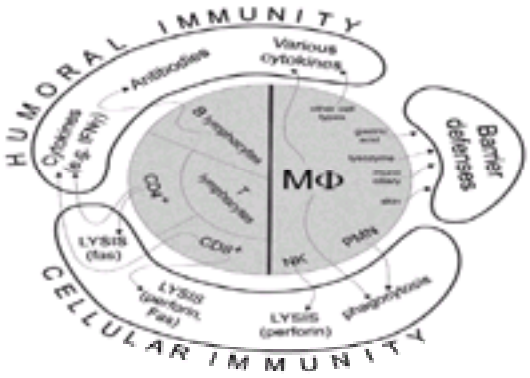

FIG. 1. Cutting the immunological cake. The central gray circle represents the immune response, which can be subdivided into antigen-specific responses (*left half*) and innate or non-specific immunity (*right half*). The correlations of these responses with an alternative means of classifying immunity (cellular, humoral, and barrier) are shown, as are some of the effector functions involved (lysis, cytokine release, etc.). *M*F, macrophages; *NK*, natural killer cells; *PMN*, polymorphonuclear leukocytes; *IFN*, interferon.

By effector function. Effector functions carried out directly by cells [e.g., natural killer (NK) cells, T cells] are classified as "cellular" immunity. When the effector functions are fluid-borne, they are termed "humoral" immunity; this term is often wrongly thought to be synonymous with antibodies, but in fact it encompasses all fluid-borne effector molecules (antibodies, cytokines, chemokines, complement, etc.). These divisions are obviously overlapping; cellular immunity can involve cytokine secretion, which is itself humoral. Finally, physicochemical defenses are termed "barrier" immunity.

By antigen specificity. Immune responses may be termed antigen specific (adaptive) or non–antigen specific (innate); as the names indicate, the former (mediated by lymphocytes) recognize specific antigenic motifs, as described later, whereas the latter (e.g., interferons, natural killer cells, mucociliary responses) are incapable of doing so. However, the key distinction between antigen-specific and nonspecific immunity is that only the former has "memory." On first exposure to a virus, both nonspecific and antigen-specific responses are activated, and the infection is (we hope) cleared. However, on second exposure to the same agent, the antigen-specific response occurs much more rapidly, and is much stronger, because of amplification of memory cells, whereas the nonspecific response occurs almost precisely as before. The beneficial effects of vaccination rely on the induction of memory cells.

Both innate and adaptive immunity are important in clearing virus infection. Innate responses, and their effector functions, are described later in the chapter; we focus first on adaptive (antigen-specific) immunity. As shown in Fig. 1, this relies on lymphocytes, of which there are two classes, T (thymus-derived) lymphocytes and B lymphocytes (which give rise to antibody-producing plasma cells). Antibodies act mainly to diminish the infectivity of free virus, whereas T cells recognize (and often kill) infected cells. Thus antibodies and T lymphocytes act in a complementary manner: antibodies reduce the infectivity of free virus in fluid phase, thereby decreasing the number of infected cells that T lymphocytes must deal with, and T lymphocytes kill infected cells before virus maturation has occurred, minimizing the release of infectious virus and thus easing the load on antibodies. Primary virus infection (when the host is first exposed to the wild virus or to a vaccine containing viral antigens) in many cases induces readily detectable antiviral antibody and T-cell responses. At the peak of the T-cell response (usually 7–10 days), some 50% to 60% of $CD8^+$ cells are virus specific (26,147); this number decreases (often in parallel with the resolving virus infection), and by 3 to 4 weeks after infection, the cell numbers have decreased, although a significant proportion (1–10%) of splenic $CD8^+$ cells are virus-specific (memory) cells. Antibody responses usually peak later than T-cell responses; antibodies are often barely detectable in the acute (symptomatic) stage of infection, but increase in number over a period of 2 to 4 weeks to a readily measurable level that often lingers for weeks or months, depending on the host and virus. Antibodies to some viruses (e.g., yellow fever and measles) can linger for a lifetime. Because antibody molecules have half-lives measured in weeks, the lifelong presence of antibody implies ongoing production, which may be stimulated by reexposure to related viruses circulating in the population. Long-term antibody production can be effected by long-lived plasma cells (224). After a second exposure to the same antigen(s) (i.e., reexposure to the wild virus, or initial exposure to wild virus after appropriate vaccination), both classes of lymphocytes display antigen-specific memory. The classic "anamnestic" or memory antibody response is seen, with

antibody levels climbing more rapidly and higher than before, and usually being maintained for a longer time. Secondary cytotoxic T-cell responses, too, are brisk, because of the presence of the memory T cells, which proliferate on antigen contact. The molecular requirements for T-cell memory remain somewhat controversial. Some workers argue that specific antigen must persist to restimulate memory T cells continuously (157), but persuasive evidence indicates that memory cells can persist in the absence of specific antigen (81,114), perhaps being sporadically stimulated in a nonspecific manner by local cytokine release during other, antigenically unrelated, immune reactions.

THE IMMUNE SYSTEM HAS BEEN SHAPED BY THE TYPES OF MICROBES THAT CHALLENGE IT

The vertebrate immune system fights a ceaseless battle against infectious agents, and both of these opposing forces have been shaped by the constant conflict. Immunological pressures bear on mutable microbes, selecting those best able to escape the unwelcome attentions of the immune system. Microbial evolution is thus driven, at least in part, by the efforts of the immune response to eradicate infection. These enforced microbial changes are mirrored in the vertebrate hosts: the immune system is molded by the nature of the microbes that it faces. For example, hosts whose immune systems are less able to counter a specific infectious agent may die; those that live (and their progeny) are better able to resist similar organisms. Hence, the vertebrate gene pool is altered by exposure to specific microbes. This battle for evolutionary supremacy places the virus in a difficult situation. If the virus is too readily eliminated by host immunity, and is in consequence unable to maintain itself in the host population, it becomes extinct. Conversely, if a virus is too virulent and cannot be controlled by host immunity, it may result in eradication of the host and thus, theoretically, viral extinction. Thus from the virus' viewpoint, it is best to be sufficiently virulent to allow transfer from an infected to an uninfected host, but to temper its pathogenicity to ensure that the host will survive long enough to permit the transfer. At either extreme, the virus may be eliminated. Frequently the initial virulence of a virus is diminished by mutation to a less virulent form, and this, in concert with the selection of more resistant hosts, results in a fluctuating equilibrium, in which both host and microbe coexist. Many examples of microbial and host changes have been documented. For example, influenza virus is the quintessence of antigenic variation in the face of host immunity, and those influenza viruses best able to evade host responses have fueled outbreaks of epidemic or pandemic proportions. The complementary outcome, in which the microbes select for survival those hosts best able to counter their pathogenic effects, is best demonstrated when the offspring have enhanced survival prospects. Such improved resistance in the progeny may, of course, be in part conferred by passive (maternally derived) immunity rather than by genetic fitness, but there are clear examples of the latter. For instance, wild Australian rabbits that survived the first onslaught by myxoma virus (a poxvirus deliberately administered in an attempt to control the exponential increase in the rabbit population) bred hardy offspring more resistant to the agent (46). Natives of the New World were devastated by smallpox and measles, introduced by the European invaders, and those who remained were better able to survive infection (135); and the appearance in dolphins (12,251) and seals (177,258) of a morbillivirus related to canine distemper virus caused high initial morbidity, which now appears to be decreasing. It has been suggested that a contemporary example of such an evolving host–parasite relationship may be that between HIV and its human host. Many host gene systems are responsible for determining the ability of the individual host to respond to an infectious agent, and several have been characterized in experimental model systems; some of them are discussed later. In summary, the immune system has been shaped at least in part by the nature of the challenges it has faced. We cited some specific examples of such evolutionary sculpture, but can we discern a more global effect whereby different classes of organisms (e.g., viruses compared with bacteria) have caused the immune system to evolve in a particular way? We shall argue later that this is indeed the case; that the two different facets of the antigen-specific immune response (antibodies and T cells) have evolved to control infection, depending on the replication site of the infecting organism (i.e., whether it is intracellular or extracellular); and that the deciding factor in determining which component of the immune response will predominate (i.e., antibody or T cell) is which of the two antigen-presentation pathways the microbial antigens best can enter.

THE ROLES OF ANTIBODIES AND T CELLS IN THE CONTROL OF MICROBIAL INFECTIONS: POINTERS FROM EXPERIMENTS OF NATURE

Antibody responses have long been recognized as important indicators of recent virus infection. Historically, a patient with an acute illness had blood drawn (acute-phase serum sample), and at a later date, often 2 to 4 weeks later, after clinical recovery, a second sample was gathered (convalescent-phase serum sample). For various candidate viruses, the levels of specific antibodies in the two samples were compared, and an increase of more than fourfold was usually considered diagnostic of recent infection. Diagnosis of a current infection requires virus isolation and growth or, nowadays, polymerase chain reaction (PCR)-based identification. The ready detection of antiviral antibodies, and the demonstration that some of them were capable on inactivating the virus, led to the reasonable assumption that antibodies were important in combating primary virus infections. This position was proven by many studies that showed that several acute virus infections could be modified or prevented by transfer of serum from an immune source. Passive antibody therapy can protect against or modify the course of several human virus infections. For example, infusion of antibodies specific for the Junin arenavirus is beneficial in Argentinian hemorrhagic fever (42,130), whereas postexposure rabies prophylaxis relies on vaccination and concurrent administration of virus-specific immunoglobulins (Igs) (122). Furthermore, in experimental models, antibodies can reduce viral titers and modulate disease. For instance, recovery from ocular herpesvirus infection is hastened by administration of anti-HSV antibody (115). Similarly, the role of antiviral antibodies in vaccination has long been unquestioned. It is important to note that the studies cited earlier showed convincingly that antibodies are sufficient for protective immunity against some viruses; they did not show that antibodies are required. Nevertheless these findings, along with the excellent correlation between vaccine immunogenicity (as judged by induction of high levels of specific antibody) and vaccine efficacy (as judged by the vaccine's protective effect) has led some workers to the misguided conclusion that antibodies alone contribute to vaccine-induced protection. “Experiments of nature” in humans strongly suggest that, for some viral infections, antiviral antibody responses can be dispensed with at little cost to the host. For example, children born with genetically determined deficiencies in antibody production, with no detectable Igs, do not show an increased susceptibility to most viral diseases, with the exception of rare enteroviral meningitides, caused most often by picornaviruses such as coxsackievirus (58,76) and echovirus type 9 or 11 (134,142). Indeed the picornavirus family is the exception that proves the rule. Before the disorder was diagnosed, a patient with common variable immunodeficiency syndrome (a defect in antibody formation) was given oral (live) polio vaccine; the patient developed paralytic disease, and continues to shed infectious poliovirus many years later (102). In addition, coxsackievirus infection of mice lacking B cells leads to a lifelong chronic infection, confirming that antibodies

are required to control picornaviruses (136). However, for most viruses, the incidence of viral disease, and disease severity, are similar in antibody-deficient individuals and normal children. These data suggest that—even though they are capable of conferring antiviral protection—antibodies are expendable in resolving some virus infections. In contrast to their ability to clear virus infections, agammaglobulinemic children show a marked increase in susceptibility to bacterial infection (60,61). Similarly, children with genetic defects in components of the complement cascade (a final effector mechanism in some antibody-mediated responses) are less able to cope with bacterial, particularly meningococcal, challenge, but their resistance to virus infection and disease appears normal (133,176). Thus antibodies are required primarily to control bacterial, not viral, infection. In the absence of antibodies, the host has an alternative means of controlling viruses: T cells. That T cells can play a critical part in eradicating human viral infections is suggested by several observations. The frequency and severity of virus infections are markedly increased in humans with impaired T-cell responses [for example, in patients with Di George's syndrome (congenital thymic aplasia), AIDS, leukemia, or recipients of immunosuppressive therapy] (60). In many of these cases, however, there also is some impairment of antibody response, and so it is difficult to draw firm conclusions. In animals, models have been developed with clean mutations in various aspects of antibody or T-cell function; these are discussed later in this chapter. However, measles infection provides an excellent example of the importance of T cells in controlling virus infections in humans. In normal children, the disease is typified by the characteristic rash, and complete recovery is usual. In contrast, in T cell–deficient children, the disease is often fatal (64,148,221). The rash itself is T-cell mediated and does not develop in severely immunosuppressed children; indeed, the presence of a rash in an immunosuppressed child (e.g., in a child with leukemia who contracts measles) is considered a positive prognostic indicator (101). In agammaglobulinemic children, the rash develops normally, and the course of the disease is unaltered by the absence of antibody responses. Furthermore, agammaglobulinemic children are subsequently immune to measles; thus antibodies in this instance are required neither for control of the primary infection nor for resistance to secondary disease (61). In summary, as outlined at the beginning of this section, overwhelming evidence shows that antibodies can control many virus infections; nevertheless, they are sometimes expendable.

Thus although both antibodies and T cells play important roles in the control of virus infection, disruption of the former has less effect on the host's ability to control virus infections but dramatically reduces the host's capacity to counter bacterial challenges. What is the molecular explanation for this phenomenon? To understand this question, it is necessary to review how antibodies and T cells see virus antigens on the virus particle or at the surface of an infected cell and to describe in some detail how these virus antigens get there. We approach this issue in the form of an overview, and then describe in greater detail the individual genes and gene families involved.

THE ROLES OF ANTIBODIES AND T CELLS IN THE CONTROL OF MICROBIAL INFECTIONS: THE IMPORTANCE OF HOW ANTIGENS ARE RECOGNIZED

Antigen Recognition by Antibodies

Antibodies recognize antigen by using regions of hypervariable sequence. The antibody–antigen union has been subjected to crystallographic analyses (7,199), which indicated that the union is more “hand-in-glove” (in which components can, to some extent, alter their conformation to accommodate one another) than “lock and key” (in which both elements are fixed, each unable to modulate to the other). Antibodies recognize intact proteins. Thus antibodies can recognize free bacteria and viruses, as well as viral proteins (most often glycoproteins), expressed on the surface of infected cells. It is therefore easy to imagine how antibodies can play a major role in the control of viruses and bacteria, by inactivating them as free extracellular entities.

However, what happens when a microbe can evade antibody recognition by locating itself within a host cell? Few bacteria can accomplish this, but viruses are obligate intracellular parasites; their replication is intracellular, often relying on subversion of host machinery. How can antibodies exert an antiviral effect at this stage? One obvious mechanism is the recognition of viral proteins on the surface of infected cells. However, many viruses delay the display of cell-surface proteins until late in the infective cycle, by which time viral maturation may have occurred, and antibody-mediated cell lysis would simply release the infectious progeny.

How can a host detect an infected cell early in the infectious process, thus maximizing its immunological advantage? Here antibodies are less effective, being limited by their recognition requirements, whereas T cells play a critical role. T cells, as will be detailed later, can recognize almost any viral protein, including those made immediately on infection; when this early-recognition capacity is allied to the ability to destroy such infected cells, T cells become a formidable component of the antiviral armamentarium.

Antigen Recognition by T Cells

T cells can be subdivided by the surface marker proteins (CD4/CD8) they express. The majority of $CD8^+$ cells are cytotoxic T lymphocytes (CTLs), although some $CD8^+$ cells exert their antiviral effects mainly by cytokine release (204), whereas most $CD4^+$ cells are helper cells that secrete cytokines to assist B-cell maturation.

T cells recognize antigens via a cell-surface heterodimer, the T-cell receptor (TcR). This molecule is structurally reminiscent of the Fab portion of an antibody molecule, but the nature of T-cell recognition differs from that of antibody recognition in one critical aspect: whereas antibodies recognize antigen in isolation, T cells react to antigen in the form of a short peptide presented by a host glycoprotein encoded in the MHC. This phenomenon, named MHC restriction, was discovered by analyses of host responses to virus infection (285,286). There are two major classes of MHC molecule (class I and class II), and there is a tight relationship between the class of MHC/peptide complex recognized by a T cell and the surface marker (CD4 or CD8) borne by the T cell. MHC class I molecules are the “classic” molecules associated with graft rejection (the phenomenon that gave the MHC its name); they are expressed on most somatic cells [neurons being a rare exception (88)], and they interact with T cells bearing the CD8 surface marker. In contrast, MHC class II molecules, previously termed Ia or Ir (immune response gene) molecules, have a much more restricted expression, being found only on specialized antigen-presenting cells (APCs; e.g., macrophages, B lymphocytes, dendritic cells), and they

interact with T cells carrying the CD4 surface marker. The relationships between surface marker, MHC class, and cell function are summarized in Table 1. The CD4/II and CD8/I relationships are determined by direct interactions between the respective molecules: CD4 binds to a specific conserved region of MHC class II (109,256), and a similar interaction occurs between CD8 and class I (57,212).

	CD8+ T cells	CD4+ T cells
MHC class that presents the antigen to T cells	MHC class I	MHC class II
Cell types that bear the MHC molecule and thus can present antigen to the T cells	Almost all nucleated cells, with the exception of neurons	Specialized antigen-presenting cells (e.g., macrophages, dendritic cells, B lymphocytes)
Source of antigen recognized	Usually endogenous antigen, made within the presenting cell	Usually exogenous antigen, taken into the presenting cell by endocytosis
Such an antigen will be made during infection by	Intracellular organisms (e.g., viruses), a few bacteria (e.g., Listeria, Mycobacterium), and some parasites	Viruses, bacteria, and other parasites; infection results in microbial proteins being shed into the fluid phase
Effector functions	Usually cytotoxic, killing target cells. Other mechanisms of antiviral activity (e.g., cytokine released)	Usually provide "help" in the form of cytokines to B cells, thereby helping in antibody production

TABLE 1. *Recognition requirements and functions of CD4+ AND CD8+ T Cells*

So evolution has produced two classes of T cells, and the major feature distinguishing them is which of the two MHC/peptide complexes each can recognize. It is clear how T cells distinguish between class I and class II (using the CD4/8 proteins); but what is the importance of their being able to make this distinction? Presumably there is some vital and fundamental difference between the class I and class II complexes, and the ability of the immune response to detect and respond to this class I/class II difference is of prime importance.

At the target cell surface, class I and class II molecules are similar in overall structure. The molecules are heterodimers, with four domains: two Ig-like domains at the cell membrane and two distal domains. The class I heterodimer comprises the class I heavy (H) chain (three domains) closely complexed with a non–MHC-encoded protein, b_2-microglobulin (b_2M). Stable expression of the class I H chain on the cell surface usually requires b2M. The class II heterodimer consists of two similar chains, a and b, each with two domains and encoded in the MHC. For both class I and class II, the two membrane-distal domains together form a structure graphically described as a “Venus fly trap,” the “groove” of which binds the antigenic peptide in a sequence-specific manner and displays it on the cell surface for the perusal of T cells (18,19). The MHC molecule is hence said to “present” the antigenic peptide. MHC molecules (both I and II) are polymorphic, and many alleles exist in the population. Much of the polymorphism lies at or near the peptide-binding groove; as a result, different MHC molecules bind different peptides. Because MHC differs among different individuals, different people will present different parts (epitopes) of a given antigen (e.g., a virus) and therefore will mount T-cell responses of different epitope specificities. Thus there are many common features between class I and class II complexes: both have four domains, both have a groove that presents antigenic peptide, and both are polymorphic around this groove.

What is the evolutionary benefit of producing two such apparently similar molecular complexes? Presumably it relates to their interactions with the specific T-cell subsets. What, then, is the essential difference between the class I/peptide complex and the class II/peptide complex, and why is it important that T cells can distinguish between them? The critical difference between the two complexes lies not in the complex itself but instead in how the MHC/peptide complex reaches the cell surface. The two classes of MHC reflect two different antigen-processing pathways (described later), one of which (class I) is optimized to present intracellular antigen and the other (class II) to present extracellular antigen. Thus when T cells distinguish between a peptide/class I complex and a peptide/class II complex, they are really discriminating based on the source of the peptide: from protein made within the APC, or from protein taken up from the extracellular milieu.

ANTIGEN PROCESSING: CLASSICal AND NON-CLASSICal PATHWAYS

There are two “classical” pathways of antigen presentation: (a) the class I pathway, in which endogenous antigen (usually made within the target cell) is processed, eventually to appear as a peptide fragment in the class I groove on the cell surface, and (b) the class II pathway, in which exogenous antigen, usually soluble protein applied to the outside of the presenting cell, is internalized and eventually also finds itself presented on the cell surface in an MHC/peptide complex. The key here is the location of the antigen; endogenous antigens are presented by class I MHC, and exogenous antigens, by class II MHC. As with most generalizations, this division is not absolute; there are examples of *de novo* synthesized antigen that enters the class II pathway, and of protocols to introduce exogenous antigens into the class I pathway. By and large, however, this generalization holds. Figure 2 summarizes the two pathways. A cell is shown, bisected by a dotted line; this hypothetical cell expresses both classes of MHC (it could therefore be, for example, an activated macrophage or dendritic cell). Below and to the right of the dotted line, the class I antigen processing/presentation pathway is outlined, and above and to the left of the line, the class II pathway is shown.

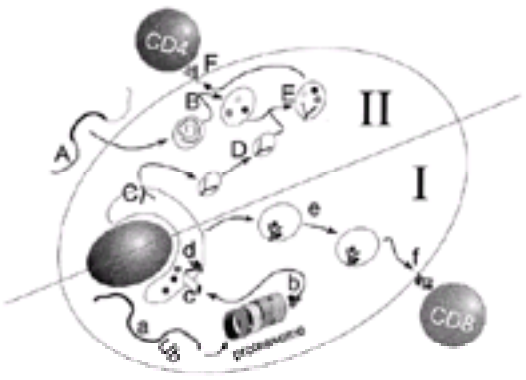

FIG. 2. Antigen-processing pathways. A cell capable of presenting antigen via both class I and class II pathways is shown, bisected by a line which separates the pathways. The letters identify various stages in the pathways, described in the text. A–F, class II; a–f, class I; Ub, ubiquitin (see text).

Antigen Presentation by Class I MHC

The thick line (a) in Fig. 2 represents a virus protein, newly synthesized in the cell cytoplasm. A certain proportion of all intracellular proteins are “tagged” for destruction by the covalent attachment of the 76-amino-acid cellular protein ubiquitin (Ub in Fig. 2). Ubiquitin covalently attaches, via its C-terminal glycine residue G76, to a lysine on the target protein; a second ubiquitin then attaches to a lysine residue on the first, and then a third ubiquitin attaches to the second, and so on. The doomed protein is therefore marked with a poly-ubiquitin chain, and this complex is taken to the proteasome (b), where it is degraded to generate shorter peptides (150). The ubiquitin system can be manipulated to increase protein degradation, resulting in enhanced induction of MHC class I–restricted T-cell responses (203,205,245,278). The peptides are next passed into the endoplasmic reticulum (ER) by a transporter mechanism, the TAP (transporter associated with antigen presentation) proteins (c), which belong to the ABC transporter family and are encoded within the MHC (100,186,249). Three peptides are shown in the ER, where they encounter the heterodimeric MHC class I complex (d) [comprising the class I protein and an accessory protein b_2-microglobulin (b_2m)]; one peptide is selected by the class I MHC heterodimer (on the basis of binding affinity in the MHC groove), and assembly of the class I/peptide complex occurs. These events have been recently reviewed in some detail (48,202). The complex passes into the Golgi apparatus (e), finally reaching the cell surface (f), where the peptide/MHC complex is recognized by a $CD8^+$ T cell–bearing TcR of the appropriate specificity. Note that peptides can reach class I molecules by a TAP-independent route, not shown in the figure; signal sequences, when clipped by signal peptidases in the ER, can be degraded, and the resulting peptides are available for MHC class I loading (73). For example, one of the CTL epitopes of lymphocytic choriomeningitis virus (LCMV) (272) is located within a putative signal sequence in the viral glycoprotein. Furthermore, recent work suggests that some class I proteins can present modified peptides (for example, glycopeptides) to T cells (230).

Antigen Presentation by Class II MHC

The thick line (A) in Fig. 1 represents a protein, but this time outside the cell. The protein is taken up by endocytosis and eventually reaches an acidic compartment, where it is degraded by proteases, generating peptides (B). Meanwhile, the class II molecule is synthesized within the ER (C) and is transported out through the Golgi/trans-Golgi (D). The class II vacuole fuses with the endosome containing the fragmented internalized protein (E), and a peptide is bound in the MHC class II groove, again selected on the basis of affinity. The mature complex is passed onto the cell membrane (F), where it is recognized by the TcR of a $CD4^+$ T cell. Note that the class II molecule in the ER (class II, C) does not bind peptides introduced by the transporters (class I, d) because the class II molecule in the ER is attached to another protein, the invariant chain (not shown), which prevents peptide binding. The invariant chain is lost as the class II molecule undergoes transport, so when fusion occurs with the endosome (class II, E), the class II molecule can bind to the peptide fragments therein (240). A recent review of presentation of exogenous antigen is available (156).

Biological Importance of the Difference Between the Two Classical Antigen-Presentation Pathways

From this it can be seen that T-cell recognition distinguishes between intracellular and extracellular sources of antigen; $CD8^+$ T cells, usually CTLs, recognize peptides from endogenously synthesized proteins, and $CD4^+$ T cells, usually helpers, detect peptides derived from exogenously applied proteins. Why is it important for the different T-cell subsets to respond differently, depending on the source of antigen? Organisms that replicate intracellularly (viruses, as well as some bacteria and other parasites) will feed antigens into the class I pathway, as well as into the class II pathway (when antigens are shed, e.g., during cell death). Conversely, obligate extracellular organisms (most bacteria) will be limited to introducing antigen mainly into the class II pathway. Therefore bacteria (extracellular) will induce mainly $CD4^+$ T-cell and antibody responses, but few $CD8^+$ T cells; whereas the response to viruses will include $CD8^+$ T cells in addition to $CD4^+$ T cells and antibodies. These considerations allow the experiments of nature to be viewed in a more molecular light. The absence of antibodies in patients with agammaglobulinemia will markedly reduce the host's ability to control bacterial infection, because this ability relies primarily on antibodies, and there is no “backup” available if antibodies are absent. In contrast, agammaglobulinemia will have much less effect on most antiviral responses because the $CD8^+$ T-cell response, effective against intracellular organisms, remains intact. Furthermore, if $CD8^+$ T cells have evolved in part to control infections by intracellular organisms, then the removal of the T-cell arm might be expected to most severely disable the host's capacity to combat such infections; this is the case. However, there are no clinical syndromes in which the class I presentation pathway alone is defective, and so it is difficult to infer how well antibody and $CD4^+$ T-cell responses could cope with virus infection in the absence of $CD8^+$ T cells. This question has been addressed experimentally in several transgenic mouse knock-out models. For example, mice lacking b_2M express little or no MHC class I on their cell surfaces

and, because $CD8^+$ T-cell maturation requires thymic expression of MHC class I, these mice develop very few $CD8^+$ T cells. Such mice mount extremely limited $CD8^+$ CTL responses, but develop readily detectable $CD4^+$ CTLs (80,146). The outcome of virus infection in these $CD8^-CD4^+$ mice varies with the virus used, but in general, there is delayed clearance of several viruses (50). These studies support the contention that $CD8^+$ CTLs play an important role in controlling virus infection, because their ablation reduces the host's ability to clear virus; however, the second pathway ($CD4^+$ T cells and antibodies) provides a certain degree of antiviral protection.

Thus there is an evolutionary relationship between the type of invading microbe, the MHC pathways that present its antigens, and the T cells that respond. Evolution appears to have honed the interactions to ensure that, upon infection, the immune response which predominates is that best suited to deal with the specific type of organism being faced. The fulcrum upon which this decision balances is the MHC antigen-presentation pathway. Most bacterial (extracellular) infections will present antigen through the class II pathway and in consequence will induce a predominantly $CD4^+$ T-cell and antibody response; antibodies can recognize intact antigen, and use various effector mechanisms (e.g., opsonization, agglutination, and complement fixation) to destroy the bacteria. In contrast, during bacterial infection, $CD8^+$ T cells, which recognize antigen only if associated with MHC class I, are infrequently induced and of limited value. Conversely, viral (intracellular) infections are susceptible to both antibodies and $CD8^+$ T cells, both of which are induced, and play important roles in recovery from infection. The explanation advanced earlier focuses on the induction phase of the immune response. However, the situation is not quite as straightforward as it at first appears. T-cell responses can be efficiently induced only by APCs, and the induction of virus-specific responses therefore requires that virus proteins be presented by the MHC class I pathway in this cell population. It has been argued that most viruses cannot infect specialized APCs, although in fact many types of virus can do so; for example, dendritic cells can be infected by retroviruses including HIV (179); RNA viruses such as measles virus (96), LCMV (20), and influenza virus (13); and DNA viruses such as pox viruses [e.g., ectromelia (232)] and African swine fever virus (65). However, many viruses do have quite tightly restricted tissue tropisms, and it appears unlikely that all viruses can infect APCs; how, then, can $CD8^+$ T cells be induced? Here we encounter the phenomenon of “cross priming,” in which exogenous proteins can be taken up by APCs and introduced into the MHC class I pathway. Several studies have clearly demonstrated that cross-priming can occur in specialized cells (201), and it has been suggested that cross-priming, far from being unusual, may be the major mode of induction of virus-specific $CD8^+$ T cells (29). Extending this cross-priming idea, it has been suggested that endogenous synthesis is important only in the recognition phase of the immune response, rather than in the induction phase (216). By this argument, antiviral $CD8^+$ T cells can be induced by exogenous protein taken up by specialized APCs (i.e., by cross priming). However, the vast majority of infected cells are not specialized APCs, and therefore cannot be “cross primed”; therefore, if the $CD8^+$ cells are to exert their effector functions, these cells must be able to present the internal antigens, and they do so via the pathway of endogenous synthesis. A recent study using transgenic mice provides strong support for the hypothesis (222), although it remains open to interpretation. Many questions remain about the true biological relevance of cross priming. For example, bacteria shed abundant protein into the extracellular milieu and are phagocytosed by APCs; if cross priming is so efficient, why do we not see brisk $CD8^+$ T-cell induction during bacterial infections?

Certain aspects of the $CD8^+$ CTL response appear particularly well suited to combat viral infections. First, the MHC allows the cell to present a fragment from a viral protein made at a very early stage of infection. Thus a cell can signal its infected status before the virus has had a chance to replicate, and lysis of the cell by CTLs is beneficial to the host, as potential virus factories are eliminated. In contrast to the ability of CTLs to recognize early transcribed (usually nonstructural) antigens, antibodies usually recognize viral cell-surface proteins, often made late in the viral life cycle during virus maturation. Second, $CD8^+$ T cells are more likely to be of direct antiviral benefit than are their $CD4^+$ counterparts because almost all cells [excepting neurons (88)] express class I molecules. Conversely, most cells are class II negative, and virus in these cells would be “invisible” to $CD4^+$ T cells. These evolutionary lessons have implications for the design of antiviral vaccines.

Non-classical Antigen-Presentation Pathways

The two classical pathways described earlier allow the host to present short peptides for the perusal of the cellular immune system. However, evolution often provides variety, and growing evidence points to the existence of alternative antigen-presentation pathways which expand the epitope universe against which the host can respond. For example, as described later, the MHC class I genes can be subdivided into two groups, class Ia genes (encoding the classical class I proteins discussed earlier) and class Ib genes which encode proteins similar to, but structurally distinct from, class Ia. Somewhat surprisingly, deletion of the class Ia genes does not completely eradicate the ability of the host to mount $CD8^+$ T-cell responses (261), and class Ia knock-out mice cope well with certain microbial challenges (213), in part because some of the class Ib proteins appear able to present modified peptide antigens to $CD8^+$ T cells (178). In mice, the class Ib MHC molecule H-2M3 is able to bind and present a peptide from the bacterium *Listeria monocytogenes* (178). It has been suggested that this molecule may present *N*-formylated peptides, characteristic of prokaryotes (110), but viral proteins too may be presented by class Ib MHC molecules (141). No equivalent of H-2M3 has yet been identified in humans. The class Ia and Ib genes are described in more detail later.

For many years, antigen presentation at the cell surface has been seen as the sole purview of the MHC locus. However, a fascinating new family of antigen-presentation molecules, not encoded in the MHC locus, has been identified. This CD1 family comprises proteins which are structurally related to classes I and II but, rather remarkably, present non-peptide antigens to T cells. CD1 glycoproteins are—like MHC class I—expressed on the cell membrane in association with b_2M but, like MHC class II, they find their way into acidic endosomal compartments where they encounter their non-peptide antigens (190). The antigens include lipids and glycolipids, which bind in the CD1 groove and are specifically recognized by $CD8^+$ T cells. CD1 proteins can present microbial antigens or self antigens. In the former case, glycolipids (from, for example, mycobacteria) are presented by CD1 to $CD8^+$ T cells bearing an apparently “normal” TcR, which confers dual specificity for the lipid antigen and the CD1 gene product (63). Certain CD1 proteins present a self molecule, glycosylceramide, which is recognized by the TcR of NK T (NKT) cells, an unusual class of mononuclear cell which expresses the NK1.1 surface marker (characteristic of NK cells) along with a TcR of very limited polymorphism (99,137).

Mouse model studies show that NKT cells may be important in tumor rejection (35), and similar cells have been identified in humans (155).

SOME HOST GENES INVOLVED IN THE IMMUNE RESPONSE

Current immunological mechanisms have evolved in response to the variety of pathogenic challenges imposed on their predecessors; implicit in this assumption is the existence of primordial genes from which present-day genes have evolved. Molecular analyses of the host genes described in the following section show that many of these genes are evolutionarily related, containing domains of similar protein folding. This has led to the inclusion of many of the genes in an Ig superfamily. The primitive gene(s) from which this superfamily has descended remains unidentified but presumably resided in a less complex organism, perhaps subserving an intercellular recognition function.

This Ig superfamily contains several families of proteins involved in the generation of an effective immune response. These include the class I and class II glycoproteins of the MHC; the CD1 glycoproteins, which present lipid antigens; the TcR proteins, present in the membranes of T cells and responsible for the antigen-specific recognition of peptide in the context of the earlier mentioned MHC and CD1 glycoproteins; proteins present in the TcR complex and necessary for T-cell function but which are not antigen specific; and of course, the Ig molecules themselves, the mediators of specific humoral immunity. Other genes, not members of the Ig superfamily but important to the immune response, also are discussed later. These genes encode the TAP transporter proteins, which lie in the MHC and are responsible for shuttling peptides from the cytoplasm into the ER, and proteins involved in antigen processing and cleavage.

The MHC Locus

The MHC loci of mice and humans, although not identical, bear strong similarities both in the overall organization of genes within the complexes and in the structure and sequences of individual genes. The murine MHC locus (on chromosome 17) comprises two regions (H-2 and Tla), whereas the human MHC locus (four megabases on chromosome 6, encoding >200 genes) is termed human leukocyte antigen (HLA). The loci have not been fully sequenced, and the cloning of the complete mouse MHC on a yeast artificial chromosome (4) doubtless will allow many interesting secrets to be unveiled. The genes within the MHC locus are divided into three classes on the basis of structure and function. The first two MHC classes, I and II, were introduced earlier and are described in more detail later. Although structurally unrelated to the class I and class II MHC genes, some of the additional genes within the MHC complex encode immunological functions (e.g., complement proteins, tumor necrosis factor, transporter proteins) and are loosely termed “class III” genes. The linkage of the class III genes to the class I/II families may be incidental or may reflect evolutionarily selected cosegregation.

MHC Class I Genes

Many texts refer to the MHC class I genes as a homogeneous group, but in fact, the group supports at least one further subdivision, into classes a and b. Class Ia proteins, by far the most studied class I molecules (and those referred to whenever the generic term class I is used) are the transplantation antigens, which led to the discovery of the MHC. These are the proteins that control MHC restriction, a phenomenon central to the specificity of cellular immune responses not only to transplanted tissues but also to virus-infected cells and tumor cells. Class Ib proteins are structurally similar to the class Ia molecules, and their functions are now being revealed. The numbers of both class Ia and class Ib genes vary between different individuals.

Three class Ia loci have been defined; K, D, and L in mice and A, B, and C in humans. The precise number of genes at each locus varies (e.g., some mouse strains lack an L gene locus; some strains have four D genes, whereas others have a single D gene), which is consistent with the occurrence of gene duplication/deletion events. Sequence homology occurs among these genes both within and between species, suggesting evolution from a common ancestor. The interspecies sequence similarities extend to the functional level because a human HLA gene expressed in a transgenic mouse appears to function similarly to the endogenous murine proteins. All share a genomic layout of eight exons that undergo splicing to generate a mature messenger RNA encoding the class I molecule, a glycoprotein of 350 amino acids. This molecule has five domains: three extracellular (a1, a2, and a3), one transmembrane, and one cytoplasmic. The class I molecules are expressed on the cell membrane in association with b_2M, a 12-kd protein encoded outside the MHC. The crystallographic structure of the MHC class I molecule has been solved. The a3 domain and the b_2M molecule, both of which are evolutionarily related to the constant region of Ig, are in intimate contact with the cell membrane, whereas the a1 and a2 domains interact at the top of the molecule to form the groove that presents the short peptides, most often nonameric, to $CD8^+$ T cells. Class I molecules are found in the membrane of almost all nucleated cells, which are therefore presumably able to present antigen. Neurons, an exception to this rule, transcribe b_2m but fail to transcribe the MHC heavy chain (88).

The peptides presented by class I MHC can originate from almost any protein synthesized within the cell, including self, tumor, and microbial proteins. It has been estimated that a single cell can display from 1,000 to 10,000 different peptides at any one time (84) and that $CD8^+$ T cell induction most often requires a threshold presentation of at least 100 MHC/peptide complexes per cell (31), although one report suggests that T cells can be activated by a single MHC/peptide complex (238). Essentially all viral proteins (including nucleoproteins, polymerases, and glycoproteins) can provide sequences to be presented to the cellular immune system. This provides a marked advantage to the host by allowing the entire coding region of the virus genome to be exposed to immune surveillance. Furthermore, the system allows presentation of virus antigens expressed early in infection. These often are non-membrane proteins, “invisible” to antibodies, and the MHC system thus provides a selective advantage to the host by permitting detection and removal of infected cells before virion particles have been produced. Analyses of MHC structure/function relationships provide a molecular explanation for the variability of T-cell responses in different mouse strains and in different individuals in a random-bred (e.g., human) population. The MHC class I proteins are highly polymorphic (i.e., there are many functionally distinct alleles at each locus). Sequencing studies of many different alleles show that the variable residues cluster around sites close to the antigen-presenting groove. Thus the functional polymorphism is caused by alterations affecting

the nature of antigen binding and presentation by individual MHC molecules; different MHC molecules will bind and present peptides of different sequence. Hence, one variable in the immune response is the ability of the host class I molecule to bind microbial sequences and present them to the T-cell repertoire. If a host, when challenged with a particular virus, lacks the class I sequences necessary to bind and present viral peptides, then that host will be unable to mount class I–restricted CTL responses, and therefore will probably be more susceptible to disease caused by the agent in question. In contrast, a host whose genotype encodes MHC molecules capable of binding and presenting a peptide from this particular virus is more likely to be able to mount a CTL response that will limit viral replication, dissemination, and virus-induced disease. Given the risk of failure to present, one might ask why we have not retained more than the six or so MHC class I alleles in each diploid host cell; if an individual could instead express, for example, 20 class I alleles, the risk of being unable to present epitopes from any microbe would be greatly reduced. The reason is straightforward. Some 98% of lymphocytes entering the thymus fail to develop into mature T cells, and a major cause of this attrition is negative selection, in which T cells with excessive affinity for self molecules (i.e., for MHC molecules associated with self peptides) are deleted. Thus the more MHC alleles we carry, the more self peptides we can present; and as more self peptides are presented, so we clonally delete more T cells in the thymus. With our present complement of MHC alleles (about six per person), we already delete some 98% of all of our T-cell specificities; increasing our MHC representation would most probably reduce our T-cell repertoire below effective levels. We are, therefore, in a state of equilibrium: our T-cell repertoire is balanced against our ability to present antigen for the perusal of T cells. We must present just the correct number of antigens; too many (too many MHC alleles) would decimate our population of mature T cells, whereas too few (too few MHC alleles) would increase the risk that we would be unable to present antigen to our T cells.

Early attempts to predict viral (or other) sequences that might bind class I MHC molecules were not consistent and thus were unsuccessful, probably because they attempted to predict the viral epitopes without taking into consideration the specific polymorphism (i.e., allelism) of the MHC molecules. However, two factors allowed more consistently correct predictive motifs to emerge for specific MHC alleles. First, the increasing database of CTL epitopes for the individual MHC alleles allowed comparison of the peptide sequences they presented, and allele-specific consensus sequences could be deduced. Second, work by the Rammensee and Nathenson groups showed that peptides can be eluted from MHC molecules and their sequences inferred or directly determined (84,207,208,251). By a combination of these two approaches, specific motifs have been identified for several murine and human MHC class I alleles. Most, but not all, peptide epitopes are nonameric, with two highly conserved anchor residues critical for binding of the peptide to the MHC molecule. The MHC class I/peptide complex has been studied at high resolution, allowing the detailed analysis of the interaction between MHC class I molecular grooves and the peptides found therein (18,19,51,132,277). The MHC groove contains several binding pockets, the most critical of which is that which binds the C-terminal residue of the peptide. The MHC residues that form this binding pocket have been identified, and their nature allows fairly confident prediction of which C-terminal residues will be favorable for a particular MHC pocket. Because the polymorphism of the amino acids forming this MHC pocket is fairly restricted, so too are the C-terminal amino acids of the binding peptides. Thus the great majority of peptides have as their C-terminal residue one of seven amino acids (I, L, V, R, K, Y, or F). Another pocket, located in the middle of the groove, appears important in determining allele-specific binding (i.e., in conferring fine specificity for specific peptide sequences) (132).

The “non-classical” class Ib MHC molecules are less well studied, but their functions are being slowly uncovered. In humans, four genes were identified and named HLA-E, -F, -G, and -H. In mice, three class Ib gene clusters, named Q, T, and M, have been found, but remain incompletely characterized. HLA-H is now known to be the gene related to 90% of cases of hereditary hemochromatosis (HH), and the HLA-H designation has therefore been replaced by HLE, the original name given to the gene conferring HH susceptibility; the protein is topologically similar to class I MHC, but its groove is too narrow to bind peptide. Thus it appears that this class Ib gene subserves no immunological function. The tissue distribution of HLA-E is similar to that of the class Ia proteins—that is, almost ubiquitous. Intriguingly, expression of this protein on the cell surface is greatly enhanced when its groove is loaded with a nonameric peptide derived from the leader sequence of class Ia molecules, ensuring that its surface expression is coordinately regulated with that of the classical molecules. In contrast to the groove of class Ia proteins, the HLA-E groove is relatively non-polymorphic, consistent with its role in binding a nonameric sequence which varies only slightly among the different class I leader sequences. HLA-E has been implicated in regulation of NK-cell activity (23), and it is possible that the very limited polymorphism allows it to interact with subtly different receptors on the NK cells (NK receptors are discussed later in this chapter). HLA-G has been implicated in antigen presentation, but it differs from other class I molecules in its distribution, being found mainly at the maternal/fetal interface; it has been implicated in protecting the fetus from rejection (113,116). The function of HLA-F remains obscure.

MHC Class II Genes

The existence in the mouse MHC of genes that regulate the humoral responses to antigen was clearly demonstrated more than 30 years ago. They were initially termed immune response (Ir) genes, subsequently termed Ia genes (easily confused with class Ia), and both terms have now been replaced by the term class II MHC glycoproteins. The class II locus of humans is termed HLA-D; and in mice, H-2I. Like their class I counterparts, the overall structure and function of class II genes appear similar in both humans and mice. Mature class II molecules are membrane-bound heterodimers resulting from the association of two MHC-encoded class II proteins, an a chain and a b chain (Fig. 3). Six a and seven b genes have been identified in the HLA-D region, divided into three clusters termed DR, DQ, and DP. Murine equivalents are present in the H-2 I region: two a and five b genes divided into two clusters termed A and E. The genes encoding the a and b chains are similar, although some variation between exon numbers is seen, even within a chain type. The resultant a or b proteins have two extracellular domains, a transmembrane region and a cytoplasmic domain. The top (membrane-distal) domain is named a1 (b1), whereas the lower one, adjacent to the membrane, is termed a2 (b2). The membrane-proximal paired a2 and b2 domains share significant homology with the class I a3/b $_2$M pairing, indicating once again common ancestry and possible functional relatedness. Indeed, there are many similarities in the overall topology of the two cell-surface MHC classes. Both classes have four extracellular domains; both the membrane-proximal domains are similar to Ig constant region, and the two distal domains interact to provide a groove for antigen presentation. The location of disulfide bridges is similar. The crystallographic structure of the class II molecule has been solved and appears similar to that of the class I heterodimer (25). Peptides bound by class II molecules are derived from a different processing pathway (see earlier) and are longer, usually between 15 and 20 amino acids. Unlike the class I peptides, in

which the C-terminal residue is firmly anchored, class II–bound peptides protrude at both ends of the groove. Some motifs have begun to emerge for peptide binding to specific class II dimers, but this work lags behind the class I studies (210).

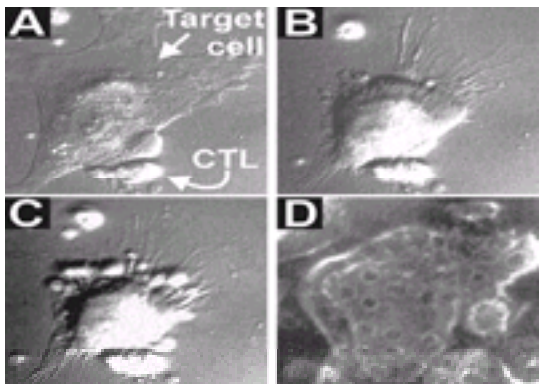

FIG. 3. Cytotoxic T lymphocytes (CTLs) kill target cells and insert perforin pores into the target cell membrane. Video-capture photographs (**A–C**) and an electron micrograph (**D**) are shown. **A:** A CTL encounters a target cell expressing an appropriate peptide/class I major histocompatibility complex (MHC), and within minutes the target cell begins to contract (**B**), and to show extensive blebbing of the cytoplasmic membrane (**C**). The CTL releases perforin, which self-assembles within the target cell cytoplasmic membrane, generating pores (visible in **D**), which permit entry of effector molecules, and also cause the cell to become hypoosmolar.

The polymorphism of class II molecules varies from gene to gene; for example, DQ a1 is highly polymorphic, DQ a2 much less so. However, the low polymorphism at certain loci is offset by the ability of class II genes to reassort. Thus in theory, the haploid genome encoding six a and seven b genes might make 42 different class II molecules, although in practice, reassortment is not entirely unrestricted. Reassortment cannot, of course, operate for the class I molecules because the heterodimer includes one monomorphic molecule (b_2M). The tissue distribution of class II molecules is markedly more restricted than that of class I. They are most abundant on B and T lymphocytes and cells of the macrophage/monocyte lineage. The class II/peptide complex is recognized by T cells bearing the CD4 surface marker; these cells are most frequently helper T cells rather than cytotoxic T cells.

CD1 Genes

The CD1 family encodes five proteins in humans (CD1a–CD1e), and the human CD1d gene has two homologs in mice (mCD1d1 and mCD1d2) (184). The intron/exon organization of these genes is similar to the MHC class I genes, and crystallographic analyses of the mouse CD1d1 protein revealed a strong similarity to the classical MHC structures, although the binding groove is deeper, presumably to accommodate the non-peptide (usually lipid/glycolipid) antigen described earlier (282). The tissue distribution of the CD1 proteins is severely restricted; like MHC class II genes, most CD1 proteins are expressed in professional APCs including B lymphocytes, macrophages, and dendritic cells.

TcR Genes

TcR genes belong to the Ig superfamily. Antigen specificity of T lymphocytes is bestowed by a heterodimeric surface-bound glycoprotein, the TcR. Four distinct genomic regions encode different TcR chains, which have been named a, b, g, and d. The great majority of circulating T cells, regardless of their helper/cytotoxic phenotype or MHC restrictions, bear ab receptors; gd receptor–bearing T cells have been identified quite recently, are far less well characterized, and are not discussed further in this chapter. The TcR genes are, like the Ig genes, products of somatic rearrangements that appose noncontiguous germline gene segments. The mature gene usually results from joining of V, D, J, and C regions; each chain type draws from its own pool of germline segments. The germline copy number of each of these regions varies among the chains but appears sufficient, when both combinatorial rearrangement and other V-region diversification mechanisms are invoked, to provide a TcR repertoire at least as large as that of antibodies. The mature TcR chains are glycoproteins of 260 to 300 residues in length, comprising a short cytoplasmic tail, a transmembrane region, and two extracellular domains, one constant and one variable. The antigen-recognition site, which recognizes the complex of antigenic peptide and MHC, thus consists of the Va and Vb regions. The crystallographic structures of several TcR/MHC class I/peptide complexes have been solved, and show that the TcR lies diagonally across the MHC/peptide complex; there is a degree of plasticity in the interaction, in which the TcR can to some extent conform to the peptide/MHC with which it interacts (55,56). In overall structure, the TcR molecule is similar to the distal (Fab) portion of an antibody molecule. However, the TcR differs from antibodies in several aspects. First, the effector function of an antibody is imposed on it by the constant region used in its generation, and there are multiple nonallelic constant-region genes to which the antibody-variable regions can be linked. In contrast, the copy number of TcR constant-region genes is very low, and the same C regions are represented in both CTLs and T helper (Th) cells. Thus the TcR C region does not dictate the T cell's effector function. The same Va and Vb gene pools are used in both class I and class II restricted T cells, indicating that the TcR does not fundamentally distinguish between the two classes of MHC molecule. Rather, the TcR recognizes the antigen/MHC complex, and other T-cell components determine the MHC class specificity (CD4/class II and CD8/class I) and the effector function (helper/cytotoxic) of the cell.

How restricted at the molecular level are T-cell responses to virus infection? This has been studied at the level of *in vitro* specificity of T-cell lines and clones, but much more rigorous analysis can be achieved by studying the TcR sequences of individual clones. This allows us to ask if responses to immunological stimuli are monoclonal or polyclonal, which is interesting not only at an academic level, but also at a practical one. If responses are monoclonal (i.e., if all TcRs are identical), then it may be possible to ablate specifically cells bearing that TcR, thus potentially diminishing

immunopathological effects related to the antiviral immune response. In contrast, if such responses are polyclonal, such intervention is likely to be difficult and unrewarding. The VDJ gene use in TcRs of cells responding to a variety of stimuli have been determined. In general, response to certain model antigens, such as cytochrome c, have shown quite restricted VDJ uses, but responses to virus infection have shown much broader use (79,279). Thus it appears unlikely that TcR-specific ablation will be a valuable therapeutic approach in control of virus-induced pathology. The catholic use of Va and Vb chains during acute infection extends also to the memory response. Certain T cells in an acute response will act as progenitors of the memory T-cell pool (175), and the selection process appears to be stochastic (228).

T-Cell Accessory Molecules

At the T-cell surface, both ab and gd receptors are intimately associated with several other proteins, collectively referred to as the CD3 complex. The CD3 complex comprises at least four transmembrane proteins that relay a signal across the T-cell membrane when the TcR is appropriately stimulated. Also on the T-cell surface, although not stably linked to the CD3/TcR complex, are the CD4 and CD8 molecules, which play critical roles in T-cell function. These nonpolymorphic glycoproteins, again members of the Ig superfamily, are differentially expressed during ontogeny, but mature circulating T cells generally express only one of the two molecules. There is a very strong correlation between the CD4/CD8 characteristic of a T cell and the MHC class that presents the antigen to that T cell. Thus almost all $CD4^+$ T cells are class II MHC restricted, whereas $CD8^+$ cells are class I restricted. There also is a correlation, although less absolute than the earlier one, between the T cell's CD4/CD8 characteristic and its effector function; most $CD4^+$ (class II–restricted) T cells are of the helper phenotype, whereas most $CD8^+$ (class I–restricted) T cells are of the cytotoxic phenotype. The CD4/CD8 molecules recognize specific regions of the MHC glycoproteins and may play a role in activating the transmembrane signal relayed by the CD3 complex (57). However, the outcome of signal transduction (help or cytotoxicity) is independent of the nature of the CD4/CD8 molecule or TcR; thus there are examples of $CD4^+$, MHC class II–restricted cytotoxic T cells. Interestingly, in animal model systems, these cells appear to modulate the outcome of virus infection, despite their presumed inability to recognize the great majority of infected cells (which will be class II negative) (39,80,146).

Immunoglobulin Genes

The humoral response to virus infection plays an important role not only in promoting clearance of primary infection but also in preventing the establishment of widespread infection on secondary exposure to the agent. All antibodies have a similar overall monomeric structure, comprising two disulfide-linked identical heavy (H) chains, each of which is flanked by a light (L) chain. The centrally located H chains usually have four domains: three constant and one N-terminal variable. The L chains contain one constant domain and one variable domain. The variable regions of each L+H pair combine to form a single antigen-binding site: an antibody monomer is thus divalent in terms of antigen recognition. The L proteins are segmentally encoded in the germline, as variable (V), joining (J), and constant (C) regions, and are linked by somatic recombination. The H proteins are similarly arrayed, although they also have diversity (D) regions. Variability at the antigen-binding site is brought about by a variety of mechanisms during somatic recombination (as for TcR). The rearranged VDJ region is then apposed to one of the constant regions; the nature of the constant region determines the class (and therefore the function) of antibody that results. There are five general classes of antibody, differing in function, time of appearance, and distribution in the body. Structurally, the classes differ in the constant region of their H chains. The classes are IgM (H chain is Cμ), IgG (Cg), IgD (Cd), IgE (Ce), and IgA (Ca). First exposure to a virus induces a rapid IgM response, which is usually independent of Th cells, and a slightly delayed IgG response, usually Th dependent and thus requiring antigen to be presented via MHC class II molecules.

In contrast, secondary exposure results in a similar IgM response but a much more rapid and massive IgG response. In many instances, the precise specificity of the secondary IgG antibodies is identical to that of the initial IgM molecules: that is, the antigen-binding sites have been retained, but the remainder of the molecule (which determines its effector functions) has been altered. This “class switching” occurs when, for example, an H chain VDJ region is moved from the Cμ gene to the Cg region; the new H chain has the same V region but a different C region. Two of these chains, in association with two unchanged L chains, generate an antibody identical to the original in specificity but different in effector function; it is now an IgG rather than an IgM. Initially, all B cells express membrane-bound IgM, but on exposure to specific antigen, they develop into plasma cells, usually undergoing class switching. The five classes of antibody subserve distinct effector functions, but only three are thought to play a role in opposing virus infection. IgM molecules form pentameric masses, each with 10 antigen-binding sites. These molecules are effective mediators of virus aggregation; they also activate both macrophages and the complement system. IgG, the main serum antibody, is monomeric, activates macrophages and complement, and can cross the placental barrier. IgA can exist as monomer, dimer, or trimer; it is transmitted to luminal surfaces (in saliva, tears, and intestinal and other secretions) to provide an initial defense against infection. IgE may play a role in immunity to parasite infection, but its major recognized task is the initiation of many allergic reactions, acting through histamine release from mast cells. The IgE-mediated release of histamine and other factors probably contributes to some of the respiratory manifestations of virus infection. The function of IgD remains obscure.

Genes Involved in Antigen Degradation in the MHC Class I and Class II Pathways

Many (but not all) of the peptides that eventually encounter MHC class I are generated by the proteasome, a multiprotein cytoplasmic organelle, the constitution of which is regulated by interferon g (IFN-g); this cytokine induces expression of three proteins, LMP (low-molecular-weight polypeptide)-2, LMP-7, and MECL-1 (multicatalytic endopeptidase complex-like), which replace three constitutive catalytic components of the “normal” proteasome, generating the “immunoproteasome” (52). Whereas MECL-1 is encoded outwith the MHC, both LMP-2 and LMP-7 are encoded next to the TAP genes, and should be considered MHC class III genes. Although several genes related to class I antigen presentation are MHC encoded, this is not true for some important genes related to the class II pathway; in both man and mouse, several genes encoding cathepsins [proteases vital to antigen degradation in the class II pathway (252)] are scattered throughout the genome (38,217).

Genes Involved in Peptide Transport and in Assembly of the Peptide/MHC Complex

Two TAP transporter genes are encoded in the MHC, called TAP-1 and -2; one copy of each combines to form a functional heterodimeric transporter. The role of these proteins in antigen presentation has been clearly demonstrated (247). Cell lines defective in transport are unable to present endogenously synthesized antigen in a normal fashion, but when the defective TAP is restored, antigen presentation proceeds (8,189). *In vivo* studies confirm these observations: TAP knock-out mice exhibit the expected phenotypes, having little or no cell-surface MHC and no mature $CD8^+$ T cells (253). There is some selectivity in the peptides transported by these molecules, as demonstrated in the rat; the class I modifier (cim) locus contains (at least) two genes (named mtp-1 and mtp-2), the latter of which has (at least) two alleles that result in presentation of different peptides by identical MHC molecules. The cim locus encodes a transporter, and the two alleles permit the passage of different peptides, thus providing the MHC class I molecules in the ER with different peptide populations from which to select (124,125,187,188). Direct evidence has been obtained showing that different transporter proteins display preferences for specific peptide sequences (153); one cim allelic product could transport peptides terminating in H, K, or R, whereas the other could not (70). Allelism has been identified in humans by sequencing the human TAP equivalents (186). Thus although the major contributor to epitope selection probably remains the class I molecule, the transporter proteins may play some role in limiting the range of peptides to which the class I molecules are exposed. However, this role is likely to be minor, for several reasons. First, many cell lines have been transfected with non-homologous MHC alleles, but these MHC molecules continue to present the same CTL epitopes as they did in their own background, suggesting that there is no major difference in the peptide pools generated in the differing backgrounds. Second, transporter heterodimers in which one component is murine and the other human appear to function the same as either of the natural heterodimers (280). Within the ER, several proteins are important to assembly of the class I/peptide complex (48). Four are quite well characterized: tapasin, which ensures association between the TAP transporter complex and the empty MHC-b_2M heterodimer, is encoded close to the MHC locus (75), whereas the genes encoding three chaperones (BiP, calnexin, and calreticulin) are not MHC linked.

CELL-MEDIATED EFFECTOR MECHANISMS

We have outlined our current understanding of immune responsiveness at the molecular level. In the following section, we discuss immune responsiveness at the organismal level, describing the biological roles of several different cell types and the effector mechanisms through which they act.

Virus-Specific $CD8^+$ T Cells

These cells have been extensively characterized in the mouse, and the results equate well with those obtained with human cells. First, the vast majority of these cells are restricted by class I MHC proteins, although a few have been identified that are restricted by class II or by CD1. The importance of these cells in the control and eradication of virus has been documented for several experimental infections. In the mouse, they are critical in combating infection with LCMV (272). In this case (105,106) and in murine cytomegalovirus (MCMV) infection (92), it is possible to fully protect a naive animal from virus challenge by immunization with a recombinant vaccinia virus (VV) expressing a single viral internal (i.e., nonmembrane) protein; the protection is mediated solely by $CD8^+$ T cells. Recombinant vaccines containing minigenes encoding isolated CTL epitopes as short as 11 residues can confer protection against normally lethal doses of challenge virus, and different epitopes can be linked on a “string of beads” to protect on several MHC backgrounds (5,6). No LCMV-specific antibody responses are induced by these vaccines, proving that protective effects can be mediated by cellular immune responses. In humans, it is clear that CTL responses can be generated against similar proteins. For example, the major CTL response to human cytomegalovirus (HCMV) is to a protein expressed immediately upon infection; a similar situation exists for varicella-zoster virus (VZV) and herpes simplex virus (HSV). Epstein–Barr virus (EBV) infects and transforms human B lymphocytes, and the control of this cell population appears to be managed in large part by class I MHC–restricted CTLs. Indeed some immunosuppressed individuals may develop EBV^+ lymphomata (198). Influenza virus infection induces CTLs directed against most viral components, but the major group is specific for the virus nucleoprotein. These CTLs, unlike anti-influenza antibodies, are cross-reactive; that is, they lyse HLA-matched target cells infected with a serologically distinct strain of influenza virus. However, their presence fails to confer absolute immunity to infection and disease caused by a serotypically distinct influenza virus. These results are sometimes used to challenge the hypothesis that the presence of virus-specific $CD8^+$ cells confers protection against virus-induced disease. It is important to understand that $CD8^+$ T cells cannot prevent infection; on the contrary, recognition by these cells requires that the target cell be infected. Only antibodies can prevent infection, whereas $CD8^+$ T cells limit virus production and dissemination; together they protect against disease. Thus the preexisting antiinfluenza CTLs, although failing to prevent infection, may diminish the ensuing morbidity (disease) and mortality (death). CTLs also have been found against measles virus, mumps, respiratory syncytial virus (RSV), and other agents. In patients with AIDS-related complex and AIDS, CTLs are detectable against gag, pol, and env proteins. CTLs to env correlate with clearance of initial viral load, and their absence heralds a return to high viral titers and AIDS. Antigen-specific recognition mediated by the TcR initiates a series of events including signal transduction across the cell membrane, which activates the $CD8^+$ T cell's effector functions. Several mechanisms have been proposed to explain the *in vivo* antiviral effects of virus-specific $CD8^+$ T cells.

CTLs Usually Release Perforin, a Pore-Forming Protein

CTLs contain granules, which align with the target cell upon recognition, and whose contents are released in a calcium-dependent manner onto the target cell membrane. These granules include a protein called perforin (183), which undergoes assembly into trans-membrane pores and thus punches holes in the cytoplasmic membrane of the target cell. Perforin shares immunological cross-reactivity with the C9 component of complement, and cloning of the murine perforin gene has allowed identification of a short stretch of amino acid homology between the two proteins. The membrane lesions caused by perforin are similar to those induced by the complement C9 complex. Thus CTLs and complement-mediated lysis seem to share one common mechanism of action. The importance of perforin in CTL activity *in vivo* has been demonstrated. Transgenic mice with a dysfunctional perforin gene are much less effective in controlling

infection by some (though not all) viruses (94,95,262).

CD8+ T Cells Can Induce Apoptosis in Target Cells

Apoptosis, or programmed cell death, is a well-recognized phenomenon responsible for several developmental processes, including the clonal deletion of T cells in the thymus. Its most characteristic features are nuclear blebbing and disintegration, resulting in a nucleosome stepladder of fragmented DNA. $CD8^+$ (and sometimes $CD4^+$) T cells can induce apoptosis when the fasL protein, expressed on the T-cell membrane (237), interacts with Fas protein on the target cell, initiating a signaling cascade which ends in target cell apoptosis. Virus-specific T cells may induce this process in infected target cells (220,269,287). A graphic representation of CTL–target cell interactions is provided in Fig. 3. In panel A, the CTL (small cell, bottom of panel) has just encountered a larger target cell expressing the appropriate peptide/MHC class I complex. Within minutes, the target cell contracts (B), and extensive membrane blebbing occurs (C). An electron micrograph shows the target cell membrane studded with pores, after CTL contact and perforin release (Fig. 3D).

CD8+ T Cells Release Antiviral Cytokines

Many $CD8^+$ T cells are capable of releasing high levels of cytokines, for example, interferon-g (IFN-g) and tumor necrosis factor-a (TNF-a). Mice lacking the IFN-g receptor have increased susceptibility to several infections, despite apparently normal CTL and Th responses (83). It has been cogently argued that a major role of the TcR/MHC/peptide interaction is simply to hold $CD8^+$ T cells in the immediate proximity of virus-infected cells, thus focusing cytokines on the infected cell (193,209), and convincing data from mice persistently infected with LCMV (168,242), from hepatitis B virus (HBV) transgenic mice (66,67), and from HBV-infected primates (68) has shown that viral materials can be eradicated *in vivo* from neurons (168,242) and hepatocytes (66,67) in the absence of cytolysis. We have recently shown that, even at the peak of the immune response, the great majority of virus-specific $CD8^+$ T cells are not producing cytokines; however, these virus-specific cells are exquisitely sensitive to antigen contact, initiating cytokine synthesis immediately upon encountering an infected cell, and terminating production the instant the contact is broken (225). This tight regulation is important because cytokines can be toxic to the host, and indeed, systemic cytokine release is responsible for many of the symptoms of microbial infection, and for the extensive weight loss seen in certain cancers.

Natural Killer Cells

Although our understanding of NK cells is in its infancy compared with that of T cells, significant advances have been made in the last 2 years (195). NK cells play an important role in the control of certain virus infections, as established by clinical studies in humans and experimental manipulations of mice. NK cell development normally occurs extrathymically; these cells are not antigen specific and therefore do not exhibit immunological memory. NK cells carry several non–antigen-specific receptors, through which they can be activated by a variety of mechanisms (112), and they kill susceptible target cells by perforin-mediated lysis. In addition to receptors through which they are activated, NK cells carry inhibitory receptors whose engagement with a specific molecule on a non-susceptible target cell *prevents* the NK cell's effector function. What might this inhibitory ligand be? Early work showed that NK cells had somewhat varied specificities (270) and could very effectively lyse target cells lacking MHC class I (265). Incubation of target cells with IFN-g increased their sensitivity to CTL, but diminished their sensitivity to NK cells (268). In 1990, the “missing self” hypothesis was proposed, which argued that NK cells are inhibited by the presence of self MHC class I, and that the absence of such molecules permits target cell lysis by NK cells (126). This is an intrinsically attractive idea, for the following reason. As stated earlier, MHC class I is vital to the control of most virus infections (and also for eradication of many tumors), and one might imagine that viruses (or tumors) that could down-regulate MHC expression would be at a selective advantage. However, such down-regulation, while protecting the cells from $CD8^+$ T cells, would make the cells more sensitive to NK-mediated lysis. Thus NK cells and antigen-specific $CD8^+$ cells together span the MHC expression spectrum.

Early studies of NK receptors and ligands were somewhat confusing, showing that only certain class I MHC molecules could inhibit recognition by certain NK cells (i.e., there was some form of MHC restriction, albeit different from that involved in T-cell recognition). These studies have been borne out, and greatly extended, by the identification of three families of inhibitory receptor proteins on NK cells, and of the target molecules with which they interact. The three NK inhibitory receptor families are (a) the CD94-NKG2 family (common to humans and rodents), (b) the Ly49 family (only in rodents), and (c) the KIR family (killer inhibitory receptor, only in humans) (112).

The first two families are members of the C-lectin superfamily and lie in an “NK complex” on mouse chromosome 6 or human chromosome 12. Despite being in the same superfamily, these two families are quite distinct. The CD94-NKG2 proteins are expressed on the NK cell surface as heterodimers of the monomorphic CD94 molecule (encoded by a single gene in the NK complex) along with one of the products of the four NKG2 genes.

In contrast, the mouse Ly49 locus contains at least nine genes, and the protein products are expressed on the cell surface as homodimers. As yet there is no evidence to suggest that different Ly49 alleles can interact to form a heterodimer, but the polymorphism of the Ly49 homodimers is increased by alternative splicing.

The KIR family is a member of the Ig superfamily, and probably includes about 12 genes; mouse equivalents have not been found. The target cell ligands with which these receptors interact are varied.

1. CD94-NKG2 receptors in humans interact mainly with the MHC class Ib molecule HLA-E (23) which, as described earlier, carries in its groove a peptide from the leader sequence of classical class I MHC proteins. Because the leader peptides vary slightly, it is possible that each different peptide/HLA-E combination is recognized by only one of the four NKG2 gene products (in association with CD94). In the majority of cases, these interactions inhibit NK cell activity (although, to complicate matters, there are reports that certain interactions can stimulate NK effector functions).

2. At least some of the Ly49 proteins interact with sites on the a1 or a2 domains of classical MHC class I molecules in mice. For example, Ly49A recognizes H-2D^d and H-2D^k, whereas Ly49C may recognize several ligands on the H-2b and H-2d backgrounds (24). The importance of MHC-bound peptide in these interactions is somewhat unclear.

3. Most of the KIR proteins interact with the a1 domain of the classical HLA class I molecules HLA-A, -B or -C, and some reports suggest that the MHC-bound peptide may alter NK recognition. Recent data (191) suggest that one of the KIR proteins is the NK receptor that interacts with HLA-G, which, as stated earlier, is expressed extensively at the fetal/maternal interface.

Thus the target cell ligands for all three NK receptors families appear to be MHC class I molecules of one sort or another, consistent with the missing self hypothesis. However, individual NK cells express on average five of the possible receptors (250), and different NK cells in an individual can express different receptor subsets. The regulation of NK receptor expression is poorly understood, and several conflicting hypotheses exist, comparison of which is beyond the scope of this chapter. Perhaps the most popular idea is the “at least one” hypothesis, which dictates that NK cells will (perhaps randomly) express one receptor, then a second, and so on, until at least one receptor has been expressed which can interact with a self MHC molecule, thus ensuring that the NK cell will not attack the host. In this model, the expression of an NK receptor able to interact with self MHC will then prevent the subsequent expression of still more NK receptor types. Consistent with this, NK cells in MHC-deficient mice expressed a wider variety of NK receptors.

Definitive studies on the role of NK cells in viral infections have been performed in the mouse model. Depletion of NK cells *in vivo* by administration of anti-NK cell antibodies leads to enhanced synthesis of some viruses, such as MCMV and VV, but not of other viruses, such as LCMV (266). NK cell–mediated resistance to MCMV is particularly profound. An age-dependent resistance to MCMV occurs in mice at about the third week of age, and coincides with the maturing NK cell response. Furthermore, adoptive transfers of NK cells into suckling mice protect them from severe MCMV infection. Lymphokine-activated killer (LAK) cells, which are NK cells highly activated by growth in culture in the presence of interleukin-2 (IL-2) and which have been used in a variety of clinical and animal model tumor therapy protocols, protect suckling mice against MCMV. The presence of prolonged NK cell activity during persistent infections may select for NK cell–resistant viruses; establishment of a persistent infection in severe combined immunodeficient (SCID) mice with an NK cell–sensitive variant of Pichinde virus resulted in the conversion of the virus into an NK cell–resistant genotype(s). The related arenavirus, LCMV, normally causes a persistent infection in mice in nature and is also NK cell resistant.

In general, NK cell activity peaks earlier than that of T cells (2–3 days) and diminishes rapidly thereafter. Clinical correlations have been observed between decreased NK cell activity as a consequence of disease or drug therapy and susceptibility to infections with HCMV and HSV-1. Examples of individuals with complete NK cell defects are rare, perhaps attesting to the importance of NK cells, but one adolescent with a complete and selective deficiency in NK cells presented with unusually severe infections with VZV, HCMV, and HSV-1 (17). Although the VZV and HCMV infections were life threatening, each infection resolved completely, probably because T-cell and B-cell immunity was normal in this individual.

We have now reviewed the most relevant aspects of cellular immunity, including T cells and NK cells. At this point, it is appropriate to present a tabular summary of the antigen-presenting molecules, the elements presented, the responding cells, and the nature of the responding cells' receptor (Table 2).

Presenting Molecule	Antigen Presented	To (Cell Type)	Responding Cell's Receptor
MHC class Ia	Peptide	CD8$^+$ T cells	Normal TcR
	Glycopeptide	CD8$^+$ T cells	Normal TcR
	Peptide (?)	NK cells	Ly49 and KIR families
MHC class Ib			
HMG	Formylated peptide	CD8$^+$ T cells	Normal TcR
HLA-E	Peptide from class Ia leader	NK cells	CD94/NKG2
HLA-F	Unknown		
HLA-G	? Fetal/maternal peptides	? NK cells	? Specific KIR
HLA-H	No immune function		
MHC class II	Peptides	CD4$^+$ T cells	Normal TcR
CD1	Microbial lipid & glycolipid	CD8$^+$ T cells	Normal TcR
	Glycosylceramide (self)	NK T cells	TcR of limited polymorphism

TABLE 2. *Summary of antigen-presenting molecules, the materials presented, the cells that recognize them, and the cells' receptors*

Antibody-Dependent Cell-Mediated Cytotoxicity

Antibody-dependent cell-mediated cytotoxicity (ADCC) may be mediated either by T lymphocytes or by NK cells. In the latter case, the antibody, usually IgG, is specific for a structure on the target-cell membrane. The antibody “coats” the target cell, and the NK cell then attaches by its Fc receptors, triggering release of perforin, and target cell death. ADCC can be brought about in a different way if the target cell bears Fc receptor. Incubation of uninfected cells with antibody to either the CD3 complex or the TcR idiotype itself causes a cytotoxic lymphocyte to attach to the target cell and lyse it. Note that in both cases, the specificity is conferred on the reaction by antibody; in one instance, the antibody is target cell specific, whereas in the other, it is effector cell specific. Although ADCC can commonly be identified *in vitro,* its contribution *in vivo* is still not known.

Macrophages

Mononuclear phagocytes (blood monocytes, tissue macrophages) are principal cellular players in the clearance and inactivation of most microbial pathogens. Interestingly, these same cells also represent a major target cell and infectious reservoir for many viruses that persist [e.g., measles, lentiviruses, and cytomegaloviruses (45,93,227), and see relevant chapters in these volumes]. There are at least four complications of infection of these cells. First, infectious virus can be transported by these cells to distant parts of the body where infection can continue.

Second, activated monocytes/macrophages are APCs, taking up, processing, and delivering viral antigens to T cells in regional lymph nodes (62,211). *In vitro* studies indicate that activated macrophages are 10- to 100-fold less efficient in antigen presentation compared with the major professional APC, the dendritic cell (see later), but are 10 to 100 times more efficient than antigen-presenting B cells. During certain virus infections, their ability to present antigens, or to initiate immune responses, can be compromised.

Third, viruses can interfere with the macrophage's capacity to degrade other microbial agents. For example, the microbe *Histoplasma capsulatum* normally replicates in quiescent macrophages, and is degraded upon macrophage activation. Activation depends, in part, on IFN-g. In a model system, persistent infection of macrophages by lymphocytic choriomeningitis virus clone 13 prevented IFN-g activation of macrophages; as a result, the mice succumbed to a normally sublethal dose of *Histoplasma* (257). This may be one reason that a number of virus infections are associated with secondary infections by microbes that are usually phagocytosed and inactivated by macrophages.

Fourth, the infection of macrophages or microglia (brain cells of macrophage lineage) can lead to pathology. For example, HIV primarily infects microglia in the central nervous system (CNS) (275) and indirectly, presumably by release of cytokines and perhaps other toxic molecules, leads to neuronal dysfunction mirrored clinically as AIDS dementia (123). Macrophages also can restrict virus infection or replication by acting as nonspecific effector cells for ADCC. The outcome of a macrophage–virus interaction is determined by a complex series of reactions that may dramatically affect the ability of macrophages to act as scavenger cell, immune effector cell, or susceptible target cell for virus replication. Mononuclear phagocytes have a vigorous phagocytic ability enabling them to eliminate virus from the circulation after a blood-borne infection. Their scavenger function constitutes an early line of defense for reducing the virus load either initially or in concert with the specific immune response. Monocytes and macrophages also can initiate a series of immune reactions through the cytokine network (see later) that assists or injures the host. Macrophages may be activated for enhanced antiviral activity by cytokines produced by virus-specific T cells.

Dendritic Cells

Recent attention in virology and immunology has focused on the dendritic cell. These are bone marrow–derived cells that are located in blood and lymph as well as in most tissues. They include Langerhans cells in the skin and mucous membranes, dermal dendritic cells, tissue-resident dendritic cells, and interdigitating dendritic cells in the thymic medulla, splenic white pulp, and lymph nodes (9,62,107). Activated dendritic cells express high levels of MHC molecules (classes I and II) together with accessory (co-stimulatory) molecules (e.g., CD80, CD86, CDIA, CD83) and, by producing a variety of chemokines, attract naive T cells. Infection or inflammation leads to the maturation of immature dendritic cells. For example, after a respiratory virus infection, immature dendritic cells lining the respiratory mucosa are infected, become activated, and carry viral antigens to T cell–dependent areas. These cells now appear as interdigitating dendritic cells and efficiently stimulate naive T cells, producing antigen-specific responses. *In vitro* studies show that only a few dendritic cells are required to provoke strong T-cell responses; for example, one dendritic cell can stimulate 10^2 to 3×10^3 T cells in a mixed lymphocyte reaction. Recent *in vivo* evidence revealed that adoptive transfer of only 10^2 to 10^3 activated dendritic cells to an immunologically naive animal could generate $CD8^+$ CTL-mediated protective immunity. In this study, transferred dendritic cells expressing an LCMV CTL epitope transgene were able to induce $CD8^+$ CTLs that were protective as early as 2 days after immunization, and lasted for at least 60 days (128).

Because dendritic cells play a primary role in the initiation of antigen presentation leading to immunity, a number of viruses can be expected to have evolved mechanisms to exploit these cells. The two best examples are HIV and LCMV. In the case of HIV, two conflicting events occur. First, it is likely that dendritic cells in the mucosal membrane are infected initially by HIV and migrate to lymphoid organs where effective presentation of HIV antigens triggers both $CD8^+$ and $CD4^+$ T-cell responses for the host's benefit. However, concurrently the dendritic cell has transported live HIV into lymph nodes, where it is believed to contribute to the spread of virus to $CD4^+$ T cells (107). LCMV has a different strategy. LCMV Armstrong clone 13 causes immunosuppression in adult mice (20) by preferentially replicating in the interdigitating dendritic cells in the T cell–dependent (white pulp) area. This leads to an early host antiviral $CD8^+$ T-cell response, which then destroys these infected professional APCs (an example of immunopathology). The result is generalized host immunosuppression. Evidence is accumulating that other viruses also can infect dendritic cells and alter their function, with resulting immunosuppression. Currently these reports are restricted primarily to *in vitro* studies, and *in vivo* confirmation is needed (for example, in measles virus/dendritic cell interactions) (104). However, owing to the olympian properties and role played by dendritic cells in acquired immunity, it is reasonable to predict that more examples of virus manipulation of dendritic cells will emerge. Furthermore, it seems likely that dendritic cells (or viruses that home to them) will prove useful for immunization.

CYTOKINES

Cytokines (for the purpose of this chapter, lymphokines and monokines) are proteins made by cells of the immune system, usually during cell activation. As soluble factors, they assist in regulation of the immune response and in elimination of viruses and other pathogens. Their activities and structure are reviewed elsewhere in this volume. Immune responses to particular antigens or microbes are often distinguished by a relatively distinct pattern of cytokines production by $CD4^+$ Th cell subsets. This in turn drives the immune system toward a predominant cell-mediated or humoral immune response (144). The subsets have been described in humans and mice. Th1 cells secrete IL-2, IFN-g, and lymphotoxin. They promote CTL-type and other delayed-type hypersensitivity reactions frequently required for clearance of intracellular organisms. Th2 cells produce IL-4, IL-5, IL-6, IL-10, and IL-13. They promote allergic-type

responses and stimulate the differentiation of B lymphocytes, mast cells, and eosinophils. The role and balance of Th1 and Th2 cells and their cytokines in viral infections is believed to be important in pathogenesis and immunity. Viruses themselves can use cytokines, or cytokine homologs, to their own advantage. Certain viruses contain genes encoding cytokine homologs, the expression of which potentially enables the viruses to modify immune responses to their own advantage. Some examples are provided later in this chapter. In addition, cytokines released from T cells, especially IFN-g, have been implicated in clearance of virus from infected cells in the absence of $CD8^+$ T cell–mediated lysis (30,67,168,242).

HUMORAL EFFECTOR MECHANISMS

Generation of B-Cell Responses and Antibody

The B-cell receptor for antigen is Ig, which is initially expressed as a membrane protein. The structure and genetics of Ig are well defined and were described earlier. During their development, B cells initially express IgM on their surface, followed by expression of different H chain classes IgG(g), IgA(a), or IgD(d). IgM and IgD may be expressed in all B cells, but once a cell has expressed an H chain class other than IgM, it remains committed to secrete that class of Ig. When a B cell encounters antigen, it usually differentiates into a mature plasma cell, secreting specific antibody as a single Ig class; memory B cells also are generated. This differentiation of B cells is controlled by specific B-cell growth and differentiation factors produced by T cells, analogous to the factors involved in the differentiation of T cells themselves. It has been suggested that B-cell responses to some viral antigens are more brisk than are those to isolated antigens because of the densely packed, paracrystalline nature of certain viral structures (284). Antibodies of all classes are usually generated in response to virus infection.

How Do the Various Antibody Classes Exert Their Antiviral Effects?

Antibodies neutralize viruses in a number of ways.

1. They may bind to the part of the virus that interacts with its cell-surface receptor, preventing virus attachment to the cell.
2. They may agglutinate many infectious particles into a single “clump,” thus reducing the number of cells that will become infected.
3. They may bind to virus glycoproteins on the cell surface, lysing the infected cell in association with complement, or modulating the intracellular viral replication.
4. Viruses may activate complement, releasing chemotactic factors such as C5a or C3q.

Recent animal experiments studying the effects of antiviral monoclonal antibodies on a wide variety of DNA and RNA infections have led to a new and important conceptual distinction between *in vitro* neutralization and *in vivo* protection. First, monoclonal antibodies that do not neutralize *in vitro* may nevertheless afford protection on *in vivo* transfer. Second and conversely, antibodies that have high neutralizing activity *in vitro* may not provide protection when adoptively transferred *in vivo.* Nevertheless, *in vitro* studies have provided much information regarding the probable mechanisms underlying the antiviral efficacy of each antibody class, and there often is a correlation between *in vitro* and *in vivo* efficacy. Note that intact antibodies are not a prerequisite for antiviral effectiveness; Fab fragments specific for RSV F glycoprotein, when instilled into the lungs of infected mice, were therapeutically effective (34). Such approaches hold promise, particularly in light of recent advances in technologies that allow the rapid production of antibodies of any desired specificity (10,97).

Immunoglobulin A

During natural infection, most viruses gain entry via mucosal surfaces, so it is not surprising that mucosal immunity plays an important role in control of viral infections (158). Development of mucosal immunity and secretory IgA are important in preventing mucosally restricted viral respiratory and enteric infections, and virus-specific circulating antibody plays an important role in limiting viremia and thereby aborting spread of virus to systemic sites. For successful induction of a secretory IgA response in the gut, virus must come into contact with a Peyer's patch, the gut-associated lymphoid tissue. Once a local response has been generated, IgA-producing memory B cells recirculate to other areas in the gut. This has been demonstrated in humans by using oral polio vaccine. The protective effects of IgA are usually attributable to antibody directly preventing virus binding to the mucosa. The approaches and concepts are discussed in detail elsewhere in this volume.

Immunoglobulin G

There are several IgG subclasses in humans and mice. For example, human IgG falls into four subclasses (IgG1, IgG2, IgG3, and IgG4), which normally constitute 70%, 20%, 8%, and 2% of the total IgG, respectively. However, IgG subclass–specific antiviral antibodies are generated in different amounts in acute or persistent infections. For example, IgG1 is the dominant IgG isotype found in HIV-infected individuals during the quiescent stage of disease, but it declines in those with progressive illness, perhaps because of a decrease in $CD4^+$ T-helper cells. IgG1 is the major complement-binding and opsonizing antibody in humans (231), and in patients recovering from acute hepatitis B virus infection, IgG1 and IgG3 dominate, with a switch from IgG3 to IgG4 (a non–complement-binding antibody) during chronic infection. IgG1 in humans corresponds to mouse IgG2a (major complement-binding and opsonizing antibody). In experimental mouse infection with LCMV, IgG2a antibody is the predominant isotype raised in acute infection with subsequent viral clearance (>90% of IgG isotype). However, during persistent LCMV infection, there is a switch to more than 90% of IgG1, a non–complement-binding antibody (243). This switch may be related to activation of different Th subsets and the cytokines they produce: in the mouse, IgG2a is associated with the Th1 subset (IFN-g, IL-2, and lymphotoxin production), whereas IgG1 is associated with the Th2 subset and low levels of IFN-g. Complexing of viruses with IgG antibody also will facilitate their phagocytosis by mononuclear cells and polymorphonuclear leukocytes via Fc receptors on these phagocytic cells. However, this latter process may actually enhance the infectivity of some viruses

(185). Sindbis virus infection of mice provides an interesting animal model demonstrating the antiviral effect of IgG. Sindbis virus, an alphavirus, can establish persistent infection of mouse neurons. Because neurons express little or no class I MHC (88,89), the virus is effectively hidden from $CD8^+$ T cells, but infusion of antiviral antibodies, or even of antiviral Fab'_2 fragments, clears virus infection almost entirely (118). The mechanism is unclear, but may involve modulation of viral replication, as demonstrated for measles virus in tissue culture (171).

Immunoglobulin M

This pentameric, decavalent molecule is produced early after virus infection, is usually independent of T-cell help, and acts as the initial antibody-mediated antiviral response. Later in infection, and on secondary exposure, most IgM-producing cells switch classes to IgG but retain antigen specificity. There is good *in vitro* evidence that IgM is effective in neutralizing the infectivity of virus in the fluid phase. This may result from the antibody preventing virus attachment to specific cellular receptors and from the aggregation of virus particles, thereby reducing the number of infectious particles.

Immunoglobulin E

IgE antibody is present at low concentration in serum; its principal biological activity appears to be mediated by binding to mast cells via specific receptors. When antigen reacts with the cell-bound IgE, inflammatory mediators are released from the mast cell. This IgE-dependent mechanism accounts for several of the clinical features of allergy, including wheezing with respiratory infections and pharmacologic relief with antihistamines. There has been little study of the antiviral IgE response or of the molecular mechanism(s) underlying its role in clinical disease.

Role of Complement

The human complement system comprises more than 20 plasma proteins, and most aspects of their interaction are now well understood (27,145). The classical pathway of complement is activated by the C1 macromolecule binding to IgG or IgM complexed to antigen. Attachment occurs via the Fc portion of Ig interacting with the C1q subunit of C1. C1r and C1s, two highly specific serine proteases, become activated in this process. C1s sequentially cleaves C4 and C2 with resultant assembly of C4b2a, the C3-cleaving enzyme or convertase of the classical pathway. C4b binds covalently to the target, whereas C2a carries the catalytic domain. The activity of C4b2a is restrained by the lability of C2b and to a lesser extent by specific regulatory proteins that inactivate C4b (these are the C4-binding protein and factor I). The more recently discovered mannan binding or lectin pathway of complement activation is similar to the classical pathway, except that it is triggered by the interaction of mannan- or lectin-binding proteins with sugars on microorganisms. A distinct plasma protease, analogous to C1s, is used to cleave C4 and C2.

The major difference involved in the initiation of the alternative, or amplification, pathway of complement activation is that it does not depend on antibody. The internal thioester linkage of C3 undergoes slow spontaneous hydrolysis in plasma, producing a C3b-like molecule. Although most of these C3b-like molecules are rapidly inactivated by factor H and factor I, some may bind directly to a target, and a proportion interact with factors B and D to form a C3-cleaving enzyme. The C3b generated by this transient fluid phase C3 convertase can then bind to surfaces. Most so-called “activators” of the alternative pathway, such as microbes and foreign surfaces, lack the membrane regulatory proteins expressed by host tissue. Therefore deposition of C3b on their membranes can trigger the alternative pathway. One property shared by activators of the alternative pathway, which are mostly particulate, is that when C3b is deposited on their surface from the fluid phase, it is relatively protected from inactivation by factors H and I. This protected C3b covalently attached to a target can then bind factor B, which is cleaved by factor D (a 25-kd serine protease in plasma) to give C3bBb, the C3-cleaving enzyme of the alternative pathway. This convertase has its catalytic site on the Bb fragment and decays rapidly, but the half-life of the enzyme is prolonged by properdin, which binds to the enzyme complex and retards this decay. An important point about the alternative pathway is that C3b, however generated (whether by the classical pathway, spontaneous hydrolysis, or cleavage of C3 by other proteolytic enzymes), serves to initiate the amplification of C3 cleavage. Thus the presence of an activator surface, lacking membrane regulators, unleashes a powerful biological positive-feedback loop. This emphasizes the importance of the regulatory proteins in the fluid phase and on cell surfaces, without which trivial amounts of C3b would result in unrestrained activation of the pathway, even in the absence of an activator surface. After cleavage of C3, additional C3b molecules may be incorporated into either C3bBb or C4b2a, giving C3bnBb or C4b2a3b; these complexes have C5-cleaving activity and are called C5 convertases. After C5 cleavage, sequential nonenzymatic binding of C5b to C6, C7, C8, and five to 10 C9 molecules results in assembly of the C5b-9 terminal complex. This membrane attack unit inserts into the lipid bilayer of cell membranes, where it can lead to osmotic lysis. By electron microscopy, the familiar lesion is visualized as a doughnut-shaped pore, and is similar to the lesion caused by CTL and NK cells when they release perforin, a protein with homology to C9.

In addition to the proteins of the classical and alternative pathways and the C5b-9 membrane attack complex, the complement system also includes cell-surface molecules that specifically bind activated or cleaved complement molecules in a receptor-mediated manner. These include receptors for C3b (CR1, CD35), iC3b (CR3, Mac-1, CD11b/CD18), and C3dg (CR2, CD21). The complement system is regulated by a number of plasma proteins (factors H and I, C1 inhibitor, C4-binding protein, S protein) and cell-membrane proteins [CD46 or membrane cofactor protein (MCP), CD55 or decay accelerating factor (DAF), and CD59, the membrane inhibitor of the membrane attack complex]. These regulatory molecules restrict inappropriate complement activation by sequestering activation fragments and/or facilitating their inactivation. The regulatory molecules do not block appropriate complement activation. They do, however, prevent chronic activation and restrict inappropriate activation (e.g., in plasma or on autologous tissue).

The major function of the complement system is to modify foreign membranes by opsonization or, less commonly, by lysis. Its second function is to promote the inflammatory response. Low-molecular-weight cleavage fragments (e.g., the C3a and C5a anaphylatoxins) induce chemokinesis and chemotaxis, mast cell degranulation, and other types of cell activation.

Complement is involved in innate as well as adaptive immunity. Complement enhances the neutralization of viruses by antibody. This is achieved by at least four different mechanisms. First, complement can blanket the sensitized (antibody-coated) virion, thus rendering it incapable of binding to its receptor. Second, complement can aggregate or clump sensitized virions, thereby reducing the number of infectious units. Third, by incorporating C3b into virus/antibody complexes, such sensitized virions can bind to C3b receptors on phagocytic cells, leading to their ingestion and degradation by these cells. Fourth, antibody and complement can directly lyse viruses possessing a lipid envelope. Complement likely plays an important role early during infection when small amounts of low-avidity antibody are made. [For a comprehensive review of the area, the reader should consult reference (78)]. Complement alone can inactivate certain viruses directly in the absence of antibody. Retroviruses from several species are lysed by human complement, in association with an anti-a-galactosyl natural antibody (206,267). This occurs because a viral protein alone (rather than an Ab/Ag complex) can act as a receptor for C1q. The alternative pathway of complement can be activated on the surface of a variety of microorganisms, including bacteria and yeasts. Thus an additional principal function of the complement pathway is as a nonspecific mechanism of host defense, capable of opsonizing or lysing a variety of microorganisms before the generation of specific immune responses. Hence it is not surprising that some viruses, notably the pox and herpes families, contain genes that interfere with selected complement molecules (36,127,226). Finally, at least three of the complement proteins are used as receptors by viruses. These include the C3d receptor (CR2 or CD21) used by EBV (47,90,154), the CD46 protein or MCP used by measles virus (41,131,151), and DAF, which appears to be used (probably as a co-receptor) by coxsackieviruses (15,215) and echoviruses (14). It is not known whether using complement proteins as a receptor confers any selective advantage to the virus. Possibilities include cell signaling via the complement protein, or protecting itself from complement attack.

Lysis of Virus-Infected Cells by Antibody and Complement

Antibody and complement can kill virus-infected cells *in vitro.* A variety of human cell lines (epithelioid, neural, and lymphoid) infected with a wide variety of human DNA and RNA viruses and expressing viral antigens on their surfaces are lysed by human serum when it contains both specific antibody to the virus and functional complement. Here, lysis appears primarily dependent on an intact alternative pathway of complement (33,223). A detailed analysis of this system using measles virus–infected cells as a model showed that the infected cell activates the alternative pathway in the absence of antibody, but that antibody is needed for lysis to occur. Despite the activation of the alternative pathway being independent of antibody, IgG enhances C3 deposition and thus facilitates lysis. The involvement of multiple cell types and viruses in similar events indicates the generality of the phenomenon. Although it is difficult to quantitate this mechanism *in vivo,* it is likely that cellular injury can be produced by antibody and complement *in vivo.*

Idiotypes and the Network Theory

The antigen-combining site of each Ig molecule itself represents a novel antigenic determinant known as an idiotype. Idiotypes can be recognized by other antibodies, and these latter “anti-idiotypic” antibodies often represent an “internal image” of the antigen to which the original antibody (bearing the idiotype) was directed. The “network theory,” formulated by Jerne (86), and for which he received the Nobel prize, stated this concept and extended it to view the whole immune system as a network of interacting idiotypes and anti-idiotypes. Simply put, all antibodies are anti-idiotypes, which also react with specific external antigens. When external antigen enters the system and produces expansion of specific clones of cells being particular idiotypes, the system is perturbed, and expansion of anti-idiotypic, anti–anti-idiotypic antibodies, and so on ensues. These were postulated to play a regulatory role in modulating the immune response. The same principles would apply to TcRs, which also bear idiotypes. These ideas have stimulated much current research. Anti-idiotypic antibodies have been demonstrated in some human autoimmune diseases and infections.

Does the network theory have any specific relevance for virus infections? Apart from their regulatory role in the immune response, anti-idiotypic antibodies that have the “image” of antigen may compete with that antigen for specific cellular receptors. For example, anti-idiotypic antibodies raised against antibody to reovirus glycoprotein can prevent the adsorption of the reovirus to its specific receptor on the cell surface, presumably because the anti-idiotype can itself bind to the receptor. In addition, anti-idiotype antibodies (which look like the original antigen) have been used as vaccines, because they induce anti–anti-idiotype antibodies, which can cross-react with the microbe, thus avoiding inoculation with the microorganism.

VIRUS STRATEGIES TO EVADE THE HOST IMMUNE RESPONSE

Viruses are relatively unstable outside a competent host, and for a virus to remain in circulation, it must be able to move efficiently among different hosts and/or to persist in an individual host. The virus' ability to evade host immunity is critical to the virus' survival both in the population and in the individual. For example, if there is widespread immunity in a population, a virus able to evade that pre-existing immunity will have an increased pool of susceptible targets. In the individual host, evasion of immunity is necessary to permit virus persistence, and immune evasion also may allow the virus to replicate to higher titers in the host, perhaps increasing its chance of transmission to a susceptible recipient.

Virus-induced immunosuppression is often directed against that component of the immune response which is most important in limiting the virus infection. For example, influenza viruses are highly sensitive to neutralizing antibodies, and this virus provides one of the best examples of antibody evasion; HSVs are controlled in large part by T cells, and HSV can inhibit antigen presentation by MHC class I; and NK cells combat primary cytomegalovirus infections, and this virus encodes an MHC homolog which may inhibit NK activity. These observations underline our contention that the intimate relationships between viruses and host immunity has been central to the evolution of both protagonists.

As with our overview of the immune response (Fig. 1), the array of viral evasion mechanisms could be categorized in a number of ways. We have chosen to classify the viral strategies as either “avoidance” (in which the virus “hides” from host immunity but does not actively interrupt it) or “inhibition” (in which the virus actively disrupts host immunity). This classification (the various underlying mechanisms of which are summarized in Table 3 and are discussed later) may have

some clinical significance, because the active inhibition of immunity may have serious consequences for the host.

Evasion Technique	Mechanism
Avoidance: Virus hides from the immune system but does not actively disturb host immune responses	Infection of immune privileged sites Down-regulation of viral gene expression Virus protein structure limits its immunogenicity Mutation or reassortment of genetic material
Inhibition: Virus inhibits either the induction or the effector phase of the immune response	Infection of thymus, leading to deletion of high-affinity T cells (negative selection), inducing partial tolerance Destruction of specialized APCs Inhibition of antigen presentation Expression of proteins that inhibit effector-cell function Expression of proteins that delay target-cell death Infection of T or B lymphocytes

TABLE 3. *Overview of how viruses can evade the host immune response*

Evasion by Avoiding the Immune Response

Infection of Immune-Privileged Sites

Certain regions of the body appear to be immune privileged, that is, not subject to the same rigorous immune surveillance as most somatic sites. Examples include the anterior chamber of the eye, perhaps because immune infiltration would be catastrophic to vision. Of all somatic cell types, perhaps we can least afford the wholesale destruction of neurons, which not only subserve critical functions, but also have very limited regenerative capacity. The CNS is protected by the blood–brain barrier, and has long been considered relatively immune privileged, but it is clear that it is accessible to activated T cells and cellular immunity and, if injured, to the passage of antibodies. Perhaps in part to ensure that neurons are less susceptible to immune-mediated destruction, they are one of the few somatic cell types that do not express class I MHC (88,89). Viruses have been quick to take advantage of this, and many viruses can infect neuronal cells (for example, polioviruses, coxsackieviruses, mengoviruses, LCMV, measles, alphaviruses). Several virus families have further exploited the loophole by using neurons as their site of persistent infection or latency. The best-characterized example, albeit still incompletely understood, is the herpesvirus family, several members of which (HSV, VZV) establish latent infection in sensory nerve ganglia. The costs and benefits of low neuronal class I expression have been recently reviewed (192).

Down-Regulation of Viral Gene Expression

How might viruses hide within cells that express class I MHC? Viruses may selectively reduce the level of expression of cell-surface glycoproteins, sometimes down-regulating them manifold in comparison with other, non-surface, viral products (169). This may help evade antibody-mediated detection, but, as has been stressed throughout this chapter, the detection of intracellular viral proteins is the major remit of T cells, in concert with the MHC. Thus the major problem facing intracellular virus is the evasion of this aspect of the host's detection systems. T-cell recognition requires as few as 1 to 100 MHC/peptide complexes to be displayed on the target cell, and this can be achieved with low levels of protein expression; it may therefore be difficult for viruses to down-regulate expression to a level preventing MHC presentation. Some viruses, such as herpesviruses, may be able to shut down protein synthesis during latency in neurons, but this luxury is available to only a few virus families. The inability to terminate protein synthesis completely is, presumably, one of the selective pressures which has driven many viruses (including even HSV) to inhibit actively MHC class I antigen presentation, as discussed later.

Virus proteins may be refractory to immune recognition. Virus proteins have been honed by constant interactions with the immune system, and over the millennia, many immunogenic sequences doubtless have been hidden or lost; those sites still recognized may reasonably be considered the residue. The intrinsic structure of a virus protein can render the protein less digestible to some part of the MHC class I processing pathway; the Gly-Ala repeats of the EBV antigen EBNA-1 act in cis to render the protein relatively resistant to proteasomal degradation (119). Furthermore, post-translational modifications can play a role. Many potential antibody epitopes on viral glycoproteins are masked by the glycosylation event (although the virus pays the price of inducing carbohydrate-specific antibodies). Although some modified peptides [e.g., glycopeptides (230)] can be presented by class I MHC molecules, it is plausible to suggest that certain modifications might prevent the protein's presentation, even if they do not actively inhibit the cells' ability to process other antigens. Consistent with this, an HCMV matrix protein appears to selectively inhibit processing of HCMV IE proteins, perhaps by phosphorylation of the IE products (59).

Mutation of Viral Gene Sequences

RNA viruses may be at a particular advantage, because the high mutation rate of RNA polymerases provides a rich diversity of virus mutants from which variants can be selected.

Evasion of Antibody Responses by Gene Mutation

This strategy is best exemplified by influenza virus, which contains a segmented RNA genome encased in a viral envelope studded with influenza proteins [hemagglutinin (HA) and neuraminidase (N)]. These proteins are critical for binding to, and entry into, target cells, and are obvious targets for the host antibody response; the host takes full advantage of the opportunity by producing neutralizing antibodies targeted to both proteins. The virus responds by generating mutant HA and N sequences, thus providing itself with the opportunity to evolve. This evolution is driven by

two requirements: the mutant proteins must retain their function (i.e., the virus must be viable), but they should be able to escape detection by the pre-existing antibodies. The resultant virus often has fairly subtle immunological changes, but these are sufficient to give it a temporary edge in the battle; it may have an expanded pool of susceptible hosts, because it should be able to infect individuals carrying the original set of antibodies. This phenomenon has been termed antigenic drift and plays a role in influenza epidemics, which occur sporadically. The process of antibody escape through mutation of viral target proteins is not restricted to influenza virus. Examples have been found in almost all viruses in which they have been sought, and indeed the need to escape antibodies doubtless has driven the diversification of many viruses into the different strains or serotypes that we recognize today. When we categorize viruses by the antibodies that do or do not recognize them, we are simply using the results of this ongoing evolutionary interplay.

Evasion of T-Cell Responses by Gene Mutation

In a manner analogous to evasion of antibody responses, viruses can mutate those sequences presented to the immune system as T-cell epitopes. The process of viral mutation toward CTL escape has been less widely studied than the antibody equivalent. Mice immunized with a minigene vaccine encoding a single LCMV CTL epitope, and later infected with LCMV, rapidly generate LCMV variants in which the vaccine epitope has been mutated (263), and CTL escape variants of LCMV replicate to higher levels in the host, although the viruses are eventually cleared (120). Studies using HIV have shown that viruses can mutate *in vivo,* in a natural infection, into CTL escape variants (181), and that this escape has important biological consequences (21). Finally, evidence of CTL escape variants comes from studies of a specific CTL epitope in EBV, presented by the HLA-A11 allele. This epitope is present in EBV strains circulating in a population in which the HLA-A11 allele is infrequent, but is mutated in virus circulating in an A11-rich population, and cannot bind to the A11 molecule (37).

Wholesale Replacement of Viral Proteins

In addition to gene mutation, which many viruses exploit, influenza virus escapes host immunity by using a second method, which is available only to virus families with a segmental genome structure. The influenza virus genome has eight RNA segments, and during co-infection of a single cell by two viruses (1 and 2), the segments from both infecting viruses can mix (reassort). The majority of RNA segments in the resulting virus may come from virus 1, but (for example) its HA-encoding segment may come from virus 2. In nature, such molecular reassortment appears to take place in non-human hosts, most probably porcine or avian, when there is co-infection of a human virus (which will infect pigs or birds only rarely) and an avian virus. The biological consequences of this event are difficult to predict, but if one of the resulting reassortants carries the avian HA but is able to infect humans, this virus may be immunologically unknown to, and highly pathogenic in, humans. It appears likely that such antigenic shift is the cause of severe influenza epidemics and pandemics.

Evasion by Active Inhibition of Immunity

Viruses have a developed a plethora of approaches to actively inhibit the development of host immunity, as outlined in Table 3.

Thymic Infection May Induce Tolerance

If viruses infect the thymus, the viral antigen presented by MHC in the thymic stroma may cause clonal deletion of virus-specific T cells (i.e., the virus is viewed as self). Thus no virus-specific cells will exit the thymus, and neither antibody nor T-cell responses will be induced by viral challenge; there is no generalized immune suppression, and the inhibition of immunity will be specific to the infecting virus. Congenital infection of mice with LCMV results in thymic infection, which begins in the fetus and is maintained for the life of the mouse. The mouse is persistently infected and cannot mount an LCMV-specific $CD8^+$ T-cell response. If the virus is eradicated (e.g., by adoptive transfer of LCMV-specific $CD8^+$ T cells), then the ability of the host to mount LCMV-specific responses is restored (103), because the transferred CTLs remove thymic cells expressing viral peptide/MHC complexes, and naive host T-cell precursors bearing TcR with specificity for the virus/MHC complex will no longer be deleted, and instead mature and exit the thymus. Recent studies indicate that, despite viral replication in the thymus, negative selection may be incomplete, with virus-specific T cells escaping to the peripheral lymphoid organs, and antiviral antibodies being generated. This occurs experimentally in LCMV infection and may similarly occur in HBV carriers. In both instances, antiviral antibodies are generated, and CTL can be induced by vaccination (162,170,180).

Destruction of Specialized Antigen-Presenting Cells

Many viruses can infect specialized APCs (dendritic cells, macrophages), the destruction of which may lead to generalized immunosuppression. Infection of, or absorption to, follicular dendritic cells by HIV-1 has been demonstrated and was proposed as the underlying cause of the late immune failure that characterizes AIDS (179,264). Certain variants of LCMV rapidly infect interdigitating dendritic cells, the major APCs, and the resulting antiviral CTL response destroys APCs and causes a transient global immunosuppression (20,283) affecting both antibodies (143) and T cells.

Inhibition of Antigen Presentation

Rather than destroying the infected professional APCs, viruses may instead inhibit antigen processing, thus providing themselves with a safe haven in which to produce progeny. This would apply not only to virus-infected specialized APCs (which express MHC classes I and II) but also to somatic cells, which can present antigen only via the class I pathway. Given that the vast majority of virus-infected cells are somatic cells, not specialized APCs, one might predict that viruses would have developed more tricks to inhibit MHC class I presentation than to disrupt the MHC class II pathway; this is the case, as recently reviewed (139). Herpesviruses are particularly skillful, blocking the class I pathway at almost every stage (87). The HSV IE protein ICP47 binds to the cytosolic surface of TAP and inhibits transport of peptides into the ER (77), whereas the HCMV US6 protein binds to the luminal aspect of TAP, to similar effect (3). The HCMV US3 gene

product retains peptide/MHC complexes in the ER (91), and the US2 and US11 proteins cause rapid degradation of class I heavy chains by the proteasome (274). Finally, IFN-g–mediated stimulation of MHC expression is inhibited by MCMV (71) and HCMV (138). Similar strategies are found in other viruses. Adenoviruses encode a 19-kd protein that binds to class I MHC and prevents its transport to the cell surface (111,229), rendering the adenovirus-infected cell relatively refractory to T-cell recognition. Although most examples of antigen presentation blockade involve class I MHC, some viruses do appear to inhibit MHC class II; for example, the EBV BZLF2 gene product binds to the HLA-DR molecule, inhibiting MHC class II antigen presentation (234) [and aiding entry of the virus into B cells (121)], as does the CMV-induced defect in IFN-g signaling mentioned earlier.

Expression of Proteins That Inhibit Effector Cell Function

Many years ago, it was shown that the pathogenicity of vaccinia virus could be modulated by addition of a host cytokine gene such as IL-2 (194). It now transpires that several poxviruses needed no help from us; they encode their own cytokine homologs, which can modulate the immune response (32,233,235). In addition, EBV encodes a potent equivalent to IL-10 (82). Finally, the HCMV UL18 protein is an MHC class I homolog expressed on the cell surface in association with b_2M; some studies have suggested that this molecule can engage inhibitory NK receptors, protecting the cell from NK lysis (197), although this is controversial (117).

Expression of Proteins Which Delay Target Cell Death

Antiviral $CD8^+$ T cells [and sometimes antiviral $CD4^+$ T cells (281)] can eradicate infected cells by induction of apoptosis. It would benefit the virus to retain cellular integrity for as long as possible, and many viruses have developed means to delay the apoptotic process. The EBV BHRF1 gene product encodes a bcl-2 homolog which prevents cell death (74), as does the adenovirus E1B/19k protein (271). The p53 and Rb proteins, important cell-cycle regulators that can drive cells into apoptosis, can be bound by SV40 T antigen (129,239), with resulting survival and proliferation of the infected cell, and the product of the poxvirus molluscum contagiosum gene MC159 protects cells from Fas-mediated apoptosis (16). Finally, reactive oxygen metabolites (free radicals) can be harmful to both viruses and cells; molluscum contagiosum virus gene MC066L encodes a selenoprotein with antioxidant functions (218).

Infection of T or B Lymphocytes

The simplest and most direct means by which viruses can disrupt immune effector mechanisms is by infecting the immune cells. As shown in Table 4, many acute virus infections, and the vast majority of persistent virus infections, involve cells of the immune system. HIV-1 infects $CD4^+$ T cells, causing their destruction directly, or through immunopathological attack. EBV infects B lymphocytes, as does coxsackievirus B3, perhaps another example of a virus “attempting” to counter that aspect of host immunity which most threatens it (136). An interesting mode of B-cell disruption is practiced by LCMV. The virus infects B cells which express surface IgM capable of binding to neutralizing epitopes on the viral glycoprotein, and these B cells present the viral epitopes on their class I MHC and are promptly killed by virus-specific CTLs; as a result, infected animals make very little neutralizing antibody (182). The specificity of this interaction is nicely shown by the fact that anti-NP antibody is produced in abundance, because B cells bearing NP-specific IgM are not selectively infected by the virus (because NP is not present on the surface of the infectious particle). LCMV also infects $CD4^+$ and $CD8^+$ T cells. During persistent infection, viral sequences and infectious virus (detected by infectious center assay) are found mainly in the $CD4^+$ population (2,22,244). Measles virus infects T cells, B lymphocytes, and APCs. Acute measles virus infection is a well-recognized cause of immunosuppression (indeed in the earlier part of this century, measles infection was used to treat certain immune-mediated diseases), and although the precise cause of the suppression remains unclear, the virus ability to infect T and B cells (and APCs) may be in some way involved.

Virus	Host	Infected Cells
Double-stranded DNA viruses		
Hepatitis B virus	Human, monkey	PBMCs, T and B lymphocytes
Woodchuck hepatitis virus	Woodchuck	PBMCs, bone marrow
Papovavirus	Human, monkey	PBMCs
Group C adenoviruses	Human	T, B, and null lymphocytes
Herpes simplex virus	Human	T lymphocytes
Epstein-Barr virus	Human	B lymphocytes
Cytomegalovirus	Human	Lymphocytes, monocytes
Pox virus	Rabbit	Spleen cells
Single-stranded DNA viruses		
Porcine parvovirus	Pig	Spleen cells
Minute virus of mice	Mouse	Lymphocytes
Positive-strand RNA viruses		
Poliovirus	Human	Lymphocytes, monocytes
Rubella	Human	T and B lymphocytes
Negative-strand RNA viruses		
Measles	Human, monkey	T and B lymphocytes, monocytes
Mumps	Human	T and B lymphocytes
Respiratory syncytial virus	Human	Lymphocytes, monocytes
Vesicular stomatitis virus	Human, mouse	T lymphocytes
Influenza A	Human	Lymphocytes, monocytes
Parainfluenza	Human	Lymphocytes, monocytes
Arbovirus RNA viruses		
Lymphocytic choriomeningitis virus	Mouse	T and B lymphocytes, monocytes
Junin virus	Human	Peripheral blood mononuclear cells
Retroviruses		
Murine leukemia virus	Mouse	B lymphocytes
Feline leukemia virus	Cat	T and B lymphocytes, monocytes
HTLV-I, -II	Human	T, B, and null lymphocytes
HIV-1	Human	T and B lymphocytes, monocytes
SIV	Monkey	PBMCs, macrophages
Ernstegamyxa (L-type virus	Mouse	Spleen cells
Bovine leukemia virus	Cow	PBMCs

TABLE 4. *Viruses that infect lymphocytes and monocytes*

IMMUNOPATHOLOGY OF VIRAL INFECTIONS: VIRUS-INDUCED IMMUNE COMPLEX DISEASE

One of the most common immunopathologic manifestations associated with viral infection (acute or persistent) is virus-induced immune complex formation. In many virus infections, antiviral antibody interacts with virus in the fluid phase, or with viral antigens on cells forming complexes that are shed into the fluid phase, resulting in the formation of virus/antibody (V-Ab) immune complexes. Such V-Ab complexes occur in most infections. Circulating complexes carry infectious virus, which can enter cells that express Fc or complement receptors (e.g., macrophages, activated lymphocytes). However, the production of circulating complexes does not inevitably lead to disease, as long as mesangial cells and macrophages can remove them sufficiently rapidly to prevent their deposition. When the infection is chronic, the continuous trapping of the complexes in renal glomeruli, arteries, and choroid plexus leads to arteritis,

glomerulonephritis, and choroiditis. V-Ab immune complex disease is the common pathogenic mechanism of animal nephritides, vasculitis associated with HBV infection, and glomerulonephritis seen in several chronic human infections, all presenting an immunopathologic picture similar to that seen in chronic human nephritis of unknown cause.

However, even in the face of persistent immune complex formation, some individuals escape disease. Why is that? It is a matter of genetics. Genetic studies of different mouse strains that displayed high or low levels of immune complexes revealed that high levels of complexes was a dominant trait. Backcrossing of F_1 mice to their parents mapped the effect to a single gene in the MHC locus (174). Additional studies using recombinant inbred mice mapped the effect to the MHC class II locus (IA in mouse, equivalent HLA-DR in humans). Thus the immune-response gene(s) control the antiviral antibody response and, at a certain antibody–antigen ratio, immune complexes can result.

The presence of immune complex disease is best documented by identification of viral antigen, host Ig, and complement in a granular pattern along the basement membrane of glomeruli or capillaries, or in the intima or media of arteries. Identification and quantitation of specific antiviral antibodies are accomplished by elution of Ig by low-ionic, high-ionic, or low-pH buffers to disassociate the V-Ab complex, recovery, and quantitation of the eluted Ig and determining the specific antiviral activity of the total Ig eluted (usually >75% compared with <1% specific viral Ig in circulation). Such immune complex depositions are constant companions of persistent viral infection of humans and animals (160,161).

VIRUS-INDUCED AUTOIMMUNE DISEASE

Viruses have been implicated in autoimmunity by three findings. First, human autoimmune responses are made *de novo* in, or are enhanced during, infection by a wide variety of DNA and RNA viruses (164,165). Second, in experimental animal models, both acute and persistent virus infections can induce, accelerate, or enhance autoimmune disease in high-responder mice (246). Third, investigation of molecular mimicry (one potential mechanism whereby microbes may cause autoimmunity) indicates that a number of etiologic agents may cause autoimmune disease (163,166).

How can viruses induce autoimmune responses? Certain viruses [or their protein(s)] have a mitogenic effect on unique lymphocyte subsets and hence act as polyclonal activators. However, because agents such as mycoplasma also can activate lymphocytes and may contaminate viral stocks, stringent evidence must be presented that the activation is due to the virus, and not to mycoplasma contamination. Viruses also can infect lymphocytes and macrophages, causing release of cytokines and chemokines. These molecules can modulate immune responses in a variety of ways (e.g., as growth or differentiation factors, or by regulating MHC class I and/or class II expression on cells). Finally, microbial agents share determinants with host (self) proteins (molecular mimicry). In this instance, an immune response mounted by the host against a specific determinant of the infecting agent may cross-react with the shared host sequence, leading to autoimmunity and, in some cases, tissue injury and disease. Many viral proteins share epitopes with host proteins, as determined by computer sequence analysis, or by analysis of monoclonal antibodies raised against a large panel of DNA and RNA viruses in which nearly 4% of more than 800 tested showed cross-reaction with host determinants expressed on uninfected tissues (236). The evidence that mimicry could cause disease came from experiments in which inoculation of a viral peptide homologous to the encephalitogenic site of myelin basic protein was able to cause the autoimmune disease, allergic encephalomyelitis (53). These observations suggest that the human viral encephalopathies which occur after measles, mumps, vaccinia, or herpes zoster viral infection, in which recovery of a virus is unusual, may have a similar pathogenic mechanism. In these instances, autoimmunity would occur only when the microbial and host determinants are similar enough to cross-react, yet different enough to break immunological tolerance. The induction and breaking of tolerance at both the B- and T-cell levels have been established in heterologous serum protein models, and the same kinetics would likely govern the establishment and the break of tolerance to microbial agents cross-reacting with host proteins. Such cross-reactions could occur either through antibody- or cell-mediated immune responses. Another process implicated in the pathogenesis of autoimmune disease is “epitope spreading,” initiated by an appropriate immune response to an infectious agent, but spreading to epitopes encoded on host proteins (140,254). For example, during the demyelination seen in Theiler's murine encephalomyelitis virus infection, the original virus-specific T-cell response extends to include T cells specific for self epitopes on myelin basic protein and proteolipid protein, and these autoreactive cells contribute to disease. It will be interesting to see if this process applies also to human autoimmune disease associated with virus infections.

VACCINE CONSIDERATIONS

At a time when new vaccines are being sought to counter new challenges (HIV, and even tumor vaccines) and because new methods of subunit vaccination are being suggested as replacements for older vaccines that have performed extremely well (e.g., live attenuated viruses), it is critical that we carefully determine the role of each aspect of the immune response in combating primary virus infection, and in preventing and/or limiting subsequent infection in an immune host. This can now be viewed in light of the foregoing discussion. Historically, two approaches have been taken to developing antiviral vaccines. First, live vaccines have been developed, usually by attenuating the pathogenic virus by tissue-culture passage in a variety of cell lines. Attenuation was then tested in animal models. When pathogenicity was sufficiently reduced, the attenuated virus was considered a candidate. Second, the pathogenic virus could be inactivated (e.g., by formalin treatment), and the killed vaccine tested for immunogenicity. A major difference is evident between these two groups: the antigens of live vaccines will be presented by both class I and class II MHCs, whereas those in killed vaccines will be presented mainly by the class II pathway. In Table 5 are listed the major vaccines in current use and their nature [live or dead (we have avoided the adjective “killed” because the hepatitis B vaccine is a recombinant protein, and thus killing of the hepatitis virus itself was not required for this vaccine)]. Included also are some of the immunological findings associated with each type of vaccine. Each vaccine has costs and benefits. Live vaccines give longer-lasting immune responses against most or all viral antigens (partly because the vaccine replicates to give a large antigenic dose), and they induce a balanced response that includes $CD8^+$ T-cell responses as well as $CD4^+$ T-cell and antibody responses. The induction of $CD8^+$ T cells may be in part responsible for the astonishing efficacy of the live vaccines listed earlier. Live vaccines carry the risk of vaccine-associated viral disease, caused by reversion to pathogenicity of the vaccine strain during its replication in the vaccinee. For example, several cases of adult polio occur annually in developed countries and are almost invariably vaccine associated; that is, the victims have been in recent

close contact with vaccinees. Molecular analyses of the viruses shed in the feces of recently vaccinated infants demonstrated that the vaccine virus had rapidly reverted toward neurovirulence (28,44). In contrast, killed vaccines should carry no real risk of revertant-associated disease, although if inactivation is inadequate, as in an early batch of the Salk polio vaccine (152), then vaccinees may receive virulent virus. However, dead vaccines do not induce good $CD8^+$ T-cell responses; the immunity is short-lasting and often not detectable against all of the viral antigens (in part because inactivation may selectively modify or destroy the immunogenicity of the various virus proteins). Furthermore, there is a risk of disease potentiation. Vaccinees who are subsequently exposed to the wild virus may get much more severe disease than do unvaccinated individuals. This has been well documented for killed measles (54) and RSV vaccines (98), which were withdrawn in large part for this reason. Such disease potentiation has rarely been shown for live vaccines, although recent experience with high-dose measles vaccine in Africa has indicated that occasional unpredictable problems might arise, thus counseling caution in use of new vaccines and mandating the continual monitoring of vaccinee status. The “ideal” vaccine therefore would combine the best features of both, while omitting the problems. It should deliver antigen into both class I and class II pathways to induce a balanced, long-lasting, and cross-reactive immunity without significant vaccine-associated risks. Since the last version of this chapter was written, many articles have been published on DNA immunization, which combines some of the advantages of both live and dead vaccines; several reviews are available (40,69,241). To date the approach has shown itself to be wonderfully adaptable and moderately successful. However, enhancements are needed, as the immunity induced by a DNA vaccine alone is usually less than that induced by a conventional vaccine.

	Live	Dead
	Polio (Sabin) Measles Mumps Rubella Yellow fever Vaccinia Varicella	Influenza Rabies Hepatitis B Polio (Salk)
Antibody induction	+++	+++
CD4 T cell	+++	+++
CD8 T cell	+++	–
All viral antigens?	Usually	Often not
Longevity of immunity	Mo/yr	Mo
Cross-reactivity among viral strains	+++	+
Disease potentiation	? High-dose measles	RSV, measles
Risk of viral disease	+	–

RSV, respiratory syncytial virus.

TABLE 5. *Summary of currently available antiviral vaccines*

TRANSGENIC MODELS OF VIRUS–IMMUNE SYSTEM INTERACTIONS

The ability to generate transgenic mice and mice with targeted gene deletions introduced by homologous recombination (known as knock-out mice) has already provided, and will continue to provide, unique opportunities to understand both the biology of virus infections and the molecular basis of virus-immune interactions. For several important human viruses (e.g., poliovirus, measles virus, and hepatitis B virus), small animal models of disease did not exist because of restricted host tropism of the virus. Transgenic mouse lines were created that express the human cellular receptor for either poliovirus [poliovirus receptor molecule (PVR) (108,196)] or measles virus [CD46 molecule (172)]. Transgenic mice expressing PVR are susceptible to poliovirus infection, and replication of virus in neurons gives rise to poliomyelitis. Measles virus infects transgenic mice expressing the measles virus receptor and gives rise to suppression of both cellular and humoral immune responses. Both models now allow probing of the generation and effect of the antiviral immune response in a well-defined genetic host (the mouse) in which various T and B lymphocytes, MHC class I and II molecules, activation and co-stimulatory molecules, and cytokine genes can be knocked out. However, neither the poliomyelitis nor the measles virus model totally recapitulates the natural human infection because, when the respective virus is provided by the natural route, little or no infection occurs. A third valuable transgenic model is that for HBV. Unlike the polio or measles virus approach, transgenic mice that express HBV sequences have been established by use of liver-associated promoters (metallothionein and/or albumin promoters) (30). Using these models, Chisari et al. (49,67) have shown the role played by both $CD8^+$ and $CD4^+$ T cells in control of HBV, and have demonstrated that IFN-g and TNF-a secreted by CTLs play a prominent role in clearing HBV sequences from the vast majority of hepatic cells. IFN-g and TNF-a triggered the down-regulation of HBV gene expression by a post-transcriptional mechanism, in which HBV RNA levels in hepatocytes are controlled by stabilizing (or destabilizing) influences of several HBV RNA-binding host proteins, whose activity is regulated through cytokine-induced signal pathways (72).

By a different approach, focal expression of a viral gene in a selected cell with a cell-specific promoter can be used as a means to evaluate virus-induced autoimmune disease (43,173,259). The viral transgene is integrated into the host's genome and passed on to progeny, essentially becoming a “self” antigen. This approach has been used to express a viral gene in the beta cells of the islets of Langerhans [a model for diabetes (159,173,259)] or in oligodendrocytes [a demyelination model for multiple sclerosis (43)]. Subsequent infection of the transgenic mouse with the appropriate virus allows one to determine whether related or unrelated viruses induce responses to the transgene, and how cytokines, or co-stimulatory molecules, might initiate or enhance autoimmune disease of the pancreas or CNS.

Gene dysfunction (knock-out) studies allow the generation of mice lacking specific immune cell populations (e.g., B cells, $CD4^+$ or $CD8^+$ T lymphocytes), T-cell effector molecules (e.g., perforin, IFN-g, TNF-a), and a litany of other molecules including specific MHC class I or class II molecules, cytokines, chemokines, activation and co-stimulatory, and adhesion molecules. Using such mice, the role of specific genes and their products can be defined during a virus infection; however, the redundancy of the genome, and the resultant capacity for compensatory changes, indicate that the results obtained with knock-out mice should be interpreted with some caution. For instance, there are several examples in which deletion of the gene has given results very different from prior studies that used monoclonal antibodies to inactivate the gene product in a developmentally normal mouse. It is not clear which of the two approaches has given us the “correct”

result. With this caveat, the various knock-out and expresser models presently available should help us to identify the roles played by various components in immunization and immunopathology, which in turn may lead to therapeutic strategies to optimize vaccination and to limit immunopathologic injury and disease.

CHAPTER 12 Interferons and Other Cytokines

Christine A. Biron and Ganes C. Sen

GENERAL FEATURES OF CYTOKINES

Cytokines are protein factors made by cells to act on cells. The family of these includes a large and growing number of molecules acting on nonimmune and immune cells to mediate a variety of functions. Although their properties cannot be described briefly, certain characteristics are shared by most cytokines (Table 1). In general, cytokines are soluble, but there are examples of membrane-bound forms. They are structurally and biochemically similar to polypeptide hormones and growth factors (1,297). In particular, specific receptors for cytokines are expressed at cell surfaces, and cytokine binding to these activates intracellular signaling pathways. In addition, cytokines typically mediate autocrine and paracrine effects in a short radius, but they can also have endocrine effects under extreme conditions. Finally, some cytokines can themselves act as growth factors. One major difference between cytokines and their hormone and growth factor relatives, however, is that cytokines are tightly regulated for limited expression under basal conditions and are induced in response to host challenges, particularly microbial infections.

Most cytokines are simple polypeptides or glycoproteins ≤ 30 kd in size. Some cytokines form homoterms or homotrimers. One cytokine is a known heterodimer.
Cytokines are tightly regulated for limited expression under basal conditions. Various stimuli induce cytokine expression at the level of transcription, translation, or posttranslational protein processing.
Cytokine production is transient. The action radius is usually short, reaching or autocrine or paracrine functions. After profound conditions of stimulation or during systemic infections, however, some cytokines are found at circulating levels with endocrine functions.
Cytokines mediate their actions by binding to specific cell surface receptors (Kd in the range of 10^{-9}–10^{-12} M). Target cell responsiveness to a particular cytokine is dependent upon expression of receptors for the factor.
Most cytokine actions can be attributed to altered patterns of gene expression in target cells. Phenotypically, cytokine stimulation leads to an increase (or decrease) in the rate of cell proliferation, change in cell differentiation state, or change in the expression of some differentiated function.
Cytokines often act by regulating expression of other cytokines through the mechanism of inducing other cytokines in cascade responses or of decreasing certain other cytokines. Alternatively or additionally, cytokines can regulate the functions of other cytokines by positively or negatively modulating their receptors.
Structurally dissimilar cytokines sometimes mediate overlapping actions (redundancy), but structurally similar cytokines sometimes mediate different actions.
A single cytokine often has multiple target cells and multiple actions (pleiotropy).
Cytokines can have synergistic or antagonistic interactions. Because cells and tissues in the body are rarely at rest, responses to a single cytokine as a time, unperturbed biologic functions are likely to be the result of such interactions.

TABLE 1. *General characteristics of cytokines*

In terms of functions, cytokines are generally pleiotropic, activating multiple distinct consequences, but different cytokines can mediate overlapping functions. They are frequently observed in cascade responses with simultaneous or sequential expression of several kinds. This is because clusters of cytokines are sometimes induced by the same signals and because certain cytokines induce downstream activation of other cytokines. Because they can have synergistic or antagonistic interactions, the interactive biologic effects of the multiple cytokines elicited during infections may be more important than effects mediated by any single factor. After challenges with particular classes of infectious agents, such as viruses, bacteria, or parasites, unique or dominant cytokine responses can be induced and linked to help drive a cascade of initial to innate to adaptive subset cytokine and immune responses that are most effective in defense against the particular agent (Fig. 1). The earliest events appear to be controlled by stimulation of host receptors recognizing unique structures expressed by classes of infectious organisms but distinct from host determinants (23,24,181). Thus, there are many different kinds of cytokines, but expression of particular subsets appears to be regulated by host responses to unique conditions of challenge.

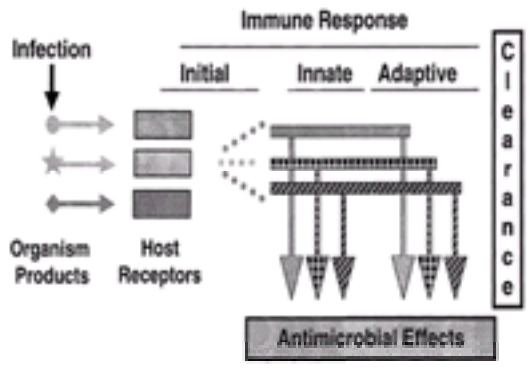

FIG. 1. General pathways of initial to innate to adaptive immune responses during infections. The picture emerging is that initial host responses to infectious agents are induced as a result of recognition, by specific receptors for unique microbial structures that are expressed in or on host cells. As a result of sensing structures expressed by classes of agents, these receptors activate a cascade of events, inducing subsets of innate and adaptive immune responses most effective in defense against the organism being encountered. Particular initial/innate cytokine responses (represented as broken lines) are major mediators in shaping the downstream immune responses.

Cytokine nomenclature reflects the evolution of knowledge from varied areas of investigations. Many of the factors have derived names from the biologic functions originally assigned to them. Examples are the interferons (IFNs), first identified by their ability to interfere with virus replication (222,297), and the tumor necrosis factors (TNF), which were demonstrated to induce necrosis of tumors (134,304). The first demonstrated function, however, is not always the most or only important one. The name interleukin (IL) was adapted for a number of cytokines originally thought to be leukocyte produced to act on other leukocytes. This has led to a long list of numbered factors (currently IL-1 through IL-18). Many of these, however, are now known to be made by, and act on, cells other than leukocytes.

Cytokines can be divided into four major groups based on general induction and function characteristics: (a) initial and innate cytokines, (b) adaptive cytokines, (c) chemokines, and (d) hematopoietic growth factors (1). The first three groups have well-characterized functions associated with abilities to mediate defense against infections by activating biochemical antimicrobial mechanisms or by regulating endogenous immune responses. These are reviewed in Table 2. Generally, initial and innate cytokines are associated during primary infections with early events; depend on nonimmune cells or cells of the innate immune system, such as polymorphonuclear leukocytes (PMNs), monocyte-macrophages (monocytic cells), natural killer (NK) cells, or dendritic cells (DCs), for expression; and contribute to innate immunity. In contrast, adaptive cytokines are associated with later events, depend on T and B cells of the adaptive immune system for expression, and contribute to adaptive immunity. Chemokines are associated with inflammation occurring during either innate or adaptive immune responses. These cytokines and their functions are discussed in more detail below. The fourth group is composed of mediators of leukocyte growth and differentiation. Although some of these factors may be induced during infections, they have been characterized primarily for function in normal leukocyte development, and such information is beyond the scope of this chapter.

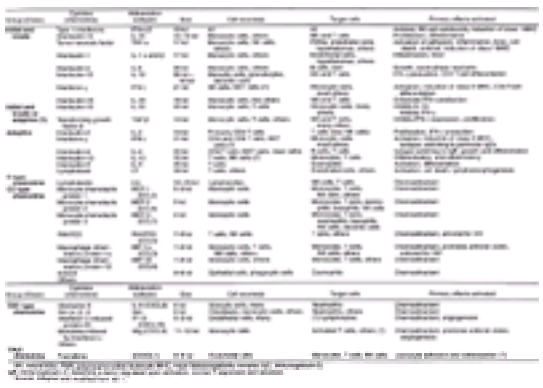

TABLE 2. *List of important cytokines and chemokines*

The focus of the material presented is current understanding of cytokine expression and function in the context of viral challenge. First, an overview is presented of important biologic functions mediated by, and kinetics of induction for, cytokine responses. This is a “low-power” view because events are considered in the context of the intact host and because the existing understanding at this level is still primarily extracellular. Known induction mechanisms and pathways accessed for mediating direct antiviral or direct and indirect immunoregulatory effects are discussed. Because the IFN cytokines induced by viral infections, such as the type I IFN family, appear to be expressed at particular high levels as well as to have unique or uniquely dominant roles in mediating direct antiviral functions and regulating immune responses, these factors are described in extensive detail. Review of type I IFN is at a “higher power” because the intracellular biochemical pathways inducing expression of these factors and delivering their antiviral functions are being precisely defined at the molecular level. The chapter concludes with general discussions of strategies evolved by viruses to avoid or utilize cytokine functions and of cytokine contributions to virus-induced disease.

SPECIFIC CYTOKINE CHARACTERISTICS, IMMUNOREGULATORY FUNCTIONS, AND FACTOR INDUCTION DURING VIRAL INFECTIONS

The immune system traditionally has been divided into innate and adaptive components based on kinetics of responses following primary challenges with infectious agents and on specificity for antigenic determinants associated with protection against secondary challenges. Innate cells, including monocytic cells, NK cells, PMNs, and DCs, express receptors with limited diversity, and tend to respond rapidly as large populations of cells. In contrast, adaptive T- and B-lymphocyte populations express an extensive range of antigen-specific receptors. Primary responses of T and B lymphocytes are delayed because specific subsets of low-frequency cells must be expanded. Innate immunity mediates defense, at times preceding activation of adaptive defense mechanisms. Innate events also make important contributions to shaping downstream immune responses. Such immunoregulatory functions are significant because only subsets of the various component immune responses activate mechanisms most effective in defense against particular challenges. Adaptive immunity is required to clear infections and mediate long-term memory defense. Thus, innate to adaptive responses are cascades in place both to mediate defense during each of the phases and to activate protective downstream immune responses (see Fig. 1). Cytokine constituent responses are known to be of major importance in delivery of both functions. Cell targets for cytokine actions express specific receptors for the factors.

To induce the chain of events activating immune responses most beneficial in defense against a particular infectious organism, the host links information available during the earliest times of infection to subset cascades. Unique microbial structures, distinct from host determinants, provide the early information. The known structures of this type are shared, and tightly conserved, by groups of pathogens sensitive to the same or similar defense mechanisms (181,319). Examples of unique microbial structures of this class are the lipopolysaccharide (LPS) structures on gram-negative bacteria, unmethylated CpG DNA motifs synthesized by invertebrate organisms, and other unique nucleic acid structures, such as double-stranded RNA (dsRNA), not detectable in normal cells but expressed in virus-infected host cells. These structures are sensed through receptors expressed by nonimmune or immune cells and result in activation of particular initial and innate cytokine cascade responses with shaping of downstream innate and adaptive immune responses.

It is difficult to assign responses to either initial or innate response phases. Initial events can be defined as those directly elicited by products of infectious agents, and innate components as those activated by initial response products. The adaptive phase depends on T or B cells. By these definitions, a particular cytokine may be part of all three phases if its expression can be stimulated directly by microbial products, and it can be produced by downstream innate and adaptive responses. Certain cytokines classified as initial or innate (e.g., IFN-a/b, TNF-a, IL-1, and IL-6) are induced in response to microbial products in both nonimmune cells and cells of the innate immune system. Other cytokines can be products of both innate and adaptive immune cells, such as IFN-g produced by NK cells as well as T cells. A few cytokines, such as IL-2, are exclusively assigned to one phase. These tend to be factors made only or predominantly by cells of the adaptive immune system. Cytokines can be related in terms of genetic homology, structural similarities, and overlapping use of receptor components.

Although much remains to be learned, initial and innate induction of high levels of the type I IFN family of cytokines (e.g., IFN-a/b) appears to be a unique or uniquely dominant characteristic of many viral infections (23,24). Other cytokine cascades often associated with responses to nonviral challenges, however, can sometimes be detected in the context of viral infections (Fig. 2). The cytokines known to be induced and functioning in the different phases of responses to primary viral infections are reviewed here (Table 3). The reader should keep in mind that the material is presented in idealized patterns based on results from infections studied in depth. Not all responses fit into these patterns because the host adapts to different conditions of viral infections, subtle or extreme, to access more appropriate defense mechanisms. Thus, many variations can arise.

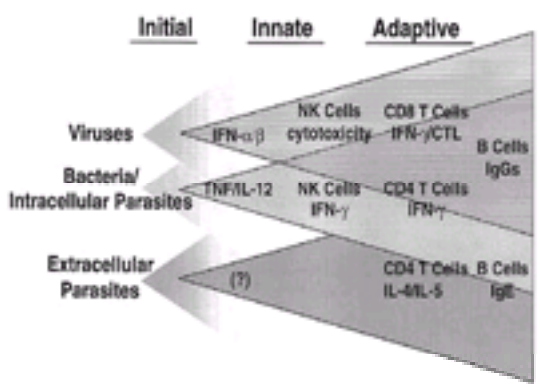

FIG. 2. Key known and proposed cytokine-regulated pathways shaping endogenous immune responses during infection with viruses, bacteria, and intracellular and extracellular parasites. Immune responses to bacteria or intracellular protozoan parasitic infections have dominant innate responses composed of interleukin-12 (IL-12) and natural killer (NK) cell interferon-g (IFN-g) production for shaping of downstream T_H1 type responses with CD4 T-cell IFN-g production. Challenges with certain organisms of these classes also are know to induce an innate cascade of proinflammatory cytokines, including tumor necrosis factor (TNF), IL-1, and IL-6. Responses to extracellular parasites of the helminth group fail to elicit an early IL-12 production and are linked to T_H2 responses with CD4 T-cell IL-4 and IL-5 production. Although responses to viruses have certain characteristics in common with T_H1 responses, they can also have dominant initial IFN-a/b production induced by unique viral products. This response is associated with NK cell cytotoxicity but not IFN-g production and is frequently accompanied by prominent downstream CD8 T-cell responses, including IFN-g production and cytotoxic T-lymphocyte (CTL) function. The patterns are idealized, and there can be overlap (represented by triangle overlap). This is clearly demonstrated during certain viral infections by induction of proinflammatory innate cytokine responses with IL-12 and NK cell IFN-g production and with mixed T-cell cytokine responses.

Virus	Cytokine expression	
	Intial and innate	Adaptive
Lymphocytic choriomeningitis virus	IFN-α/β	IFN-γ, IL-2 IL-4, TGF-β
Murine cytomegalovirus	IFN-α/β TNF, IL-1α, IL-6 IL-12, IFN-γ	IFN-γ, IL-2
Herpes simplex virus type 1	IFN-α/β TNF, IL-1α, IL-6 IL-12, IFN-γ	IFN-γ, IL-2 IL-4, IL-5
Influenza	IFN-α/β TNF, IL-18 IL-12, IFN-γ	IFN-γ, IL-2 IL-4, IL-5, IL-10
Human immunodeficiency virus	?	IFN-γ, IL-2 IL-4, IL-5, IL-10
Respiratory syncytial virus	IFN-γ IL-1, IL-6	IFN-γ, IL-2 IL-4, IL-5, IL-10

IFN, interferon; IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor.

TABLE 3. *Cytokines induced during viral infections*

Initial and Innate Cytokines

At least two clear pathways induce initial to innate cytokine responses. The first leads to IFN-a/b production and is elicited during many viral infections. The second leads to TNF, IL-6, IL-12, and downstream innate IFN-g and is elicited during many nonviral and certain viral infections. Numbers of other cytokines have been reported to be produced at the same time as, or to facilitate, these pathways. They include IL-1, IL-15, and IL-18. Still others, including IL-10 and transforming growth factor-b (TGF-b), have the potential to regulate particular innate cytokine responses negatively.

Interferon-a/b Cascade and a Potential Interleukin-15 Branch

Interferon-a/b

The type I IFNs are a superfamily with four subfamilies: IFN-a, IFN-b, IFN-w, and IFN-t. The IFN-a/b members are the best characterized and are known to be induced in response to viral infections. The factors are products of a single IFN-b and multiple IFN-a genes (222,297). They can be made by virtually any cell type in response to appropriate stimulation, and intracellular infections with viruses can be potent stimulators of IFN-a/b. These cytokines were first identified by their antiviral functions.

The transcriptional activation of the IFN-a and IFN-b genes is being extensively defined in regard to various mechanisms underlying stimulation during infections. Regulation of IFN-a/b genes is complex with potential for many pathways to expression. A well-characterized pathway is from one microbial product, that is, dsRNA, expressed in certain virus-infected, but not in uninfected, cells. Others, however, including interactions between certain viruses and their receptors and intracellular expression of particular viral proteins, exists (100,306). Several positive and negative regulatory gene elements participate in the transcriptional regulation process by binding specific transcription factors activated upon virus infections. The transcription factors are present in inactive forms in the cytoplasm of all cells. Their activation often requires phosphorylation of specific serine and threonine residues. The protein kinases involved in this process remain elusive, although participation of the IkB kinase complex and protein kinase R (PKR) in activating the NFkB transcription factor has been demonstrated (172). NFkB is one of the factors required for inducing transcription of the IFN-b gene and certain IFN-a genes. The other activated factors needed for induction of all IFN genes constitute the family of interferon regulatory factors (IRFs). There are at least 10 members of the IRF family (198). These molecules contain DNA-binding domains recognizing specific DNA elements (the interferon response element) in the IFN genes and in many IFN-inducible genes. The IRFs also contain transcriptional regulatory domains to activate or repress transcription, depending on the cell and gene context. Some IRFs are constitutively present in cells, whereas others are induced by IFNs. A few IRFs have cell type–dependent expression. The two IRFs most relevant for induction of the IFN genes are IRF-3 and IRF-7. A virus-activated factor that also mediates this process contains IRF-3, IRF-7, and the transcriptional coactivators p300 and the creb-binding protein (CBP) (306). This complex, in conjunction with NFkB and Atf-2/c-Jun, is recruited to the promoter region of the IFN-b gene to activate its transcription.

An interesting cascade operating in the IFN gene induction process has been recently discovered (173). The first members of this cascade are the IFN-b and specific IFN-a genes. They are activated by virus infection through the use of ubiquitously present IRF-3. These IFNs are then secreted and act through the IFN-a/b receptor to induce synthesis of IRF-7, not usually present in untreated cells. IRF-7, in turn, is used for the induction of other IFN-a members whose genes cannot be induced by IRF-3. This observation provides a molecular explanation for the phenomenon of priming for viral infection–induced IFN production by pretreating cells with a low IFN dose. It also couples, in a physiologic sense, the signal transduction pathways and the transcriptional induction mechanisms used by IFN and IFN-inducible genes. Thus, the direct intracellular signaling pathways for initial IFN-a/b induction, in response to infections, are being delineated clearly, and secondary type I IFN responses are induced in innate response to expression of the initial IFN-a/b gene products.

There are likely to be many additional mechanisms for IFN induction. The existence of the complex gene family may in fact be in place to respond to different stimulatory pathways. Several other biochemical pathways to IFN-a/b expression being identified include pathways induced during nonviral infections (66) or in response to the CpG DNA motifs synthesized by bacteria (15,277,288). Some of these mechanisms may preferentially stimulate IFN-a/b expression in particular cell types because they are preferred targets or are uniquely equipped to respond. In this regard, it is interesting to note that low-frequency populations of human DCs are potent producers of type I IFN in response to challenge with herpes simplex virus or influenza virus or to stimulation with CD40L (40,73,264). Much remains to be learned about IFN-a/b expression, but systemic levels of the factors appear to be uniquely induced to high and sustained levels during many viral infections, including those with lymphocytic choriomeningitis virus (LCMV) and murine cytomegalovirus (MCMV) (22,24). Production at this level is likely to be in part the result of recruiting large numbers of

cells, including nonimmune cell types such as fibroblasts and vascular endothelial cells, into IFN-a/b production. Major functions for such systemic and sustained IFN-a/b responses are to protect the many different host compartments and distal sites at risk for spreading or for secondary waves of infections. The conditions, however, are also likely to exert unique immunoregulatory effects on ongoing and developing immune responses (see later). A few viruses are reported to be poor inducers of IFN-a/b—most notably, respiratory syncytial virus (RSV) (45,232).

All nucleated cells express IFN-a/bRs. These are heterodimers comprised of IFNAR1 and IFNAR2c chains. A variety of generalized antiviral and cell-type specific immunoregulatory functions are activated as a result of binding the IFN-a/b forms to these receptors. The information available on the intracellular biochemical pathways activated through the IFN-a/bRs and on the complex potential and known immunoregulatory functions of IFN-a/b is reviewed later. Many IFN-a/b actions have been identified in vivo. Although some of these are direct, others are likely to be secondary effects. IFN-a/b cytokines can regulate expression of a number of other cytokines and cytokine receptors and, as a result, modify downstream consequences mediated by other factors.

Interleukin-15

In the context of cytokine cascades, IFN-a/b expression has a possible link to the induction of another innate cytokine, IL-15 (299). This factor was first identified as a stimulator of T-cell responses but is now known to activate both NK and T cells to proliferate, to be important for NK cell development, and to have a variety of other immunoregulatory functions. It is thought to be made by a number of different cell types and is known to be produced by monocytic cells in response to appropriate stimulation. The high-affinity receptor for IL-15 is a trimer (IL-15R) with a, b, and g chains (299). The IL-15Ra chain is specific for IL-15, but the b and g chains also bind the adaptive cytokine, IL-2, with a lower affinity and associate with an IL-2Ra chain to form the high-affinity IL-2R receptor. IL-15 can be made by a variety of cells, including monocytic cells. This cytokine may be induced with other proinflammatory cytokines (37). Its induction at the mRNA level, however, has also been observed after stimulation with type I IFNs, chemical inducers of type I IFNs, or viral infections (12,75,322). Expression of IL-15 is dependent on IRF-1, and this transcription factor can be activated by stimulation with IFN-a/b. Thus, there is a potential for IL-15 to be induced during viral infections either through direct stimulation or indirectly as a result of IFN-a/b–mediated effects.

***Other Immunoregulatory Functions of Interferon-* a/b**

IFN-a/b can positively or negatively regulate other cytokine functions by modulating expression of these factors or their receptors. Of particular relevance during innate responses, type I IFNs can inhibit expression of IL-12 (52,124,180). Other early changes induced by or associated with IFN-a/b expression are modifications in immune cell distribution *in vivo* (22,24,99,115), activation of NK cell cytotoxic activity (22), inhibition of NK cell responsiveness to IL-12 (200), *in vivo* induction of modest NK cell and memory CD8 T-cell proliferation (22,289), enhancement of pathways for presenting antigen on class I molecules of the major histocompatibility complex (MHC) (see later), and facilitation of T-cell IFN-g responses (31,53,234,235,251). Thus, the products of the initial and innate induction of the IFN-a/b cascade have the potential to regulate a variety of downstream innate and adaptive immune responses. Moreover, at extremely high concentrations, IFN-a/b inhibits the proliferation of a variety of cell types.

The Tumor Necrosis Factor-* a, *Interleukin-1, Interleukin-6 Cascade and an Interleukin-12, Interferon-* g *Branch

Other initial and innate cytokine responses may include a cascade of TNF-a, IL-1, and IL-6. This clustered response has been best characterized after stimulation with LPS components from gram-negative bacteria (1). TNF-a expression appears to be a major regulator of the cascade because treatment with factor alone induces the other two cytokines, but LPS can induce IL-1 in the absence of TNF-a. Often called the proinflammatory cytokine cascade, this response is generally detectable during inflammation. IFN-a can sometimes be seen under these conditions (86), but it is not clear that the factor is induced to the levels elicited by viral infections. Additional cytokines, such as IL-12, IL-15, IL-18, and NK cell–produced IFN-g, have also been reported to be associated with the innate TNF-a, IL-1, and IL-6 cascade under particular conditions, most notably stimulation with bacteria and bacterial products. An understanding of pathways to induction of this cytokine cluster is advancing. For example, CD14 and Toll-related receptors act in concert to bind LPS to induce signal transduction cascades, ultimately activating expression of the TNF-a, IL-1, and IL-6 genes (135,319).

Although the list of conditions under which certain of these proinflammatory cytokines are produced during viral infections is growing, less is known about how viruses elicit them. Expression of messenger RNA (mRNA) or protein is elevated for TNF-a, two major forms of IL-1, IL-6, and the two chains of heterodimeric IL-12 during infections with a variety of viruses, particularly the herpesviruses, including cytomegalovirus (CMV) (see Table 3) (2,121,122,192,207,208,226,243,244). TNF-a, IL-6, and IL-12 proteins are all expressed in the circulation during some viral infections and IL-18 has been detected during MCMV infection (223). The IL-1 cytokines are not readily detectable at the protein level. Induction of biologically active IL-12 during initial and innate immune responses elicits downstream induction of IFN-g production by NK cells, and NK cell–produced IFN-g can also be detected in the circulation during MCMV infections (208,209,243). The systemic TNF-a, IL-1, and IL-6, as well as the IL-12–to–IFN-g branch, cascade responses are likely to be in place to induce antimicrobial functions, promote inflammation at distal sites, and communicate with other organs, such as the brain and liver, to elicit secondary responses. As is the case with most cytokines, these responses must be tightly controlled. Under conditions of profound stimulation, including bacterial sepsis and certain viral infections, constituents of the proinflammatory cascade can be produced systemically, reach high levels in serum, and induce toxic shock conditions with coagulation, vascular collapse, and death.

*TNF-*a

Many of the important biologic functions mediated by TNF-a are related to its inflammation-promoting activity, that is, induction of enhanced adhesive properties of vascular endothelial cells and PMNs as well as vascular permeability (1,134,300). TNF-a mediates a variety of additional immunoregulatory and antiviral functions. Cell death (320), activation of monocytic cell functions (1), DC migration (231,302), enhancement of IFN-g responses (1), up-regulation of class I

MHC expression (1,296), and activation of certain antiviral pathways (91,159,197,314) are among the responses known to be induced by or associated with TNF-a expression. Under toxic shock conditions, TNF-a is required for disease induction and the detrimental conditions resulting in death (105,134). During systemic responses, the cytokine can also function as an “endogenous pyrogen” to communicate with hypothalamic regions of the brain and induce fever (1). TNF-a is made by a number of cell types, but activated monocytic cells are often the major producers. It is a member of a cytokine family including a related form, called lymphotoxin (LT), made primarily as an adaptive cytokine (41). TNF-a is synthesized as a type II membrane protein. The released form of the molecule is produced by proteolytic cleavage at an extracellular, membrane-proximal site. Both membrane-bound and released forms can mediate biologic functions. A number of different receptors for TNF-a, including TNF receptors type 1 (TNFR1) and 2 (TNFR2), are expressed on diverse cell types (283).

Interleukin-1 and Interleukin-6

The other members of this cascade, IL-1 and IL-6, are also made by both nonimmune cells and cells of the immune system. In comparison to TNF-a, however, they appear to be induced more readily in particular nonimmune cells (1). There are three gene products in the IL-1 family: IL-1a and IL-1b, functioning as stimulatory factors, and an IL-1 receptor antagonist, IL-1ra. Both IL-1a and IL-1b are synthesized as precursor molecules requiring proteolytic cleavage to generate mature forms. The IL-1a precursor may have some biologic activity, but the IL-1b form has to be cleaved to acquire function. An IL-1 protease, called the IL-1b-converting enzyme (ICE), or caspase 1, is responsible for most of the IL-1b processing (71,150). All three products of the IL-1 gene family can bind to two different characterized receptors. A type 1 receptor, however, may have higher affinity for IL-1b and is primarily responsible for IL-1–mediated responses. The type 1 receptor is expressed on virtually all cell types. A type 2 receptor can competitively inhibit IL-1 binding to the functional type 1 receptor and may be expressed on a more limited range of cell types. The functions mediated by IL-1 overlap with those mediated by TNF, in that the factor has been reported to enhance inflammatory and IFN-g responses and to be an endogenous pyrogen. In contrast to TNF-a, however, it does not appear to be required for many of the detrimental effects induced during cascade responses but can be a major contributor to eliciting IL-6. The two best-characterized functions of IL-6 are to promote B-cell growth and activate hepatocytes (1). Thus, prominent features of the proinflammatory cascade in total are (a) toxic potential of TNF-a, (b) overlapping functions for TNF-a and IL-1 in promoting inflammation and communication with the brain, (c) IL-1 induction of IL-6, and (d) unique IL-6–dependent links to other immune and hepatic responses.

Interleukin-12

Expression of IL-12, IFN-g, IL-15, and IL-18 can also be induced under conditions of LPS stimulation (37,279,317). In contrast to the expression of TNF-a, IL-1, and IL-6 by a variety of cell types, IL-12 appears to be primarily produced by monocytic cells, certain DCs, and PMNs (290). IL-12 is unusual among cytokines because it is a heterodimeric molecule composed of 35-kd (p35) and 40-kd (p40) subunits. Generally, the p35 subunit is constitutively expressed, and the p40 subunit is induced in response to challenge. Biologic activity is dependent on the presence of both chains. The receptor for IL-12 is composed of two subunits, the b1 and b2 chains, and is primarily expressed by NK and T cells (290). IL-12 was originally identified as a potent inducer of cytotoxicity and IFN-g production by NK cells and activated T cells. It is now clear that a major function for the factor is induction of NK cell IFN-g production under conditions of challenge with a variety of agents (21). It also appears to promote a particular subset of CD4 T-cell responses associated with IL-2 and IFN-g production (21,170,290).

Interferon-g

IFN-g was originally called type II because it can induce antiviral states. It was called immune IFN because, in contrast to the type I IFNs, it is made exclusively by cells of the immune system (29). IFN-g is primarily an NK cell product during innate responses, but it can be made by T cells during adaptive responses. A heterodimeric IFN-g receptor, distinct from the IFN-a/b receptor with IFNGR1 and IFNGR2 molecules, is expressed on virtually all nucleated cells. Despite the use of different receptors, certain IFN-a/b and IFN-g functions are shared because the signal transduction pathways activated through these receptors partly overlap (see later). However, IFN-g can mediate a number of unique immunoregulatory functions. Activation of monocytic cells to deliver antimicrobial defense mechanisms is an extremely important IFN-g function. After exposure to this cytokine, mononuclear phagocytes are induced to synthesize enzymes required for reactive oxygen intermediates contributing to the killing of phagocytosed organisms, particularly bacteria. IFN-g can act alone to induce nitric oxide synthase 2 (NOS2 or iNOS) (165). This enzyme contributes to the production of NO radicals for antimicrobial defense against a variety of agents, including viruses. TNF can enhance iNOS induction by either IFN-g or IFN-a/b, but the IFN-g effects are more potent. Thus, IFN-g is an important intermediary in induction of known effector mechanisms contributing to resistance against infections. Because there is a growing list of other enzyme responses to IFN-g, including the induction of a series of molecules having homologies to enzymes dephosphorylating guanosine triphosphate (GTP), that is, GTPases (28,36,286,287), there are likely to be additional or alternative mechanisms for IFN-g–induced antimicrobial defense. IFN-g can promote and amplify inflammatory responses by up-regulating expression of TNF receptors to potentiate the effects of this cytokine and by activating vascular endothelial cells. Finally, IFN-g enhances expression of a particular subset of chemokines. All of the effector mechanisms and inflammatory pathways are important consequences of IFN-g induction during either innate or adaptive responses.

A number of other immunoregulatory functions can be mediated or induced by IFN-g. IFN-g can activate NK cell cytotoxicity, but this may be of less importance than IFN-a/b activation during viral infections (22,92,208,211). Many other immunoregulatory functions appear to be in place to shape the development of adaptive immune responses. In particular, IFN-g induces increased class I and class II MHC expression on a wide variety of cell types (164), enhances CD4 T-cell differentiation to responses associated with IL-2 and IFN-g production by promoting expression of the IL-12 receptor (92,235,278), and acts on B cells to facilitate immunoglobulin class switching to particular subclasses, most notably immunoglobulin G2a (IgG2a) in the mouse (21). Taken together with the enhancement of mononuclear phagocytic cell functions, these immunoregulatory effects of IFN-g are likely to be most important in promoting antigen processing and presentation to CD4 T cells and in helping particular antibody responses against extracellular pathogens.

Interleukin-18

Less is known about the induction and function of IL-15 and IL-18. The IL-15 characteristics and proposed IFN-a/b induction were reviewed earlier. IL-18 was identified by its ability to promote IFN-g expression, and as a result, it was first named IFN-g–inducing factor (IGIF) (204). It is also sometimes called IL-1g because it has structural and biochemical similarities to the other IL-1 molecules. In particular, it is synthesized as an inactive precursor molecule and requires proteolytic cleavage by ICE (or other caspases) for release of the active form (71,87,101). Although only limited information is available concerning the IL-18 receptor, it is known to be different from those binding IL-1. It appears to be expressed on NK, T, and B cells. IFN-g expression can be induced by IL-18 alone or in synergy with IL-12. Most of the work characterizing induction of IL-18 expression has been done following stimulation with Propionibacterium acnes and LPS challenges. The cytokine appears to be readily elicited in response to this stimulation protocol and is found at high levels in liver (176,279). A natural soluble binding factor exists, IL-18–binding protein (203). IL-18 may not be required for driving T-cell IL-2 and IFN-g responses, but it can enhance them by facilitating IFN-g production and T-cell IL-12 receptor expression (233). In addition, there are intriguing data that indicate that IL-18 can act with IFN-a/b in promoting T-cell IFN-g responses (251).

Other Innate Cytokines

A number of other cytokines made by nonimmune or innate immune cells have the potential to mediate immunoregulatory functions during infections, including IL-10 and TGF-b, factors known to be potent inhibitors of IFN-g expression (163,239). These cytokines are induced under particular conditions of viral infections (250,276). Nonadaptive immune cell populations can be sources of the factors, but IL-10 and TGF-b have been more frequently observed at times of adaptive immune responses to viral infections.

Two other cytokines, IL-4 and IL-13, have structural similarities, share receptor components for intracellular signaling, induce overlapping biologic responses, and have potential to inhibit IFN-g expression and promote a subset of CD4 T-cell responses associated with IL-4, IL-13, and IL-5 production (44). These cytokines can be produced during adaptive immune responses and are induced at times of T-cell responses to certain viral infections. Little is known, however, about their expression during innate responses. Populations of mast cells and NK T cells, with similarities to classic NK cells but also expressing T-cell receptors for antigens, can be induced to make IL-4 under particular conditions of stimulation (18). It is not yet clear, however, whether these responses are activated during innate immune responses to challenge, and there is no definitive evidence for IL-4 stimulation during innate responses to viral infections. Likewise, although NK cell subsets making IL-5 or IL-13, but not IFN-g (22,110,220), have been identified, infection conditions under which such populations would be induced have not yet been defined.

Adaptive Cytokines

In comparison with initial and innate cytokine responses, adaptive cytokine responses are delayed and are associated with T-cell activation. A number of cytokines are produced during adaptive immune responses. Some of these are made exclusively by T cells. Some, however, are also made by other cell types but are produced at moderate or high levels by activated T cells. T-cell subsets can develop to produce preferentially particular adaptive cytokines, and the subset responses have been shown to be associated with defense against particular types of agents (see Fig. 2) or types of cytokine-mediated disease. For example, helper T-cell subtype 1 (T_H1) responses result in high production of IL-2 and IFN-g, are major contributors to delayed type hypersensitivity, and contribute to defense against bacterial or intracellular protozoan parasite infections (21,130,218). In contrast, helper T-cell subtype 2 (T_H2) responses result in IL-4, IL-13, and IL-5 production; are associated with antigen-induced airway hyperresponsiveness (asthma); and contribute to defense against certain parasitic infections (218,313). In general, polarization toward T_H1 responses is beneficial in defense against nonviral intracellular pathogens because IFN-g activates macrophage-dependent antimicrobial functions against such organisms. Development of T_H2 responses is beneficial in defense against extracellular parasitic pathogens, such as helminths, in part because IL-5 elicits production and recruitment of eosinophils and defense mechanisms delivered by these cells. Both cytokine profiles can promote B-cell production of antibody but are associated with different classes of antibody isotype production. High-level production of IgE is a characteristic of T_H2 responses.

The picture emerging from *in vitro* experiments and studies of nonviral infections is that development of a particular adaptive cytokine response is dependent on activation of T cells through their receptors for antigen (TCRs), the magnitude of stimulation, and the cytokine milieu in which the T cells are stimulated (2,25,92,235,260,278). For the most part, “polarized” subset responses have been characterized with CD4 T cells. Antigens for their activation are processed from extracellular forms and presented by class II MHC molecules. They are called helper responses because they promote T- or B-cell responses. As stated earlier, induction of IL-12 and IFN-g during innate immune responses preferentially promotes T_H1 CD4 T cells. In contrast, T_H2 CD4 T cells are promoted by the absence of IL-12 and IFN-g and the presence of IL-4 and IL-10 (218). A variety of infections with nonviral agents have been shown to result in polarized T_H1 or T_H2 profiles, but the T-cell cytokine responses characterized during a number of viral infections appear to be of a more mixed phenotype (see Fig. 2 and Table 3). In addition, some infections, particularly viral, induce CD8 T-cell responses. Antigens for activation of these cells are usually processed from intracellular forms and presented by class I MHC molecules. CD8 T-cell responses are generally associated with IFN-g expression and MHC class I–restricted, cytotoxic T-lymphocyte (CTL) function. Our understanding of the innate response conditions promoting particular CD8 T-cell functions is still limited.

Type 1 T-Cell Cytokine Responses

Interleukin-2

T cells produce IL-2, and a major function for this factor is promoting T-cell proliferation. Activated T cells express the

high-affinity trimeric form of IL-2R, comprised of the g and b chains shared with IL-15R and a specific IL-2Ra chain (299). NK cells generally express the g and b chains but are infrequently found with the high-affinity form of IL-2R. As a result, NK cells can be activated in response to IL-2 but are much less efficient than activated T cells in binding and utilizing the factor at the major times of production. In addition to acting as an autocrine growth factor for T cells, IL-2 is a potent inducer or facilitator of T-cell IFN-g production (51,271). B cells can respond to IL-2, and the factor promotes antibody synthesis. Viral infections have been shown to induce IL-2 expression (see Table 3). CD4 T cells are major producers, but CD8 T cells can express IL-2 under conditions of profound activation and during certain viral infections (2,51,128,129,275).

Interferon-g

Given its roles in supporting T-cell expansion and enhancing IFN-g expression, it is not a coincidence that IL-2 production is associated with T-cell IFN-g responses. T-cell IFN-g production is an important contributor to antiviral defense, and the pathways accessed for this are similar to those used by NK cell–produced IFN-g. The same cytokine is simply being made by two different cell types. The immunoregulatory functions, including facilitating switching of immunoglobulin classes and enhancement of antigen processing and presentation on MHC molecules, also predictably overlap. A major difference between NK cell and T-cell responses, however, is that T-cell responses are sustained for longer periods of time. As a result, there is potential for continued access to T-cell IFN-g production. Another apparent difference is that in contrast to the systemic NK cell IFN-g responses sometimes observed early during infections, T-cell IFN-g responses appear to be more often restricted to particular compartments. A likely contributing factor is the profound stimulatory effect for IFN-g expression mediated through TCR engagement (2,38). This signaling pathway needs T-cell exposure to antigen presented on MHC molecules. As a result, it provides an intrinsic regulation for need; that is, if viral antigen is cleared in vivo, T cells will not be stimulated through their TCRs.

A chain of events with innate IL-12 and NK cell IFN-g responses facilitating adaptive CD4 T-cell IFN-g responses is required to achieve optimal protection against nonviral, intracellular bacterial infections such as those with Listeria monocytogenes (130). Through this pathway, an NK cell IFN-g response can “pass off” a major function to a longer lasting-lymphocyte subset with different conditions for responding. It is not clear that such a pathway is needed during viral infections. CD4 T cells are induced to produce IFN-g, but T-cell IFN-g responses have been observed in the absence of endogenous biologically active IL-12, during a number of viral infection (53,188,207,213,258). This may be in part because many viruses elicit specific CD8 T-cell responses primed to produce high levels of IFN-g upon engagement of their TCRs. Most notable among these are infections of humans with Epstein-Barr virus (EBV) (141), influenza virus (55), and human immunodeficiency virus (HIV) (55,116) and infections of mice with LCMV (34,53,194), influenza virus (78), polyomavirus (160), and murine gamma-herpesvirus 68 (MHV-68) (274). Studies in culture suggest that the requirements for IFN-g expression in response to TCR stimulation are different for CD8 than for CD4 T cells, or that CD8 T cells may be more readily induced to produce IFN-g (38). Another pathway with IFN-a/b promoting CD8 T-cell IFN-g responses is being defined in the context of viral infections (see later).

Type 2 T-Cell Cytokine Responses

Interleukin-4 and Interleukin-13

As stated earlier, IL-4 and IL-13 have structural and functional similarities. T cells are major producers of both cytokines. IL-4 was first identified by its function in promoting B-cell responses. It is now know to be important in regulating IgE production and mast cell and eosinophil functions (1). IL-13 mediates overlapping functions, and both cytokines appear to contribute to recruitment of cells into tissues during allergic reactions (1,313). The cytokines use a common dimeric receptor expressed largely on nonlymphoid cells, including macrophages and vascular endothelial cells. One of these chains, however, can pair with the g chain common to the IL-15 and IL-2 receptors to form a specific IL-4 receptor on lymphocytes. Although polarized T_H1 and T_H2 responses are induced during certain nonviral infections, a number of different viral infections have been reported to express some level of IL-4 along with IL-2 and IFN-g (see Table 3). For the most part, IL-4 appears to be expressed at very low levels. Little information is available concerning the induction and function of IL-13 during viral challenges.

Interleukin-5

The major known function of IL-5 is induction and activation of eosinophils. These populations have not been observed frequently, or reported to mediate defense, during viral infections. They have been detected during respiratory viral infections, in particular those with RSV, and a predisposition for IL-5 expression after infectious challenge is induced by vaccination with the heavily glycosylated RSV G protein (see Table 3) (107,112,206,269).

Other Cytokines Made by T Cells

Lymphotoxin

T cells make a variety of other cytokines, including TGF-b and IL-10. They can make TNF-a but do not appear to be a major source of the factor under most conditions of in vivo challenge. They are important producers of a related cytokine, LT. LT has been called TNF-b because of its homology to TNF-a. It can compete for binding to TNF receptors. As a result of binding to these, it can induce functions overlapping with TNF. However, LT can also form a unique complex recognized by a different receptor identified as the LT b-receptor. This cytokine is often produced along with IFN-g by activated T cells and is generally considered part of T_H1 responses. A major unique function of LT is promotion of lymphomorphogenesis (41). Induction of LT expression at the mRNA level has been reported during a number of infections, but protective functions specifically mediated by LT under these conditions have not been defined.

UNFOLDING OF ENDOGENOUS IMMUNE RESPONSES DURING VIRAL INFECTIONS

The kinetics of virus-induced immune responses, as revealed during primary purposeful infections of mice and natural human infections, is schematically presented in Figure 3. Certain viruses activate component responses overlapping with those characterized as T_H1, but they also appear to elicit unique components. In particular, during initial and innate immune responses, uniquely dominant characteristics include prominent initial and innate IFN-a/b release and NK cell cytotoxicity (22,208). In LCMV infections of immunocompetent mice, IFN-a/b responses are observed without induction of detectable IL-12 (52,207). Moreover, although there are examples of both IFN-a/b and IL-12 initial and innate responses after infections with MCMV or influenza virus (188,207), they have dichotomous functions. During MCMV infections, IFN-a/b is necessary for induction of NK cell–mediated cytotoxicity but not IFN-g production. Conversely, and in contrast to the IL-12 role in activation of both NK cell responses during certain nonviral infections (23,256), IL-12 is required for MCMV infection–induced NK cell IFN-g production but not cytotoxic activity (207,208). Many of the NK cell–mediated antiviral effects depend on their being induced to make IFN-g (22,207,210), but the contribution of NK cell–mediated cytotoxicity to defense is less well documented (22,284). Thus, there are examples of initial and innate cytokine responses to viral infections sharing characteristics with those setting up for T_H1 responses during nonviral infections. These are associated with induction of NK cell–mediated antiviral effects, but there is also induction of IFN-a/b under these conditions. Moreover, certain viral infections induce IFN-a/b but fail to induce detectable IL-12.

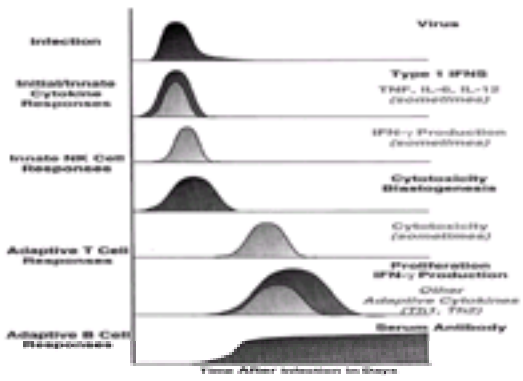

FIG. 3. Kinetics of known endogenous cytokine and cellular immune responses to viral infections during primary challenges. Initial events can include induction of prominent interferon (IFN)-a/b responses. Some viral infections also induce detectable tumor necrosis factor (TNF), interleukin-6 (IL-6), and IL-12 responses with an associated natural killer (NK) cell IFN-g production. NK cell cytotoxicity and blastogenesis are elicited as a result IFN-a/b responses. Adaptive responses include CD4 and CD8 T-cell responses with high-level expression of IFN-g, moderate expression of the T_H1 cytokine IL-2, and low-level production of the T_H2 cytokine IL-4. Dramatic CD8 T-cell proliferation with IFN-g production can be induced in a wide range of infections. Class I–restricted and virus-specific cytotoxicity mediated by CD8 T cells can be detected during some viral infections. B-cell antibody responses are extended for long periods of time.

In addition to the differences observed during initial and innate events, adaptive immune responses to viral infections can be contrasted with those to nonviral infections in terms of CD4 T_H1 and T_H2 and magnitudes of CD8 T-cell responses. Studies examining expression of the T_H1 cytokines, IL-2 and IFN-g, and the T_H2 cytokines, IL-4 and IL-5, indicate that T-cell responses to viral infections can be of mixed phenotypes with high IFN-g, moderate IL-2, and low IL-4 levels (35,97,112,166,167,187,201,237,250,275,310) (see Table 3). Moreover, CD8 T-cell responses can be induced to uniquely high levels with profound expansion, along with priming and activation of IFN-g production and cytotoxicity (2,6,34,53,78,194,274). Because these CD8 T-cell responses contribute to antiviral defense, their induction is important to the host. Remarkably, IL-12–independent T-cell IFN-g responses have been demonstrated during LCMV (53,207,213), influenza virus (188), and MHV (258) infections. Moreover, patients with deficiencies in IL-12 responsiveness have notably increased susceptibility to bacterial, but not viral, infections (5,62). Thus, the paradigm emerging from the studies of nonviral agents—that IL-12 is a required innate cytokine for promoting critical T-cell IFN-g responses—cannot be applied to the viral infections studied to date.

Given the direct pathways to IFN-a/b induction and the many immunoregulatory functions of cytokines, these factors are good-candidate molecules for dominant regulators of endogenous adaptive immune responses to viral infections; that is, they provide the key link between information available at early times during the infection and downstream immune responses. As stated previously, their expression results in profound early changes in cell distributions and modifies expression and function of other cytokines. By recruiting T- and B-cell repertoires into specialized areas for antigen presentation, the IFN-a/b–induced trafficking changes may increase the likelihood of activation of low-frequency antigen specific cells. Alternatively or additionally, they may localize adaptive cell populations into specific cytokine milieus elicited during innate responses to viral infections, and these could in turn mediate immunoregulatory functions directing downstream immune responses.

They may also uniquely regulate the endogenous cytokine milieu to promote the particular T-cell subset responses needed during viral infections. IFN-a/b set up conditions actively inhibiting IL-12–regulated pathways because they block IL-12 induction (52,53,124,180). This may be important to protect against viral infection–enhanced sensitivity to IL-12–induced toxicities (210,212) but would also limit access to a pathway promoting CD4 T-cell IFN-g responses. On the other hand, IFN-a/b may drive preferential stimulation of CD8 T-cell responses by enhancing class I MHC presentation, or IFN-a/b–induced NK cell-mediated cytotoxicity may negatively regulate T-cell responses (22,273). Finally, recent studies of a limited number of viral infections—influenza virus (83), herpes simplex virus (HSV) (144), and Sindbis virus (245)—in mice deficient in IFN-a/b functions show that these cytokines modulate viral cell tropism. If so, the characteristics of the primary host immune responses might be altered because of differences in antigen presentation or cytokine production resulting from infection of different target cells. Thus, many of the effects mediated by IFN-a/b have

the potential to promote particular T-cell subset responses during viral infections.

Nevertheless, understanding of exactly how CD8 T cells are regulated *in vivo* is still limited. IFN-a/b can enhance human T-cell IFN-g production under certain specific conditions in culture. However, experiments to date have examined only IFN-g roles for modest effects in association with IL-12 (169), for CD4 T-cell subset IFN-g responses (31,234,235), and for dramatic effects in association with IL-18 (251). Studies of the effects of blocking endogenous IFN-a/b functions during infections of mice with LCMV indicate that two divergent supporting pathways can act to promote CD8 T-cell IFN-g responses (53). Under normal conditions of infections, the CD8 T-cell IFN-g response is dependent on endogenous IFN-a/b effects but is IL-12 independent. In contrast, in the absence of IFN-a/b functions, an IL-12 response is revealed to substitute an alternative pathway to IFN-g. Thus, there appear to be important IFN-a/b–controlled pathways uniquely shaping T-cell IFN-g responses during viral infections, but the immune system has plasticity for accessing divergent innate mechanisms to achieve the same goal.

Although there are mechanisms by which IFN-a/b may promote activation of CD8 T cells and CD8 T-cell IFN-g responses, the cytokines are not essential for induction of CD8 T-cell cytotoxic function. Deficiencies in IFN-a/b functions are associated with poor detectable CTL responses during LCMV, but not vaccinia virus (VV), infections (193,294). CD8 T-cell cytotoxicity is essential for antiviral defense during certain viral infections (118), but the requirements for eliciting CTLs *in vivo* are poorly understood. IL-2 promotes CD8 T-cell expansion *in vivo* and enhances IFN-g production by these cells (51,275). As a result of supporting cell expansion, the factor also enhances the magnitude of CTL responses (51). It is not, however, absolutely required for *in vivo* induction of CD8 T-cell–mediated cytotoxicity (51,137). This may be in part because mixed cytokine responses can be observed during viral infections and because IL-4 can support certain CD8 T-cell responses (14). Alternatively or additionally, IL-15 made by non–T-cell populations may help promote CD8 T-cell responses (299). CD4 T-cell help for induction of acute CD8 T-cell responses is observed in some but not all viral infections (68,191,227), but CD4 T cells or IFN-g responses may be important for the general maintenance of CD8 T-cell memory (2,298). IFN-g does not appear to be required for CTL induction (96).

Acute and vaccine-induced changes in the conditions of RSV infections merit special consideration. Responses to respiratory infections with this virus appear to stand out from those characterized during many other viruses because RSV is a poor IFN-a/b inducer (45,232), eosinophils can sometimes be observed during infections with this agent (85), and vaccination with the highly glycosylated RSV G protein can predispose host responses upon challenge with the infectious agent to include IL-5 production and an accompanying lung pathology (7,94,206,269,304). Surprisingly, vaccination with one RSV antigen epitope presented to CD8 T cells as well as the G protein can enhance IFN-g production and protect against priming for the detrimental IL-5 response and disease (268). These observations suggest that there may be a particular requirement for inducing CD8 T-cell IFN-g responses at times of secondary CD4 T-cell responses to drive T_H1 over T_H2 responses preferentially to RSV. Although highly speculative, it is possible that the requirement is a result of the fact that alternative IFN-a/b–facilitated CD8 T-cell IFN-g responses are missing during infections with this virus.

CHEMOKINES

A group of low-molecular-weight cytokines, about 8 to 12 kd in size, with chemotactic functions are being described (see Table 2) (236,240,255). Because they are chemotactic cytokines, the mediators are called chemokines. This area of research is in a dramatic expansion period, and many newly identified factors are likely to be added to this group. The factors have important proinflammatory functions and can be induced in response to challenge with a number of infectious agents and their products and in response to particular cytokines. Although characterization of production has largely focused on immune cells, particular chemokines can be made by a variety of immune and nonimmune cells. The factors are broadly distributed into four families, C, C-C, C-X-C, and C-X3-C, based on their amino acid sequences. The C family has only one known member, lymphotactin. This factor targets lymphocytes for chemotactic responses. Many of the members of the C-C chemokine family are known to be produced by activated T cells and monocytes, but at least two members—the macrophage inflammatory protein-1a (MIP-1a) and a factor *r*egulated upon *a*ctivation, *n*ormal *T* *e*xpressed and *s*ecreted (RANTES)—can also be made by NK cells (26,72,205). C-C chemokine cell targets include monocytes, lymphocytes, and NK cells. The C-X-C chemokines are largely produced by activated monocytes, but certain family members can be produced by other cell types. A C-X-C chemokine, with a particular requirement for IFN-g in induction, is the monokine induced by IFN-g (Mig) (8,32,315,316). This factor may be uniquely restricted for, and especially potent at, induction of activated T-cell migration. Major target cells of the C-X-C chemokines include neutrophils, monocytes, and lymphocytes. The C-X3-C family has one known member, fractalkine. Monocytes and lymphocytes are major target cells of this factor.

Identification of specific roles for particular chemokines is complicated by the fact that they bind to and utilize different, but overlapping, receptors, and that the expression of multiple cytokines is generally induced simultaneously. As an example, the ligands MIP-1a, RANTES, and the monocyte chemotactic protein-1 (MCP-1) can all bind to the CC chemokine receptor CCR5 in culture systems (236). Moreover, conditions associated with MIP-1a induction are reported to induce other CC chemokines, including RANTES, during infections with VV (8), LCMV (11), mouse hepatitis virus (MHV) (142), HSV, and HIV (26,72). Nevertheless, there is good evidence supporting a specific requirement for a single chemokine (MIP-1a) during inflammatory responses *in vivo*. MIP-1a is crucial to migration of protective NK cells into infected livers during innate responses to MCMV infection (249). This results in local IFN-g driven Mig production (248). In addition, the chemokine is required for tissue inflammation at times associated with adaptive immune responses to influenza virus, coxsackievirus (50), and HSV infections (291).

Under the specific conditions of HIV infection, particular chemokines can also mediate direct antiviral functions (48). This is because HIV strains use the chemokine receptors CXCR4 and CCR5 as coreceptors with CD4 molecules for virus infection and because the natural chemokine ligands for these specific receptors can block HIV infection (4,19). The ligands include RANTES and MIP-1a. Both T and NK cells are capable of delivering this chemokine-mediated mechanism of protection.

CYTOKINE RECEPTORS AND SIGNALING PATHWAYS

Most cytokines use similar mechanisms to signal from the extracellular milieu to specific genes in the nucleus (113,281). The cellular receptors to which cytokines bind are generally type I ectoproteins with a single transmembrane domain (Fig. 4). Functional receptors may be composed of one, two, or three distinct protein subunits, each of which is a transmembrane protein. Particular subunits may be common to receptors of several cytokines. In some cases, one subunit binds the cytokine with high affinity, whereas in other cases, only composite multisubunit receptors do so. Structurally, the extracellular regions of these receptors contain fibronectin type III–like domains, cysteine-rich immunoglobulin-like domains, or combinations thereof. The carboxyl-terminal region of at least one of the receptor proteins forms a cytoplasmic tail used to recruit particular and crucial signaling proteins to provide specificity of intracellular signaling. Unlike many growth factor and hormone receptors, the cytoplasmic domains of cytokine receptors do not have intrinsic enzyme activity. Instead, they recruit specific tyrosine kinases, which are activated through events at the extracellular domains, resulting in ligand binding and receptor dimerization. A common family of such tyrosine kinases is the Janus kinase (Jak) group. One or more members of the Jaks are bound to specific sites on the cytoplasmic domain of different cytokine receptors. Ligand-bound receptors activate the Jaks, causing phosphorylation of specific tyrosine residues on the receptor subunits and on the Jaks themselves. Other tyrosine kinases, such as members of the sarcoma (Src) family, are also associated with particular cytokine receptors. Tyrosine phosphorylation of receptors and receptor-associated tyrosine kinases triggers a chain of events with cytoplasmic proteins containing Src-homology 2 (SH2) domains, to recognize phosphorylated tyrosines, recruited to the receptor and subsequently tyrosine phosphorylated. The most important signal transducing proteins for gene induction by cytokines are the signal transducers and activators of transcription (STATs). (Particular cytokine–cytokine receptor interactions associated with major specific STAT molecules are listed in Table 4.) Tyrosine phosphorylated STATs form homodimers or heterodimers and translocate to the nucleus, where they, by themselves or in association with other specific proteins, bind to specific DNA elements in cytokine-inducible genes to activate transcription. Thus, STATs are the true messengers carrying activation signals from specific receptors on the cell surface to specific genes in the nucleus.

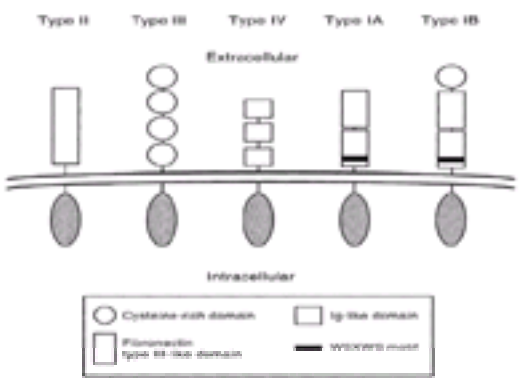

FIG. 4. Shared structural features among various cytokine receptors. The receptors are divided in groups by the nature of structural motifs present in their ligand-binding extracellular domains. Four such motifs are shown here. Type II receptors include those for type I and type II interferons (IFNs); these receptors are discussed in more detail in Figure 5. IL-10R is also a type II receptor. Type III receptors include TNF-RI and TNF-RII. Type IV receptors include IL-1RI and IL-1RII. Type IA receptors include IL-2Rbc, IL-2Rbc, IL-3Ra, IL-3Rbc, IL-4Ra, IL-5Ra, IL-7Ra, IL-9Ra. Type IB receptors include IL-6Ra, IL-6Rb, and IL-12Rb.

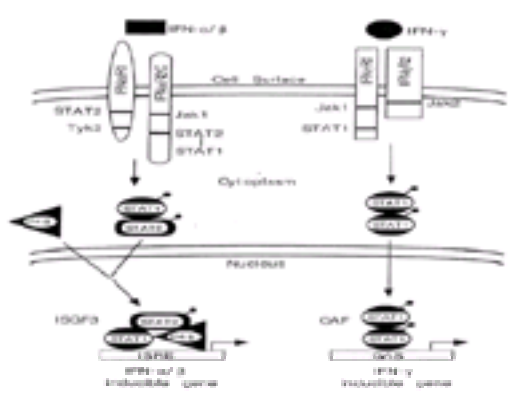

FIG. 5. Interferon (IFN)-signaling pathways. Binding of the IFN-a/b ligands to the extracellular domain of their receptor causes activation of Jak1 and Tyk2 and resultant Tyr-phosphorylation of STAT1 and STAT2. The phosphorylated STATs form a heterodimer and translocate to the nucleus, where they form a trimeric complex (ISGF3) with P48. ISGF3 binds to the ISRE elements of the promoters in IFN-a– and -b–inducible genes to activate their transcription. IFN-g binds to a different heterodimeric receptor, the intracellular domains of which bind to Jak1, Jak2, and STAT1. Ligand-induced activation of the tyrosine kinase causes STAT1 Tyr-phosphorylation, its dimerization, and nuclear translocation. The STAT1 homodimer (GAF) binds to the GAS elements of IFN-g–inducible genes and activates their transcription.

Cytokine	Jak	STAT
IFN-α/β	Tyk2, Jak1	1, 2, 3, (4)
IFN-γ	Jak1, Jak2	1
IL-2	Jak1, Jak3	(1), 3, 5
IL-3	Jak1, Jak2	5, 6
IL-4	Jak1, Jak3	6
IL-5	Jak2	
IL-6	Tyk2, Jak1, Jak2	1, 3
IL-7	Jak1, Jak3	
IL-9	Jak1, Jak3	3
IL-10	Tyk2, Jak1	1, 3
IL-11	Jak1	3
IL-12	Tyk2, Jak2	3, 4
IL-13	Jak1	6
IL-15	Jak1, Jak3	(1), 3, 5

IFN, interferon; IL, interleukin.
Parentheses denote cell-type specific activation.

TABLE 4. *Activation of JAK and STAT by various cytokines*

Because the Jak–STAT pathways were discovered through analysis of the mechanisms used by IFNs (271), signaling by these cytokines is described in detail. The pathways used by TNF also are discussed in brief because of their distinct nature. Little is known about the pathways used by cytokines for activating many of the immunoregulatory functions described earlier. Moreover, as most of the work characterizing these pathways has been done in culture, much remains to be learned about how they function in the context of the mixed cytokine responses elicited during viral infections in the host.

Interferon Receptors and Cell Signaling

IFN-specific intracellular signaling processes culminate in transcriptional activation of a set of IFN-inducible genes. Many of these genes are also induced in virus-infected cells by dsRNA or other viral products. The genes encoding the Jaks and the STATs themselves are often transcriptionally regulated by cytokines, thus providing positive feedback loops to the signaling systems. The intricate and partially overlapping signaling pathways used by IFNs and other cytokines provide opportunities for “cross-talking” among them, causing either synergistic or antagonistic outcomes. The cross-talking is physiologically relevant because a single cytokine is never induced in isolation in a virus-infected organism. Instead, cells are exposed *in vivo* to mixtures of cytokines simultaneously, and resultant changes in their gene expression reflect equilibrium between the multiple activated signaling pathways.

Interferon Receptors

Cells of all lineages, except possibly mature erythrocytes, express cell surface receptors for both type I IFNs (IFN-a, IFN-b, IFN-w) and type II IFN (IFN-g). Receptor numbers vary from 100 to 2000 per cell, and ligand-binding constants vary between 10^{-11} and 10^{-9} M. The receptors are multimeric transmembrane glycoproteins whose extracellular domains bind IFNs and whose cytoplasmic domains bind Jaks, STATs, and other signaling proteins. The type I IFNs bind to a receptor that has two major subunits, IFNAR1, a protein with 530 residues, and IFNAR2c, a protein with 315 residues (162). Neither subunit alone can bind IFN-a/b with high affinity, but the receptor complex can (49). The two IFNAR subunits associate with the tyrosine kinases Tyk2 and Jak1, respectively. Fully functional type I IFN receptors may contain additional transmembrane protein components because several other proteins coprecipitate with the ligand–receptor complex and because certain biochemical events cannot be reconstituted with the IFNAR1 and IFNAR2 molecules alone. The IFN-g receptor has two different subunits, IFNGR1 and IFNGR2, whose intracellular domains respectively bind the Jak1 and Jak2 kinases. IFNGR1 has 472 residues, whereas IFNGR2 has 315 residues (58). Functional IFN-g is a dimer binding to two IFNGR1 subunits to generate binding sites for two IFNGR2 subunits. Thus, the occupied, active receptor complex consists of two molecules each of IFN-g, IFNGR1, and IFNGR2. The crucial events in both type I IFN and IFN-g signaling are IFN-driven dimerizations of receptors. This leads to a cascade of tyrosine phosphorylation of proteins bound to the cytoplasmic domains of the receptor subunits.

Intracellular Signaling by Interferons

Both type I and II IFNs use similar principles in cellular signaling (Fig. 5). Specific protein tyrosine kinases of the Jak family are associated with cytoplasmic domains of the receptors, and ligand binding to receptor extracellular domains causes their activation to initiate a cascade of protein tyrosine phosphorylation events, with the STATs among the phosphorylated proteins (271). Once phosphorylated, STATs can form specific multimeric complexes that translocate to the nucleus and bind to specific cis-acting DNA elements present in the 5' regulatory regions of IFN-inducible genes. Thus, strong and specific transcriptional signals are transmitted from the outside of cells to specific genes in the nucleus. These signals are generated within minutes of ligand binding to the receptors. The effects are transient, decaying within hours of initiation. As a result, target gene transcription is activated in responding cells for only short periods of time.

At least seven proteins are essential for IFN-a/b signaling, including the two subunits of the receptor, two members of the Jak family of protein tyrosine kinases (Jak1 and Tyk2), two members of the STAT family (most notably STAT1 and STAT2), and a specific member of the IRF family, P48 (117,136,151,247,271). The interferon-stimulated response element (ISRE), cis-acting DNA sequences present in the regulatory regions of the IFN-a/b inducible genes to receive the stimulatory signal, has been defined (58). The relevant transcription factor binding to ISRE is ISGF3, a complex composed of three proteins, STAT1, STAT2, and P48. All of these proteins preexist in untreated cells, but the ISGF3 complex is formed only in IFN-treated cells after tyrosine phosphorylation of STAT1 and STAT2. P48 is a member of the IRF family of proteins, all capable of specifically binding to ISRE (198). Some IRF members stimulate transcription, whereas others repress it. Although the initial phase of positive signaling is transmitted to the ISRE by ISGF3, transcription of the IFN-stimulated genes (ISGs) may be sustained by specific IRF members, such as IRF-1. In addition to these proteins, the protein tyrosine phosphatase SHP-2 may also be involved in IFN-a/b signaling (69,117).

The previously described Jak–STAT pathway is thought to be the major signaling cascade used by IFN-a/b, but there is experimental evidence to implicate other STAT molecules, such as STAT4 (43,58). Moreover, cytosolic phospholipase A2 may be activated under particular conditions of IFN-a/b stimulation (76). An additional subtype-specific signaling pathway may be in place because a mutant cell line lacking Tyk2 cannot respond to IFN-a1 or a2 but retains a partial response to IFN-b and IFN-a8 (80). The possible existence of an IFN-b–specific pathway is supported by identification of a gene preferentially induced by IFN-b, that is, bR1 (228). IFN-a/b also activate the mitogen-activated protein (MAP) kinase pathway. This could be initiated by tyrosine phosphorylation and activation of an IFNAR1-associated MAP kinase identified as ERK2 (59).

The major IFN-g signaling pathway requires at least five cellular proteins: the two subunits of the receptor, the protein tyrosine kinases Jak1 and Jak2, and STAT1 (13,301). These receptor-bound STATs are also phosphorylated by the Jaks to cause their dissociation from the receptor complex (259,262,263). The dissociated Tyr-phosphorylated STAT1 proteins form a reciprocal homodimer, called the g-activated factor (GAF), and GAF translocates to the nucleus. The most commonly used cis element in IFN-g–responsive genes is called g-activated sequence (GAS) (61). GAF binds to GAS to promote gene transcription (see Fig. 5). Optimal transcriptional activation, however, requires further phosphorylation of STAT1 homodimers at Ser727 (59,309,316). The Pyk2 kinase with a MAP kinase–like specificity has been implicated in this process. IFN-g can also signal to ISRE and other elements. The compositions of the corresponding trans-acting factors remain to be determined. The IFN-g signal to ISRE may not be as strong as that mediated by IFN-a/b. Conversely, although ISGF3 is the major effector of IFN-a/b signaling, STAT1 homodimers are also formed under these conditions and can bind to GAS elements to drive transcription of some ISGs, such as the IRF-1 gene. Because only a subset of ISGs are induced, this pathway appears to be less prominent that the one induced by IFN-g. The STATs present in ISGF3 or GAF can interact with the basic transcriptional machinery by binding to the universal coactivator with its CBP/p300 components (323). Because induction of many genes by IFN-g, such as 9-27, P48, and class II MHC (see later), is not mediated by GAS elements, additional signaling pathways must exist. Although some features of these alternative pathways have been reported, their full descriptions await further investigation (27,157,230).

The mechanisms used by cells to down-regulate and terminate IFN signaling are not well understood. It is clear, however, that many components of the signaling pathway are inactivated in the process. Receptors are dephosphorylated (98) and down-regulated from the cell surface (221), and activated Jaks are inhibited by the suppressors of cytokine signaling (SOCS) family of proteins whose expression is induced by IFN (69,195,272). In addition, activated STAT1 is dephosphorylated by SHP-1 or similar tyrosine phosphatases (60) and possibly degraded by a proteasome-mediated process (131).

Interferon-Independent Signaling for Gene Expression in Virus-Infected Cells

Many IFN-a/b–stimulated genes are activated in virus-infected cells through signaling pathways independent of IFN. The IFN-independent pathways can be activated by dsRNA produced in cells infected with many viruses. These pathways are most convincingly demonstrated in cells devoid of type I IFN genes or incapable of responding to IFNs (16). The dsRNA-elicited signal is also received by the ISRE element. However, dsRNA-signaling does not require STAT1, STAT2, Jak1, Tyk2, or P48 used by IFN-a/b. Instead, dsRNA or virus-signaling is mediated by the dsRNA-activated factor (DRAF) (57) or virus-activated factor (VAF) (56) complexes binding to ISRE. The protein constituents of these factors are not as well defined as those of ISGF3 but contain IRF-3 and CBP/p300 (152,175,307,321). Regulation of these factors is poorly understood. IRF-3 phosphorylation is required, but the cognate protein kinase has not yet been identified. The dsRNA-dependent protein kinase PKR is likely to be involved in a cascade leading to activation. The pathway used by dsRNA to signal to ISRE is not well defined, but it and the ISGF3 pathway used by IFNs are distinct (143). Viruses may use yet another pathway to activate transcription from the same cis element because binding of virions or the relevant viral glycoproteins to the cell surface receptors can be sufficient to trigger transcription of specific ISGs (30,196,326).

Signaling by Tumor Necrosis Factor

There are two distinct TNF receptors to which both TNF-a and LT (also called TNF-b or LT-a) bind: TNFR1 or P55 and TNFR2 or P75. Their extracellular domains have homologies to many other cell surface receptors, such as Fas, nerve growth factor (NGF) receptors, and two poxvirus decoy TNF receptors, T2 and A53R. The cytoplasmic domains of the two TNF receptors are quite distinct, indicating that they elicit different intracellular signals. In general, TNFR1-generated signals cause cytotoxicity, increased cell proliferation, and antiviral activity, whereas TNFR2-generated signals are important in hematopoietic cells for specific functions (282,283). TNF binding to cell surface receptors causes pleiotropic intracellular responses, including activation and induced synthesis of transcription factors such as NF-kB and AP-1. As a result, transcription of many cellular genes is induced or repressed (296). The specific pathways used by TNF for signaling are not well characterized. MAP kinase is activated (295). Under most of the conditions studied to date, the Jak–STAT pathway does not appear to be activated by TNF. There are reports that TNF causes sphingomyelin hydrolysis generating lipid ceramide that activates a specific protein kinase to transmit the signal (133). The supporting evidence is, however, incomplete.

Because signaling by TNFR1 can cause apoptosis, it has been classified as a death receptor and has a characterized death domain in its cytoplasmic tail. Binding of TNF to the receptor causes its aggregation and the recruitment of intracellular signal transducers. One class of such proteins contains death domains as well (111). The TNFR1-associated death domain (TRADD) molecule is an example of a protein binding to the death domain of TNFR1. The second class of proteins, including those identified as TNF-receptor associated factors (TRAFs), do not contain death domains (114,242). They interact with each other and the receptor via a conserved C-terminal domain. A general picture of the signaling processes suggest that they lead to either apoptosis primarily through TRADD or activation of NFkB and cell survival through TRAFs (241,320). The balance between the two opposite outcomes depends on cell type. Thus, most normal cells are not killed by TNF, probably because strong NF-kB activation protects the cells from apoptotic effects. TRAF2 mediates both NF-kB activation and C-Jun N-terminus kinase (JNK) activation by TNF.

ACTIONS OF CYTOKINES ON VIRAL REPLICATION AND IMMUNE RESPONSES

Many cellular actions of cytokines are mediated by differentially induced proteins. These molecules are not expressed, or are expressed at a low level, in untreated cells. Most are products of genes whose transcription is directly induced, but some are products of genes requiring ongoing protein synthesis for expression. The latter proteins are likely to represent a second stage of a gene induction cascade. A variety of approaches, including gene array technology (63), have revealed that IFNs induce synthesis of a surprisingly large number of cellular proteins, counting in the hundreds. Type I and II IFNs induce two partially overlapping sets of proteins. Many of the type I IFN-inducible proteins can also be induced by host cell responses to dsRNA or virus infection (326). Although IFN-a and IFN-b primarily induce the same proteins, some proteins may be induced by one better than the other.

The characteristics of a few extensively studied IFN-induced proteins are described later. Their biochemical and cellular regulatory functions are well understood, and many of them play major roles in the antiviral functions of IFNs (Fig. 6). Particularly active in antiviral defense are certain enzymes with binding activity for dsRNA and molecules called Mx proteins. Progress is also being made toward understanding the induction and function of MHC molecules in response to IFNs. By promoting antigen processing and presentation, these effects can facilitate the development of adaptive T-cell responses. (TNF-a is also known to induce certain of these, but the pathways for induction are not as thoroughly characterized.) Exciting new information is becoming available about the biochemical pathways of IFN-mediated regulation of cell proliferation. These effects are likely to be important in shaping endogenous immune responses and in therapeutic effects resulting from IFN-a/b treatments of cancers. Finally, although less well characterized, IFN or TNF-a activates pathways inducing a nitric oxide synthase important in antiviral defense.

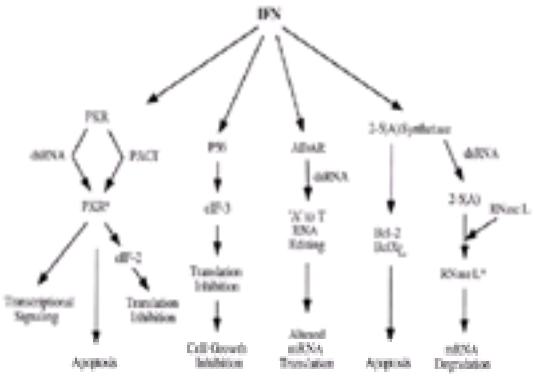

FIG. 6. Interferon (IFN)-induced biochemical pathways affecting cell growth and metabolism. Among the many proteins induced by IFNs are PKR, P56, ADAR, and 2-5(A) synthetase. IFN-induced PKR is inactive as such and requires either dsRNA or another cellular protein, PACT, for its activation by autophosphorylation. Activated PKR (PKR*) is a protein kinase with stringent substrate specificity. It can phosphorylate eIF-2a to inhibit protein synthesis. It can also cause cellular apoptosis and participate in specific transcriptional signaling pathways. The IFN-induced protein, P56, binds to the P48 subunit of eIF-3 and inhibits its function, causing translation inhibition and cell growth inhibition. The IFN-induced ADAR adenosine diaminase edits (A to I) dsRNA structures in viral and cellular RNAs, thereby changing their coding properties. The IFN-induced 2-5(A) synthetases are a family of enzymes, all of which are activated by dsRNA to synthesize 2'-5'–linked oligoadenylates [2-5(A)]. 2-5(A) binds and dimerizes inactive RNase L, causing its activation (RNase L*), and activated RNase L degrades mRNA. A specific isozyme, 9-2, of 2-5(A) synthetase has an additional cellular activity. It binds to the Bcl-2 family of proteins and causes cellular apoptosis.

Enzymes Dependent on Double-Stranded RNA

Studies of the IFN-induced proteins have led to the discovery of three interesting classes of enzymes, all of which bind to and require dsRNA for their functions: (a) the family of 2-5(A) synthetases (229) whose products, the 2'-5'-oligoadenylates, activate a latent ribonuclease, RNase L, to cleave cellular and viral RNAs (265); (b) the PKR, affecting many cellular processes and resulting in inhibition of viral replication (312); and (c) an isoform of dsRNA-specific adenosine deaminase, which converts adenosines to inosines (217). The functions of these enzymes are known to be important for induction of an antiviral state by IFNs, and the mechanisms for induction of the antiviral effects have been extensively studied.

As a result of binding dsRNA, the 2'-5'-oligoadenylate [2-5(A)] synthetases are activated to polymerize adenosine triphosphate (ATP) into 2'-5'–linked oligoadenylates. All 2-5(A) synthetase proteins are IFN induced, although basal levels are present in many cell lines. There are three size classes of these enzymes: small, in the 40-kd range; medium, in the 70-kd range; and large, in the 100-kd range (229,254). Each class is encoded by separate genes, which are all clustered in one genetic locus. Within each class, multiple isozymes are produced by alternative splicing of primary transcripts. Different isozymes have different posttranslational modifications and different subcellular locations. Studies with natural and recombinant proteins have shown that the three classes have different dsRNA optima and synthesize 2-5(A) of different lengths (90,252). Many small viral RNAs, such as adenoviral VAI RNA, EBV EBER RNA, and HIVI TAR RNA, can also activate these enzymes (64,168,261). Oligomerization of the small and medium proteins is essential for their enzyme activity (90,253). Recent studies with a medium isozyme, P69, have revealed that the catalytic domains of these proteins have an abbabbb structure similar to the catalytic domain of DNA polymerase b. Three Asp residues in this domain form the catalytic triad, and their mutation inactivates the enzyme without affecting ATP and dsRNA binding (253). The residues responsible for dimerization of P69 have also been identified.

The 2-5(A) product molecules activate RNase L by causing dimerization of inactive monomeric RNase L (265). The

N-terminal half of the protein containing P-loop motifs and ankyrin repeats binds 2-5(A) and serves as a repressor of enzyme function. The C-terminal half contains a region of protein kinase homology, a cysteine-rich domain, and the ribonuclease domain. Trimeric 2-5(A) is required for the activation of RNase L, dimers are inactive, and much longer oligomers of 2-5(A) may have inhibitory activity. The 2-5(A) synthetase–RNase L system has been shown to inhibit replication of specific families of viruses, especially picornaviruses. Constitutive expression of either the small or the medium isozyme causes inhibition of replication of encephalomyocarditis virus (EMCV) but not vesicular stomatitis virus (VSV) (42,89). Cells expressing a dominant negative mutant of RNase L and RNase L–null mice are deficient in the anti-EMCV effect of IFN-a/b (324). The constituents of the 2-5(A) synthetase–RNase L system can also affect cell growth. RNase L has been implicated in apoptotic pathways (324); and a small isozyme of 2-5(A) synthetase, 9-2, causes cellular apoptosis (88). The 9-2 activity is unique to this form of the 2-5(A) synthetase family and unrelated to 2-5(A) synthesis and RNase L binding. The function has been traced to a unique C terminus of 9-2 acquired by alternative splicing. This region contains a Bcl-2 homology 3 (BH3) domain, which enables it to interact with the antiapoptotic proteins Bcl2 and BclxL. Much remains to be learned about the effects on cell growth and death, however, because constitutive overexpression of P69 can cause a contrasting dose-dependent increase in cell doubling time and the formation of multinucleated cells (89).

Another dsRNA-activated enzyme is PKR (312). This enzyme is expressed in all cells at a low level but is induced to a higher level upon IFN treatment. The protein is inactive, but dsRNA binding activates it to cause its autophosphorylation in serine-threonine residues. Phosphorylated PKR can phosphorylate other proteins. The PKR dsRNA-binding domain is at the N-terminal half and the catalytic domain is in the C-terminal half of the molecule. The dsRNA-binding domain contains two dsRNA-binding motifs of about 70 residues. These motifs are present in other members of this family of dsRNA-binding proteins but not in 2-5(A) synthetases. The domain also mediates direct protein–protein interaction, causing PKR homodimerization (215) or allowing heterodimerization among different members of this family of proteins. The kinase domain contains the usual kinase subdomains and an insert domain shared with other eIF-2a kinases. PKR can be activated by other cellular and viral RNAs with partial double-stranded structures and heparin or other polyanionic compounds as well as by authentic dsRNA. Recently, a protein activator of PKR, PACT, has been identified (214). PACT also has the dsRNA-binding motifs and dimerizes with PKR. Activation of PKR by PACT is independent of dsRNA. Low concentration of dsRNA can activate PKR, whereas higher concentrations inhibit it. Many viruses, such as adenovirus, exploit this property by producing a large quantity of VAI RNA that inhibits PKR (280). Binding of dsRNA causes a conformational change in PKR, exposing the ATP-binding site and autophosphorylation. The most well-characterized PKR substrate is the translation initiation factor eIF-2a. Its phosphorylation inhibits the function of eIF-2 and causes an inhibition of translation. Thus, activation or overexpression of PKR causes an inhibition of cellular protein synthesis, and this is one mechanism for IFN-induced inhibition of viral replication. PKR can also phosphorylate histones, HIV Tat protein and IkB *in vitro* (312). It interacts with STAT1, STAT3, and P53 as well but does not phosphorylate them. A new nuclear dsRNA-binding protein substrate of PKR, DRBP76, has recently been identified (216).

Overexpression of PKR leads to inhibition of EMCV replication, and a dominant-negative PKR mutant or an antisense PKR cDNA suppresses the anti-EMCV action of IFN-a and IFN-b. To circumvent the actions of PKR, many viruses have evolved different mechanisms to inhibit its function. These viral evasion strategies are discussed in a separate section later. There are other cellular functions of PKR in addition to its antiviral effects. PKR has been shown to be required in transcriptional signaling by dsRNA (312). Through an as yet undefined pathway, dsRNA-activated PKR activates the IkK complex and causes degradation of IkB. PKR is also involved in cellular signaling by TNF-a, LPS, and IFN-g. There are suggestions that PKR may act upstream of the MAP kinase P38. Because PKR is a cell growth inhibitor, its transdominant inhibitors can promote unregulated cell growth and transformation of NIH/3T3 cells. In virus-infected cells, PKR promotes cellular apoptosis. Viruses encode or induce many antiapoptotic proteins to keep the cells alive during replication. One such inhibitor, P58IPK, is a cellular protein induced by influenza virus (280).

The IFN-inducible dsRNA-specific adenosine deaminase, ADAR, differs from 2-5(A) synthetases and PKR in the role dsRNA plays. The dsRNA structures are substrates of ADAR, whereas they are regulatory factors activating or antagonizing enzymatic functions of the other molecules. ADAR catalyzes C6 deamination of adenosine to inosine in viral and cellular RNAs (156,217). Consequences of this IFN-induced RNA editing are changes in target RNA coding capacities. Such site-specific editing can cause amino acid substitution and, as a result, synthesis of proteins with altered functions (155,156).

Mx and Guanylate-Binding Proteins

The Mx proteins and other guanylate-binding proteins are abundantly induced by IFNs in a number of species (270). The human MxA and MxB proteins are induced primarily by type I IFNs. These proteins belong to the dynamin superfamily of GTPase involved in endocytosis and vesicle transport (109). The Mx proteins were originally discovered as IFN-induced proteins with the ability to block replication of influenza viruses. Later, they were shown to be capable of inhibiting many other RNA viruses, including members of the Orthomyxoviridae, Paramyxoviridae, Rhabdoviridae, Bunyaviridae, and Togaviridae families (106). The Mx proteins are thought to interfere with virus replication through a dynamin-like force–generating mechanism by wrapping around viral nucleocapsids. The MxA protein associates, in the GTP-bound form, with the nucleoprotein component of Thogoto virus to cause an inhibition in nuclear transport of the viral nucleocapsids and viral genome transcription (132). The existence of considerable residual effects of IFN-a/b against EMCV in mice lacking functional RNase L, PKR, and Mx suggest the presence of additional pathways (325). Another family of IFN-induced proteins includes the guanylate-binding proteins, GBP-1 and GBP-2. They bind and hydrolyze GTP; that is, they have GTPase functions and may have mild antiviral activities (9).

Major Histocompatibility Complex Expression

Among the IFN-induced proteins playing major roles in recognition of virus antigens by cells of the immune system are the MHC proteins (29,153). The class I MHC proteins are induced by both types of IFNs, but the class II proteins are induced by IFN-g only. Enhanced surface expression of class I MHC proteins facilitates activation of CD8 T cells. Along with the class I proteins, IFNs promote the expression of other proteins that help constitute the class I MHC, including

b_2-microglobulin, three subunits of the proteasome LMP-2, LMP-8 and LMP-10, PA28, TAP, tapsin, and gp96 (185). The IFN-g–induced class II MHC response promotes CD4 T-cell activation. IFN-g up-regulates the class II MHC heterodimer, the invariant chain protein, two DM proteins that assist in assembly of the class II complex, and the transcription factor CIITA that is required for transcription of these genes (164). IFN-g regulates the expression of three cathepsins believed to be responsible for cleavage-processing of exogenous proteins into peptides for loading onto the class II MHC complex. IFN-g also induces the high-affinity Fcg receptor and the components of the complement system (54). PML and SP11, two human proteins localized in nuclear bodies within the nucleus, are IFN inducible (303).

P200 Gene Family

In mice, type I IFNs strongly induce synthesis of various members of the *P200* gene family (145). The cluster contains at least six IFN-regulated linked genes. The protein products of these genes are related in that they all contain at least one unit of a conserved domain of about 200 amino acids. The p202 protein inhibits cell proliferation by binding to and inhibiting the functions of a number of transcription factors, including NFkB, E2F, P53, c-fos, c-jun, and the retinoblastoma protein Rb (47). The p204 protein, on the other hand, inhibits rRNA transcription by binding to the UBF1 transcription factor that is required for ribosomal RNA synthesis (154). Genes from the homologous human locus are also induced by IFNs. Their products, IFI16 and MNDA, are DNA-binding nuclear proteins.

ISG56 Gene Family

In humans, a genetic locus encodes several proteins that are strongly induced by type I IFNs. They include P56, P54, P60, and P58 of the *ISG56* gene family (305). The corresponding mouse proteins also are known. These proteins are structurally related. They contain multiple tetratricopeptide domains thought to mediate protein–protein interactions. P56 is the product of gene *561* or *ISG56* (139). This gene is not expressed in untreated cells but induced very rapidly upon IFNa/b treatment. It is also induced by dsRNA or by infection with viruses. Both the mRNA and the protein are relatively short lived, and the protein, P56, is primarily cytoplasmic (103). The P56 cellular function is still poorly understood, but the molecule interacts with Int-6. The Int-6 protein has cytoplasmic and nuclear isoforms, arising from alternative translation initiation sites. The full-length cytoplasmic protein has a nuclear export signal at the N terminus and a nuclear localization signal near the C terminus (102). An internally initiated protein lacks the nuclear export signal and hence stays in the nucleus. P56 interacts with both proteins and keeps the nuclear isoform sequestered in the cytoplasm. Int-6 is identical to P48, a subunit of the translation initiation factor eIF-3 (10). As expected, P56 binds eIF-3, and purified recombinant P56 inhibits *in vitro* translation by blocking eIF-3 function (104). *In vivo* P56 and P48 are colocalized in the cytoplasm. When P56 is overexpressed in cells, the rate of protein synthesis is decreased, and the rate of cell growth is affected as a consequence.

Inducible Nitric Oxide Synthase

The inducible nitric oxide synthase (iNOS), alternatively identified as nitric oxide synthase 2 (NOS2), can be expressed in activated macrophages to mediate a variety of antimicrobial functions. Much of the work characterizing iNOS induction has been done in mice and in response to IFN-g or LPS stimulation. Inflammatory macrophages from humans, however, also express iNOS (165). Signaling for iNOS induction is incompletely characterized. The promoter regions of both mouse and human genes are complex, and there are likely to be multiple pathways to iNOS induction. The transcription factor, NFkB, can play a role in induction elicited by LPS. Moreover, the absence of IRF-1 results in significant iNOS deficiencies, and the absence of IFN-g induction of IRF-1 is likely to be a pathway to this effect (120). Although IFN-g is a potent inducer, TNF-a and TNF-a in synergy with IFN-a/b can also act as inducers of the enzyme (165). Through biochemical pathways with NADPH to oxidize and consume L-arginine, NOS enzymes catalyze production of NO, with L-citruline as a second product (165). NO is a lipid- and water-soluble gas that reacts with oxygen and its intermediates to yield other reactive molecules. The iNOS-dependent pathways have been shown to contribute to defense during a range of infections, including those with the RNA virus, VSV, and the DNA viruses, VV, EBV, HSV, and MCMV (2,126,127,165,182,284). Because of the variety of reactive intermediates and products, NO has the potential to mediate antiviral activity by modifying downstream target molecules. It has been shown to promote maintenance of EBV latency by down-regulating an intermediate-early transactivator protein (171) and to interrupt VV replication and protein synthesis by blocking required enzymes and intermediates (126,182).

VIRAL STRATEGIES FOR COUNTERACTING OR TAKING ADVANTAGE OF CYTOKINE AND CHEMOKINE ACTION

Viruses have evolved many strategies either to inhibit cytokine- or chemokine-mediated effects detrimental to their replication or to take advantage of cytokine and chemokine functions to promote viral propagation and spread in the host. In particular, viruses constantly try to evade antiviral IFN action. A virus that is a potent inducer of IFN and also highly sensitive to its antiviral effects will reproduce poorly and hence be at an evolutionary disadvantage. Thus, in nature, equilibrium is maintained between viruses and the IFN system. In the laboratory, this equilibrium can be shifted either way by increasing IFN concentration or viral multiplicity of infection: at high virus load, IFN is ineffective, and at high IFN dose, virus replication is totally shut off. A global strategy used by many virulent viruses is to inhibit cellular RNA and protein synthesis. As a result, both IFN synthesis and synthesis of IFN-induced proteins are impaired. Other viruses have developed more targeted and sophisticated strategies to interfere with different steps of the IFN and other cytokine systems (Table 5). These strategies are discussed subsequently.

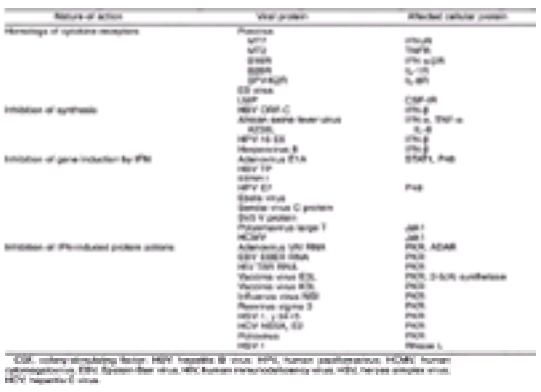

TABLE 5. *Viral interference with cytokines*

Inhibition of Interferon Synthesis

IFN synthesis is inhibited by some viral gene products. Hepatitis B virus ORF-C product inhibits IFN-b gene induction, as does the viral terminal protein (307). For IFN induction by VSV, mutations in the M protein may dictate this capacity of the virus (74). African swine fever virus that infects macrophages inhibits phorbol myristil acetate (PMA)-induced synthesis of IFN-a and TNF-a. Here, the product of the viral A238L gene encodes a homolog of IkB to inhibit NFkB actions in cytokine induction (224). Other viruses produce cytokine homologs. The myxoma virus MT-7 protein can bind IFN-g and serve as its decoy receptor. This protein can also bind several chemokines (252). VV encodes a homolog of IFN-a/b receptor that, unlike the cellular receptor, can bind type I IFN of many species (3,179). Tanapox virus–infected cells secrete a protein that can bind to and inactivate IFN-g, IL-2, and IL-5 (70).

Inhibition of Interferon Signaling

Another common step of interference by different viruses is at the level of signal transduction by IFNs. The Jak–STAT pathway loses its regulation and is constitutively activated by human T-lymphotrophic virus (HTLV) tax proteins (183) and by spleen focus-forming viral envelope protein gp55 that binds to the erythropoietin receptor (318). Herpesvirus saimiri activates the Jak–STAT pathway using lck, a src-related tyrosine kinase (161). In the opposite scenario, many viral proteins inhibit the Jak–STAT pathway. Infection with HCMV appears to decrease Jak1 levels in infected cells by enhancing degradation of the protein, and a consequence of this effect is disruption of induction of class II MHC expression on the surface of infected cells (184). Murine polyomavirus large T antigen binds to Jak1 and inhibits IFN signaling. This activity requires the pRB binding sites of the large T molecule. As a result, ISGF3 is not activated in response to IFN-a/b, and consequently, other viruses such as VSV are also not inhibited by IFN in cells expressing large T (308).

P>The most thoroughly studied example of interference with IFN signaling is that mediated by the adenoviral E1A proteins. Adenoviruses are insensitive to IFNs because several adenoproteins counteract the IFN system at multiple steps, with the earliest step at an IFN-signaling block by E1A. As a result of the E1A-mediated effect, IFN also cannot inhibit the replication of other viruses. E1A expression does not allow ISGF3 formation. The defect can be ascribed to a lowered cellular level of one or more of the signaling proteins, including STAT1 and P48 (146,147). E1A also disrupts the interactions between the STAT proteins and CBP/P300 required for ISG transcription by interacting with both STAT1 and STAT2 (20). Other DNA viruses can interfere with IFN-signaling. The hepatitis B virus (HBV) polymerase protein or its subdomain TP blocks ISGF3 activation (79). The EBV EBNA1 oncogene blocks gene induction and cell growth inhibition by IFN without interfering with the activation of ISGF3, indicating that the block may be at the level of ISGF3–coactivator interactions (123). The human papillomavirus E7 protein abrogates IFN- a signaling and blocks ISGF3 activation. In this case, E7 directly binds to P48 and inhibits its translocation to the nucleus (17). Numerous RNA viruses have also been shown to interfere with IFN signaling. Ebola virus inhibits both IFN- a and IFN-g signaling in endothelial cells (108). Sendai virus C proteins prevent the antiviral action of IFN, possibly by interfering with signaling (84). One specific C protein appears to be responsible. A similar virus, SV5, has a viral V protein blocking the activation of ISGF3 in response to IFN-a/b and GAF in response to IFN-g (65). This dual block is achieved by targeting STAT1 for proteasome-mediated degradation. Several viruses have strategies to block other steps. The HPV16 E6 oncoprotein binds to IRF-3 and blocks its transactivation functions (238). IRF-3 is activated in response to dsRNA and virus infection and promotes transcription of IFN genes and many ISGs. In the presence of E6, IFN- b is not induced by Sendai virus infection. Human herpesvirus type 8 (HHV-8) encodes a transcription factor similar to the IRF proteins (189). The viral IRF interferes with the actions of cellular IRF proteins and thereby blocks IFN and ISG expression. Thus, a variety of viruses have evolved to overcome potent antiviral effects induced by IFNs by blocking IFN-signaling pathways.

Interference with Functions of Interferon-Induced Proteins

Many viruses have developed mechanisms to counteract specific functions of various IFN-induced proteins. There are known viral inhibitors of the two well-studied IFN-induced antiviral pathways requiring dsRNA for activation. EMCV infection causes an inhibition of binding of 2-5(A) to RNase L, although IFN pretreatment overcomes this inhibition. Analogs of 2-5(A), which block activation of RNase L, are synthesized in herpesvirus- or SV40-infected cells (39). The most frequent IFN-induced antiviral mechanisms targeted, however, are those mediated through activation and function of PKR (119). Adenovirus produces abundant amounts of spoiler VAI RNA that bind to the dsRNA-binding domain of PKR but do not activate it. Similarly, EBV produces EBER RNA, and HIV-1 produces TAR RNA; at high concentrations, these viral products block PKR activation. The VV E3L protein, influenza virus NS1 protein, and reovirus sigma 3 protein, on the other hand, prevent PKR activation by binding dsRNA. VV also encodes K3L, which functions as a decoy of eIF-2 and an alternative substrate of PKR. A phosphoprotein of HSV-1 neutralizes PKR action by inhibiting phosphorylation of eIF-2 (46). The HSV-1 g 34 · 5 protein complexes with protein phosphatase 1a (PP1a) to promote dephosphorylation of

eIF-2a. PP1a may also be responsible for inactivating the enzyme itself by causing PKR dephosphorylation. Influenza virus activates a novel cellular chaperone protein, P58IPK, which inhibits PKR, possibly by interfering with its dimerization. Poliovirus and HIV promote degradation of PKR through unknown mechanisms. Hepatitis C virus encodes two proteins interfering with PKR action. The NS5A protein binds to the dimerization domain of PKR to block its activation (81), and differences in natural resistance to IFNs between different strains of HCV can be attributed to mutations in the NS5A protein. Another protein of HCV, the E2 glycoprotein, has also been shown to inhibit PKR (285). E2 contains a sequence identical to the phosphorylation sites of PKR and eIF-2 and binds to PKR to inhibit its action. The previous examples of many viruses evolving a variety of mechanisms to inhibit PKR support the notion that PKR functions as a major antiviral enzyme in the IFN system.

Other Mechanisms

In addition to those directed at IFN functions, viruses have evolved a number of other far-reaching mechanisms to counteract or take advantage of host cytokines or their actions (93,266,267). Although it is not possible to review all of these in detail, a few examples are given here. The large poxviruses are packed with genes having potential to inhibit or modify host immune responses. One of these is the T2 protein, which can protect virus-infected cells from the antiviral effects of TNF actions (93,158). The myxoma virus MT-2 molecule is a homolog of the cellular receptor for TNF and is released from infected cells to serve as a binding decoy and block signaling through functional host TNF receptors. Myxoma virus also produces a homolog of EGF/TGF-a (3). HHV-8 encodes a cytokine similar to IL-6, which promotes the growth of transformed B cells (33). The EBV BCRF-1 protein is highly homologous to mammalian IL-10 (186). The viral protein is biologically active and is thought to aid viral pathogenicity by suppressing production of immunostimulatory cytokines and by promoting B-cell growth and transformation. This gene function is essential for the transforming capacity of EBV. A VV gene for an enzyme promoting steroid production may act to inhibit endogenous immune responses by accessing the immunoregulatory pathways induced by these hormones (190). A different mechanism is used by the cow poxvirus to block IL-1b. It encodes an inhibitor of IL-1b converting enzyme that is required for the production of IL-1b by proteolytic cleavage from a larger precursor. Finally, there is an example of one virus, measles, using as its receptor a cell surface molecule delivering a signal to regulate IL-12 expression negatively (125).

Certain viruses also have genes with homology to host chemokines or chemokine receptors and other gene products with chemokine-binding activities (82,95,140,177,219,266,293). It is not yet clear whether all of these function to help virus escape from immune defense or whether they might also act to promote viral replication. In soluble forms, the chemokine receptor homologs could act as natural chemokine receptor antagonists or blockers. This appears to be the case during myxoma virus infections, in which certain viral products with chemokine-binding activity are virulence factor for infections and interfere with recruitment of leukocytes into virus-infected tissues. In contrast, chemokine homologs might promote virus spread by calling in cell for infection, and this appears to be the case with a chemokine homolog expressed by MCMV (77,246).

CYTOKINE-MEDIATED PATHOLOGY

Although characterization of immunopathology during viral infections has traditionally focused on adaptive immune responses resulting in particular antibody-dependent immune complex– or CTL-mediated diseases, cytokines can also contribute to immunopathology. This has been long appreciated in the case of bacterial infections. Cytokine-dependent consequences detrimental to the host have been clearly delineated during gram-negative bacterial sepsis and after exposure to LPS (105) as well as in response to gram-positive bacterial toxins such as the staphylococcal enterotoxins (174). High-level exposure to the first class of agents induces proinflammatory cytokines by innate immune response mechanisms. These conditions are associated with high systemic levels of TNF-a, IL-1, IL-6, IL-12, and IFN-g and with TNF-a essential for the detrimental effects and most of the other factors acting to increase sensitivity to TNF-a. Exposure to the bacterial endotoxins activates large proportions of T-cell subsets to produce cytokines amplifying the proinflammatory innate cytokine cascades. If uncontrolled, the conditions can result in coagulation, vascular collapse, and multiple-organ failure. Remarkably, the functions of certain of the proinflammatory cytokines, such as TNF-a, IL-1, and IL-6, include alerting the neuroendocrine system to the problem and activating the hypothalamic–pituitary–adrenal axis to induce the release of glucocorticoid (GC) hormones from the adrenal glands (178). The GC hormones can mediate a number of immunoregulatory effects to limit detrimental consequences of the endogenous cytokine responses. In particular, they can inhibit the expression of certain of the cytokines (2,178,202,257).

Little attention has been paid to potential cytokine-mediated diseases during viral infections. Recently, MCMV infections have been shown to induce systemic proinflammatory cytokines overlapping with, but not exactly identical to, those known to be induced under conditions of LPS exposure, that is, significant serum levels of TNF-a, IL-6, IL-12, and IFN-g but low or undetectable IL-1 responses (243,244). Under these conditions, an adaptive immune response–independent, but TNF-dependent, liver necrosis is induced and results in significant organ damage (209). Such a pathway may contribute to liver disease during other viral infections. In particular, infections with mouse hepatitis virus type 3 (MHV-3) also induce liver necrosis and disease associated with macrophage activation and coagulation (67,148,149). The conditions of systemic cytokine induction during MCMV infection result in an IL-6–dependent induction of endogenous GC production (243), and the GC response acts to protect the host from a TNF-dependent lethality during the infection (244).

Results of treatments with IL-12 (210,212) or challenge with LPS (199) suggest that there may be conditions under which T-cell responses to viral infections promote cytokine-mediated or cytokine-dependent disease during viral infections. Such pathways are likely to contribute to pathology during infections with Dengue virus (138) and perhaps Hantaan viruses, but this remains to be thoroughly investigated. Recent evidence suggests that effects mediated through the LT b-receptor also may contribute to viral pathogenesis (225).

SUMMARY

This chapter has reviewed current understanding of cytokine responses and functions during viral infections. We have

attempted to present the broad picture, but emphasis has been on unique pathways activated by and during viral infections. A focus has been on IFN-a/b. Key aspects of the integrated responses are schematically represented in Figure 7. Many viruses have evolved specific mechanisms to exert control over the responses and their functions. The overall balance is crucial to the host. As the material reviewed shows, our understanding is becoming sophisticated, but much remains to be learned. This is an active period of investigation. The authors look forward to the next few years of study and the knowledge to be derived from the results of this work, particularly in the areas of understanding how the systems work at the biochemical level to regulate immune responses *in vivo.*

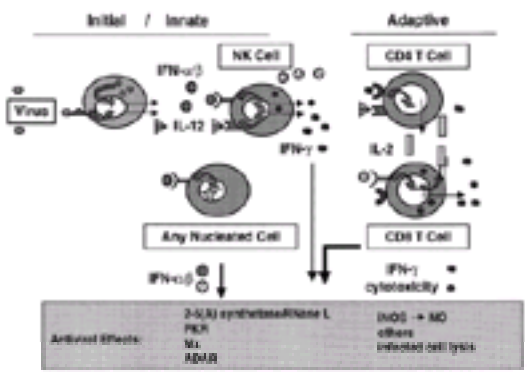

FIG. 7. Summary of known specific responses and their effects during viral infections. Initial events during infections include induction of interferon (IFN)-a/b ( ) in response to viral products. These cytokines then activate a variety of biochemical events through receptor stimulation of a Jak/STAT signaling pathway with activation of the ISGF transcriptional complex ( ) and lead to expression of proteins contributing to antiviral defense mechansims, including, but not limited to, 2-5 (A) synthetase/RNase L, PKR, and Mx. The IFN-a/b cytokines also promote the induction of innate natural killer (NK) cell cytotoxicity ( ) and can enhance adaptive T-cell IFN-g ( ) responses. Certain viral infections also induce an initial or innate interleukin-12 (IL-12) response ( ) response. This factor is associated with NK cell IFN-g production. Many viral infections induce profound CD8 T-cell expansion with activation of CD8 T-cell IFN-g production and cytotoxic T-lymphocyte (CTL) functions. T-cell IFN-g responses can be IL-12 independent during viral infections. IL-2 ( ) can promote CD8 T-cell expansion and facilitate optimal responses mediated by these populations.

CHAPTER 13 Virus Evolution

Victor R. DeFilippis and Luis P. Villarreal

DEFINING EVOLUTION

Evolutionary change is a temporal process that is derived from the differential reproductive success of individuals and their inherited phenotypes that alters corresponding genotypes between generations. Evolution is therefore an inevitability in populations of entities that (a) self-replicate and (b) exhibit heritable variation in phenotypes that affect reproduction. Charles Darwin described evolutionary change as “descent with modification,” implying that characters exhibited by an ancestral population differ from those exhibited by its descendant population. Furthermore, this primarily statistical difference is brought about by the simple fact that not every member of the ancestral population is represented by progeny in the descendant population. The assortment of phenotypes inherited by the descendants of the chosen replicators is rarely identical to that of the previous generation, thus resulting in a changing phenotypic makeup through time. Evolutionary change does not need to be driven by reproductive success that is influenced by phenotype in any way, however. Genetic drift results from stochastic changes in population size that are independent of reproductive traits. This often results in a “sampling error,” bringing about a new mixture of genotypes that differs from that in the previous generation.

Viruses, being autonomous replicators that can exhibit profound degrees of intrapopulation genetically based phenotypic variation, are of course subject to the laws of evolution. Viruses do, in fact, use evolutionary change as both short- and long-term survival strategies that can allow the immediate escape of host antiviral responses as well as the transmission to new hosts, often through unpredictable environments. This is not to say, however, that viruses must evolve rapidly to exist. Many viruses change very little between generations, and this is often due to low mutation rates or unchanging, consistent host environments.

The Process of Evolution

Natural Variation

Naturally occurring variation in the form of genetically derived phenotypic diversity is an evolutionarily requisite characteristic of populations. Such diversity is the “raw material” on which both selection and drift act to influence characteristics of subsequent generations. This variation has many bases that will be discussed in more detail later, but the two primary causes of viral genetic diversity are mutation (including genetic exchange) and population size. As both increase, so too does the spectrum of characteristics available for inheritance by viral descendants.

The extent of this variation differs tremendously among viral types. Many RNA viruses, for instance, exist as *quasispecies* that are often broad distributions of mutant (and recombinant) viral genomes existing as a population within a single host. For example, a great deal of research has examined the quasispecies population structure that exists in foot and mouth disease virus (FMDV). FMDV has a single-stranded RNA genome about 8,500 nucleotides in length. It has been estimated that in natural populations of FMDV, nucleotide substitution rates range from 0.9×10^{-2} to 7.4×10^{-2} replacements per nucleotide per year (37). This translates into enormous genetic heterogeneity observable in natural isolates of the virus. As reported by Domingo and colleagues (37), during an outbreak of FMDV infection, 0.7% to 2.2% of nucleotides differed among typical sampled viral isolates. Within an infected individual, it was estimated that 0.6 to 2 nucleotide substitutions were occurring per round of genome replication.

In contrast to the highly variable RNA viruses are many DNA viruses that experience much lower mutation rates and thus vastly lower genetic variability. Included among these are the small DNA viruses such as papillomaviruses and polyomaviruses. These viruses use the highly accurate DNA replication machinery of their mammalian hosts and therefore exhibit substitution rates on the order of 10^{-7} to 10^{-8} per nucleotide per year (13,123). Not surprisingly these rates are close to those of their hosts. Perhaps as a result, these viruses often exist as silent, apathogenic infections and in addition are known to cospeciate with their hosts (116). This is not to say, however, that such viruses must display low genetic or phenotypic variation. Because of the almost incomprehensibly large population sizes (both intrahost and

interhost) that can approach 10^{12} particles within a single organism, the amount of total genetic variation is seemingly always adequate for adaptive survival and evolution no matter the environmental obstacle.

Natural Selection

Natural selection is a discriminating force that allows the production and survival of progeny from a subset of a parental population. This selectivity is driven by the specific abiotic and biotic conditions under which the population exists, and the heritable phenotypes that are best suited for reproduction under these conditions are the ones “allowed” to be transmitted to a subsequent generation. When natural selection is in operation, the result is a descendant population made up of genetic successors that exhibit phenotypes chosen from the previous generation based on their suitability to specific (yet variable) environmental characteristics.

It is commonly accepted that natural selection therefore leads to a certain type of evolutionary change that is termed *adaptive. Adaptation* refers to both the process by which a population becomes better suited for survival and reproduction in a given environment and the actual *phenotypic character* that arises by way of natural selection that bestows this ability. The closely affiliated and frequently employed word *fitness* is best understood as a relative term that describes the genetic contribution an individual makes to a subsequent generation compared with that made by other individuals in the same population. Fitness is therefore based on natural selection and increased by adaptation.

Different types and degrees of natural selection exist. The magnitude of natural selection is primarily determined by (a) the amount of change in the reproductive environment through time and (b) the width of the range of phenotypes allowed to reproduce in a certain environment. Along these lines there are three main types of natural selection that act on populations: (a) directional selection; (b) stabilizing selection; and (c) diversifying (disruptive) selection. These are best distinguished using an example. Figure 1 represents a hypothetical frequency distribution of some polymorphic phenotype in a viral population (e.g., rate of replication). Under directional selection, replication rates that fall within either area A or C might be selected for, and the result would be a correspondingly faster or slower mean rate of replication in the following generation. This type of selection might be more common in a changing environment. Under stabilizing selection, replication rates that fall within area B would be selected for, and consequently replication rates in areas A and C would be selected against. The result would be a similar mean replication rate in the descendant population but with less overall variation in that rate. This type of selection is common in stable environments that often have limited reproductive resources. Under diversifying selection, replication rates within both areas A and C would be selected for, resulting in an increase in the diversity of this phenotype in the next generation. This type of selection may occur when either replication environment or phenotypic diversity is highly variable.

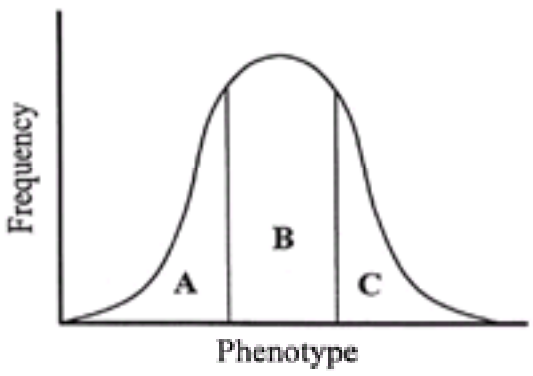

FIG. 1. Hypothetical phenotype frequency distribution.

Genetic Drift

Changes in genetic makeup through time (i.e., evolutionary change) need not be adaptive or driven by natural selection. Random and even predictable fluctuation in population size that translates into differential reproductive success can obviously influence future gene frequencies. Viruses can be particularly susceptible to the effects of genetic drift because host–host transmission frequently involves population size “bottlenecks” that occur independently of viral fitness. In other words, a specific viral type may be supremely adapted to replication in a particular host environment but, due to events of pure chance, is prevented from survival or reproduction. The outcome may be that a virus type of lesser reproductive capability is allowed to survive despite the decrease in mean population fitness this will cause. It is in this way that populations may actually become less adapted to their environments.

This phenomenon is well exemplified by viruses that rely on transmission routes, such as aerosol droplets, that involve extremely small inocula despite huge intrahost viremic population sizes. For example, human respiratory droplets are typically less than 1 to 10 μM in diameter. Therefore, on average, a given droplet is likely to carry few if any viral particles (6,58). Although there are few complete investigations of naturally occurring genetic drift imposed by host–host viral transmission, a number of studies have looked at the effects of experimental bottlenecks on population fitness. Vesicular stomatitis virus (VSV) is a negative-stranded RNA virus that frequently infects humans and other mammals. Duarte and colleagues examined the effects on viral fitness of experimental bottlenecks produced between clonal plaque–plaque transfers (45). Using direct replication competition assays, they found that after as few as 20 passages, profound decreases in viral fitness were observed in the VSV clones.

Why does this occur? The answer is an elementary statistical phenomenon known as *sampling error.* For an extremely large, highly diverse population (common among viruses), the ratio of highly fit to less fit genotypes may actually be a very small number. During a transmission event, only a few particles might be selected. The genotypic makeup of these

particles does not accurately represent the full genetic or fitness distribution of the original population and therefore often does not include members of the highly fit class because of their comparatively small numbers. The outcome is a new population established in a similar environment but with members of a small, less fit (on average) class of viruses. Mechanisms of escape from this form of evolutionary down-spiraling are discussed later (see Generation of Genetic Diversity).

Natural History

Evolutionary biology is a science that studies not only the mechanisms and processes by which evolutionary change takes place but also the historical record of that change. By applying knowledge about episodes of biological change and stasis in the past to our current understanding of the evolutionary process, it may be possible to predict the pattern and direction of change in the future. But why does one want to predict such change? Viruses and viral change have a profound impact on human health, agriculture, and indeed overall quality of life. The harmlessly silent viruses of today can undergo evolutionary change (via adaptation or otherwise) and seemingly overnight give rise to the nightmarish pandemic of tomorrow. What were the natural events that led to the global spread of lethal human immunodeficiency virus (HIV)? Why does influenza virus periodically cause widespread epidemics of dramatically high virulence? Questions such as these will probably never be answered completely, but significant progress is being made in epidemiology of viral and other infectious diseases with the help of evolutionary concepts and historical reconstruction.

Microbiologists and virologists in particular are at a severe disadvantage when investigating the past (geological) history of their target organisms. This is for two main reasons. First, evolutionary virology is a relatively new science that has only been made possible by modern advances in computing technology, microscopy, and molecular biology. Therefore, the amount of accumulated knowledge from past research is extremely small compared with other biological fields. Second, viruses leave no fossil record, in contrast to many multicellular organisms. Evolutionary virologists are therefore constrained to retracing past events mainly through mathematical analysis of protein and nucleic acid sequences from viruses that have been isolated almost exclusively during the 20th century. This by no means has a crippling effect on evolutionary investigation, however, because techniques of both sequence data production and sequence analysis are currently quite sophisticated and rapidly growing with advances in microprocessing, molecular biology, and information technologies (67). For instance, automated sequencing now allows determination of entire viral genome sequences in mere days. Multiple phylogenetic algorithms can reconstruct with great accuracy the evolutionary relationships of genes, proteins, and even genomes. In addition, population genetics theory can elucidate parameters such as population size fluctuations, evolutionary rate, and time to common ancestry.

Viral taxonomy is a principal benefactor of modern evolutionary analysis. Taxonomy is a science based on the hierarchical classification of organisms into separate groups based on similarity. This similarity is most ideally reflected in phylogenetic relationships. Taxonomy of cellular, especially sexually reproducing, organisms has its basis in the fundamental (lowest) unit of species. Many definitions of species exist, and all have evolutionary relevance. The commonly cited “biological species,” however, is described as a group of actually or potentially interbreeding organisms that are reproductively isolated from other such groups. This immediately presents an impasse to virologists because sex is not a required step in viral reproduction. Nevertheless, although viral classification schemes do include taxonomic groupings with names identical to those found in cellular taxonomy (i.e., species, genus, family, order), their functional definitions are mostly distinct.

The International Committee on Taxonomy of Viruses defines a *viral species* as a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche (100,132). This is a necessarily broad definition that provides tremendous room for interpretation. In general, characters such as serologic cross-reactivity, host range, tissue tropism, gene sequence divergence, and transmission properties are used to denote viral species (132). Taxonomic ranks such as genus and family are assigned according to more slowly evolving characters like morphology, replication strategy, and genome characteristics (e.g., gene order) (100). The evolutionary relationships of viral groups are often assumed to mimic their taxonomic assignments, and although this may typically be assumed as accurate, it is not an inherent law of the science. Classifying viruses according to their true phylogenetic relationships, especially on the lower levels, may be a lofty goal given the practically exclusive reliance on molecular data analysis for determination of viral evolutionary history. In addition, gene sequences may actually transmit conflicting phylogenetic signals as a result of intergenomic genetic exchange. Phylogenetic information should be used as an influential consultant to taxonomic decision making and must not be an edict accepted as biological truth.

The limitations of molecular phylogenetics are conspicuous when considering viral taxa. This is most clearly demonstrated by the effects of viral recombination (discussed in more detail under Recombination). Phylogenies reconstructed using information from short, single, contiguous regions of viral genomes can be misleading. For example, in a report by Khimani and colleagues, phylogenetic analysis of complete murine leukemia virus (MuLV) genomes uncovered a likely recombination event involving only the *env* genes of Hortulanus MuLV and Cas-Br-E MuLV, two retroviruses isolated from wild mice (77). Nucleotide diversity analysis of other genomic regions (including *gag*) phylogenetically pairs Cas-Br-E with Moloney MuLV, whereas data from *env* nucleotide sequences indicate that the closest virus to Cas-Br-E is actually Hortulanus MuLV. This can be explained by a recombinational event that took place between the viruses, making their *env* sequences more similar than other genomic regions and thereby manifesting as disparate phylogenetic results. A taxonomist assuming that the closest relative to Cas-Br-E is Moloney MuLV based on *gag* sequence data is therefore likely deceived by not seeing the bigger picture.

VIRAL ORIGINS

General Considerations

Regarding viral origins, clearly two distinct issues emerge as important. First is the issue of original virus ancestors. This refers to the ultimate, ancient, and earliest appearance of particular viral groups. Second is the origin of modern viruses that have arisen long after the first viral progenitors and continually arise even today. The latter subject is discussed in

subsequent sections. Most researchers would agree that the available evidence points to multiple origins for viruses of different types. The unique reproductive strategy shared by all viruses (i.e., obligate molecular parasitism accompanied by genome encapsidation and intercellular transport) has most likely arisen more than once in biological history.

Viruses have presumably existed for many millions, and probably billions, of years on our planet, yet, as already emphasized, they have left no known fossil record. This predictably complicates investigation into their origins. We are left with their genomes, their genome products, their replicative behavior, and their hosts to formulate hypotheses about how viruses were evolutionarily conceived. This can be difficult, especially when considering rapidly evolving viral genomes (e.g., RNA-based genomes) whose informational content is periodically nearly replaced or "turned over." There are three primary theories used to explain the ultimate origin of viruses. These need not be mutually exclusive, however, and as discussed later, it is very possible that more than one evolutionary process was involved in the appearance of some viral groups.

The first theory is perhaps the most intriguing from the standpoint of Earth's biological history. It involves the possibility that viruses are actually remnants of a primordial precellular world. This was originally based on their structural simplicity but has since been adapted to incorporate genome biochemistry. The theory encountered a fair amount of scorn from researchers on the grounds that virus replication is so dependent on host cellular machinery that it is unlikely viruses could arise in the absence of such hosts (4,18). Discovery of and research into the enzymatic capabilities of RNA (22) have endowed this theory with a resurgence in attention because most known viruses use RNA as their genomic nucleic acid.

RNA-based primordial life is now strongly considered as possible, even likely (59,75). Therefore, even though modern RNA viruses may not possess characters detectable as being shared with precellular relatives, it is not inconceivable that they are ultimately derived from such a source. In fact, viroids (small, naked RNA plasmids) have been hypothesized to represent direct descendants of precellular molecular ancestors on account of their genomic material and self-splicing capabilities (19,34,35). Like viruses, viroids are infectious obligate molecular parasites, many of which replicate using a rolling, circular mechanism. Unfortunately, a lack of significant identifiable genomic homology between viroids and any known viruses prevents useful phylogenetic estimation of the evolutionary relationship between these two groups. It has been suggested, however, that RNA-based agents (perhaps related to viroid-like molecular entities) encoding reverse transcriptase facilitated, or even caused, the origination of DNA as genomic material (30,43,85,94).

Another theory suggests that viruses are descended from cellular pathogenic microorganisms such as bacteria that have gone through a process of "retrogression" (or, more accurately, an evolutionary decrease in complexity). This idea was constructed before the advent of modern molecular biology and therefore was based on crude viral characteristics such as size and pathogenic attributes (64,83). Modern advances in molecular techniques have allowed for more detailed examination of viruses, their genomes, and the effects they have on their hosts. Consequently, huge disparities between viruses and other pathogenic microorganisms have been elucidated. This has resulted in an all but total rejection of the retrograde hypothesis, but, as discussed later, it may still have some legitimacy, especially in combination with other theories of virus origins.

The third theory explaining the origin of viruses proposes that viral ancestors are cellular genetic elements that have "escaped." This currently has a great amount of empirical support and is therefore a widely accepted theory explaining the origins of some virus types. This "endogenous theory" was first alluded to by Lwoff in 1957, who discussed it in relation to bacteriophage latency (92), and was further developed along those lines by Waterson in 1960 (138). The idea was strengthened by Temin in his discussions about the origins of retroviruses (126,127). Evidence in support of this theory is most convincing when one considers the retroviruses and DNA viruses. The data exist mostly in the form of homologous coding sequences found in both viral and cellular genomes. These include DNA- and RNA-dependent DNA polymerases and oncogenes. In addition, the overall sequence similarities between some endogenous retroid agents and retroviruses cannot be ignored. The endogenous theory is more difficult to extend to riboviruses, which rely on RNA-dependent RNA synthesis—an activity that does not take place in DNA-based cellular hosts, the supposed viral progenitors.

Origins of RNA Viruses

Viruses are the only forms of life known to possess RNA genomes. In fact, RNA is the most common genomic nucleic acid among known viruses. Riboviruses are viruses that have RNA genomes that do not replicate via a DNA intermediate. They may have positive (+) sense (messenger sense), negative (–) sense (antisense), or double-stranded (ds) RNA. Of all known viral taxa, positive-sense RNA riboviruses are by far the most common (62) and include the picornaviruses and togaviruses among many others. Negative-sense RNA riboviruses include the orthomyxoviruses and arenaviruses. Double-stranded RNA viruses include the reoviruses. It is not known whether riboviruses and retroviruses are a monophyletic assemblage (i.e., descended from a single common ancestor). It is interesting to note, however, that all riboviruses use a virally encoded RNA-dependent RNA polymerase (RdRp) for genome replication, whereas all retroviruses use an RNA-dependent DNA polymerase (reverse transcriptase)—thus implying that the two groups have separate origins. In addition, a great deal of evidence exists indicating that since their appearance, both ribovirus and retrovirus genomes have obtained heterologous sequences from other viruses as well as their hosts.

A good starting point for discussion about the origins of riboviruses is evolutionary analysis of RdRp. Amino acid sequences of RdRp proteins are extremely important for two main reasons. First, sequence analysis of RdRp points to a single evolutionary origin of this protein for all riboviruses (62). It has been hypothesized that this ancestor arose before the first eukaryotic cells and is certainly one of the first enzymes to appear in biological history (76,109). Second, analysis of extant viral RdRp proteins from diverse groups has yielded extraordinary and unexpected phylogenetic information about the relationships therein. This has contributed strongly to the division of riboviruses into distinct taxonomic units.

Riboviruses are classified into eight main supergroups based on morphologic and genomic characteristics as well as phylogenetic analysis of their more highly conserved proteins. Phylogenetic analysis of RdRp (as well as other proteins,

such as virally encoded helicase) has indicated that the three main ribovirus genomic classes (+, –, and dsRNA) represent distinct monophyletic groups (17,61,80). Interestingly, within these groups, viruses do not always cluster phylogenetically according to host taxa, tissue, or replication ecology. For instance, based on RdRp sequence analysis, the flavivirus-like viruses (hepatitis C, West Nile, Japanese encephalitis, Dengue fever, and yellow fever viruses), which replicate in mammalian cells, are closely related to (and even derived from) the luteovirus, potyvirus, and tobamovirus groups that infect plant hosts exclusively (17). Perhaps even more remarkable has been the phylogenetic placement (based on RdRp sequences) of +RNA bacteriophages Qb, MS2, GA, and SP with such eukaryotic viruses as Dengue 4, yellow fever, and hepatitis C (80). These examples demonstrate the evolutionary fluidity exhibited by the RNA viruses with respect to the conditions under which they can replicate and persist.

Determining which RNA virus group is the most ancestral using molecular data exclusively is a complicated endeavor. If one assumes that evolutionary diversification increases with time, the +RNA viruses have been around the longest because they far exceed the other two groups in number of recognized taxa. It has been suggested, however, that dsRNA viruses gave rise to +RNA viruses, which gave rise to –RNA viruses (17,61). This might be consistent with the concept of dsRNA viruses as ribovirus ancestors because some phylogenetic analyses have placed them both within and even outside the +RNA evolutionary tree (61,81). In addition, it is known that dsRNA viruses are frequently pathogens of the more primitive bacterial and fungal species and less so of the “newer” eukaryotic species—perhaps another indication of their age. It is also possible that dsRNA viral genomes have evolved more than once.

These results tend to generate more questions regarding ultimate riboviral origins, however. It has been hypothesized that riboviruses (as well as other viruses) are derived from escaped host genetic material such as mRNA, perhaps even coding for RdRp. There are many solid examples of homologous cellular coding regions within riboviral genomes. For instance, bovine viral diarrhea virus (BVDV) is a +RNA flavivirus. A particular strain of this virus was found to have an approximately 270 base pair insert present in its genome that was nearly identical to the host mRNA coding for ubiquitin (27). Such insertions represent recent evolutionary events and are qualitatively much unlike the hypothetical escape of previral host RNA but do illustrate the blurry line between host endogenous and mobile exogenous genetic material.

The theory that riboviruses are living relics of the RNA world is frequently neglected because hard evidence is seriously lacking and it is also difficult to imagine their replication cycle, as we now know it, existing without a cellular host genome to be parasitized. The most likely group of extant life forms to resemble inhabitants of precellular Earth is the riboviruses. We argue that this theory should not be completely ignored for all riboviruses, and two important facts clearly stand out. First, riboviruses do not rely on DNA directly for any stage in their replication. This characteristic was certainly exhibited by all self-replicating entities in a precellular or pre-DNA world but is currently exhibited by no other organisms known. Second, RNA-dependent RNA polymerization would be required in an RNA biosphere, and it is probable, if not mandatory, that a protein or RNA–protein complex evolved to accomplish this efficiently. The only RdRp that is known to exist as a protein functionally related to reproduction is a component of every ribovirus genome.

One theory of riboviral origins that may be rejected with a high degree of confidence is evolutionary retrogression. This is because it is nearly impossible to imagine either (a) a previously autonomous RNA-based organism because none are known today or (b) the characteristic of genome nucleic acid actually changing from DNA to RNA during evolutionary retrogression.

Origins of DNA Viruses

More than 26 families of viruses use DNA, either single or double stranded, as genomic material. These viruses are common as parasites of prokaryotes, archaea, and eukaryotes. Although fewer in taxon numbers than the riboviruses, the DNA viruses as a group are in many ways more diverse. DNA viral genomes vary tremendously in size from as small as 1.8 kilobases (kb), as in the single-stranded porcine circulovirus, to as large as 670 kb, as in bacteriophage G. DNA viruses may be enveloped or nonenveloped, cytoplasmic or nuclear, polymerase encoding or non–polymerase encoding. Unlike the riboviruses, however, there exists no evidence that evolutionarily links the major divisions of DNA viruses. It is therefore likely that some DNA virus groups have had separate, independent origins.

It is perhaps easiest to begin by distinguishing two major lineages of DNA viruses. The most logical separation is between those that encode a DNA-dependent DNA polymerase (DdDp) and those that do not. As with RdRp discussed previously, the DdDp protein serves a function indispensable with respect to reproduction and is accordingly well conserved through evolution. DdDp proteins are much more divergent and varied than RdRp and are classified into four families (labeled A to D) based on amino acid similarity or disparity. All replicative viral DdDps belong to either family A or B, and all exhibit 3'5'-exonuclease activity. All DdDps, whether viral or cellular, are thought to have evolved from a single common ancestor (16,79,136). Viruses that encode family A polymerases include bacteriophages of the genera *Siphoviridae* and *Podoviridae* as well as the mycobacteriophages of fungi. Family B polymerases are contained within the genomes of phycodnaviruses of algae, herpesviruses, poxviruses, adenoviruses, and ascoviruses of vertebrates and other eukaryotic taxa, and baculoviruses of invertebrates.

Polymerase-encoding DNA viruses are a highly divergent group that may or may not have arisen from a single common viral ancestor. Sequence analysis of DdDp has resulted in some interesting, sometimes unexpected, results. It should be noted here that viral DNA polymerases are thought to be at least as old as any of their corresponding cellular homologs, prompting one to speculate about the ultimate origin of this protein (134). Viruses that use protein-primed DNA replication, such as the mammalian adenoviruses and bacteriophages f29 and PRD1, are closely related despite the distant relationship of their hosts (79). In addition, cytoplasmic eukaryotic viruses, such as vaccinia and entomopoxvirus, are paired with the T-even phages of bacteria (79). Other revealing information regarding the deeper relationships between DNA viruses include certain capsid morphologic and assembly characteristics that are shared between herpesviruses and bacteriophages, which may point to shared ancestry among these two groups (21,56,120).

An evolutionary link between the large DNA viruses and the small DNA viruses of eukaryotes (i.e., the papillomaviruses, polyomaviruses, and parvoviruses) cannot be established based on genomic analysis. This is because of an apparent

lack of homologous sequences, the existence of which may be driven by the high frequency with which DNA viruses are known to undergo recombination (see Recombination). Recombination between co-infecting viruses and between host and virus acts to create genetic homogeneity within virus types and heterogeneity between virus types. Because of their small genome size and their very strong dependence on host replication machinery, the small DNA viruses are perhaps the most likely candidate viruses to have arisen from endogenous cellular genetic material. Unfortunately, there currently exists no direct evidence in support of this method of origination.

Origins of Retroviruses

Retroviruses include both exogenous (horizontally transmitted) and endogenous (vertically transmitted) enveloped agents that contain RNA genomes but use reverse transcription (RNA ® DNA) as part of their replication process. To accomplish this, the viruses require the use of an RNA-dependent DNA polymerase (reverse transcriptase). Unlike most DNA and riboviruses, the retroviruses share obvious similarities with many nonviral, usually mobile cellular genetic elements. It is widely believed that retroviruses are evolutionarily derived from host genomic elements such as the LTR retrotransposons (126,127). The basic difference between the two groups is the presence of a genomic region coding for an envelope (packaging) structure in the former group. The acquisition of a genomic encapsidation strategy subsequently allowed for cell–cell and eventually host–host transmission. It is also accepted that all retroviruses, retrotransposons, hepadnaviruses, and caulimoviruses share a distant common ancestor (42,95,146).

The distribution of all retroid agents (defined as any genetic element that encodes reverse transcriptase) within the Earth's tree of life is quite skewed, with most being found in eukaryotes, much fewer being found in eubacteria, and none known to use genomes of the Archaea. The retrotransposons are found within the genomes of animals, plants, fungi, and protozoa, but because of their abundance and variety as well as the diversity of their replicative strategies, it is believed that they are possibly the oldest class of retroid agents (47). When considering just the retroviruses, only mammals, birds, and insects are known to act as hosts. This relatively small host phylogenetic distribution, along with similarity between different retroviral genome sequences and organization, suggests that the retroviruses have arisen recently in evolutionary time, especially when compared with most DNA and riboviruses (41).

Retroid agents, including retroviruses, have undoubtedly played many important roles in the evolution of life. The ubiquity and apparent ancientness of reverse transcription has led to speculation that this process was integrally involved in the transition from RNA to DNA as genomic material (30,43,85,94). In addition, the overwhelming presence of retrotransposons and endogenous retroviruses in the genomes of most eukaryotes provides abundant opportunity for emergence of new, exogenous retroviral agents (e.g., HIV).

VIRAL DIVERSIFICATION

As exemplified by the immense variety we observe in their morphology, replication strategies, host ranges, environmental tolerances, and transmission strategies, extant viruses have been shaped by a fantastic sequence of evolutionary change and divergence. As we shall see, the amount of viral evolution is related to both random and directional forces. Extremely mutable viruses need not change phenotypically between generations, and viruses with presumably stable genomes can change quickly depending on stochastic and environmental conditions. Although a broad generalization is often inadequate, two primary characteristics allow viruses to exhibit such great evolutionary plasticity: access to genetic variability and exposure to selective pressure.

Generation of Genetic Diversity

Genetic diversity within a virus population is ultimately the result of mutation or recombination. In addition, reassortment may allow the spread of beneficial genes after cellular co-infection. Without heritable genetic and corresponding phenotypic variability, a population, viral or otherwise, will not evolve. It has been theorized that the adaptive ability of a population is proportional to the amount of genetic variation therein. The average genetic variation exhibited by a specific virus type is dependent on diverse characteristics of its replication biology. For example, the fidelity of its genome replication, frequency of co-infection, population size and structure (both host and virus), mode of transmission, and replication rate all influence the generation of genetic variation.

Mutation

Mutation refers to the molecular synthesis or modification of a descendant gene that differs from the parental or template gene. This may include a deletion, insertion, or mismatch. The mutation or error rate therefore refers to the frequency of such errors per nucleotide per round of synthesis and is a good quantity with which to compare the mutability of virus types. Mutation differs from the process of base substitution in that the latter refers to the actual fixation or significant increase in frequency of a mutant gene in a population and is actually the result of evolutionary, not molecular, processes. As a group, viruses exhibit the broadest range of mutation rates among known genetic entities (97). For instance, natural mismatch mutation rates for genomic regions of some RNA viruses, such as phage Qb (12,38,40), VSV (69,115,143), and FMDV (36) have been estimated to be as high as 10^{-4} to 10^{-3}. Even more extraordinary, sporadic G ® A and A ® G error rates on the order of 10^{-2} to 10^{-1} (a process termed *hypermutation*) have been observed in some RNA virus and retrovirus types (97). The concept of *error threshold* refers to the highest possible mutation rate for a specific quantity of genetic information beyond which sustainable transmission of the information is not possible (48,125). Many viruses, such as poliovirus and VSV, have been hypothesized to exist very close to this value (70,71).

The number of viral mutations occurring per unit of time is largely determined by two main factors: polymerase fidelity and generation time. Polymerase fidelity differs greatly among nucleic acids. RNA polymerases and reverse transcriptases lack proofreading mechanisms that result in much higher mismatches per copying event (26,69,118). DNA viruses that rely on host replication apparatuses for genome duplication (e.g., papovaviruses) should not exhibit mutation rates that exceed those of their hosts. DNA viruses that encode their own polymerase exhibit varying mutation rates depending on template characteristics, proofreading capabilities, and intracellular conditions. In fact, little research has

been undertaken examining mutation rates of DNA viruses or their polymerases, but it is known that these rates do not approach those of riboviruses or retroviruses (44,97).

The number of mutations that occur per unit of time is also influenced by the number of replication events during that period, that is, generation time. Virus *generation time* is a measure that is difficult to estimate with accuracy in nature, and it is likely that it varies considerably among types and among hosts. Generation time may be affected by such characteristics as genome size, host tissue differentiation, cell cycle, availability of infectible host cells, and presence of antiviral agents. For instance, the generation time of HIV *in vivo* has been estimated at 2.6 days (107) and can translate into up to 200 sequential replications per year inside one host (114). Generation times of strictly vertically transmitted viruses, however, such as human endogenous retroviruses, match those of their hosts and thus can average many years. Shorter generation times result in more genetic variation per time unit; this is commonly observed in viruses that exhibit life strategies that involve acute infection.

Recombination

The importance of recombination in the evolution of viruses cannot be understated and is the focus of a great deal of research effort. Recombination is defined here as a process whereby genetic material is exchanged, resulting in the formation of a descendant nucleic acid composed of material from two or more parental nucleic acids. Recombination involving viruses may be between different viral genomes or between a viral genome and some other genetic entity (e.g., host genome, co-infecting parasite genome, plasmid). As is mutation, recombination is an important source of genetic variation. Recombination, however, can often be associated with a more immediate evolutionary reward (i.e., rapid divergence). In other words, a beneficial gene that may take mutation millions of generations to produce can, in theory, be accessed in one recombinational event between the gene's possessor and the virus “in need” of the gene. The evolutionary response to such genetic variation is discussed in more detail later (see Response to Selection).

Recombination between viruses can only occur during simultaneous co-occupation of a single host cell by more than one viral genome or its parts. The “horizontal” introduction of foreign genetic material into a viral genome will increase a population's genetic variation and allow novel combinations of genes on which natural selection can act. Much evidence exists indicating that viral recombination occurs within as well as between types. This evidence has given rise to a well-supported “modular” theory of virus evolution, which says that many viral genomes represent mosaics of genetic material obtained through recombination between types (15). For instance, the genomes of potyviruses are known to contain coding regions that closely resemble genes from flaviviruses, pestiviruses, picornaviruses, caulimoviruses, and tobamoviruses (60,84,137). Phages are also thought to undergo promiscuous recombination, especially as indicated by their tail fiber regions. As discussed by Kutter and colleagues (82) and Haggard-Ljungquist and associates (66), the makeup of tail fiber genes of many phages, including Mu, P1, P2, and T4, is clearly derived from genetic exchange between viral types.

As already briefly mentioned for BVDV, recombination is frequently noted between virus and host genomes. Baldo and McClure have demonstrated multiple instances of horizontal transmission of deoxyuridine triphosphatase (dUTPase) genes between many DNA and retroviruses and their eukaryotic, eubacterial, and archaeal hosts (8). For instance, using sophisticated sequence alignment and phylogenetic techniques, it was shown how dUTPase sequences from several mammalian poxviruses strongly cluster evolutionarily with dUTPase sequences from mammalian genomes rather than with those from other poxviruses. In addition, the authors demonstrated that it is highly likely that such dUTPase genes are of eukaryotic origin and were acquired by the viral genomes via horizontal transmission. Such events underscore the importance of recombination as a tool for generation of phenotypic diversity.

Reassortment

Interviral reassortment can occur when two or more viruses with segmented (or diploid, such as lentiviruses) genomes simultaneously co-infect a host cell. The genome partitions are (often randomly) packaged into progeny virions. These resultant progeny may therefore house genomic segments from more than one parent. This increases genetic variability because the offspring may contain novel combinations of genomic segments. This process is an important progenitor to virus survival and diversification, as illustrated by the antigenic shift commonly observed among the influenza viruses. As pointed out by Cann, two co-infecting influenza viruses, each with eight original genomic segments, may give rise to 2^8 (256) potential progeny genomes (20). Virus families that possess segmented genomes include the Orthomyxoviridae (7 to 8 –RNA segments), Reoviridae (10 to 12 dsRNA segments), Arenaviridae (2 –RNA segments), Birnaviridae (2 dsRNA segments), Bunyaviridae (3 –RNA and ambisense RNA segments), Nodaviridae (2 +RNA segments), and some members of Geminiviridae (2 single-stranded DNA segments). Segmented genomes are much more common in riboviruses. It has been suggested that this type of genome packaging, which allows for reassortment as a method of genetic exchange, has arisen and persisted evolutionarily because recombination in this nucleic acid is uncommon in many virus families (9,24,110,142).

Reassortment has been most thoroughly studied in the influenza A viruses that frequently infect fowl, swine, and humans often in agricultural settings. The pig has been considered a “reassortment vessel” for influenza viruses because it is known to be susceptible to both human and avian strains of the virus (141). Until recently, humans have not appeared to be directly susceptible to avian influenza strains, or vice versa (122). Therefore, it is theorized that swine, which harbor their own strains of the virus, are often co-infected with strains from more than one species. This co-infection can give rise to reassortants that can and do cause periodic influenza pandemics when successfully passed to human hosts. The process of reassortment in itself is obviously not enough to cause such a zoonosis. Its importance in this case is the production of genetic and phenotypic variants that can, under the appropriate conditions, become established in a new species or ecological niche. The potential variability of influenza attests to the importance of reassortment in viral diversification and has led some to suggest that segmentation and reassortment are an adaptation by which RNA viruses can maintain genetic variation to facilitate evolutionary survival (24,110).

Response to Selection

It is imperative to point out that the mere presence of genetic and phenotypic variation is not sufficient to direct or predict the evolutionary trajectory of any organism. Such variation, however, is a prerequisite for evolutionary change. Viral populations may be observed to change genetically through time. This change occurs because (a) there exist genetic differences between the successfully reproducing individuals in an ancestral population and (b) their genes are passed on to descendants disproportionately. When such disparities occur in response to forces imposed by the reproductive environment (i.e., nonrandomly), we say that evolution is driven by selection. This is not to say that selection, either natural or artificial, will have some directional or diversifying effect on viral characteristics. In fact, the opposite, a genetic homogenization of the population, can frequently be observed.

Selection is manifest as differential survival and reproduction of individuals competing for some limited reproductive resource. Unfortunately, the word *individual* can be a complicated term in the evolutionary sense, especially when considering viruses and other microparasites. This is because selection is capable of acting on many different types of characters—those that are exhibited by populations, individual genomes, gene combinations, even individual genes. Nevertheless, individuals that are capable of producing descendants at a higher overall rate than other simultaneously replicating individuals are considered to be of higher fitness. A detailed discussion of fitness and its components is beyond the scope of this chapter, and the reader is directed elsewhere for more thorough treatments of viral fitness (31,39). The overall result of differences in fitness is evolutionary change by way of natural selection acting on those differences.

Adaptation

Adaptation refers to a character that arises via natural selection and thus confers on its bearer the ability to succeed genetically in a specific environment. The word may also refer to the actual process of acquiring such traits. Adaptations are therefore an evolutionary response to selective pressure presented in the form of environmental conditions that affect reproductive output. Viruses are of course exposed to myriad such conditions. Selective pressures are directly related to survival and replication within a host and transmission between hosts (discussed in more detail under Ecology). Does selective pressure alone create adaptation? The answer is no. Replicative barriers and unexploited reproductive opportunities provide a mechanism by which certain mutants or novel genetic combinations can survive and ultimately outcompete other members of their population. These mutants exist in proportion to the amount of genetic variation that exists. The phenotypes that bestow higher relative fitness (adaptations) may eventually become fixed in the population as a result of the reproductive success they provide to the individuals that bear them.

Selection arising from direct competition between virus strains for access to reproductive resources has been observed in the laboratory to give rise to ongoing adaptation. Clarke and colleagues examined fitness changes in distinct, competing clonal populations of VSV (25). They used relative fitness tests to measure changes in the competitive ability of VSV populations that initially had identical fitness. When cultured together through time, one of the virus populations was inevitably totally displaced by the other. “Winner” and “loser” strains were then mixed with their ancestral wild-type strains to examine the absolute changes in their fitness (adaptive evolution). In all cases, the derived virus populations were able to outcompete and displace their ancestral populations. Adaptive change proceeded in such a way that overall competitive ability of present generations surpassed that of previous ones and was lower than that of the future generations. This exact outcome is predicted by an evolutionary concept termed the *red queen's hypothesis* (133), which states that when two or more populations exist in direct competition for some resource, the processes of adaptation and counteradaptation must be continually occurring for both populations to survive. Such adaptation within natural host populations is more difficult to confirm and has even been discounted for some mammalian RNA viruses (114).

Certain adaptations may not allow a virus to outcompete other individuals directly but instead may permit entry into an unusual reproductive environment. This may initially release a virus from competition because it will inevitably exist at a very low population density in its new surroundings. The result will be a new population (and eventually many populations), perhaps exhibiting a completely different reproductive lifestyle. Such is often the case when viruses cross tissue, host, or vector species barriers. For example, canine parvovirus (CPV) did not exist before the late 1970s, and it spread worldwide in less than 2 years (104). CPV is derived from feline parvovirus (FPV), and the two viruses differ genetically by only three amino acids of their VP2 capsid protein (103,105). Parrish was able to demonstrate that CPV viruses that were otherwise normal but contained lysine at VP2 position 93 were able to replicate in feline cells but lost their ability to replicate in canine cells (103). Furthermore, otherwise normal FPV that contained asparagine at positions 93 and 323 were able to replicate in both canine and feline cells. These latter two changes represent a recently acquired adaptation that allowed replication in a new, susceptible host species and subsequently enabled the rapid (and extensive) spread of parvovirus into the world population of canines.

Evolutionary Stasis

The presence of genetic variation does not ensure evolutionary change. Such change is dependent on the existence of some degree of either directional or diversifying selective pressure. Stabilizing selection, on the other hand, may result in long periods of little to no evolutionary change and can, when strong enough, cause tremendous genetic homogeneity among individuals in a population despite high rates of mutation or genetic exchange. This type of selection may be acting in situations where successful viral replication is contingent on (a) numerous factors that must converge precisely; (b) conditions that must reach extreme thresholds of optimality; and/or (c) environmental circumstances that are predictable but rare. Given such strict requirements, any phenotypic deviation from some selected ideal may translate into an infinitesimal probability of reproduction. The observed result would be very slow, if any, evolutionary change.

An excellent example of this is the arthropod-transmitted equine encephalomyelitis viruses (EEV) in the alphavirus genus. These viruses belong in the family Togaviridae and have +RNA genomes. Investigation of the evolutionary rates of EEVs has revealed that despite exhibiting the high mutation rates typical of riboviruses, they actually evolve very

slowly (111,128,140; reviewed in 139). For instance, sequential isolates of Eastern EEV from North America covering a period of 52 years revealed only 0.7% sequence divergence during this time (140). It has been estimated that the alphaviruses evolve at a rate that is on average ten times slower than other riboviruses (140). Weaver and colleagues have postulated that these viruses reproduce under stringent conditions that involve obligatory replication within both mosquito and mammalian hosts (139). The superimposition of an additional (and phylogenetically distant) species onto the virus replication cycle likely equals a proportional increase in the degree of selective constraints in operation. This theory is supported by the observation that other arthropod-borne RNA viruses (e.g., flaviviruses such as dengue 2 virus and yellow fever virus) also exhibit unusually slow rates of evolution (32,129).

Ecology

Ecology is a science that investigates the interactions between an organism and its environment. Environment refers to the physical, biological, and stochastic elements that constitute the habitat that allows an organism to reproduce at a given time. The environment thus uniquely determines the type and degree of natural selective pressure exerted on a population. Viruses have both general and specific requirements for replication and existence. All viruses require the use of a host cell's adenosine triphosphate (ATP), ribosome, nucleotide, transfer RNA (tRNA), and amino acid resources. Many viruses also require use of other cell functions and components, such as replication and splicing machinery. Often, viruses use more advanced host characteristics, especially when dealing with the demands of transmission. Here, they may take advantage of host ecology, feeding habits, sexual behavior, social structure, and so forth to facilitate host–host transfer.

Although viruses as a group are presumably capable of using any cellular organism for replication, individual virus types are usually specialized in the host species they parasitize. The specific set and degree of environmental conditions within which an individual (e.g., virus type, species) is adapted for survival and reproduction is referred to as an *ecological niche* (31,73). The ecological niche is unique to a particular life form and thus should be considered as a characteristic of that life form. For example, the ecological niches of bacteriophage lambda and HIV-1 differ dramatically, whereas the ecological niche of HIV-1 shares similarities with that of human T-cell leukemia virus and shares even more similarities with HIV-2. As discussed later, however, the ecological niche of a virus is not fixed and evolves just as any other viral trait or phenotype.

Most viruses exist with two main reproductive objectives: survival and replication within host cells and successful transmission of progeny to new host cells for subsequent survival and reproduction. This translates into distinct environments in which viruses must exist, that is, the intra- (within) host and inter- (between) host (57).

The Intrahost Environment

The intrahost environment consists of the replicative resources and conditions to which a virus is exposed both within the host organism (extracellular) and within the host cell (intracellular). This environment contains two primary forces that exert evolutionary pressure on infecting viruses: first, competition between individual viruses for intrahost resources, and second, the antiviral defense mechanisms exhibited by the infected host.

Intrahost resources required for replication (i.e., “reproductive substrate”) fundamentally include living cells of a necessary tissue type. Once an intrahost virus population has become established in, for instance, a multicellular eukaryote, the relative abundance of infectible cells is usually extremely high and not a limited resource for which viral genotypes “compete”; it has been estimated that less than 1% of susceptible host tissue is actually infected in most human viral infections (65). Within cells, competition for resources such as replication and translation machinery is dependent on the multiplicity of infection (moi) and thus the frequency of co-infection by multiple genotypes (23,131).

Investigation into intrahost competition is rare, and information about its overall influence on viral evolution is scarce. Turner and Chao have conducted an elegant series of laboratory experiments on the segmented dsRNA virus f6, which has provided evidence that intracellular competition between co-infecting viruses can be intense (130,131). In their studies, f6 was grown at both high and low moi for the purposes of examining the effects of genetic exchange (sex) between genotypes on rate of viral adaptation. What they discovered was that intrahost competition was often so intense that instead of evolving strategies to exploit the host species more effectively, viral adaptations arose that were aimed at influencing virus–virus competition. When multiple individuals of a virus type infect a single cell, genes are translated, genomes are copied, genomes are packaged, and virions are released. Genomes that are replicated faster accumulate higher copy numbers. Therefore, the probability of a “fast” genome being packaged into a given set of capsid proteins is proportionally higher regardless of whose genes were translated to produce these proteins. As a result, intracellular competition between viral genotypes can give rise to characters whose influence is focused on individual success in the presence of competitors rather than on optimal exploitation of the host species. This is also exemplified by the existence of defective interfering particles that arise and are capable of persisting during high moi infections. These particles are derived as mutants of the wild-type virus and are only capable of replication in the presence of high levels of the fully competent parental viruses whose enzymes and structural proteins they parasitize (10,78,112).

A larger (mostly theoretical) research effort has focused on the interaction between viruses and host antiviral defenses and the evolutionary effects of this interaction. Antiviral responses are theorized to create directional or disruptive selective pressures that drive viral diversification of traits that are susceptible to such responses (5,11). In many ways, the coevolution of viruses and the antiviral capabilities of their hosts should mimic classic predator–prey dynamics commonly cited in ecological research. The effect of a host's antiviral response on the evolution of a virus is selection for viral types that can evade this response. This outcome feeds back as selective pressure on hosts to evolve fresh antiviral responses against the new viral types and so on. Unfortunately, strong empirical evidence in support of these types of cause-and-effect viral–antiviral coevolutionary dynamics is severely lacking. The topic is discussed in greater detail under Antiviral Evasion.

The Interhost Environment

To persist evolutionarily, a virus must give rise to progeny that successfully infect at least one new host organism of the same or different species. To infect a new host, two principal conditions must be met. First, new, susceptible hosts must exist, usually within a limited spatial scale. Second, viruses must have access to a vehicle or pathway of safe transport to a new host. The interhost environment thus includes all the conditions to which a virus is exposed when it is not occupying a host organism. These conditions are mostly determined by host species biology (e.g., airborne, vector-borne, food-borne, water-borne). Viruses evolve transmission strategies that take advantage of their host species physiology, habitat use, population structure, and behavior. Viruses may also evolve ways to alter specific host characteristics such that they facilitate host–host transmission.

Viruses may be transmitted between hosts vertically (i.e., from parent to offspring through the germline), horizontally (i.e., from host to host via an extracellular stage), or through some combination of the two. The different pathways are advantageous under different ecological circumstances. For instance, vertical transmission may be selected for when direct host–host contact is rare, such as cases in which host populations are sparsely distributed, host organisms are sessile, or host populations are small. Viruses may also use mobile vectors (e.g., arthropods) for transmission to overcome these effects. Horizontal transmission may succeed when potential new hosts are abundant or when host–host contact is frequent.

It is difficult to define general rules of transmission that are followed by all viruses. Horizontal transmission, for instance, may take place by way of the external environment (e.g., aerosol) or by direct contact between hosts (e.g., tactile or sexual). Viruses have evolved diverse adaptations to allow for transmission through these routes. Exposure of some viruses to harsh conditions in the external environment (e.g., ionizing radiation, temperature extremes, pH extremes, aridity) necessitates characteristics that maintain the virion's viability. Many insect viruses (e.g., nuclear polyhedrosis and granulosis viruses) use multiparticle occlusion within proteinaceous crystalline structures to enhance environmental stability (1,14). An occlusion body may include only a few or as many as tens of thousands of viral particles each and can remain viable in the external environment for long periods of time (28). Particles have been observed to remain infectious after 21 years of laboratory storage and after exposure to pH values between 2 and 9 (28).

Bottlenecks and Founder Events

As mentioned under Genetic Drift, evolutionary diversification need not involve natural selection. Stochastic events often result in survival of individuals on the basis of pure chance rather than fitness. Such incidents can lead to immediate fixation of phenotypes and genotypes. A bottleneck refers to a large decrease in population size resulting in the survival of a small percentage of the original population (such as is common during host–host transmission of many viruses). A founder event refers to a situation in which a small number of individuals quickly become isolated from their original population, often in an unusual habitat. Both situations can exert a powerful influence over the genetic makeup and future evolution of the group. This is due to the general statistical phenomenon known as sampling error that can cause a small founding population to have a genetic makeup that is significantly dissimilar from the parental population. Under these circumstances, the probability that rare mutations (either beneficial or deleterious) are selected for future replication is much higher than if natural selection were allowed to operate on the population as a whole. If poorly adapted genotypes (with respect to the specific environment) are passed on, extinction is likely. This has been referred to as *Muller's ratchet* (99). Simply stated, this means that because any mutation is most likely deleterious (and as such, restorative back-mutations rare), its fixation via genetic drift will result in a decrease in population fitness. If, however, well-adapted genotypes are passed on, future generations will closely resemble members of the founding population instead of the parental population, and rapid evolutionary change will be observed.

Bottlenecks in natural virus populations are not frequently investigated but are most certainly a common occurrence in the life cycle of many viruses. The most obvious viral bottleneck can happen during host–host transmission. In HIV-1, for instance, transmission between hosts may involve infected cells or individual viral particles. In either case, the number of individual genomes (i.e., one to hundreds) that give rise to the virus population in the new host is extremely small relative to the original population size (i.e., more than 10^{10}). The effects of HIV transmission bottlenecks are illustrated by comparison of virus genetic variability between the infectious (donor) and infected (recipient) hosts. Heterogeneity in HIV populations generally increases with time after infection (96,102). Therefore, comparison of populations within recently infected hosts with those in the presumed donor hosts reveals great disparity in the amount of genetic variation between the two, indicating that the more homogeneous new population underwent a recent bottleneck event.

Founder events, as traditionally defined by evolutionary biology, have not been extensively examined in nature. This is not to say that they are rare or unusual, however, and they are known to be often responsible for adaptive radiation. In viruses, founder events may involve transmission to new or novel tissue types or, more importantly, new host species. The well-adapted founding virus may survive, reproduce, and evolve in this new environment. This will be discussed more extensively under Emergence and Evolution of Viral Disease.

VIRUS–HOST COEVOLUTION

Adaptation of viruses to abiotic conditions (e.g., temperature, salinity) obviously brings about no reciprocal change in those conditions. Adaptations that overcome or circumvent host characteristics, however, especially when they result in a decrease in host fitness, can generate selective pressure on the host. This selective pressure will make counteradaptations in the host advantageous. Thus, viruses and their hosts are often engaged in a coevolutionary process in which adaptive responses in one group impose selection on the other, which gives rise to more adaptation, and so forth (93). It is in this way that virus evolution in the present can indirectly influence virus evolution in the future. Although virus–host coevolution has not been extensively reviewed, many specific examples have been investigated (13,51,63,116)

Coevolution need not necessarily involve an “arms race” between host and virus. Situations may exist in which harm to the host is so strongly selected against that traits that cause host “overconsumption” cannot arise and persist. There exist numerous instances of both benign and mutualistic virus–host relationships. When the relationship between virus and host is so intimately weaved that neither can survive without the other, the evolutionary histories of the two groups may appear identical. In fact, it can even be questionable as to whether a particular virus is an autonomous entity. It is therefore insufficient to consider virus or host evolution outside the context of the effect that each has on the other's existence.

Virulence and Avirulence

Virulence, a relative measure of the amount of host damage (i.e., decrease in host fitness) caused by a specific parasite infection, is a complicated and perpetually evolving trait. Viruses are obligate parasites that cannot live outside their hosts. Because of this, any premature death to the host results in death to (i.e., nontransmission of) at least some infecting viruses. Therefore, it might seem paradoxical that viral infection would bring about any decrease in host life span. Indeed, it is still a common misconception among some scientists that all parasites evolve to become simply innocuous esidents of their host species and that the evolutionary age of a host–parasite relationship can be estimated by observing the level of virulence exhibited. The evidence against this idea is now overwhelming, which leaves researchers with numerous questions regarding why levels of virulence vary between parasite groups and strains.

Virulence is often (although not always) positively associated with the replication rate of the virus within the host. Intrahost virus concentration often increases at the expense of the cells being infected. This increase, however, although endangering the health or life of the host, also increases the probability that at least some of the viral progeny will be transmitted to a new, susceptible host. Therefore, the evolutionarily acceptable level of virulence is set by its relationship to transmission. An extremely virulent (lethal) virus that infects a host whose ecology prevents rapid host–host transmission no matter the intrahost viral titer will become extinct quickly.

Virulence as a trait is determined by the effects (both direct and indirect) of virus replication within the host. Therefore, characteristics that increase or decrease relative pathogenicity of virus strains often evolve under selective pressure that is based on competition for intrahost replication resources (54,55). In other words, virus strains within a host will exhibit varying rates of replication. Strains that manufacture viable progeny (reproduce) more rapidly will accumulate a larger relative population size. Assuming the size of the intrahost population is positively related to transmission probability, the larger population will have correspondingly higher fitness. The virulence level ultimately tolerated by a virus–host system is specific to the biology of both the virus and the host.

Is the level of virulence exhibited by a virus actually an adaptation that has arisen with the help of natural selection? It is probable that many specific symptoms of viral infection that have negative effects on host fitness may persist because they are associated with an increase in viral transmission. For instance, symptoms such as coughing and sneezing caused by viruses infecting respiratory regions (Adenoviridae, rhinoviruses, Coronaviridae, Paramyxoviridae, Orthomyxoviridae), diarrhea caused by enteric viruses (rotaviruses, Caliciviridae, astroviruses), and lesions caused by many sexually transmitted viruses as well as some poxviruses all have clear adaptive significance when considering interhost transmission routes because they place (shed) infectious particles into a suitable environmental position for entry into a new host. It has also been hypothesized that at least for some arboviruses, virulence represents a way to facilitate vector-mediated transmission by disabling a normally active and mobile host, thereby allowing easier access to feeding vectors (49,50). Dengue virus and yellow fever virus rely on hematophagous insect vectors for host–host transmission and induce fever, muscular aches, and/or encephalitis, which typically result in host inactivity. The host's sedentary state may allow for easier feeding by mosquitoes and therefore increase interhost transmission.

Conversely, many viruses exist as inapparent (silent) infections or even as symbionts that actually increase host fitness. These viruses obviously have a very different evolutionary relationship with their hosts. For instance, some human endogenous retroviruses exist as fully functional, chromosomally integrated, vertically transmitted agents that cause little to no apparent harm to their host (88,91,106). Their success is apparent in the fact that many have existed within the various primate lineages for tens of millions of years (119,124).

Polydnaviruses (PDVs) have actually evolved to the point of providing an essential role in the reproduction of their hosts. These viruses are found in the chromosomes of two families of endoparasitic wasps and are thus transmitted vertically (53,121). During oviposition within a susceptible lepidopteran larva, the eggs are coated with viral particles and transferred into the host body cavity. Once inside the host, PDV proteins assist development of wasp larvae by impairing host immune attack against the eggs. In addition, viral products actually alter the developmental rate of the larval host to allow for optimal tissue consumption by the young wasps (7,46,74,117,135). The important point is that viruses need not be pathogenic to exist, but only to increase the likelihood of being investigated by scientists.

Antiviral Evasion

Pathogenic viruses and their hosts appear to exist in a perpetual arms race of accumulating adaptation and counteradaptation. If a host were totally unable to develop and maintain any defense against containment or elimination of a viral infection that consistently caused a decrease in fitness, given enough time, the virus would have no habitat because of a corresponding reduction in host population. If a virus were likewise unable to penetrate the antiviral or innate defenses of a particular host species, it could also never exist therein. What we are able to observe in nature is the middle ground between these extremes. When considering the highly complex antiviral immune response of mammals, a correspondingly and equally complex array of evasion strategies has also evolved in the affected viral groups.

Escaping destruction by an intact immune system may be accomplished by escaping direct interaction with its components. This may involve replication within immunologically privileged tissue that is inaccessible to the host antiviral

response. The classic example of this is the herpesviruses (e.g., varicella zoster virus, herpes simplex virus [HSV]) that exist latently in nonreplicating sensory neurons that are not surveilled by the host immune system. In addition, the viruses turn off nearly all gene expression during latency, which further decreases their susceptibility because of the absence of viral encoded antigens. The viruses periodically move through axons to epithelial or opthalmic sites for replication and transmission (where they may eventually be suppressed by the immune response) but never actually leave the host completely. Other viruses replicate within tissues that experience limited antiviral activity. Human polyomaviruses BK and JC replicate within nephritic epithelial tissue and therefore not only benefit from limited T-cell penetration but also gain access to urination as a mechanism of dispersal (2).

A more typical way of escaping the host antiviral defenses is to be invisible to them. This is accomplished in a number of ways. Immunosuppression, for instance, results in the inability of the host to detect and destroy viruses effectively. This can involve the use of proteins, either viral or cellular, to disrupt the host antiviral response. Many viruses have the ability to sabotage production or function of host cytokines using their own gene products. Host molecules, such as interferons, interleukins, and other cytokines, are susceptible to the action of immunosuppressive viruses. Viral encoded molecules may prevent host gene transcription (e.g., hepatitis B virus terminal protein) or translation (e.g., adenovirus E1A), inhibit cytokine activated enzymes (e.g., RNAse L inactivation in HSV infection), or sequester molecules via complement binding (e.g., interferon-g–receptor decoy produced by myxoma virus). Viral gene products may also interfere with other aspects of the host antiviral response, such as antigen presentation (vaccinia virus, HSV) and down-regulation of host cell genes required for proper antiviral function (e.g., class I and II major histocompatibility complex, intercellular adhesion molecule, and lymphocyte function associated antigen 3 [LFA-3]) (see Chapter 11).

Another way for a virus to remain (at least partially) invisible to an adaptive host immune response such as exists in mammals is to change its appearance continually. This applies not to individual virions but rather to an infecting viral population. Many riboviruses and retroviruses, for instance, exhibit mutation rates that promote constant modification of the population's viral (especially surface) proteins through time. These proteins are markers that the immune response uses to separate self from nonself. Viruses such as HIV may persist in the host for long periods because their rate of and tolerance for protein modification exceeds that which can be successfully identified and cleared by the adaptive immune response (101,113). In this case, the phenotype that allows host occupation is mutability. In addition, HIV further diminishes the host's abilities to find and clear the virus by infecting and eventually destroying the very cells responsible for carrying out these activities (CD4+ cells, macrophages). Perhaps a classic demonstration of contemporary virus–host coevolution is the relative ability of some human hosts to exhibit increased resistance to HIV infection because of possession of a homozygous deletion in the CCR5 cell surface coreceptor. This deletion results in the inhibition of HIV cell entry (72). Many other viruses also infect cells of the immune system, including monocytes (cytomegalovirus, influenza virus) and B lymphocytes (Epstein-Barr virus, MuLV).

Pathogenic viruses that infect mammalian hosts are under continual selective pressure to reproduce in the presence of sophisticated and highly specific antiviral responses that have arisen through millions of years of evolution. Although it may seem that such hosts would have the upper hand in this ongoing battle, viruses continue to develop strategies of host occupation. Viruses are capable of much more rapid evolutionary responses to the antiviral threats they encounter because of their short generation times and huge population sizes (relative to their hosts), which translate into tremendous phenotypic variation from which natural selection can choose. More than 50 virus genes have been identified as influencing immune functions on numerous levels, and this number will most certainly grow (108). Such facts represent a strong demonstration of the impact that host antiviral immune responses have on the evolution of viruses.

Emergence and Evolution of Viral Disease

The overall importance of a given virus to society at large is related to its ability to cause disease in humans or economically or otherwise important species. This characteristic is only exhibited by a very small subset of all virus types on our planet. As already mentioned, however, viruses are capable of extraordinarily rapid modification and diversification (both genetic and phenotypic). Consequently, the benign, even unknown virus that today exists silently may represent tomorrow's crisis. Evolutionary theory has tremendous relevance to the investigation of viral disease emergence and spread. It is by way of the evolutionary mechanisms we have discussed that viruses (a) occupy novel host species and tissues and (b) change their symptomatology and pathogenicity for the purposes of (or as a by-product of) maintaining host–host transmission within a population. In addition, many of the ecological opportunities presented to viruses that lead to unfortunate (disease-related) consequences arise directly from intentional human activity; it is imperative to understand this as a catalyst of virus diversification to estimate the risks associated with such activity (33).

Individual virus types originate and are often considered new when they begin replication in atypical host species or tissue or when different symptoms are associated with infection. In fact, many viruses that are avirulent in the host species to which they evolved are highly virulent in other (often closely related) species upon exposure and infection. This is well exemplified by the myxomavirus, which infects New World rabbit species of the genus *Sylvilagus*. In this natural host, the virus exhibits little, if any disease. On introduction by humans into European rabbit pests (*Oryctolagus cuniculus*) occupying Australia, however, the virus initially had a higher than 99% mortality rate (3,52).

Viruses can only emerge into human populations when they are both adapted to do so and provided with the appropriate host exposure (68). We can do little to control the phenotypes that arise in natural virus populations, yet we do have the power to change the type and frequency of virus–host contact. The ability of a virus to reproduce sustainably in atypical host species generally appears to decrease with decreasing phylogenetic (evolutionary) relation between the species. In other words, a human lentivirus has a better chance of replication within a chimpanzee than within a salamander. Because of this, we can expect human viral diseases to emerge more frequently from mammal species than from other vertebrate or invertebrate groups.

Hantavirus is an excellent example of viral disease emergence through ecological opportunity. Hantaviruses are RNA viruses that naturally occur as persistent, nonfatal, genetically stable infections of rodents. The virus is shed in feces, saliva, and urine, and human contact with the virus can lead to infection and an often fatal respiratory illness (87). A hantaviral outbreak occurred in the western United States in the summer of 1993. Strains of the virus retrieved from

autopsy tissue matched those found in local rodent populations (genus *Peromyscus*), in which the virus exists as a persistent, asymptomatic infection (98). It was further discovered that rodent populations during that period were 10-fold higher than in previous years, and this was attributed to abnormally large amounts of rodent food brought on by increased rain (98). The explosion of local rodent populations most likely resulted in abnormally frequent human–rodent contact as well as an increase in viral load within individual rodent hosts. This contact was an ecological opening that increased opportunities for the resident hantavirus to infect a novel host species (it should be noted that in this case, human infection is an evolutionary dead end for the virus because sustained transmission between human hosts has failed to occur; this is obviously not true for every host species jump).

Ecological opportunity may also arise from certain changes in host behavior or population structure that directly affect competition between viral strains for host–host transmission. For instance, evidence suggests that HIV-1 existed in the human population for many years before the AIDS epidemic of the late 20th century (29,144,145,147). It has been suggested that its previously avirulent residence was altered in response to changes in human social conditions (e.g., population density, urbanization, transportation, sexual promiscuity, intravenous drug use), which allowed for greater transmission opportunities and thus permitted, even promoted, changes in virulence (49,50,89,90,147). Such a change in life cycle may have resulted in a modern adaptive radiation that is today manifest as the HIV and AIDS epidemic.

CONCLUSION

The study of viral evolution is a science unique within biology. Viruses are an astoundingly diverse assemblage of entities that is at least as varied as any higher-level cellular taxonomic group. Yet viruses mutate, adapt, and evolve at a diversity of rates that simply has no comparison in the cellular world. In addition, viruses are capable of influencing host evolution in ways we are just now beginning to uncover. The explosion of genomic sequence data (in humans as well as numerous other species) is bringing forth evidence of the enormous transformative power viral agents have had on their host organisms. This influence can be expected to endure for perhaps the remainder of Earth's biological future. Viruses and viral disease are certain to affect human health and quality of life for the foreseeable future both for the positive and negative. Joshua Lederberg made this point more eloquently in 1993: “The survival of the human species is not a preordained evolutionary program.... Our only real competitors remain the viruses....” (86).

CHAPTER 14 Epidemiology

Neal Nathanson

DEFINITIONS AND METHODS

Epidemiology deals with the occurrence of diseases in populations. Historically, epidemics of viral disease were recognized long before their causal agents were discovered, and viral epidemiology was one of the first aspects of the science of virology to be developed. Evolving insights into the pathogenesis and molecular aspects of virology have provided an increasingly rational basis for understanding the epidemiology of viruses, and in this chapter, the biology of virus infections is used to explain the essentials of viral epidemiology. Readers interested in epidemiologic methods should consult several excellent introductory texts (27,45).

Rates: Incidence and Prevalence

The quantification of disease occurrence is the cardinal feature of epidemiology. To accomplish this, the concept of rates was introduced, and these have become the basic coinage of epidemiology. Rates are fractions in which the numerator is the number of cases of disease and the denominator is a measure of the population. Incidence (also called *attack rate*) is mainly used for acute diseases of short duration. A population and a time frame are defined, such as the population of Philadelphia for the year 1995, and the number of cases incident in that population during that interval of time is counted. Note that the denominator includes both size of population and time frame; that is, the denominator may be expressed as “million person-years” or “hundred-thousand person-weeks.” The incidence rate is then expressed as “cases per million person-years,” or a similar term. Also note that the time element is often omitted in expressing incidence; the reader must then determine by context the time frame used.

Prevalence is the alternate way of expressing rates and is most frequently used for chronic diseases, particularly when onset is insidious and not readily dated. When point prevalence is computed, a particular date is selected as “prevalence day,” and the population recorded for that day constitutes the denominator; all cases “prevalent” on that date constitute the numerator. Prevalence is expressed as a ratio, such as “cases per million”; note that there is no time parameter in this ratio.

In epidemiology, consistency is a virtue. When cases and populations are counted before computing rates, care must be taken to use the same definition for numerator and denominator. For instance, if incidence is computed for the population of Philadelphia for 1995, a case hospitalized in the city but resident outside the city would not be counted; likewise, a case with onset in December 1994 but still ill in 1995 would not be counted. Figure 1 illustrates the computation of incidence and prevalence rates.

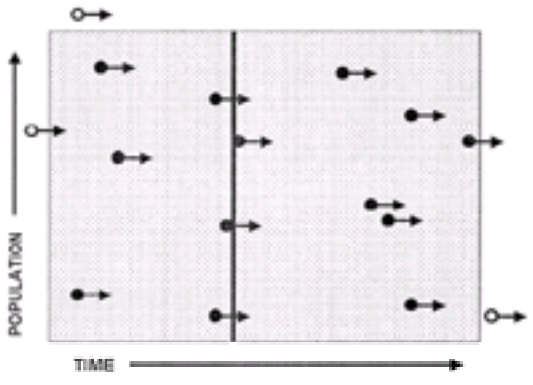

FIG. 1. Computation of incidence rate and prevalence ratio. The *shaded area* defines a population and a time frame that can be expressed as person-time units. Cases of disease are indicated by *circles* (placed according to the date of their onset) and *arrows* for duration of illness. *Solid circles* would be counted for computation of incidence, whereas *open circles* would be excluded because they had onset outside the designated time frame or were resident outside the population boundaries. Incidence equals the number of cases divided by population-time units. Prevalence would be determined by a *single vertical line* across the *hatched area:* cases active at that time point would be divided by the size of the population to compute the prevalence ratio.

Sources of Data

In practice, the accurate collection of data for the computation of rates is often a major undertaking, whereas the computations are relatively simple. Furthermore, the practicing epidemiologist must frequently work with incomplete and inaccurate information. In most developed countries, denominator (population) information is usually good, and numerator (case) information is the major problem. For infectious (viral) diseases, there are several alternate sources of case data.

Surveillance denotes the continuous reporting of disease; by law, many viral diseases are designated as “reportable” and, in theory, the reporting of all cases is required. Cases are reported by practicing physicians or hospitals to local health jurisdictions, which in turn relay reports to a central state office, from where they are transmitted to a national center (the Centers for Disease Control and Prevention in the United States). The weakest link is the initial report; in practice, only a small fraction of cases of many common viral diseases (such as 10% to 15% of measles or hepatitis B) are reported to the national center. If the proportion of cases reported is consistent among geographic locales and among years, however, these reports may be used to monitor trends. Consistency is an important caveat because the proportion of cases reported may increase if the absolute number decreases, such as during a campaign to reduce or eradicate poliomyelitis or measles. Reporting of certain rare or serious diseases, such as poliomyelitis or acquired immunodeficiency syndrome (AIDS), is often close to 100%; in such instances, reported cases can be used with much greater confidence for calculation of rates.

Epidemic investigation is the traditional approach to collecting information on outbreaks of disease. Such investigations are usually initiated by public health authorities. The investigation is tailored to the situation and to the resources at hand, but experience has set certain guidelines, particularly for recurring outbreaks such as food-borne diseases. The purposes of such studies are several: to classify the illness and determine the causative organism; to assess the extent of the outbreak and its economic and health impact; to abort the outbreak or prevent recurrent episodes; and to reassure the public. On occasion, the first recognition of a new disease or isolation of a previously unknown virus has been accomplished as a result of an epidemic investigation. Recent examples are the identification of Lassa virus, Marburg virus, and pulmonary syndrome hantavirus.

Serologic surveys may be used to detect the footprints that a virus leaves in a population. Surveys are particularly useful for viruses because most viral infections leave an imprint on all infected individuals, that is, the presence of antibody, which often is lifelong. Because many viruses cause asymptomatic infections or nondescript illnesses in addition to diagnosable diseases, serologic surveys may identify inapparent as well as apparent infections. In some instances, it is possible to infer the interval between detection of antibody and prior occurrence of infection by assays for immunoglobulin M (IgM) as well as IgG.

Prospective and Retrospective Studies

Modern epidemiology has made one outstanding contribution to the discipline: the extension of hypothesis testing from the laboratory to populations. In general, the epidemiologist attempts to test the hypothesis that one (or several) population variables influence the occurrence of a specified disease and, if so, to quantify this effect and estimate confidence limits. Two general designs are used for such studies: *prospective* (also called *cohort* or *longitudinal*), and *retrospective* (also called *case-control*) protocols. The essence of these designs is summarized next, and the reader is referred to appropriate texts for methodologic exposition (45) (Table 1).

Group	Total cases	Population	Rate per 100,000 person-years	Relative risk
Prospective study[a]				
Vaccinated	100	1,000,000	10	0.33
Unvaccinated	900	3,000,000	30	
Group	**Cases**	**Controls**	**Ratio**	**Relative risk**
Retrospective study[b]				
Vaccinated	10	25	10/25 (0.4)	0.33
Unvaccinated	90	75	90/75 (1.2)	

[a]Prospective study: two populations, vaccinated and not vaccinated, are followed for 1 year, and cases occurring in each are recorded. Rates are calculated, and the ratio of rates gives the relative risk for those who were vaccinated. In this instance, relative risk is lower for those with than without the attribute (immunization). The validity of this design depends on the assumption that vaccinated and not vaccinated groups would be at equal risk except for the attribute under study.

[b]Retrospective study: 100 cases and 100 controls are randomly picked to be representative of the groups from which they are drawn. Subjects in each group are classified as vaccinated or not vaccinated, and two ratios are computed: vaccinated cases/vaccinated controls and unvaccinated cases/unvaccinated controls. The ratio of these ratios yields the relative risk associated with vaccination. The validity of the retrospective design depends on two assumptions: (1) the cases and control groups are truly representative of the larger groups from which they are drawn, and (2) the number of cases is very small (less than 1/100) relative to the total population.

TABLE 1. *Hypothetical data to illustrate computations for a prospective and a retrospective study of vaccine efficacy*

Prospective Studies

The population is divided into two groups, one with and one without a specified attribute. Both groups are followed prospectively for the incidence of the disease under study, and incidence rates for both groups are then computed. A hypothetical example is shown in Table 1; in this example, the population attribute is immunization against a specified viral disease, and the attack rate in the immunized population is one third the rate in the nonimmunized control group. The relative risk (RR) associated with immunization is 0.33, and vaccine efficacy is 67% [(1 – RR)100]. There is one important assumption underlying the validity of such a study: the immunized and nonimmunized groups are at equal risk for the disease under study. For a variety of reasons, this assumption is often not correct; differences between the two study groups may be minimized by dividing each according to parameters, such as age, race, socioeconomic status, and so on, and then comparing rates for each subgroup. Even better, if possible, is to divide the study population into treated and placebo groups, which are then followed under a single- or double-blind protocol. Table 2 summarizes one such study and documents the problems of comparing groups (in this instance, vaccinated and unvaccinated) that are not at the same risk for disease (in this instance, poliomyelitis).

Study area	Vaccination group	Population	Paralytic cases	Rate per 100,000	Estimated efficacy
Placebo areas	Vaccinated	201,229	33	16	72%
	Placebo	201,087	115	57	
	Not inoculated	339,030	121	36	
Observed areas	Vaccinated	222,300	38	17	63%
	Controls	725,173	330	46	
	2nd grade, not inoculated	123,605	43	35	

[a]Vaccine was administered in the spring of 1954, and children were followed prospectively through the summer poliomyelitis season. Placebo areas were divided into volunteers who were vaccinated, volunteers who received placebo inoculations, and nonvolunteers (not inoculated). Observed areas were divided into second-grade volunteers (vaccinated), second-grade nonvolunteers (not inoculated), and first and third graders (controls).

Source: Data from ref. 28, with permission.

TABLE 2. *The 1954 field trial of poliomyelitis vaccine: comparison of attack rates for vaccinated and unvaccinated children*[a]

Retrospective Studies

Prospective studies are usually cumbersome because they require the enrollment of large numbers of subjects who must be followed for a period of months or years; the less frequent the expectation of disease, the larger the population or longer the follow-up needed. Needless to say, costs of prospective studies can be great, limiting them to special situations, such as the introduction of a new vaccine illustrated in Table 2. Retropective studies are much more cost-effective because they involve small numbers of subjects and do not require longitudinal follow-up. Table 1 shows a simplified version of such a study. In this instance, 100 cases of the study disease and 100 unaffected control subjects are identified and classified according to the attribute (vaccination) under study. For vaccinated and unvaccinated individuals, a cases/controls ratio is computed. Because these ratios have the same relationship as the rates computed in the prospective study shown in the upper half of Table 1, the relative risk can be computed as the fraction of the two ratios (0.4 / 1.2 = 0.33). Two assumptions underlie the validity of the case-control design: the two samples (cases and controls) must be representative of the groups from which they are drawn, and the incidence must be low so that cases make up less than 1% of the total population. Because retrospective studies are particularly useful to study risk factors for rare diseases, the second assumption is usually correct. The main flaws in retrospective studies are the choice of cases and particularly the selection of representative controls, a subject considered in depth in epidemiologic texts (45,72).

BASIC BIOLOGIC CONCEPTS

Immunity

Most acute viral infections confer lifelong immunity. Upon reexposure at any interval after initial infection, there is often a reinfection with minimal virus replication and an anamnestic immune response. Such reinfections are usually covert and almost never severe, and they result in minimal shedding of infectious virus. For certain viruses, such as poliovirus or rhinovirus, immunity is type specific and confers little protection against exposure to a different serotype. These simple

facts have profound implications for viral epidemiology. For epidemiologic purposes, a population may be divided into two groups: susceptible and immune. All people who have been infected at any time in the past may be considered immune and are exempt from disease and unlikely to act as links in a transmission chain, whereas susceptibles can both spread the agent and experience disease.

Persistent viral infections differ from acute infections because the infected individual may be capable of transmitting infection over many years and may develop disease at any time during virus persistence. In the instance of persistent viruses, the population may be divided into uninfected susceptibles and “immune” people who carry serologic markers of prior infection but who are still capable of acting as links in the chain of infection. Important examples are hepatitis B virus, human immunodeficiency virus (HIV), and several herpes viruses (herpes simplex, varicella zoster, and cytomegalovirus).

Parameters That Determine Incidence

For acute infections, the following three parameters together determine incidence: the proportion of the population susceptible, the proportion of susceptibles infected, and the proportion of infected people who become ill (case/infection ratio). If these three parameters are written as fractions and then multiplied, the product is incidence (cases/population), as shown in Figure 2.

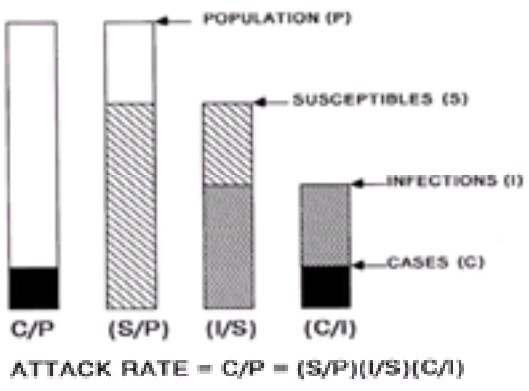

FIG. 2. The attack rate factored. A diagrammatic representation of the fractional parameters that, when multiplied and reduced, yield the fraction c/p (cases/population) or attack rate.

Proportion Susceptible

When a population is exposed to a specific virus, the susceptible part of the population will determine the spread of the agent and will account for all the cases of overt disease, and the proportion susceptible will reflect the past history of infection with the specific virus in the population under consideration.

Proportion Infected

The proportion of susceptibles infected during a fixed period of time (e.g., year or season) can vary widely, depending on the dynamics of transmission, which is influenced by factors such as the density of the susceptible population and season of year.

Case/Infection Ratio

The proportion of infections resulting in overt disease is characteristic for each virus and is strikingly different for different agents. One of the most important contributions of modern laboratory methods to viral epidemiology was the revelation of inapparent infections and the insight that most infections caused by some viruses were inapparent (67). The relative frequency of inapparent infections is expressed as the *case/infection ratio*, that is, the number of cases per 100 infections. The lethality of disease is a different parameter and is designated as the *case/fatality ratio*. Table 3 lists selected common viral infections and shows estimated case/infection ratios and case/fatality ratios for each. It is noteworthy that there is no regular relationship between case/infection ratio and severity of illness. For instance, measles has a very high case/infection ratio (above 95:100) but a low case/fatality ratio (less than 0.1:100 in the United States). Conversely, poliomyelitis has a low case/infection ratio (less than 1:100) but a much higher case/fatality ratio (about 5:100).

Virus	Cases per 100 infections	Fatalities per 100 cases	Comment
Smallpox	>95	<1	Variola minor
	>95	25	Variola major
Measles	>95	0.1	USA, 1970
	>95	2	Africa, 1988
Poliomyelitis	<1	5	USA, 1955
Hepatitis B	50	3	USA, adults
	<1	<0.1	Taiwan, infants

TABLE 3. *Estimated case: infection and case fatality ratios for selected viral infections*

Each of these three parameters can, under certain circumstances, be an important determinant of epidemics or other differences in incidence. The factors that account for variation in each parameter are discussed in subsequent sections of this chapter.

Incubation Period and Generation Time

The course of infection in a single individual can be conveniently divided into several periods. The interval from acquisition of infection to onset of illness is the incubation period. Note that onset of illness must be explicitly defined for each disease; it is often best measured by the first day on which pathognomic signs or symptoms are reported. For most viral diseases, the infected individual begins to shed virus before onset of illness and continues to shed during and sometimes after recovery from the acute illness. Therefore, the infected person is infectious for others over a period of time, and transmission may occur at any time during this period of infectiousness. The average period between infection and transmission is the generation time. From studies of selected outbreaks, it has been possible to determine the average interval between onsets of successive waves of cases. The generation time is often assumed to be equal to this interval, as the best approximation available. Generation time is usually slightly less than incubation period; that is, infections are transmitted slightly before onset of pathognomonic symptoms. These relationships are shown in Figure 3 for a typical acute viral infection; note that these definitions do not readily apply to certain persistent viral infections.

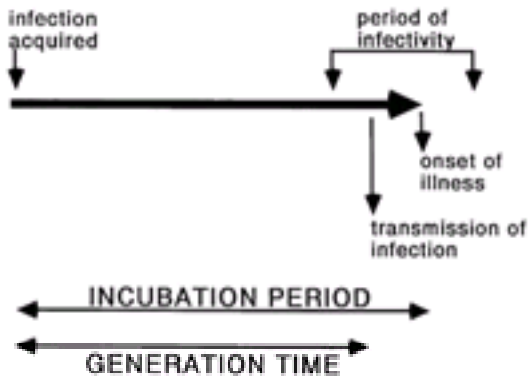

FIG. 3. Incubation period and generation time. Incubation period is the interval between acquisition of infection and onset of illness, whereas generation time is the interval between acquisition of infection and transmission to another person. This diagram shows the mean for each parameter; in practice, there is a spread around this mean.

Incubation periods for any viral disease vary around the mean, as illustrated in Figure 4. When a frequency distribution of individual incubation periods is plotted, it usually has a longer tail at the high end of the distribution (right-hand skew). If the frequency is plotted against the logarithm of time, the data often approximate a normal distribution. This log-normal distribution is characteristic of the incubation periods of many viral diseases and permits the comparison of the distributions of different incubation periods (70). The term *dispersion factor* has been introduced to quantitate the distribution of incubation periods; the dispersion factor is defined as the ratio of two incubation periods, as illustrated in Figure 4. The dispersion factor tends to be constant regardless of the absolute value of the incubation period; for most viral infections, it falls in the range 1.15 to 1.70.

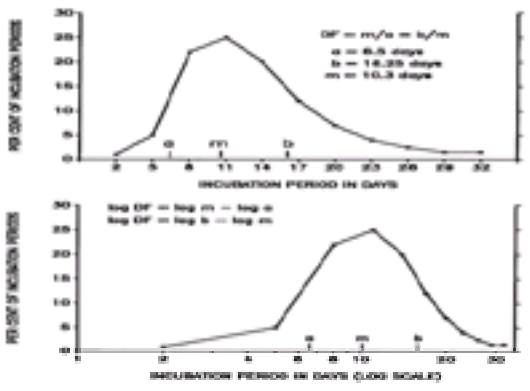

FIG. 4. Log normal distribution of incubation periods. **Upper panel:** incubation period distribution is shown for poliomyelitis; there is a right-hand tail. **Lower panel:** the appearance of incubation periods when plotted on a logarithmic scale. Logarithmic incubation period approximates a normal distribution, and the standard deviation may be computed (on the logarithmic scale). The dispersion factor (DF), a measure of the variation of incubation periods, is the antilogarithm of the standard deviation. The mean (m) is shown, together with one standard deviation (points a and b on the graph). The log DF equals the interval (log m – log a) or the interval (log b – log m). In this instance, the mean is about 10.3 days, a is 6.5 days, b is 16.25 days, and the dispersion factor is ± 1.58; that is, about two thirds of the incubation periods fall into the range (1.58 × mean) to (mean /1.58). (Data from refs. 8,13,38,56, and 69, with permission.)

TRANSMISSION OF VIRUSES

There are two major patterns of transmission into which most viruses may be classified: viruses maintained in a single species and arboviruses that alternately infect insect and vertebrate hosts. There are a few apparent exceptions, such as rabies and influenza viruses, which spread across species boundaries, but even in these instances, cycles of transmission within different species may be self-contained. For agents that infect humans, a second distinction may be made, namely, between those viruses that rely on human transmission for their perpetuation (the majority) and those viruses maintained in an extrahuman cycle for which humans are a deadend host. Examples of these patterns are set forth in Table 4.

Transmission pattern	Maintenance cycle	Example
Human to human	Human to human	Measles
		Hepatitis A
Animal to human	Animal to animal	Rabies
		Hantavirus pulmonary syndrome
Vector to human	Vector to human	Dengue
		Urban yellow fever
Vector to human	Vector to vertebrate	St. Louis encephalitis
		Western encephalitis

TABLE 4. *Major transmission patterns of viral infections of humans*

Viruses Maintained Within a Single Host Population

Each virus has a characteristic mode of host–host transmission. Viruses that cause acute short-term infections require efficient transmission to subsequent hosts and are usually spread by the aerosol respiratory route or by the gastrointestinal oral route. Such infections are characterized by the excretion of high titers of infectious agent over a limited period of time, as in the instance of influenza or smallpox. Viruses that cause persistent infections do not require such highly efficient modes of transmission because they are excreted continuously or intermittently for many years. Horizontal transmission is often used to designate all of these modes of transmission.

Vertical transmission is used to denote transmission between parent and offspring. Such transmission may occur during gestation, by passage of virus across the placenta (as in rubella and AIDS); perinatally during birth (herpes simplex or hepatitis B); or from the mother through colostrum or milk (AIDS). Germline transmission, another mode of vertical spread, is seen with certain animal retroviruses, such as murine leukemia virus, which are transmitted as an integrated provirus but which may be transcribed into infectious virus. Although retroviral sequences are carried in the human genome, there are presently no proven instances in which these have also been shown to function as infectious virions. Selected examples of horizontal and vertical transmission are listed in Table 5.

General category	Transmission mechanism	Example (virus)
Horizontal	Aerosol–respiratory	Influenza
	Gastrointestinal–oral	Rotavirus
Vertical	Placental–fetal	Rubella
	Maternal–parturition	Herpes simplex

TABLE 5. *Transmission mechanism of human viruses maintained by the person-to-person route*

Arboviruses

Arthropod-borne viruses (arboviruses) are usually maintained by continuously cycling between an insect host and a vertebrate host. In most instances, the virus replicates optimally in a single species or in a few closely related species of insects, which constitute the major, if not exclusive, vectors. Because most blood-feeding insects have a clear feeding preference for a few vertebrate species, this determines and limits the vertebrate species involved in the maintenance cycle. For some viruses, there are alternate maintenance cycles limited to the insect host, with transovarial or sexual transmission from generation to generation of insects. These insect cycles may be critical to perpetuation of the virus during adverse conditions, such as overwintering, but otherwise play a minor role in viral dissemination.

There are only two arboviruses, dengue and urban yellow fever, for which humans are the major vertebrate host. In other instances, such as St. Louis encephalitis and La Crosse encephalitis, humans are accidentally infected when the vector mosquito happens to feed on humans as an alternate to the preferred vertebrate blood source, such as birds or

woodland rodents.

Deadend Hosts

A *deadend* or *terminal host* is one that is not involved in maintaining a virus; such infections rarely result in transmission to other human or nonhuman hosts. Humans are occasional deadend hosts for a number of viruses that are maintained in extrahuman cycles. These include all arbovirus infections, with the special exceptions noted previously. In addition, there are a number of relatively exotic infections, most notably rabies, in which humans are deadend hosts. Transmission of rabies is often by bite, but for most other deadend infections in this group (such as Korean hemorrhagic fever and Bolivian hemorrhagic fever), environmental exposure to fomites is responsible. In such instances, the exact mode of transmission is obscure, although aerosolization of virus is often postulated. Table 4 lists examples of viral infections in which humans are deadend hosts.

Transmission of Persistent Infections

The transmission of persistent viral infections differs in many ways from that of classic acute infections. Persistent infections that are latent, such as herpes simplex or varicella zoster, are transmissible intermittently, during periods of activation. Thus, one individual may be infected in childhood and transmit infection 50 years later during a recrudescence; the ability for a single link in the infection chain to extend over such an interval has important implications for perpetuation and eradication of infection, as described later. Infections, such as those caused by hepatitis B and HIV, which are constantly transmissible over many years, are often transmitted inefficiently. Thus, hepatitis B is transmitted to susceptible household contacts at a frequency of less than 1 per 100 person-years of exposure, and HIV is transmitted to sexual contacts at a rate of less than 1 transmission per 100 contact episodes. For such infections, transmission may require passage of body fluids or of viable infected cells from infected to recipient host. Despite inefficient transmission, the number of new infections initiated by each persistent infection may be high. An epidemic curve caused by such a virus may stretch over years rather than weeks, and its mathematic modeling is profoundly different from that of acute virus infections because infectious individuals are not rapidly converted to noninfectious immune individuals but rather continue to accumulate over a long period.

Quantitation of Transmission

The transmission of acute viral infections may be quantified by the term *transmissibility,* or *T,* which is defined as the number of new infections initiated by each existing infection. Note that there is no time frame in this definition; instead, the focus is on the number of new infections initiated per generation. When T is greater than 1, incidence is increasing; when T is less than 1, it is waning. If the generation time has been estimated, as has been done for most acute viral infections, it is possible to use computer simulation to estimate T (46,86,87). T is determined by (a) the number of contacts between an infected individual and others, (b) the proportion of those contacts that are susceptible, and (c) the probability of transmission per susceptible contact.

DESCRIPTIVE EPIDEMIOLOGY AND ITS INTERPRETATION

A hallowed maxim in epidemiology is that a complete description of epidemic or endemic disease must include the parameters person, place, and time. The collection and display of this descriptive information is a necessary first step in understanding the epidemiologic mechanisms leading to occurrence, distribution, and course of an epidemic. This systematic approach is a surprisingly powerful tool in analysis. A few selected examples are presented in this section to demonstrate the application of descriptive epidemiology.

Person

In tabulating cases of a viral disease, the epidemiologist instinctively looks for features that distinguish affected individuals from the general population. Clues may exist in any feature, such as age, sex, race, occupation, residence, or any aspect of personal conduct, and none should be overlooked. Such variables are frequently the most important initial step in dissecting an outbreak.

The first recognized outbreak of St. Louis encephalitis in 1933 is a classic exercise in “shoe-leather” epidemiology (48); this led to the proposal that the disease was transmitted by an arthropod vector rather than by person-to-person contact. When this outbreak occurred neither the disease nor the causal agent were known. Because it was an acute neurologic disease, occurring in the summer, it was first thought to be a form of poliomyelitis or to be transmitted in the same manner (i.e., by interpersonal contact). The characteristic encephalitic manifestations made it relatively easy to identify many of the cases on a purely clinical basis. When these cases were assembled and rates estimated, it became apparent that the incidence was greater in the suburbs of St. Louis than in the city proper. Furthermore, there was a striking concentration of cases among the inhabitants of one institution located in the suburbs, but a comparison of several adjacent institutions revealed even more dramatic discrepancies, illustrated in Table 6. First, there were no cases in the personnel in an infectious disease hospital caring for many acute encephalitis cases; this was strong evidence against person-to-person transmission. Second, there were high rates in an almshouse but very low rates in two insane asylums; investigation revealed that the almshouse lacked screens, whereas the other three institutions were screened. These observations were strongly reminiscent of the classic findings of the Reed commission investigating yellow fever in Havana (68) and suggested mosquito transmission. Finally, it was observed that the suburbs of St. Louis, although home to many affluent residents, lacked the system of storm sewers present in the city; there were many more sites with standing ground water in the suburbs, and in the hot, dry summer of 1933, these were prime mosquito breeding sites. Although primitive, these observations suggested the mechanisms of transmission to the investigating epidemiologist.

Institution	Population	Cases	Rate per 100,000
Mental hospital	400	0	–
Hospital for the insane	4000	0	–
Isolation hospital	500	0	–
Almshouse (infirmary)	1200	13	10,800

[a]Of these four institutions, three had adequate screening whereas one (infirmary) did not. The isolation hospital cared for 300 patients with St. Louis encephalitis, but no cases occurred among the staff, estimated at 500.

TABLE 6. *Attack rates for St. Louis encephalitis in four institutions in the suburbs of St. Louis during the epidemic of 1933*[a]

The “Cutter incident” offers another example in which descriptive epidemiology defined an unusual distribution of disease in a population, leading directly to the cause (56). In mid-April 1955, newly approved, inactivated poliomyelitis vaccine was distributed throughout the United States for immunization of children 5 to 9 years of age, who were considered the highest risk age group and therefore given preference in the use of limited vaccine supplies. About 2 weeks later, at the end of April, reports were received of cases of acute paralytic poliomyelitis, occurring in a small number of recently immunized children. Because this was close to the seasonal trough in poliomyelitis incidence, there were relatively few cases of poliomyelitis occurring in the general population at that time, so that a small number of vaccine-associated cases were particularly striking. Furthermore, vaccine-associated cases were confined to a few of the western states, and it quickly became apparent that this geographic distribution related to the manufacturer of vaccine. Vaccine had been produced by five manufacturers, and most cases were associated with vaccine produced by Cutter Laboratories, which was mainly used in western states. When rates were tabulated for different production pools of Cutter vaccine, the association focused on two high-rate pools, as indicated in Table 7. Subsequent investigation showed that there were inadequacies in the inactivation and safety testing protocols recommended by the government, permitting the release of vaccine lots containing residual infectious virulent virus.

Production pool	Number of inoculations	Paralytic poliomyelitis cases	Rates per 100,000
468	73,700	34	46.1
746	48,000	17	35.4
460	34,100	0	—
463	63,400	1	1.5
467	56,700	1	1.8
762	54,400	1	1.8
766	57,200	0	—
767	3,100	0	—

[a]Cutter vaccine was administered April 18–27, and this table is limited to cases with onsets between April 18 and May 14.

TABLE 7. *The cutter incident: attack rates among children receiving cutter vaccine, according to production pool, United States, spring, 1955*[a]

Age Distribution

Age distribution of viral disease reflects differences in risk, which have important implications for the biology of virus infection. For many endemic human viruses, infection reaches 100% of the population at some time in life. In such instances, disease is confined to children or to children and young adults because older people are immune as a result of prior inapparent or apparent infection. Poliomyelitis is such an example, and the differences in age distribution of disease in different regions or in the same population in different eras reflects differing rates in the transmission of infection (21,22). Where this enterovirus is transmitted readily, all cases are confined to very young children; contrariwise, in countries with more rigorous personal hygiene, infection may be delayed so that poliomyelitis occurs up to 30 years of age or older (65,67). Figure 5 compares these age distributions and shows the parallelism with the acquisition of immunity.

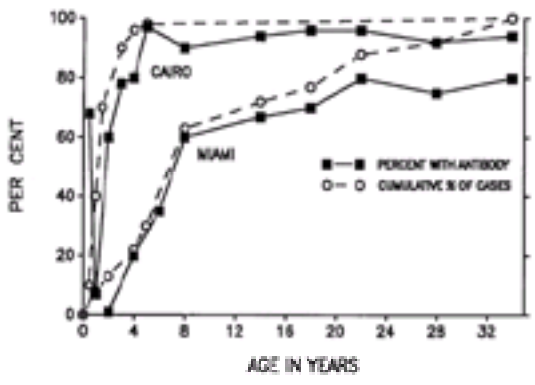

FIG. 5. Age distribution of poliomyelitis cases and immunity. A comparison of cumulative distribution of cases of

poliomyelitis and prevalence of type 2 (Lansing) antibodies in two populations, Cairo and Miami, to show that the age distribution of cases reflects the ages at which infection is acquired. There are few cases in individuals older than 3 years of age in Cairo and in those older than 30 years of age in Miami, the ages at which cumulative infection prevalence reaches 100%. (Data from ref. 65, with permission.)

For viruses that never infect more than a small proportion of a population during a lifetime, age distribution reflects differences in exposure or in the case/infection ratio rather than immunity. An example is St. Louis encephalitis (SLE), which produces unpredictable outbreaks in different areas of the central United States and is infrequent enough so that most age groups are susceptible. It has been repeatedly observed that SLE attack rates are lower in children and much higher in the elderly (10-fold differences). A classic investigation (47) of an epidemic in Houston showed that, surprisingly, the frequency of infection was similar for all ages, indicating that age-specific differences in the case/infection ratio accounted for age-specific attack rates.

Age-specific differences in case/infection ratios can be a key determinant of epidemiologic patterns. In some instances, infants experience much more severe disease than do adults. A classic example is the outbreak of measles that occurred in the Faroe Islands in 1846 (63). Because measles had not occurred in this isolated site for more than 50 years, women of childbearing age were seronegative, and their infants lacked maternal antibody. During the epidemic, the case fatality rate was about 20% in infants and below 1% in children and young adults (Table 8). This episode illustrates the biologic role of passively acquired maternal antibody. On the other hand, hepatitis B causes inapparent but persistent infection in infants, in contrast to acute liver disease followed by immunity in adults. In developing countries, infections are frequently transmitted from persistently infected mothers to their neonatal infants, whereas infection in developed countries is mainly transmitted to older children and adults (81). These differences account for the paradox that the attack rates for hepatitis B are higher in developed countries, whereas cumulative infection rates are much higher and the virus carrier state is more frequent in developing countries, as illustrated in Table 9.

Age group (y)	Annual mortality per 100		
	1835–1845	1846	Excess in 1846
<1	10.8	30.0	19.2
1–9	0.5	0.5	—
10–19	0.5	0.4	—
20–29	0.5	0.7	0.2
30–39	0.8	2.1	1.3
40–49	1.1	2.7	1.6
50–59	0.9	4.4	3.5
60–69	2.0	7.7	5.7
70–79	6.5	13.1	6.6
80–100	16.8	26.0	9.2

[a]The mortality for 1846 is for January to August, the period of the epidemic. The excess mortality provides a crude estimate of measles-specific mortality during the epidemic. At least 80% of the population had measles during the epidemic, which was the first to occur since 1781.

Place

Historically, mapping the distribution of disease preceded the development of epidemiology and became more significant with the introduction of place-specific rates. It remains one of the most powerful and intriguing aspects of descriptive epidemiology.

Two outbreaks of St. Louis encephalitis in two cities of Texas illustrate the complexities of geographic epidemiology. A large outbreak in Houston in 1964 was concentrated in the center of the city with decreasing rates toward the outskirts (Table 10). Subsequent serologic surveys showed that infection rates paralleled cases and also showed that high rates were associated with the lowest economic strata, open foundations, unscreened windows, and lack of air conditioning as well as with areas of standing water close to the banks of the river that flowed through center city. Conversely, in Corpus Christi, attack rates were highest in the suburbs, as shown in Table 11. In Corpus Christi, the determining factor was mosquito breeding in pools of standing water associated with lack of a storm sewer system rather than with reduced

protection from mosquito attack.

Circle	White upper class	White middle class	White lower class	Nonwhite	Totals
1 (innermost)	–	70	102	77	77
2	54	73	51	50	50
3	14	20	30	20	20
4	2	10	6	7	7
5 (outermost)	3	8	–	6	6

[a]The city was divided into concentric circles and into socioeconomically and racially stratified census tracts within each circle before computation of rates.

TABLE 11. *Regional and socioeconomic differences in attack rates for St. Louis encephalitis, Corpus Christi, Texas, 1966*[a]

A striking example of geographic variation over a large area is the regional difference in attack rates for AIDS, shown in Figure 6. High rates are associated with two relatively small, high-risk groups in the population, namely, male homosexuals and intravenous drug abusers; both groups are concentrated in a few cities. AIDS associated with drug abuse is mainly an East Coast phenomenon, whereas AIDS in the homosexual population is seen on both coasts. Because HIV was only recently introduced into the population, its pattern is still evolving, with an increase in rates in areas initially little affected.

Time: Seasonality

Many acute viral infections exhibit striking seasonal patterns in incidence that are very consistent. These differences reflect seasonal differences in transmission of infection because case/infection ratios remain stable at different times of year. Some viral infections peak in the winter, whereas others peak in the summer. In general, respiratory infections spread more readily in the winter, although they may peak at different times, such as January for influenza (23) and March for measles (86,87). Conversely, enteroviruses peak in the summer, although rotaviruses are a striking exception (85). Arbovirus infections are confined to the summer months when their vectors are active.

The underlying biologic explanation for seasonal differences has remained elusive. It is clear, however, that these variations correlate with changes in climate. An example is the seasonality of poliomyelitis in New England, which contrasts with the relative absence of seasonality for poliomyelitis in Hawaii, where humidity remains relatively constant throughout the year (Figure 7). This observation has led to the proposal, for which there is some evidence, that viruses

differ in their sensitivity to humidity, with poliovirus rapidly inactivated during winter months of low humidity, whereas influenza virus remains viable under the same conditions (57,87).

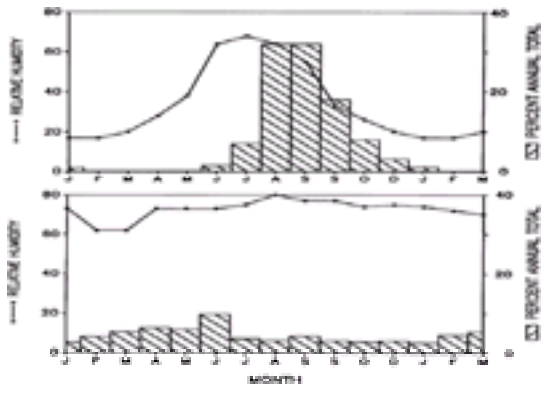

FIG. 7. Seasonal distribution of poliomyelitis in New England and in Hawaii, and the seasonal variation in relative humidity. **Upper panel:** cases for 1942 to 1951 in New England. **Lower panel:** cases for 1938 to 1952 for Hawaii. (Data from refs. 24,57, and 75, with permission.)

Time: Secular Trends and the Emergence of New Diseases

Secular trends in incidence of viral diseases fall into two categories: natural occurrences and those associated with programs of control or eradication. The latter are dealt with in a subsequent section.

One of the most dramatic aspects of historical epidemiology is the appearance of a new viral disease. This may reflect (a) the true appearance of a new virus in the population, a rare but real possibility; (b) an increase in the case/infection ratio so that an endemic infection is associated with a marked increase in disease incidence; or (c) the recognition of an existing but previously unidentified disease that can now be clearly diagnosed as a result of new laboratory tests accompanied by heightened practitioner awareness.

Emergence of a Virus New to the Population

AIDS and other diseases associated with HIV are an only too familiar example of the emergence of a virus new to the population. AIDS first appeared in the United States and Europe in about 1979, and serologic studies have demonstrated that infection first occurred in the male homosexual population of San Francisco 1 to 2 years before the recognition of the disease (16,17). The emergence of AIDS was reinacted in India and southeast Asia in the mid-1980s when newly developed serologic and virologic methods permitted the infection to be followed from its earliest entry into the population. A strong web of circumstantial evidence suggests that HIV-2 may have been derived from viruses indigenous to sooty mangabeys and HIV-1 may have originated in simian immunodeficiency virus strains circulating in chimpanzees, both in subsaharan Africa (30,59).

Canine parvoviruses appeared in the dog populations of the world in the late 1970s and spread round the world rapidly, causing a major pandemic. Circumstantial evidence strongly suggests that canine parvovirus was derived from feline panleukopenia virus, a long-established virus of cats (64). Wild-type feline panleukopenia virus will not replicate in canine cells, but a few point mutations will confer the ability to replicate in canine cells and cause disease in dogs.

Bovine spongiform encephalopathy (BSE) was first detected in the United Kingdom in the mid-1980s and was quickly identified as a spongiform encephalopathy similar to scrapie, an endemic disease of sheep. Detailed epidemiologic investigation (83) strongly suggested that BSE represents a common source epidemic because of the contamination of meat and bonemeal nutritional supplements routinely fed to dairy cattle. It is likely that scrapie-infected sheep tissues were included in the raw material used to produce the feed supplement and that a change (introduced in the late 1970s) in the production methods permitted scrapie infectivity to survive the production process at a residual level. The rapidly evolving epidemic (Fig. 8) led to the exclusion (in 1988) of ruminant tissues from feed supplements, which should result in the termination of the epidemic. However, the long incubation period (average, about 4 to 5 years) of BSE indicated that the epidemic might continue to evolve until about 1993 and begin to decline thereafter (59).

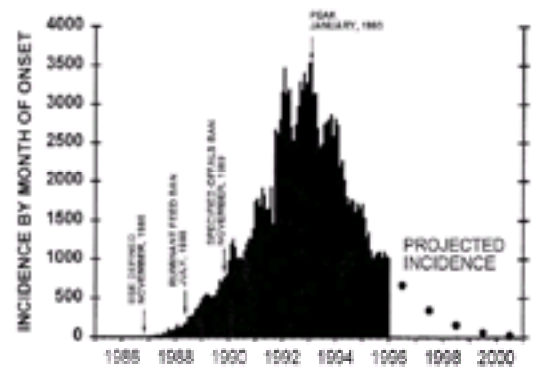

FIG. 8. The course of the epidemic of bovine spongiform encephalopathy (BSE) in the United Kingdom, shown as cases by month of onset, 1987 through April 1995. (Data taken from refs. 3,6,7, and 83, with permission.)

Increase in the Case/Infection Ratio

The dramatic appearance of epidemic poliomyelitis (known as *infantile paralysis*) in Europe and the United States in the 19th century (57,66) is illustrated in Figure 9. In retrospect, it is clear that polioviruses had been endemic for millenia but that cases of paralysis were few and sporadic. The likely explanation is that an improvement in standards of personal hygiene reduced the transmission of this enterovirus, delaying infection of young children beyond the age during which they were protected by maternal antibody (see Fig. 5) and resulting in the first epidemics of infantile paralysis. Support for this view (66) has been provided by the reenactment of the appearance of poliomyelitis in other countries (in the Middle East and Africa) (29) during the 20th century. In such instances, it was possible to conduct serologic studies that demonstrated the high prevalence of antibodies even before the appearance of clinical epidemics (66). Furthermore, the secular trend continued in the United States, with a gradual stepwise increase in the age distribution of paralytic poliomyelitis (Table 12), so that by the time of vaccine introduction in 1955, the term infantile paralysis had become outmoded.

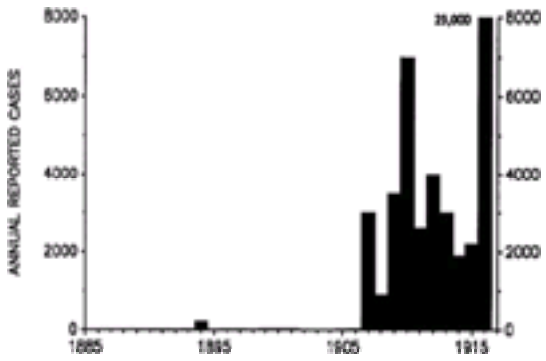

FIG. 9. The appearance of epidemic poliomyelitis in the United States, 1885 to 1916. The graph is based on reported cases (mainly paralytic) during an era when reporting was estimated at about 50%. (Data from refs. 44 and 57, with permission.)

Years	Percentage 0–4 y	Percentage 5–9 y	Percentage 10+ y
1912–1916	70	18	12
1920–1924	48	24	28
1925–1929	40	30	30
1930–1934	28	38	34
1935–1939	28	28	44
1940–1944	22	28	50
1948–1952	18	27	55

New Recognition of an Existing Virus

La Crosse virus is a mosquito-transmitted bunyavirus that causes La Crosse encephalitis. The causal agent was first isolated from a fatal case in 1964 (80) and led to the ability to distinguish this disease from the rubric of “arbovirus encephalitis, etiology unknown.” Beginning in 1964, about 100 cases have been reported annually mainly from the midwestern United States. It is likely that the emergence of this “new” disease reflects only the ability to make the specific diagnosis because the incidence has not risen since the 1970s (37) and because serologic studies (35) indicate that infections were occurring at a similar frequency long before isolation of the virus was reported in 1965.

A striking new acute pulmonary syndrome with high mortality was first reported in the southwestern United States in 1993, and combined epidemiologic and laboratory investigation quickly indicated that the agent (Sin Nombre virus [SNV]) was a previously unknown bunyavirus belonging to the hantavirus genus (39,60). Since the original reports, isolated cases due to related viruses have been detected in the southern and western United States, and several virus isolates have been made. SNV is an indigenous virus of deer mice (*Peromyscus maniculatus*), in which it causes a persistent infection accompanied by virus excretion leading to production of virus-infected aerosols and exposure of humans. Almost certainly, the emergence of SNV is the result of the recognition of a long-existing agent and disease that was brought to attention because of an unusual cluster of cases associated with a transient increase in the deer mouse population.

Possible Increased Frequency of Viral Disease Emergence

It appears that new virus diseases may be emerging at an increasing frequency, and the subject has captured considerable attention recently (53,54 and 55,59). A number of secular trends have enhanced the probability of emergence of new virus diseases (Fig. 10). First, the population of the world has inexorably continued to increase, and

urbanization has concentrated a higher proportion of people in densely populated areas, facilitating the transmission of any new infection. Second, modern transportation permits the carriage of infections around the globe within a single incubation period. Third, manmade perturbations of the environment are occurring at an increasing pace, which increases the likelihood of transmission of zoonotic and arboviral infections to humans. Finally, advances in fundamental virology have made available a new armamentarium of methods for the detection of previously unknown pathogenic viruses.

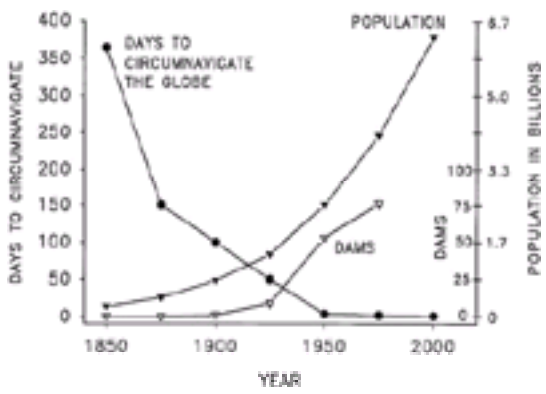

FIG. 10. Since the middle of the 19th century, many global changes have enhanced the probability of the emergence of new virus diseases of humans and animals. This chart depicts three examples of such trends. The rise in the human population has been accompanied by a massive increase in large urban populations, markedly increasing the risk for epidemic spread of infection. Dramatic reductions in the time to travel over long distances have increased the possibility of global transport of infectious agents over short periods of time. The number of large dams (dams more than 75 meters high built in the United States, 1890 to 1975) exemplifies increases in manmade manipulation of the environment. (Data from refs. 4,5, and 49, with permission.)

EPIDEMICS AND THEIR CAUSES

No medical phenomenon is more dramatic than the occurrence of an epidemic. The immediate cause of any viral epidemic is heightened transmission of the causal agent, and epidemics can be classified according to their principal mode of transmission as either common source or propagated.

Common Source Epidemics

Common source outbreaks are, as the term implies, due to exposure to the virus, usually either in food, water, aerosol, or injected product. Common source outbreaks have the potential to be explosive because of the simultaneous exposure of many individuals; because the exposure is frequently limited in time, such outbreaks may be of relatively short duration. Finally, common source outbreaks challenge the epidemiologist because unraveling the source may lead to termination of an ongoing outbreak or prevention of future recurrences.

Two examples illustrate common source epidemics. At the beginning of World War II, the military decided to immunize a large number of troops against yellow fever because it was clear that there would be action in several tropical theaters where jungle yellow fever might be encountered. The attenuated 17D strain of yellow fever virus was a newly developed vaccine considered to be a safe and effective immunogen. Because the vaccine efficacy depended on the infectivity of 17D virus, it was decided to enhance stability by including serum in the final formulation. Human serum was used to avoid serum sickness, and almost 1,000 donors were used, most of whom were medical students at Johns Hopkins University. Unfortunately, at least one individual was a carrier of hepatitis B virus. As a result, more than 400,000 troops received contaminated vaccine, causing a massive epidemic of hepatitis B (about 20,000 cases) in the spring of 1942 (71). Although the onsets of cases were spread over time, when the common source was recognized and cases were plotted from the time of initial immunization with 17D vaccine, they formed a classic log-normal distribution (Fig. 11) that provided a definitive estimate of the distribution of incubation periods for hepatitis B. Although this epidemic was originally considered to be one of infective hepatitis (hepatitis A), the great length of the incubation period (14-week mean) and the absence of secondary spread to contacts provided strong epidemiologic evidence that this disease was a distinct entity.

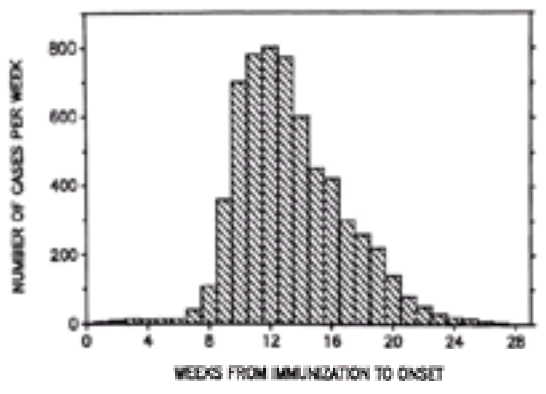

FIG. 11. Distribution of incubation periods for a common source epidemic of vaccine-associated hepatitis B. The graph shows cases of jaundice tabulated by weeks from immunization with 17D yellow fever vaccine to onset, for military units in California. (Data from ref. 71, with permission.)

An outbreak of hepatitis A occurred in 1961 in Pascagoula, Mississippi (51). In some cases, detailed food histories were taken that showed, by comparison with controls, that there was an association with raw oysters. Subsequent investigation disclosed that certain oyster beds in Pascagoula Bay were located near the discharge point for inadequately treated sewage from the city, and cases were associated with oysters supplied from these beds. This was one of the first instances of shellfish-associated hepatitis A, and it was later demonstrated that oysters, through their siphoning system, are capable of concentrating virus up to 1000-fold.

Propagated Epidemics

Propagated epidemics, as the term implies, involve host–host spread of virus. The occurrence of an epidemic is therefore due to the action of the three parameters that determine disease incidence, namely, the proportion of the population susceptible, the proportion of the susceptible population infected, and the case/infection ratio. To produce the unusually high incidence that defines an epidemic, at least one of these parameters must be operating above its usual level. In some outbreaks, it is possible to implicate a specific parameter.

Measles incidence in Iceland during a 50-year period is shown in Figure 12. There are intermittent epidemics alternating with periods of complete absence of measles. In this extreme situation, the virus invades the population, spreads widely and quickly, and fades out when the concentration of susceptibles drops below the level needed to perpetuate the virus. The virus disappears entirely, allowing susceptibles to accumulate as cohorts of infants are born. After enough susceptibles have accumulated, a single importation of measles can initiate a new epidemic. In this situation, the parameter required for epidemic initiation is the proportion of susceptibles in the population.
